PREFACE

The International Radiation Protection Association (IRPA) is an autonomous, non-government association. IRPA has over 15,000 members in 31 associate societies which are active in 36 different countries: Argentina, Australia, Austria, Belgium, Brazil, Canada, China, Czechoslovakia, Denmark, Finland, France, Germany, Greece, Hungary, Iceland, India, Luxembourg, Mexico, Netherlands, Norway, Peru, Philippines, Poland, South Africa, Spain, Sweden, Switzerland, United Kingdom, USA, USSR, Yugoslavia.

The primary purpose of IRPA is to provide a system whereby those engaged in radiation protection activities in all countries may communicate more readily with each other and through this process advance radiation protection in many parts of the world. The first international IRPA Congress was convened in Rome, Italy in 1966. Subsequent IRPA congresses took place in

Brighton, UK, 1970
Washington, D.C., USA, 1973
Paris, France, 1977
Jerusalem, Israel, 1980
West Berlin, Germany, 1984
Sydney, Australia, 1988

The Eighth International Congress of the International Radiation Protection Association (IRPA8) will be held in Montreal, Canada from May 17 - 22, 1992. IRPA8 is co-sponsored by the Canadian Radiation Protection Association.

IRPA8 will be preceded by the second International Workshop on Non-Ionizing Radiation in Vancouver, British Columbia from May 10 - 14, 1992. This workshop is a joint project of the Canadian Radiation Protection Association and the International Non-Ionizing Radiation Committee of the International Radiation Protection Association. Proceedings from this workshop will be published separately.

The present two volumes contain the preprints of papers to be presented at IRPA8 in Montreal. More than 500 abstracts were submitted for consideration by the International Congress Program Committee. Most of the abstracts were accepted and allocated to oral or poster sessions. Oral and poster presentations are regarded by the Committee as being of equal importance. Poster papers will be on display throughout the Congress, and will be summarised by rapporteurs in the appropriate oral sessions.

PREFACE

L'Association internationale de Radioprotection (AIRP) est une association autonome, non gouvernementale. L'AIRP compte plus de 15.000 membres dans 31 sociétés affiliées, actives dans 36 pays: Afrique du Sud, Allemagne, Argentine, Australie, Belgique, Brésil, Canada, Chine, Corée, Danemark, Espagne, Etats-Unis d'Amérique, Finlande, France, Grèce, Hongrie, Islande, Italie, Inde, Irlande, Israël, Japon, Luxembourg, Mexique, Norvège, Pays-Bas, Pérou, Philippines, Pologne, Royaume-Uni, Russie, Suède, Suisse, Tchécoslovaquie, Yougoslavie.

L'objectif premier de l'AIRP est de fournir un forum aux personnes travaillant dans le domaine de la radioprotection dans tous les pays, facilitant ainsi la communication entre eux, afin de faire avancer la radioprotection partout dans le monde. Le premier congrès international de l'AIRP a eu lieu à Rome, en Italie, en 1966. Les congrès suivants de l'AIRP se sont tenus à:

Brighton, Royaume-Uni, 1970
Washington, USA, 1973
Paris, France, 1977
Jérusalem, Israël, 1980
Berlin Ouest, Allemagne, 1984
Sydney, Australie, 1988

Le Huitième Congrès International de l'Association Internationale de Radioprotection (IRPA8) se tiendra à Montréal, Canada, du 17 au 22 mai 1992. IRPA8 est projet conjoint de l'Association Canadienne de Radioprotection et de l'AIRP.

IRPA8 sera précédé du second Atelier International sur les Rayonnements Non Ionisants, à Vancouver, Colombie Britannique, du 10 au 14 mai 1992. Cet atelier est un projet conjoint de l'Association Canadienne de Radioprotection et du Comité international des Rayonnements Non Ionisants de l'Association Internationale de Radioprotection. Les compte-rendus de cet atelier seront publiés séparément.

Les deux volumes des compte-rendus IRPA8 contiennent des textes pour pré-publication des communications présentées à Montréal. Plus de 500 résumés de communication ont été soumis au comité du programme du congrès international. La plupart des résumés ont été acceptés et une séance a été déterminée pour chaque communication pour présentation orale ou par affiche.

Authors of both types of papers were invited to submit four pages of camera-ready text for publication in these volumes. Plenary papers were allocated up to eight pages. All papers are reproduced without editorial amendment. The responsibility for the content and format of papers rests with the individual authors.

The papers are arranged by session in chronological order of presentation, as far as possible. This sequence is adopted to enable papers to be located easily and to avoid the need for registrants to carry both volumes throughout the Congress. In addition to the usual tables of Contents, the second volume includes an Author Index.

Abstracts are provided in place of the papers which were not received in time for inclusion in the proper sequence. Some late papers are included in an Addendum in the second volume.

These volumes constitute the record of the Congress, and provide an interesting collection of papers which describe the current worldwide practice of radiation protection. We thank the authors for their indispensable contribution to the Congress.

The members of the International Congress Organising Committee and the International Congress Program Committee have worked hard to ensure a successful Congress. It is our pleasure to thank them for efforts that merit the gratitude of those who attend the Congress, and of subsequent readers of these volumes.

Aux yeux du comité, les deux types de communication, orale ou par affiche, ont une importance égale. Les affiches demeureront en place pour la durée du congrès et seront résumées par un rapporteur lors de la séance à laquelle elles ont été attribuées. Les auteurs des deux types de communication ont été invités à soumettre 4 pages de texte prêt à photographier pour publication dans ces volumes. Les conférenciers invités des séances plénières soumettaient 8 pages de texte. Tous les textes ont été reproduits sans aucune modification, tels que soumis. Les auteurs étaient responsables du contenu et du format de leur texte.

Dans ces deux volumes de compte-rendus, les communications sont groupées par séance, selon l'ordre chronologique de leur présentation, dans la mesure du possible. Le premier volume contient les communications présentées lors des deux premiers jours; ainsi il ne sera pas nécessaire de porter les deux volumes tout au long du congrès. En plus des tables des matières de chaque volume, on trouvera un index des auteurs dans le second volume. A la fin du second volume se trouvent les communications recues tardivement. Les deux volumes de compte-rendus constituent les archives du congrès, et présentent une collection intéressante de travaux décrivant les réalisations mondiales de la radioprotection à l'heure actuelle. Nous remercions les auteurs pour leur contribution indispensable au succès du congrès.

Les membres du comité organisateur et du comité du programme du congrès international ont fourni beaucoup d'efforts pour assurer le succès du congrès. C'est avec plaisir que nous les remercions de leurs efforts; ils ont mérité la gratitude de tous les participants au congrès, et des éventuels lecteurs de ces volumes.

REMERCIEMENTS

Les travaux d'organisation du huitième congrès International de radioprotection ont débuté en avril 1988, immédiatement après la décision de l'assemblée générale de l'Association internationale de radioprotection d'accepter l'invitation de l'Association canadienne de radioprotection.

Outre les quelques 1000 auteurs et co-auteurs qui constituent l'essence même de ce congrès, plus d'une centaine de personnes, membres de comité officiels pour quelques uns et non-membres pour la majorité, ont travaillé de pieds fermes afin que tout soit prêt à temps et que les participants bénéficient du cadre idéal pour l'échange de connaissances et l'avancement de la radioprotection.

Durant les quatre années qu'ont duré les préparatifs, nous avons bénéficié d'un solide appui financier sans lequel, l'organisation de ce congrès n'aurait pas été possible. Nous désirons remercier particulièrement les organismes suivants pour leur importante contribution:

Hydro-Québec,

Commission de la santé et de la sécurité du travail du Québec,

Gouvernement du Québec,

Gouvernement du Canada,

Hydro-Ontario,

New Brunswick Electric Power Commission,

Commission des communautés économiques européennes,

Énergie atomique du Canada Ltée.

Jean-Pierre Gauvin
Président IRPA8

ACKNOWLEDGEMENTS

Duties required for the organisation of the Eight International Congress of Radiation Protection began in April 1988, immediately following the decision of the General Assembly of IRPA to accept the Canadian Radiation Protection's invitation to host IRPA8.

In addition to the 1000 authors and co-authors, who constitute the essence of this congress, over one hundred individuals, members of official committees, and non-members for the majority worked laboriously to prepare everything in time and to ensure that the participants benefit from the best frame for exchanging knowledge and for the advancement of Radiation Protection.

During the four years of the preparatory works, we benefitted from a strong financial support, without which it would have been impossible to hold the Congress. We wish to thank particularly the following organisations for their important contribution:

Hydro-Québec,

Commission de la santé et de la sécurité du travail du Québec,

Government of Québec,

Government of Canada,

Toronto-Hydro,

New Brunswick Electric Power Commission,

Commission of European Communities

Atomic Energy of Canada Ltd

Jean-Pierre Gauvin
Chairman, IRPA8

TABLE DES MATIERES -- TABLE OF CONTENTS

SESSION 1	OPENING CEREMONIES AND SIEVERT LECTURE CÉRÉMONIE D'OUVERTURE ET CONFÉRENCE SIEVERT	
	ETHICAL ISSUES IN RADIATION PROTECTION GIOVANNI SILINI. (ITALY)	1
SESSION 2A	COMPARISON OF RISKS - INFORMATION AND EDUCATION OF THE PUBLIC COMPARAISON DES RISQUES - INFORMATION ET SENSIBILISATION DU PUBLIC	
	COMPARABILITY OF RISKS CHRIS HUYSKENS. (THE NETHERLANDS)	18
	BILAN D'UNE ETUDE REGIONALE SUR CERTAINES NUISANCES SUBIES PAR LE PUBLIC JOCELYNE AIGUEPERSE, ANGUENOT F., HARDY S. (FRANCE)	22
	INFORMATION DES MEDECINS A PROPOS DES RISQUES NUCLEAIRES: EXPERIENCES DES INDUSTRIES ELECTRONUCLEAIRES FRANCAISE, BELGE, ALLEMANDE MICHEL BERTIN (F), J.M. CORDIER (B), D. HUBERT (F), J. LALLEMAND (F), H. PFOB (G), G. HEINEMANN (G). (FRANCE, BELGIUM, GERMANY)	26
	THE COMPARATIVE ESTIMATION OF THE RADIATION AND CHEMICAL CARCINOGENIC RISK INDUCED BY THE ATMOSPHERE CONTAMINATION DUE TO THE RELEASES FROM COAL-FIRED POWER PLANTS V.A. KNIZHNIKOV, V.A. KOMLEVA, N.K. SHANDALA. (U.S.S.R.)	30
	METHODS AND PRINCIPLES FOR MAKING PRIORITIES IN RADIATION PROTECTION J.O. SNIHS. (SWEDEN)	34

TABLE DES MATIERES - TABLE OF CONTENTS

SESSION 11	PLENARY: RADIATION PROTECTION - IONIZING AND NON IONIZING RADIATION SÉANCE PLÉNIÈRE: PROTECTION RADIOLOGIQUE - RADIATIONS IONISANTES ET NON IONISANTES	
	REVIEW OF THE EVIDENCE FOR CANCER PROMOTION FROM EXPOSURE TO 50-60 HZ MAGNETIC FIELDS M. REPACHOLI. (AUSTRALIA)	1031
	THE WORK OF COMMITTEE 4 OF ICRP ROGER H. CLARKE. (UNITED KINGDOM)	1039
SESSION 12A	PROTECTION CONCEPTS, POLICIES AND STANDARDS -I CONCEPTS, POLITIQUES ET NORMES DE RADIOPROTECTION - I	
	THE NEW ICRP RECOMMENDATIONS: HOW WILL THEY BE TRANSLATED INTO PRACTICE? OSVALDO ILARI, A. GONZALEZ, G. HASON, C. BORRAS, E. BOUTRIF. (FRANCE)	1043
	APPLICATIONS DES RECOMMANDATIONS DE LA CIPR. UTILISATION DES CONTRAINTES ET DES NIVEAUX DANS DES CAS CONCRETS HENRI JAMMET, A. SUGIER. (FRANCE)	1047
	THE REVISED INTERNATIONAL COMMISSION ON RADIOLOGICAL PROTECTION (ICRP) DOSIMETRIC MODEL FOR THE HUMAN RESPIRATORY TRACT WILLIAM J. BAIR. (U.S.A)	1053
	IMPLICATIONS OF 1990 ICRP RECOMMENDATIONS ON RADIATION PROTECTION PRACTICES IN THE MINERAL SANDS INDUSTRY GEORGE KOPERSKI. (AUSTRALIA)	1057
	LES NOUVELLES GRANDEURS OPERATIONNELLES DE L'ICRU ET LEUR IMPACT SUR LES TECHNIQUES DE DOSIMETRIE EN RADIOPROTECTION G. PORTAL. (FRANCE)	1061
	MESURE DES NOUVELLES GRANDEURS OPERATIONNELLES A L'AIDE DES APPAREILS DE RADIOPROTECTION DESTINES A LA SURVEILLANCE DES ZONES DE TRAVAIL ET A LA SURVEILLANCE INDIVIDUELLE R. PRIGENT, J. CHARY, M. CHEMTOB, Y. HERGAUT, P. LEBOULEUX. (FRANCE)	1065
	THE PRACTICAL IMPLICATIONS OF THE NEW ICRP ANNUAL DOSE LIMIT AT OLYMPIC DAM OPERATIONS JIM HONDROS. (AUSTRALIA)	1069
	DOSE LIMITS REDUCTION CONSEQUENCES ON THE OPERATION OF NUCLEAR POWER PLANTS E. PALACIOS, J.M. ESPECHE, A. CURTI, G. MASSERA, F. SPANO. (ARGENTINA)	1073

ASQRAD: A COMPUTER CODE FOR THE QUANTIFICATION OF RADIATION DETRIMENT	1077
J.D. ROBB (UK), PJ STOKELL (UK), THIERRY SCHNEIDER (F), J.P. DEGRANGE (F). (UNITED KINGDOM, FRANCE)	
UP TO WHEN ALARA IS RELIABLE	1081
GIAN-MARIA A.A. SORDI. (BRAZIL)	
A STUDY OF THE HUMAN URINARY EXCRETION OF CHRONICALLY INGESTED URANIUM-INSIGHTS ON THE GASTROINTESTINAL ABSORPTION FACTOR	1085
MARIA LIMSON ZAMORA, J. ZIELINSKI, R. FALCOMER. (CANADA)	
EVALUATION OF INTERNAL CONTAMINATION DOSE TO EMBRYO AND FOETUS	1089
F. BREUER, L. FRITELLI. (ITALY)	
APPLICATION OF THE PROPOSED NEW ICRP LUNG MODEL TO BIOASSAY	1093
JOHN JOHNSON, ROBIN HILL, A.C. JAMES. (U.S.A.)	
A ROLE OF THE HYBRID SCALE IN RADIATION PROTECTION	1097
SHIGERU KUMAZAWA. (JAPAN)	
AN INTERIM UK RESPONSE TO REVISED RISK ESTIMATES AND ICRP 60	1101
W.P. BINES, P.F. BEAVER. (UNITED KINGDOM)	
TOWARDS UNIFORM STANDARDS OF RADIATION PROTECTION IN HEALTH CARE IN EUROPE	1105
P.P. DENDY. (UNITED KINGDOM)	
SESSION 12B	
NIR -III: HUMAN AND LABORATORY STUDIES	
RNI -III: ÉTUDES ÉPIDÉMIOLOGIQUES ET DE LABORATOIRE	
AN IN VITRO MORPHOLOGICAL INVESTIGATION ON THE SUBCELLULAR EFFECTS OF 50 HZ MAGNETIC FIELDS	1109
W. MALORNI, S. PARADISI, E. STRAFACE, M.T. SANTINI, G. DONELLI. (ITALY)	
CHAMPS ELECTRIQUES ET MAGNETIQUES ET CANCERS : EXISTE-T-IL UNE RELATION	1113
J. LAMBROZO, P. GUENEL, M. GOLDBERG, A. CHEVALIER, E. IMBERNON, B. HUTZLER, G. WARRET, W. DAB. (FRANCE)	
HEALTH EFFECTS OF ELECTRIC AND MAGNETIC FIELDS: PROGRESS AND NEW DIRECTIONS	1117
MARIA STUCHLY. (CANADA)	
HYPERSENSITIVITY TO ELECTRICITY - A WORKPLACE PHENOMENON RELATED TO LOW-FREQUENCY ELECTRIC AND MAGNETIC FIELDS	1121
BENGT KNAVE, U. BERGQVIST, R. WIBOM. (SWEDEN)	
AN APPROACH TO TACKLE VISUAL DISPLAY UNIT USER HEALTH PROBLEMS	1125
HAZEL MCCALLUM, BRIAN HEATON. (UNITED KINGDOM)	

	ETUDE DE L'EXPRESSION DES ONCOGENES DANS DES FIBROBLASTES HUMAINS APRES IRRADIATION AVEC UN LASER A IMPULSIONS TRES BREVES	1129
	DOMINIQUE DORMONT, TH. FREVILLE, H. RAOUL, D. COURANT, D. COURT. (FRANCE)	
	EVALUATION DES EFFETS CYTOGENETIQUES D'UN RAYONNEMENT LASER A IMPULSIONS TRES BREVES	1133
	GENEVIEVE GUEDENEY, D. COURANT, J.L. MALARBET, M.T. DOLLOY, M. COURT. (FRANCE)	
	A STUDY ON THE INFLUENCE OF 50-Hz MAGNETIC FIELDS ON THE CYTOTOXIC ACTIVITY OF HUMAN NATURAL KILLER CELLS	1136
	C. RAMONI, M.L. DUPUIS, P. VECCHIA, M. GRANDOLFO. (ITALY)	
	ELECTROPHYSIOLOGICAL CHANGES IN RATS AFTER MODULATED MICROWAVE IRRADIATION	1140
	L. SZABO, G. THUROCZY, G. KUBINYI, J. BAKOS. (HUNGARY)	
	IN VITRO STUDY ON THE GENOTOXICITY OF 2450 MHZ MICROWAVE IRRADIATION IN HUMAN PERIPHERAL BLOOD LYMPHOCYTES	1144
	L. VERSCHAEVE, A. MAES, A. ARROYO, C. DE WAGTER, L. MARTENS. (BELGIUM)	
SESSION 12C	EDUCATION AND TRAINING -II (PANEL)	
	ÉDUCATION ET FORMATION -II (TABLE RONDE)	
	CERTIFICATION OF HEALTH PHYSICISTS IN ASSOCIATE SOCIETIES	1148
	JILL FITCH. (AUSTRALIA)	
	RADIATION PROTECTION QUALIFICATIONS	1149
	J.R.A. LAKEY, M. WASSON. (UNITED KINGDOM)	
	LE CEFRI ET LA CERTIFICATION EN RADIOPROTECTION DES ENTREPRISES FRANCAISES	1153
	JEAN-CLAUDE MARILLIER. (FRANCE)	
SESSION 12D	OCCUPATIONAL EXPOSURE -IV: DOSIMETRY	
	EXPOSITIONS PROFESSIONNELLES -IV: DOSIMÉTRIE	
	THE ROLE OF CEDR IN WORKER HEALTH PROTECTION	1157
	BARBARA BROOKS. (U.S.A)	
	DOSIMETRIE DU PERSONNEL : SES POSSIBILITES ET SES LIMITES	1158
	G. WOLBERT, G. COUDERT, R. DOLLO, M. BERTIN. (FRANCE)	
	REFLEXIONS SUR UNE METHODE PRATIQUE D'UNIFORMISATION DE LA COMPTABILITE DES DOSES	1162
	BOUSSARD, R. DOLLO, M. DE KERVILLER, M. PENNEROUX. (FRANCE)	
P-32	PERSONNEL MONITORING IN U.S. RESEARCH INSTITUTIONS	1166
	V.N. EVDOKIMOFF. (U.S.A)	

CENTRAL INDEX OF DOSE INFORMATION (CIDI)	1168
W.J. ILES, K.A. FILLARY, E. GREENSLADE, G.M. KENDALL, T.O. MARSHALL, W.P. BINES, M. WILLIAMS. (UNITED KINGDOM)	
IMPACT OF ICRP60 ON DOSES RECEIVED BY OCCUPATIONAL EXPOSED WORKERS IN EDUCATIONAL ESTABLISHMENTS IN THE UNITED KINGDOM	1172
A.G. RICHARDS. (UNITED KINGDOM)	
CUMULATIVE RADIATION EXPOSURE AT BNFL SELLAFIELD: A HISTORICAL PERSPECTIVE	1176
K. BINKS, R. WAKEFORD, R. STRONG, D.J. COULSTON. (UNITED KINGDOM)	
DEVELOPMENT OF TLD BADGE READERS FOR PERSONNEL MONITORING IN INDIA	1180
S. KANNAN, P. RATNA, M.S. KULKARNI, T.V. VENKATESWARAN, U. MADHVANATH. (INDIA)

1992 SIEVERT LECTURE

ETHICAL ISSUES

IN

RADIATION PROTECTION

Giovanni Silini
Via S. Maurizio, 22 24065 LOVERE (Bergamo) Italy

PREFACE

Contrary to those who preceded me in this series of lectures, I never knew Professor Rolf M. Sievert because when he died in 1966 I was just starting my work in animal radiation biology and only later did I become acquainted with the subject and problems of radiation protection. However, judging from what I have come to know about Sievert through his work and conversations with friends who were associated with him, this large congress of people would not have been possible without his pioneering work. In him, scientific excellence was paralleled by penetrating intuition. In a 1947 lecture in honour of Sylvanus Thompson, commenting on the fact that a new epoch, that of atomic energy, was about to come, he had the following to say: "We cannot as yet estimate what risks of injury by radiation this epoch can bring. We have, however, reason to expect that the problem of protection against injuries by ionizing radiation will be of an entirely other magnitude than hitherto, and it is probable that it will become a general social problem of prime importance". Clearly, a remarkable foresight about a discipline that has gradually flourished internationally to its present state.

The honour that IRPA has bestowed upon me by asking to deliver this lecture is in sharp contrast with the little I have achieved in radiation protection. Others, with better credentials and authority, might have done a better job. But since this burden has fallen upon me, I can only hope that what I am about to say will not be too unworthy of the person we remember and of those who paid tribute to his memory in past lectures.

INTRODUCTION

My intention today is not that of delivering a sermon. It is simply to bring you to consider some of the ideas that underlie the principles and the numbers that we are confronted with every day in our professional life. It is to discuss the fundamental values that are implicit in our practical activities, and to verify that we have not lost touch with the principles of human respect and compassion that must inspire our work as members of a scientific community.

Radiation protection is not a fundamental science, a free intellectual re-construction of the why's and how's of nature, that may be regarded as intrinsically good, in so far as it only tends to enlarge the boundaries of human knowledge. Radiation protection is an applied discipline. Its purpose is to define the limits within which some human activities with potentially harmful consequences may safely be carried out. This requires discussion of the principles on which protection of the individuals and of the species should be based, and necessarily involves ethical considerations.

As some of you may know, ethical principles are of two kinds: there are the very general first-order ones, that is the values that should ultimately guide all choices for any action; and the more limited second-order principles, dealing mainly with the meaning and the applicability of the ethical language and the analysis of ethical concepts (Mackie 1977). Of the first set of principles, only one, perhaps, is required by radiation protection: the principle that to improve health and living conditions and thus to minimize the suffering of human beings is a good aim in itself, and therefore an objective that we ought to work for.

It is characteristic of ethical principles to be universalized, in the sense that when a principle is seen as ethically right, those who adopt the principle are committed to follow it under all relevant circumstances, irrespective of any qualitative differences of those stating, or affected by, the principle in question. A further stage in this process of universalization is to apply the principle irrespective of how individuals might vary in respect to their physical and mental qualities, resources or social status, including those individuals who will only be born in the future (Mackie 1977). Usually, radiation protection does not demand adoption of a third and more advanced stage of universalization, that of applying a principle irrespective of preferences, tastes, values or ideas.

So, except for one very general first-order principle, radiation protection does not require any other major ethical statement. In this context, therefore, morality is understood in the restricted sense of a methodology to set special constraints of conduct in the interest of those exposed to radiation to develop guidelines to restrain the selfish inclination by some agent or agents to act against such interest. This more limited function is however important in promoting the development of universally acceptable ethical behaviours.

Since radiation protection principles are meant to apply to all persons and societies, they should be sufficiently flexible to be adopted in countries with a wide spectrum of religious, political, social and economic conditions. They should also be sufficiently comprehensive to apply reasonably to all activities involving radiation exposure, even those for which exposure has a low

probability of occurrence. Finally, they should cover both present and foreseeable exposure situations.

Owing to all these requirements, it is obvious that such principles could not be derived from sets of values belonging to the cultural heritage of any particular group, but should be built on universally-shared secular values. These are, for example, the equality of rights for all human beings; the need to reasonably balance the interests of any individual against those of all others; the requirement to protect our species by preserving the material conditions for its continuation; and, finally, the right for each person to try to achieve freedom from one common heritage of the human condition, which is suffering and sorrow.

The main question I should like to discuss is: to what extent do we cover all these requirements in our particular field?

Present radiation protection doctrine (ICRP 1990) is based on a body of scientific knowledge, one underlying assumption and three general principles. My objective is to discuss first the adequacy of the existing scientific information for the purpose of setting safety standards; then to consider the foundation of the underlying assumption; and finally, to discuss a few aspects of the three general principles. All this, of course, in the light of ethical considerations.

THE BASIC SCIENTIFIC DATA

Let me start with the scientific bases on which the system is built (Silini 1991). As you all know, we classify radiation effects into a few major groups, according to their nature and mode of expression at different dose levels. For some effects, our knowledge derives from direct experience in man, gained in many cases in an attempt to cure disease; sometimes as a result of accidents in the course of industrial activities; and in a few cases as a consequence of deliberate acts of warfare or the development of weapons.

Broadly speaking, we identify at high dose deterministic effects on cells, tissues or the whole body. These may be clinically dramatic, but are usually not too difficult to avoid, except in the course of accidents. Experience of these effects in man is large. Therefore, their prediction as a function of dose, time and radiation quality is rather well founded (UNSCEAR 1982, 1988).

At low or very low doses and dose rates effects of a different nature are seen. They are called late somatic (or stochastic) and consist in the appearance of an excess of cancer and leukaemia above the natural rate. Their existence is proven, but precise assessment of their rate of induction per unit dose is difficult in man. To this end, primary data obtained from human epidemiology must be adapted for general use to account for various dependencies on dose, dose rate, organs, age, time of induction and other variables of radiobiological interest. Recently, our understanding of all these risk-related variables has considerably increased. As a result, one feels that current estimates are more realistic than in the past and, perhaps, less likely to increase further, barring drastic changes in the projected trend of the primary data or new and unexpected findings. Of course, our knowledge of these effects is only descriptive. We still lack the understanding of the mechanisms through which cancer (and radiation-induced cancer in

particular) is brought about.

For both classes of somatic effects - the deterministic and the stochastic - there is enough experience in man, so that models of induction in animals may simply be used to fill the gaps and to generalize dose-time relationships and trends with radiation quality. This is good, because the species-specificity of many of these effects is so pronounced that it would simply be impossible to project rates of induction across species. It is acceptable, however, to use animal data in order to project general trends with dose and time or to validate mechanisms.

Unfortunately, for a third class of effects, the stochastic hereditary ones, we are still to a large extent dependent on data from experimental animals. The existence of clinically relevant hereditary effects brought about by alteration of germinal cells in man has never been demonstrated, but the absence of such evidence is not in itself a cause for reassurance nor concern. Since radiation may definitely cause such effects in many other living species and we know of no special reason why the human genome should be an exception, we must assume that the human species may also be susceptible. The best we can do, under these circumstances, is to take the estimates of hereditary effects in species that are phylogenetically near to man and try to adapt these estimates for our species, on the basis of present knowledge of human genetics. Scientifically this procedure is unsatisfactory. Ethically it is justified out of necessity, as the only possible course of action.

An important ethical issue deals with the assessment of those hereditary effects that may appear in man in the very far future. A significant step forward - at variance with previous (ICRP 1977) practice - has been taken recently by ascribing all genetic damage to the person exposed. This implies that all hereditary harm, be it the early-appearing dominant or the very long-term recessive damage, is treated in exactly the same way and given exactly the same weight. Provisionally, and until our capacity to qualify hereditary radiation effects will improve, this seems the most reasonable decision to make.

Equally unsatisfactory is our inability to account for the type of genetic disorders which are most relevant in man, the non-mendelian multi-factorial disorders. Thus, we must take note - with some disappointment - that the slight apparent reduction of radiation-induced hereditary risk estimates observed over the years is due both to a decrease in our confidence to quantify part of this damage, and to a real decrease of the overall estimates. Future progress as to the relative contribution of these two components is expected to depend critically on advancements in fundamental human genetics, rather than in radiation genetics (UNSCEAR 1986).

THE MAIN GENERAL ASSUMPTION

The main general assumption on which radiation protection rests is that, at sufficiently small doses and dose rates, there is a non-threshold linear relationship between the dose and the probability of induction of late somatic and genetic effects. I am purposely using the word assumption because this statement cannot be scientifically demonstrated at the low doses that would be required. In fact, the relatively low incidence (per unit dose) of radiation-induced cancer and hereditary diseases is masked by a very

incidence (per unit dose) of radiation-induced cancer and hereditary diseases is masked by a very high background of other neoplastic and genetic conditions, that are unrelated with radiation exposure in excess of the natural level. This happens for two reasons. One is biological, because we have no means as yet of recognizing radiation-induced conditions from those that are caused by other agents. The second reason is statistical, because it is impossible, at the low doses and with the small populations usually available, to demonstrate the significance of a small number of supposedly radiation-induced health effects over a large number of effects of the same kind of uncertain etiology.

The implications of the non-threshold linearity assumption are clear. It postulates, in essence, that each dose of radiation, however small, has a finite probability of producing effects of the stochastic type; and that each dose increment, however minute, will increase this probability in a manner which is directly proportional to the increment. The two aspects need separate discussion.

The first aspect has to do with the absence of the threshold. Radiation protection is among the very few health-protection disciplines to postulate absence of threshold in the dose relationship for stochastic effects. In other fields of toxicology one usually identifies a level of dose that carries positive evidence of harm, and then sets the "safe" limit well below that level. Such a procedure implicitly assumes that the dose-effect relationship has some threshold below which the toxic agent is considered harmless. By excluding a threshold, radiation protection not only adheres to a probabilistic approach to risk assessment, but also implicitly refuses to consider small risks as irrelevant. In fact, even if they are sufficiently low to be of no relevance for the individual, they might not be quite so irrelevant as source-related collective risks. This is the reason why both the individual and the collective aspects of the risk must be considered in any assessment.

Going now to the ethical implications of the linear relationship between dose and probability of effect, there are justifications of a scientific nature for, and practical advantages in, this assumption.

Scientifically, we know that radiation energy is transferred to living matter along the tracks of ionizing particles. It seems reasonable to believe that, when the number of tracks per cell is on the average well below one (which happens at low doses and dose rates), single-track mechanisms giving rise to linear dose-effect relationships must be eventually the only ones operating, while double-track mechanisms (giving rise to quadratic relationships) must vanish. No matter to what extent linear relationships may be modified by various processes of repair of the initial damage, the kinetics will continue to be linear as long as the repair mechanisms will not themselves become dose-dependent, which only happens at very high doses and dose rates.

There are also practical considerations. On the one hand, in the presence of a high background level of radiation, linearity of risk due to a small dose increment is not an unacceptable proposition. On the other hand, postulating any non-linear relationships would imply the need of keeping track of the radiation history of each person, in order to calculate the attendant risk for each dose increment. Since radiation protection cannot clearly be tailored to each individual, the problem of assessing risks would have to be solved on the basis of large averages for and

between individuals, which would be equivalent to assuming linearity from the start. Finally, dose-related assessments and restrictions would be difficult, because the impact of each source would also depend on the exposure from other sources.

The question is then: if linearity between dose and the probability of stochastic effects is a scientific certainty or an inescapable practical necessity, where lies its ethical quality? It lies in the value assigned to the slope of the dose-linearity relationship, that is in the number we choose as the "nominal probability coefficient" for planning of radiation protection. Obviously, this value should not be too low, otherwise the resulting radiation protection requirements would not be stringent enough. Nor should it be made artificially low by applying correction factors (for dose and dose rate, for example) under conditions where dose and dose-rate effects are not operating: such an approach would equally result in less stringent standards of protection.

It is less obvious that the nominal probability coefficient should not be too conservative, particularly in the face of the inherent uncertainties. However, excessive conservatism would unduly penalize practices involving radiation in comparative exercises against other practices carrying health risks. Excessive conservatism may also result in an uneven - and therefore inefficient - distribution of resources available for protection against different sources of health risk. A realistic assessment of the coefficient is therefore to be advocated, in spite of the scientific and practical difficulties involved in such assessments. And the best way to achieve this goal is through reasonably frequent reviews of the scientific evidence and adjustment of the values as needed.

There are many ethical problems that could be discussed in connection with the assumption of non-threshold linearity. I will briefly touch on two.

The first problem concerns the existence of a variability in the appearance of stochastic damage among members of a population and the question for whom radiation protection standards should be developed. It is well established that susceptibility to cancer is not uniform, as shown by families with high predisposition to develop some tumour types. We also know that individuals homozygous for some genes are particularly sensitive to the immediate effects of radiation; and that cells in vitro that are homo- or hetero-zygous for these genes are also more radiosensitive than cells from normal individuals. What we ignore is whether people susceptible with respect to "natural" tumour induction may also be more prone to develop radiation-induced tumours; and we have as yet no easy way to identify people with abnormally high sensitivity to radiation; consequently, individual radiosusceptibility to cancer induction, and its distribution in the population, is an unexplored field.

Under these conditions, should radiation protection be planned with respect to the most sensitive or to the average member of the population? The answer is that probability coefficients for cancer induction are normally derived from people with all degrees of sensitivity. Thus, by using real epidemiological data as our reference point, we derive average values of population susceptibility, which include the most sensitive individuals. Such a procedure should be sufficient for planning of protection, provided that the distribution of genes linked with hypersensitivity could be dealt with individually in the context of occupational medicine.

The hypothesis of non-threshold linearity, among its many advantages, allows doses and probabilities of stochastic effects to be summed up in space and time. Integration in space I will consider later; here I am concerned (and this is my second question) with assessment of radiation effects in time, i.e., with the potential damage to future generations and how should protection be planned for exposures taking place late (and sometimes very late) into the future.

The question has many facets. There is first a general problem arising from the need of taking actions (of allowing actions to be taken) in the presence of uncertainties of different kind about the long-term future. To cite just a few, think of the uncertainties inherent to the inadequacy of the human mind to foresee long-term phenomena; or the uncertainties about the behaviour of any human group and the need to monitor the group's actions by independent evaluators. Other uncertainties arise in predicting the future of human societies and their degree of stability in the face of changing ethical values, political organizations, social structure, economic trends. And, finally, how can we reliably forecast the future of our environment and the modifications caused upon it by present and future human behaviour (Ethical Aspects on Nuclear Waste 1988)?

Then there is the question of our responsibilities to future generations and how to compare and value short-term effects with the very long-term damage resulting from present practices? Science is unable to suggest any answer to this kind of problem. Life is evolutionary by definition and the balance between species is unstable over long periods of time. There are no obvious ethical concepts to be derived from evolution and its mechanisms. Solutions to these problems must therefore be sought at a different level. If it is true that all human beings are equal regardless of ethnic, religious and national characteristics and that this right to equality could not be exercised without a right to a liveable environment, then there must be a principle of intergenerational equity by which we ought to respect the right of future generations by refraining from practices that may compromise their opportunities in the future. There is, in other words, an implicit social contract by which, since we derive from our ancestors our life and living means, we owe to our followers the same heritage we receive. We cannot obviously decide and plan for them, but we can at least avoid pre-empting their future decisions by giving them the same opportunities we received (Shrader-Frechette 1981).

These statements are clearly too general to provide practical guidance. To translate principles into practice, radiation protection charges to the account of present practices the commitment of any future somatic harm. It also attributes to the account of any exposed person all the hereditary damage - dominant and recessive, monogenic and polygenic - estimated on the basis of doses received by that person. By doing so, it gives exactly the same weight to all types of harm caused by an exposure received, now or in the future, irrespective of the time at which such damage will become manifest.

THE THREE GENERAL PRINCIPLES

Going now to the main principles of the ICRP system of dose limitation, I would like to preface the discussion by pointing out that the system is to be taken in its entirety and no one part (especially individual dose limitation) should be applied in isolation. One should also add what might appear redundant but, as the latin sentence goes, "repetita iuvant": just as it is necessary

that the scientific data leading to practical recommendations be assessed in a fair manner, it is also imperative that implementation of the system be undertaken in good faith. Periodic evaluations of its effectiveness should help to improve performance and to achieve, together with a gradual lowering of the overall doses, a more even distribution of them in space and time.

JUSTIFICATION OF A PRACTICE

In its most recent enunciation by the ICRP, the first general principle of radiation protection, that of justification of a practice, states that "No practice involving exposure to radiation should be adopted unless it produces sufficient benefit to the exposed individuals or to society to offset the radiation detriment it causes". At first sight, the principle appears utterly obvious: only a fool, in fact, could consider to undertake actions which are more harmful than beneficial. However, when closely examined, the statement appears very complex. Two concepts, benefit and detriment, are difficult to define and to apply to the other two terms, individuals and society.

The ethical problems posed by the interplay of these four terms are numerous. They turn, first of all, on how to define benefits in a comparable and consistent way and, above all, in a way which is fair to both individuals and groups. Secondly, who is to do this balancing operation and when? Thirdly, how should one compare radiation-related benefits and detriments with benefits and detriments induced by other practices?

Before discussing ethics, let us first be clear on some points: there is no wish on the part of radiation protection experts to take any of these decisions. In democratic societies, the role of balancing quantities and values of different nature, which are incommensurable by any rational standard, is left to people elected to exercise political authority. In stating this principle, radiation protection simply intends to put forward some requests: firstly, that the radiation-induced health detriment should specifically be considered as one element in the decision process; secondly, that the role of radiation protection specialists should not be that of choosing between a range of viable options, but that of advising about the viability of an option involving the use of radiation; and, fourthly, that judgements should not be taken once and forever, because options considered viable in a given context at a given time, may not continue to be so with changing conditions or the passage of time.

In general, estimates of all the consequences of a decision, beyond the most immediate ones, are extremely complex because they interplay with the primary or secondary results of other decisions, taken independently by other agents. In practice, therefore, one simply assesses the ethical quality of the most immediate consequences of a proposed decision, leaving aside the obscure chain of second- and third-order events and their possible interplay.

Similar arguments apply to the complexities of the socio-economic situations to be faced when making such decisions. Each individual belongs to different circles (family, group, work-force, nation, etc.) with different dimensions, aims and requirements. Circles of different order may cooperate or conflict with each other at any given time, and their interests may also change with time. Given such a high degree of complexity, how could one possibly trace what may be satisfactory or detrimental for each actor in the game of life? An open mind, reasonableness and

a balanced judgement are pre-requisites for fair decisions and these appear under such circumstances the most valuable ethical requirements.

One often regards the principle of justification as a very extensive one, involving decisions at the national or international level in respect to large programs of action: these are certainly the most striking cases to which the principle applies. However, justification of generalized medical practices involving exposure to radiation is a process of the same nature; actually, the principle of justification should apply to any single medical practice. It is true that any doctor carries out this process almost implicitly. It is also true that in medical practice benefits and risks accrue to the same patient, and this makes decisions somewhat easier. Furthermore, the risks of not

undertaking an examination are often more relevant than its potentially harmful consequences, i.e., medical practices are often heavily justified. But all these are simply secondary connotations of one and the same process of justification.

As a final note, it seems fair to ask that whoever has the responsibility of justifying a practice (from a clinician prescribing an x-ray examination, to a political body deciding upon a nuclear programme) should be well informed of the values at issue and the responsibilities at stake for all active and passive subjects of that practice. Personally, I am not satisfied that this is always so, and I am sure that many of you have often felt the same way. This is exactly why there is a need for the apparently obvious principle of justification.

OPTIMIZATION OF PROTECTION

I will now turn to the second basic principle, the optimization of protection. In its newest formulation this principle reads: "In relation to any particular source within a practice, the magnitude of individual doses, the number of people exposed, and the likelihood of incurring exposures where these are not certain to be received should all be kept as low as reasonably achievable, economic and social factors being taken into account. This procedure should be constrained by restrictions on the doses to individuals (dose constraints), or the risks to individuals in the case of potential exposure (risk constraints), so as to limit the inequity likely to result from the inherent economic and social judgements." The complications introduced into the new text are due to the deepening of the concept since the time it was first stated, to a novel attempt to enlarge it to include the so-called potential exposures, and to a desire to minimise the inequities in the resulting distribution of doses. All these, however important, are secondary technical specifications superimposed upon a general principle.

This stipulates that when attempting to minimize the doses received by individuals and groups, one comes to a point where further investments (of financial resources, staff, services, etc.) are grossly out of proportion with the doses saved. And, since optimization is not performed in a vacuum but in a world with limited resources, at that point it is no longer advantageous to invest for increasingly small returns. I should hasten to state that this process of balancing doses and resources takes place under a ceiling of doses that should not be exceeded deliberately under normal circumstances: these are the individual dose limits that must be met irrespective of cost.

The optimization principle is obviously modelled on utilitarianism, a philosophical theory that takes human general well being to be the foundation of morality. In its most extreme form, utilitarianism assumes that right actions are those that cause the greatest happiness to the greatest number of people, happiness being defined as the balance of pleasure over pain. It further assumes that it is possible to measure and to algebraically sum up pleasure and pain, and to take as the right action that which produces the least negative or the greatest positive balance (Engelhardt 1991).

To philosophers, the main merits of utilitarianism are its coherence and unselfishness, that provide a unitary procedure for morally correct decisions. But there are also objections: for example, it is really possible to quantify all the values to be balanced? Is the greatest total happiness the goal to be pursued or is the distribution of happiness also an important factor? For these and other reasons, utilitarianism is not universally accepted as a true ethical system (Mackie 1977).

To be sure, radiation protection adopts and recommends the concepts of the theory in a restricted sense, starting from the main premises; for example, human well being is given the more limited meaning of absence of effects on health. Radiation protection borrows the ideas of the theory simply as a device to counteract selfish interests on the part of individuals and groups against other individuals and groups. In other words, it uses its main principles as a methodology to help setting boundaries to the pursuit of narrow egoistic tendencies.

It is interesting to point out that the utilitarian theory, which is based on a purely aggregative principle, does not itself provide any precise answer regarding boundaries. The main criticism about the theory is actually that it is open to the possibility that the happiness of some may be reached through the misery of others. To avoid such a danger, a distributive principle must be added to the aggregative rule of the theory, to limit the unfairness (or at least

the most extreme unfairness) in the sacrifice of some for the sake of others. So much for the ethical foundations of utilitarianism.

Discussions on optimization must start from its objective, which is that of limiting exposure and thus decreasing the associated health detriment. If disease and suffering have the same value, irrespective of their etiological agent, it appears intuitively preferable to make the most out of the resources available. There is no apparent reason why, for the same amount of human detriment avoided, one should invest more resources to reduce radiation damage, while, for example, neglecting the prophylaxis of some infectious disease through vaccination, or the reduction of transportation accidents by an efficient communication system, or the cure of cardiovascular emergencies by increasing the number of intensive care units over the territory. All these are aspects of a well integrated system of health planning and should be looked at and cared for in a uniform manner to achieve a distribution of resources that avoids a maximum of detriment and suffering.

To help achieve optimization, a variety of formal decision-making techniques may be used. One of these, cost-benefit analysis, requires that the two quantities to be weighted against each other should be expressed in the same units, usually monetary units (ICRP 1983). This need has often

should add now) that is the variable that matters.

At the same time, it has been pointed out that probably the most correct way to project the occurrence of radiation-induced cancer into the future from present epidemiological data is through a multiplicative model in which the natural rate of induction and the radiation dose together determine the final outcome of a given exposure (an additive model had been used until now).

All these considerations and facts prompted the ICRP to adopt a different course of action in the selection of the limits. The Commission proposes now to enlarge the perspective of the exercise and to consider a wide range of attributes associated with radiation-induced effects (neoplastic lethal and non-lethal and severe hereditary conditions). These attributes are: the probability of death from effects over the entire life; the life time lost when radiation-induced death occurs; the combination of both these parameters, that is the reduction of life expectancy; and the increase in the probability of dying in each one year at any age, conditional upon having reached that age. Then the Commission calculates the value of the attributes at doses of between 10 and 50 mSv/year (corresponding approximately to 0.5-2.5 Sv in a working life time) and selects as the limit the annual dose that it considers just short of unacceptable.

There is obviously a degree of subjectivity in selecting such a value, but hopefully not a great amount of arbitrariness. It is important to spend one minute to illustrate the main points of the reasoning.

First of all, why set the limit at the level which is just unacceptable and not at one which is clearly acceptable? Because under the assumption of linearity without threshold the only dose acceptable without question is zero. This alternative would, therefore, reject all doses from man-made radiation and would also be meaningless in view of the high level of unavoidable natural radiation. On the other hand, setting the limit at a dose just short of unacceptable carries the corollary that to keep a worker continuously at the limit implies a risk which is definitely too high.

Secondly, new scientific evidence and its re-interpretation had shown that the nominal risk coefficient for tumours and genetic effects combined had increased since 1977. On the basis of the previous limit and of the new nominal risk coefficients, a worker continuously exposed at the limit would see his life expectancy reduced by about one year with an attributable probability of death of about 9%: these figures would universally have been regarded as unacceptable and the limit should have been decreased. The question is: how much?

To use the words of the Commission, the new limit should be such "that the total effective dose received in a full working life would be prevented from exceeding about 1 Sv received moderately uniformly year by year and that the application of its system of radiological protection should be such that this figure would only rarely be approached". On this basis "the Commission now recommends a limit on effective dose of 20 mSv per year, averaged over 5 years (100 mSv in 5 years), with the further provision that the effective dose should not exceed 50 mSv in any single year".

I would be lying to you if I should claim that this decision was an easy one to make. It was a compromise just short of unacceptable to any of those who had to take it and came to be judged as tolerable for the Commission as whole, with various shades of dissatisfaction. But this is inevitable: as I said before, when deciding on these matters each person carries his own human, cultural and professional sensitivities which add to the logical line of thought (and I specifically mean adding in the sense of enriching). My own tendency would have been more restrictive, and therefore I have to remind myself all the time that limits are recommended for universal use and should cut across the needs of various groups and societies. They are suggested values, that individual countries may accept or reject, hopefully to adopt lower limits. Actually, the system itself recommends various ways to reduce the risk implied by the primary limits.

As to the limit of dose for the public, the ICRP proceeds in analogy with that for workers. It still aims at a dose level just short of unacceptable for continuous exposure and it still assesses the limit by comparing various attributes of lethal, non-lethal and hereditary harm. It comes eventually to a recommended level of 1 mSv per year. An alternative procedure, that of selecting a fraction of the natural background to be the limit would have been unacceptable in principle, because the fact that we are exposed to doses from natural radiation sources (even with ample fluctuations in space and time) cannot in principle justify the addition of any dose, however small, from man-made sources. Comparisons with background are useful a posteriori, but would be unwarranted a priori for the purpose of selecting limits.

The choice for the public of a limit which is considerably smaller than for the workers (about a factor of 20, at present) is ethically justified on the grounds that this limit applies to a much larger population, that exposure is for the whole life (and not only for the working life); and that the public at large includes here also the most susceptible young ages. Also, members of the public are only protected by source control and not by individual monitoring. All these considerations make sense from a general point of view. What is more perplexing to me is why workers should in theory be allowed (as they in practice do) to receive higher doses than other members of the public of the same age. Explanations usually given are that workers are paid to do a given job, but my objection is that this implies acceptance of the concept that a potential risk to human health and life may be traded for money. It is also said that workers undergo the relevant risks voluntarily as a matter of free choice. But is this true under conditions of high unemployment? And, in any case, is it fair to ask anybody to choose between no work and work under high risk?

The fact does remain that limits for professional exposure are normally higher than for public exposure for many human activities. I have no argument to oppose the wide public acceptance of this state of affairs. It could be an excess of scruples on my part, and it could be utopian and unrealistic even to contemplate such an idea: but I would eventually like to see a system in which each person is protected as a human being, irrespective of any working condition. And I believe that on this point there is room for further improvements.

CONCLUSIONS

At the end of this presentation, I should try to answer the question that has long been in my mind and perhaps in your mind too, since I started the present talk. Is the present system of radiation protection founded on sound ethical grounds? Overall, I believe that the answer should be yes, because the ethical propositions on which it is founded are good; the methodologies to develop the basic principles into a set of recommendations are morally acceptable; and the system appears reasonably coherent, flexible, stringent enough to keep the risks low, but not zero, which would be an impossible target to achieve, as long as there are benefits to be gained from the use of radiation.

Naturally, as is true of all human endeavour, the system could still be improved. Some improvements will come about in due course as new experience is gained. This applies, for example to the updating of risk estimates based on new scientific evidence. From it, as in the past, revision of the present recommendations will probably derive.

Other improvements will presumably require original research and development in order, for example, to further clarify the meaning of the principle of justification, or to include environmental, in addition to human, protection.

To meet further and more advanced requests, revolutionary, rather than evolutionary, approaches of the present system might be necessary. I am referring here to my suggestion to protect individuals as human beings and not as workers and public; or to the further universalization of the basic ethical principles to take into account non-objective health detriment and other preferences, desires or ideals.

Such further developments would almost certainly make the system more stringent. As it become so, some people may find it more acceptable but others may look upon it as too obtrusive. We certainly should ask ourselves whether we have taken the present system as far as it could go in order to preserve coherence, which is undoubtedly its main merit. On the other hand, we must see that protection against radiation is not pushed too much, because it may fall out of perspective and be unfairly penalized in comparison with protection against other health hazards.

My personal feeling at present, from a global perspective, is that adoption of the system, imperfect though it may be, by all countries would be likely to save more doses than might be saved by further marginal improvements in countries where the system is already well in operation. If this feeling is correct, then we should continue working, as we have done in the past, in order to develop the system rationally, while trying all the time to behave reasonably.

COMPARABILITY OF RISK

Chris J. Huyskens

Eindhoven University of Technology, Radiation Protection Department
P.O. Box 513, 5600 MB Eindhoven, The Netherlands

INTRODUCTION

The concept "risk" means different things to different people. When technocrats judge risk in their field of expertise, their responses correlate highly with quantitative estimates of probabilities. However, judgements and interpretations by non-experts attach much more importance to cognitive dimensions of perception. Risk evaluation by quantitative risk assessments or by risk perception should not be regarded as competitive but as complementary.

CONCEPT OF RISK

A great deal of discussion is often devoted to formulating "a proper definition of risk". Literature shows that there is an enormous variety of definitions and interpretations [2, 3, 5, 6, 8].

In health related sciences "risk" is often addressed as a multi dimensional combination of harmful health effects and their probabilities. In technological safety analysis, "risk" usually is expressed as a mathematical representation of probabilities of undesired events. In non-technology related sciences, interpretations are close to the loose meaning in every day language, referring to the threat of undesired events or the dread of harmful consequences. These different interpretations of risk cause considerable confusion in risk communication.

Quantitative definitions for any risk parameter in assessment studies should fulfil the conceptual requirement that they provide information about the basic triplet of risk components: scenario, probability and consequences [3].

- The "scenario" identification refers to the question "what can happen or what can go wrong?".
- The "probability" issue which refers to the question "how likely is it that things will happen?"
- The description of "consequences or measures of damage, which should answer the question "if it does happen, what are the consequences?"

The complexity of such a concept, especially because of each of these three components is of a multi dimensional nature in itself, leads to the necessity of simplification. Any definition of risk is conceptually adequate as long as it addresses all three fundamental components. Otherwise risk assessment or risk evaluation is impossible.

REDUCTION OF COMPLEXITY

It is a trivial statement that reduction of complexity of reality goes hand in hand with simplification. This is legitimate, because it is a necessary requirement to manage the complexity of risk assessments. However, one must realize that each step of simplification incorporates choices, value judgements or even policy judgements.

TYPOLOGY OF RISK DEFINITIONS [2]	TYPOLOGY OF COGNITIVE RISK DIMENSIONS [2,4]
<ol style="list-style-type: none"> 1. Uncertainty about safety or health 2. Possibility of undesired consequences (loss, damage, injury, death) 3. Lack of perceived controllability of a practice 4. Conditional probability - (mathematical expectation) - of a single type of harm (or loss) 5. Frequentistic presentation of a mono-dimensional index of harm 6. Multi attributive weighted aggregate of probabilities and consequences (utility theory) 7. Multi dimensional presentation of probabilities and consequences 	<ol style="list-style-type: none"> 1. Character and severity of harm or consequence 2. Controllability and influencibility by prevention and mitigation 3. Number of population at risk 4. Familiarity with consequences or activities 5. Voluntariness, intentionality and degree of involvement 6. Persistence, delay and transgenerational aspects

Any choice of definition and any choice of methodology in risk assessment is influenced by cultural, professional, institutional or even policy considerations. For this reasons Fischhoff [5] calls the choice for definition "a political act", which like any other choice in policy issues is inherently controversial. The choice of a risk parameter and the choice of methodology influences the outcome of any analysis and subsequently also influences conclusions and decisions. This is not meant as a criticism, but as a warning. Many risk analysts pretend that quantitative risk assessment is objective. This in my view, is not correct. Because even the choice of a risk definition or quantity is a value judgement in itself. There exists no dichotomy between subjective or objective risk evaluations. What does exist is a distinction between (i) quantitative risk assessment methodologies which assign preferential choices to the use of quantifiable parameters as simplified representations of risk and (ii) qualitative socio-psychologic methodologies which predominantly address the cognitive dimensions of risk perception. It is a matter of fact, proven by extensive psychological research that qualitative risk perception is generally uncorrelated with quantitative risk assessments [1, 2, 4, 5].

QUANTIFICATION

In quantitative risk assessments, the complex nature of risk is reduced by the choice of a highly simplified risk parameter. The ultimate simplification is reflected in probability assessments where only one single component of health detriment or harm is taken into account. Proponents of such simplified approach, especially amongst technocrats and policy makers, argue nevertheless that such a single dimensional "yard stick" of risk is suitable for policy decisions, because they assume such risk quantity is measurable. Most of these focus on mathematical representations for probability. The underlying assumption is of a typical technocratic nature. It is assumed that interpretation and comparison of numbers is more objective than any qualitative approach. What I wish to stress here, is that any choice of a quantifiable parameter to characterize only a few or even one single isolated aspect of risk, involves subjective judgement and therefore puts restrictions on the utility and significance of such quantitative risk estimates.

Further it must be realized that the probability aspect of risk in itself is of a multi dimensional nature. Distinction must be made between the "stochastic" probability of occurrence of hazardous events, the "frequentistic" probabilities that such events will lead to exposure and further the "conditional" probability that such exposure may result in harmful consequences. Technocrats sometimes seem to forget that probability does not merely refer to frequency, but that it also reflects subjective probability aspects by "best estimates" and "expert judgements". This variety of interpretations of probability implies a warning against aggregation into a single "probability estimate".

CETERIS PARIBUS

Interpretation and comparison of quantitative risk estimates become meaningless or even misleading when it is not guaranteed that respective practices or situations are otherwise comparable. This so called "ceteris paribus" principle requires that all factors, circumstances and assumptions that are not explicitated in the outcome of risk quantification, shall be mutually equivalent. This means that all technological, physical, biological and social descriptors shall not be essentially different. This "ceteris paribus" principle implies that quantified probability estimates must regard the same type of consequences as well as the same nature of scenarios. The required equivalence of consequences is a very restrictive constraint to the comparability of probabilities, because there exists not only a large variety of essentially different consequences, but each of them has widely different arguments. Even when only health detriment is considered, there still remains a variety of components.

Well-known examples of (apparently) single dimensional risk quantities are (a) fatal accident frequency rate - FAFR, (b) frequency of death per person year, (c) uniconhort and (d) loss of life expectancy. Each separately these quantities provide an extremely narrow and biased view on risk. For this reason they are hardly intercomparable. Covello et al. [8] emphasize this by explicit warning that "use of such data for risk comparison purposes can severely damage your credibility".

The multidimensional character of damage and harm shows somewhat better in multi attribute utility techniques. There risk is defined as a weighted combination of value judgements over the various attributes of harm. This can be described as a vector presentation in which each element or dimension represents a quantifiable attribute, such as probabilities and magnitude of consequences. The overall risk is then evaluated as the weighted sum of scores on different attributes. It seems often forgotten that such quantitative approach can be highly sensitive to small variations in weighting factors or the choice of attributes [5].

PERCEPTION

The limited comparability of quantitative risk estimates has clearly emerged in psychological research on risk evaluation. The impact of so called cognitive dimensions of risk, is apparent. Such descriptors are of a physical, biological and social character. The typology of cognitive dimensions is more of an effect related nature [2, 4, 7] and includes (i) the threat to biosphere, (ii) the threat to human health, (iii) the catastrophic nature of consequences, (iv) the intentionality and voluntariness of risk, (v) the distribution in time and space.

The major conclusion from psychological surveys is that people do not deal with risks in a consistent manner. The main arguments of the apparent great variety in risk perception and risk judgements are reasonably well-understood [1, 2, 7]. There exist a variety of mutually incommensurable, unequal interpretations and notions of the concept of risk and the extent of the problem analysis. Public perceptions of risk differ from assessments by experts. What is even more important is to recognize that perceptions can seem indifferent to risk communication. Additionally there are two other issues of main importance. At first, there is the issue of "equity". This involves problems about the fairness with regard to unequal distribution of benefits on one hand and cost and risk of a practice on the other hand. Further there is the issue of individual and collective partiality. Prejudice, with regard to the nature of the practice or situation as well as with regard to the type of harm or consequences. Especially where it involves large scale practices and low-probability - high-consequence type of activities, social political views and selective preferences are so extremely dominant that they cannot be implied in risk assessment methodology. Decision making then requires procedures which pay utmost care to social balance and acceptance. The role of risk comparison and risk assessment in such decision making processes is very limited, if at all existent.

CONCLUSION

The issue of comparability of risk is dominated by the following issues:

- the choice of definition; technocratic quantitative interpretations of risk are not by definitions objective. Any simplified risk definition implies value judgements.
- the scope of the problem; comparison of partial components of risk is more meaningful than presentation of absolute numbers. The pursuit of a unified, one dimensional risk quantity is unrealistic. It is a misjudgement of the gap between technocratic risk assessment and public risk acceptance.
- the "ceteris paribus" principle is an essential requirement for any risk comparison; the required equivalence of conditions is a very restrictive constraint to the comparability of numerical estimates.
- risk quantification and risk perception are uncorrelated; it is a requirement for risk management and risk regulation to imply both components in the structure of decision making. Risk quantification is predominantly a source or practice related assessment, while risk perception is highly consequence and effect related. They both rely on implicit value judgements. Explication of such hidden dimensions of risk is an essential requirement for comparability.

ANALYSIS OF A COMPARATIVE PUBLIC RISK ASSESMENT STUDY

ABSTRACT :

The main aim of this study has been to inventory the risks existing in a region (South East of France) so as to compare different activity sectors within geographic units of varying size. The overall data obtained shows that the mean annual radiological and chemical exposures do not result in a marked health risk for the sources considered, except for pollutants produced within the home, for which levels may exceed occupational exposure limits for periods of several days, or even weeks.

1 - INTRODUCTION

Cette étude (Programme Grand Delta) est développée depuis 1980 à l'IPSN. La région choisie est représentative du territoire national : 1/5 de la surface, 1/5 de la population (10 millions d'habitants) et les principales activités y sont représentées. Ce très vaste sujet n'a pu être traité de manière exhaustive. L'essentiel de l'étude a concerné le risque chronique et, plus précisément celui lié à la production électrogène (charbon, fioul, uranium), aux chauffages résidentiel et tertiaire, à la pollution à l'intérieur de l'habitat, à l'irradiation naturelle et à l'irradiation due au radiodiagnostic. Au cours de ces études, seules ont été prises en compte les nuisances créées par les activités qui s'exercent au sein de la région Sud-Est de la France. L'exposition calculée (dose intégrée délivrée aux populations) correspond à une durée de fonctionnement des installations de 30 ans. A chaque fois que cela s'est avéré possible, l'exposition a été corrélée à un effet sanitaire. Cela suppose l'existence d'une relation exposition-effet particulièrement délicate à établir, et qui en fait n'existe que très rarement pour les produits chimiques.

2 - METHODOLOGIE ET RESULTATS

La méthodologie utilisée découle directement de celle mise en oeuvre pour les études d'impact sur l'environnement des installations soumises à autorisation. Elle se résume en trois phases successives : évaluation des émissions, des expositions et des conséquences sanitaires. La description détaillée de ces évaluations a fait l'objet de publications [1,2].

2.1. Emissions

Les quantités de polluants émises par les installations des cycles électrogènes ont été, soit fournies par les industriels, soit obtenues à la suite de campagnes de mesures à l'émission, soit, à défaut, à partir de données publiées dans la littérature internationale. Dans le cas du chauffage résidentiel, l'évaluation des émissions tient compte, d'une part de la distribution de la population, des habitations et du mode de chauffage, et, d'autre part des consommations de combustibles de la région. Les consommations départementales du chauffage tertiaire ont été ventilées dans les seules zones urbaines. Les émissions à l'intérieur de l'habitat ont été caractérisées expérimentalement. Une soixantaine de produits a été analysée représentant 8 types d'utilisation différentes. Pour chacune d'elles, l'ensemble des produits analysés représente au moins 75% des ventes sur le marché français. Les émissions d'un foyer ouvert, simulant un feu de cheminée, ont été déterminées au cours des différentes phases de la combustion du bois (allumage, combustion, braises, ajout d'un morceau de bois).

2.2. Expositions

Rejets atmosphériques : les concentrations résultantes dans l'environnement sont évaluées à l'aide d'un modèle de dispersion atmosphérique de type panache gaussien simplifié qui tient compte de facteurs d'appauvrissement du panache : les dépôts sec et humide, les décroissances et filiations radioactives, ainsi que la transformation physico-chimique du SO₂ en sul-

fates. Les situations météorologiques des 12 stations concernées sont des moyennes sur 25 ans pour chacune d'elles. Les concentrations moyennes annuelles sont présentées dans un système de mailles de 100 km² issu de la grille européenne (mailles de 10.000 km²) mise au point à l'IPSN. Dans chacune de ces mailles, la concentration de chacun des polluants rejetés par l'ensemble des installations concernées est cumulée. L'exposition des populations est ensuite évaluée pour chacun des polluants et chacune des principales voies d'atteinte : directe (inhalation, exposition externe) et indirecte (ingestion par la chaîne alimentaire).

Rejets liquides (uniquement pour le cycle de l'uranium) : le Rhône est divisé en 9 tronçons dans lesquels les caractéristiques hydrodynamiques sont considérées comme constantes. Les expositions individuelles et collectives ont été calculées pour les principales voies d'atteinte à l'homme : eau de boisson, consommation de poissons et de produits irrigués, exposition externe. Pour évaluer l'exposition collective, on considère que toute la production agricole et piscicole est consommée par la population de la région sans tenir compte de la distribution géographique.

Radiodiagnostic (radiologie dentaire et radiodépistage systématique exclus) : l'évaluation de l'exposition collective et l'estimation de la dose moyenne par habitant dans chacun des départements composant la région étudiée, sont issues d'une étude effectuée au niveau national [3].

Radioactivité naturelle : la cartographie étudiée par l'IPSN étant incomplète pour les départements de la région étudiée, on a utilisé la valeur de 2 mSv/a proposée par l'UNSCEAR [4].

Intérieur de l'habitat : les concentrations résultantes dans les pièces d'un habitat à la suite de l'utilisation de produits domestiques ont été calculées à l'aide d'un modèle simplifié de transfert atmosphérique selon différents scénarios d'utilisation [2]. Si le facteur d'émission est une fonction du temps, les concentrations sont recalculées en tenant compte de la fonction d'émission déterminée expérimentalement. Les concentrations résultantes de la combustion de bois en foyer ouvert ont été mesurées dans la pièce à différents stades de la combustion à 1,5 m du foyer.

2.3. Effets sanitaires

Exposition radiologique

Compte tenu de la précision associée aux évaluations des expositions, on a admis, à partir de la CIPR 26, 0,01 effets stochastiques d'origine somatique par homme.Sv et 0,02 effets stochastiques somatiques et génétiques par homme.Sv.

Le nombre d'effets sanitaires calculé pour le public du Sud-Est de la France qui résulterait des rejets atmosphériques et liquides de radionucléides des installations des cycles énergétiques est de l'ordre de 0,1 pour le cycle de l'uranium et de 0,002 pour les centrales thermiques fossiles. Compte tenu des installations effectivement en activité dans la région en 1987, le nombre de ces effets est faible comparé à celui dû au radiodiagnostic (35) ou à l'irradiation naturelle (200). A titre de comparaison, le nombre de décès par tumeur enregistré en 1987 dans cette région est de l'ordre de 30.000 et représente environ 25% de la mortalité régionale, pourcentage comparable à la moyenne nationale.

Les valeurs annuelles maximales déterminées pour un groupe fictif recevant toutes les expositions maximales issues des installations des cycles électrogènes sont bien inférieures à la recommandation de la CIPR pour le public (5 mSv/a) et à la valeur moyenne annuelle retenue par l'UNSCEAR résultant de l'exposition naturelle (2 mSv).

Exposition chimique

Il n'existe pas, pour les polluants chimiques, d'indicateur unique de nuisance comme c'est le cas pour les produits radioactifs. Trois approches ont donc été suivies en fonction des données scientifiques disponibles et de leur pertinence :

- évaluation de la quantité incorporée dans un tissu ou organe cible ou dans l'organisme entier, quantité que l'on compare à celle présente chez un homme standard de 70 kg ou à une valeur seuil à partir de laquelle apparaît un dommage;
- évaluation d'un excès de mortalité ou de morbidité lorsqu'une relation exposition-effet a été établie. Si elle est de type linéaire sans seuil, les effets sont calculés, comme pour les radionucléides, à partir de l'exposition collective annuelle régionale exprimée en homme.µg/m³.
- comparaison à des valeurs limites d'exposition dans l'environnement ou plus souvent à des recommandations pour la santé du public. A la différence des radionucléides, on n'a pas distingué, en l'absence d'indicateur unique de nuisance, un "groupe référence" qui aurait reçu toutes les expositions maximales. Mais notons que la comparaison aux valeurs limites d'exposition répond en partie aux questions que l'on se pose quand on a recours à la notion de "groupe référence".

La surmortalité théorique calculée pour l'ensemble SO₂ et sulfates émis par le cycle électrogène d'origine fossile (centrales thermiques et raffineries) et les chauffages résidentiel et tertiaire atteint environ 100 décès dont 80% seraient dus au chauffage résidentiel. Un résultat identique est obtenu avec les poussières. Les concentrations de SO₂ et de poussières calculées dans les mailles (10⁻³ à 10 µg/m³), qu'elles résultent du cycle électrogène d'origine fossile, ou du chauffage résidentiel ou tertiaire, sont inférieures à la valeur guide de l'OMS (50 µg/m³) relative aux effets combinés du complexe SO₂-poussières [5].

Pour les métaux-traces émis par les centrales thermiques fossiles, en appliquant les relations exposition-effet données par l'OMS [5], le nombre de cancers calculé est inférieur à 1 pour l'ensemble arsenic, chrome (assimilé à Cr VI) et nickel. Pour le cadmium, les quantités stockées dans le cortex rénal (tissu cible) de la population sont bien inférieures (10⁻⁴ à 2.10⁻² µg/g) à la valeur à partir de laquelle peut apparaître un dommage pour le rein (200 µg/g de cortex rénal). Les quantités de nickel stockées dans l'organisme s'échelonnent de 1,7.10⁻⁵ à 8,5.10⁻³ µg par kg corporel. Elles sont très inférieures à la valeur observée chez l'homme standard, soit environ 7 µg par kg corporel. Pour l'ensemble des métaux traces émis, les concentrations calculées dans les mailles de 100 km sont très inférieures (10⁻⁸ à 10⁻⁶ µg/m³) aux valeurs guides recommandées par l'OMS [5].

Les concentrations calculées dans les pièces d'un habitat standard, compte tenu de différents scénarios d'utilisation des produits domestiques, peuvent dépasser les valeurs limites d'exposition professionnelle pendant plusieurs heures (toluène : utilisation de colle de revêtement à base organique), voire plusieurs jours (naphthalène et triméthylbenzène : application de cires). L'exposition au 1,4-dichlorobenzène (p-DCB) émis par les blocs WC désodorisant d'atmosphère peut quelquefois conduire à une probabilité de risque légèrement supérieur à 10⁻⁶ [6]. Enfin, les concentrations d'hydrocarbures polycycliques aromatiques, reconnus cancérigènes, émis par un feu de bois et mesurées dans la pièce à 1,5 m du foyer, peuvent atteindre des valeurs élevées au début de la combustion : benzo(a)anthracène + Chrysène (189 ng/m³), dibenzo(ak)anthracène (83 ng/m³), benzo(a)pyrène (70 ng/m³) et benzo(b)fluoranthène (58 ng/m³). Ces valeurs sont au moins divisées par 10 en fin de combustion.

3- DISCUSSION ET CONCLUSION

Le principal objectif du programme Grand Delta a été, dès son origine, de dresser un inventaire des risques d'une région en faisant en sorte que l'on puisse établir une comparaison entre secteurs d'activité au sein d'unités géographiques plus ou moins grandes.

La première difficulté rencontrée a été l'obtention des données indispensables à la première phase de l'étude, à savoir, la connaissance des émissions relatives aux activités répertoriées. A ce jour, ce problème existe toujours malgré la volonté des autorités d'obtenir une plus grande transparence. Une banque de données a tout de même pu être constituée à l'aide des informations des exploitants, de mesures, ou encore d'estimations à partir de la littérature internationale en l'absence d'autre

solution. Ces données relatives au cycle électrogène, aux chauffages résidentiel et tertiaire, au radiodiagnostic, à l'irradiation naturelle et à la pollution à l'intérieur de l'habitat, ont, pour certaines d'entre elles, été utilisées dans des modèles de transfert à l'environnement : air, eau et sol. Il est évident que ces modèles ne peuvent fournir qu'un ordre de grandeur comparé aux mesures réelles dans l'environnement. Ils sont cependant le passage obligé car il est impossible d'implanter, au niveau d'une région, suffisamment de capteurs pour mesurer la concentration moyenne annuelle de chacun des polluants existant.

Une fois estimées les concentrations dans les divers milieux, il faut caractériser l'atteinte à l'homme qui constitue la finalité de l'étude. Pour cela, il faut recourir à d'autres modèles décrivant le métabolisme du polluant inhalé ou ingéré et définir les coefficients de transfert (poumon → sang, absorption intestinale...). On sait que les "constantes biologiques" varient en fonction des formes physico-chimiques de l'élément considéré. Une nouvelle fois, on n'accédera donc qu'à un ordre de grandeur de la quantité de polluant transféré.

Toutes ces remarques ont pour but d'attirer l'attention de l'utilisateur éventuel de ces résultats sur les réserves qu'il faut apporter dans leur exploitation en tant que valeurs vraies dès que l'on parle d'effets sanitaires associés calculés. Ceci d'autant plus que contrairement à l'exposition radiologique il n'existe pas, pour les polluants chimiques, d'indicateur unique de nuisance et que seules quelques rares relations exposition-effet sont utilisables.

Il n'en est pas de même pour les analyses relatives aussi bien aux résultats entre eux (différents scénarios, différents filières) qu'à leur comparaison à des valeurs références (quantité présente chez l'homme standard, valeur seuil à partir de laquelle apparaît un effet, concentration moyenne dans l'environnement...). Le bilan de cette étude se matérialise donc, bien plus par une mise en perspective des risques chroniques résultant de différentes activités que par une évaluation absolue des effets sanitaires qui en résultent.

L'ensemble des résultats obtenus montre qu'en moyenne annuelle, les expositions radiologiques et chimiques ne conduisent pas à un risque sanitaire important pour les sources considérées à l'exception des pollutions générées à l'intérieur de l'habitat pour lesquelles, sous certaines conditions, les valeurs limites d'exposition travailleur peuvent être dépassées, et ce, pendant plusieurs jours voire plusieurs semaines.

INFORMATION ABOUT RISKS OF NUCLEAR POWER PLANTS
PROPOSED BY NUCLEAR INDUSTRIES TO MEDICAL DOCTORS
IN FRANCE, BELGIUM AND GERMANY

ABSTRACT

Information and post-graduate training of the medical profession are performed in continuation of academic studies and should endeavour to respond to the concrete questions that physicians have in mind and may have to deal with. They must strive to emphasize this distinctive and somewhat new role of the doctor that consists in putting a premium on health education at the expense of the only therapeutic role. This aspect of radiological urgency is liable to affect physicians as frustrating, which may, at least partly, account for the widespread impression among a strong majority of them in our 3 countries that they are still insufficiently informed, despite the effort conducted for many years by the physicians of the nuclear electricity utilities. France, Belgium and Germany have adopted the same approach.

INTRODUCTION

La radioprotection repose sur un ensemble de principes qui, au delà du respect de la réglementation, visent à intégrer cette protection dans la conception des installations, la préparation du travail, la formation approfondie et sans cesse réactualisée des agents mais également l'information du monde extérieur. L'accident de Tchernobyl a montré qu'une information utile en temps de crise ne peut se faire que si elle est précédée d'une information préalable de qualité pour bénéficier auprès du public d'une légitimité et d'un "capital confiance". A cet égard, le médecin et l'ensemble des professions médicales et paramédicales constituent sans doute un interlocuteur important car ils sont considérés par le public comme des

personnes compétentes aptes à donner des conseils avisés sur les activités potentiellement "dangereuses" pour la santé. Les professionnels de la santé réclament tous une information de qualité et le but de cette communication est :

- de décrire les besoins d'information et les actions menées depuis de nombreuses années auprès du corps médical et paramédical par les médecins des entreprises électronucléaires ;
- de comparer les approches retenues par la France, la Belgique et l'Allemagne, dont les motivations et les moyens sont très proches et se confondent dans certains cas, par exemple l'information transfrontalière des médecins et pharmaciens français, belges et allemands résidant autour des centrales nucléaires de Chooz et de Cattenom ;
- de souligner le rôle d'interface privilégié que peut et doit jouer le médecin du travail ;
- enfin, d'insister sur l'aspect spécifique de l'urgence nucléaire. Le rôle du médecin, en cas d'urgence radiologique, est surtout un rôle d'information, d'explication, de conseil, de dialogue avec les experts alors que les gestes médicaux sont réduits à peu de choses. Cet aspect particulier de la conduite à tenir doit être pris en compte.

LA DEMANDE DES PROFESSIONNELS DE LA SANTE

Les médecins et autres professionnels de la santé se déclarent prêts, dans l'éventualité d'un accident nucléaire, à "participer aux soins" et surtout à relayer et expliquer l'information délivrée par les experts. Ils sont à ce titre **demandeurs d'information**. Ceci ressort à l'évidence de tous les sondages effectués ces dernières années. Entre 1986 et 1991, 6 enquêtes portant sur un nombre important de médecins, près de 20 000 au total, menées en France montrent toutes que les médecins réclament une information complémentaire indépendante et réactualisée régulièrement. Ils ont conscience de représenter un relais d'information privilégié dans la mesure où ils jouissent d'une crédibilité incontestée auprès de la population. Dans nos 3 pays, le corps médical jouit à cet égard d'un rôle d'autant plus important qu'il est choisi librement. Ils font confiance aux hospitaliers mais également aux médecins des entreprises nucléaires, qu'ils considèrent comme des confrères spécialisés et compétents. Cette bonne acceptation du médecin du travail dans la formation continue mérite d'être soulignée.

La demande d'information varie évidemment en fonction de la proximité des installations nucléaires, mais la quasi-totalité des médecins souhaite une information complémentaire et spécifique de qualité.

LES MOYENS

Il faut, bien sûr, agir dans le prolongement de la formation acquise en faculté. Dans nos 3 pays, un enseignement de base est dispensé dans toutes les facultés de médecine. Mais il est réel que le contenu et peut-être la qualité de cette formation varient sans doute d'une faculté à l'autre, que cette formation intervient très tôt dans le cursus des études médicales, et que cet enseignement était plus sommaire il y a une quinzaine d'années. De plus, de nombreuses formations complémentaires sont organisées ; en France ainsi qu'en Belgique et en Allemagne, la radiobiologie et la radioprotection sont actuellement enseignées dans le cadre de nombreux certificats de spécialité (radiologie, médecine du travail, médecine d'urgence...).

Les différentes actions entreprises par les sociétés productrices d'électricité peuvent être classées en 3 niveaux complémentaires :

- Niveau européen, comme l'information transfrontalière.
- Niveau national, selon différentes modalités :
 - . Formation médicale continue. Les sociétés électriques n'ont bien entendu aucune initiative propre à prendre dans ce domaine mais elles apportent leur expérience à la demande des organisateurs.
En France, une formation nationale coordonnée par l'UNAFORMEC a été mise en place dans le contexte spécifique de la formation médicale continue.
 - . Information relayée par des périodiques médicaux de grande diffusion.
 - . Envoi systématique de documents, dont toutes les enquêtes montrent qu'ils répondent à l'attente du plus grand nombre de médecins.
- Et surtout au niveau local et régional. En effet, chaque site organise, indépendamment, des contacts et visites en fonction des demandes exprimées localement. Cette décentralisation permet de répondre de manière adaptée aux besoins et de tenir compte des sensibilités locales différentes selon les régions ; elles sont organisées par les collectivités médicales à compétence territoriale.

Ces initiatives locales et régionales représentent :

- + pour la Belgique, durant les 6 dernières années, 52 réunions pour les sites de Doel et Tihange ;
- + pour EDF, entre 1989 et 1991, environ 200 réunions pour l'ensemble des sites ;
- + pour l'Allemagne : Réunions régulières des associations spécialisées sur le plan fédéral et des Länder (environ 200).

A ce titre, des visites d'installations s'avèrent très utiles. Elles permettent non seulement d'appréhender de façon plus concrète la nature des risques mais également et surtout de nouer des relations personnelles qui permettront, ultérieurement, d'établir un réseau de correspondants et de compétences auxquels le praticien saura faire appel.

BILAN - CONCLUSION

Ces moyens sont-ils suffisants et adaptés ? Il est, bien sûr, très difficile de répondre à cette question mais les sondages effectués auprès des médecins permettent néanmoins d'analyser comment cet effort est perçu.

Le contenu de l'information doit, bien sûr, avoir pour objectif de répondre aux interrogations que se pose le médecin. A cet égard, l'urgence radiologique ne ressemble à aucune autre urgence médicale, dans la mesure où aucune prise en charge thérapeutique immédiate n'est attendue de la part du médecin. Or le praticien, face à sa responsabilité de médecin, veut savoir - et cela est légitime - quel serait son rôle précis dans l'éventualité d'une situation accidentelle. Cela se traduit souvent, dans la demande formulée par le médecin, par le désir de disposer de conseils pratiques, de "conduites à tenir" dans différentes circonstances. Et il arrive au praticien d'être "déçu" de ne pas avoir à faire de geste médical salvateur... L'urgence, dans ce domaine particulier de la santé publique est celle de l'information relayée au niveau des patients. Cet aspect de la prise en charge de l'accident est absolument essentiel et pour répondre aux nombreuses questions et inquiétudes des patients, pour conseiller utilement certains groupes particuliers (femmes enceintes, enfants, réticences de certains malades vis-à-vis d'examen radiodiagnostiques...), il doit avoir une "culture" nucléaire suffisante.

Enfin, le praticien doit connaître la spécificité de la surveillance médicale du travail et doit avoir un ordre de grandeur de la dose reçue en irradiation professionnelle et médicale afin de mieux mettre en perspective ces sources d'irradiation par rapport à l'irradiation naturelle...

THE COMPARATIVE ESTIMATION OF THE RADIATION AND CHEMICAL
CARCINOGENIC RISK INDUCED BY THE ATMOSPHERE CONTAMINATION
DUE TO RELEASES FROM COAL-FIRED POWER PLANTS

V.A.Knizhnikov, V.A.Komleva, N.K.Shandala

Institute of Biophysics, the USSR Ministry
of Public Health, Moscow, USSR

ABSTRACT

In experiments with 1000 white mongrel mice which inhaled benzo(a)pyrene (BP) and fly coal ash for a long time, these agents increased significantly lung tumour incidence, with the latent period shortened. BP is found to be 10-1000 fold more carcinogenic than fly coal ash. The BP inhalation at a sanitary standard level ($0.1 \mu\text{g}/100 \text{ m}^3$ of air) appeared to be equivalent, in murine risk, to the whole-body exposure to a total gamma dose of about 2.5 Sv . The coal ash inhalation in a concentration of $0.05 \text{ mg}/\text{m}^3$ caused the same risk as a dose of 0.05 Sv .

INTRODUCTION

Up to date, relativ contributions of different carcinogenic agents to lung cancers in the population are not quite clear. Therefore, an attempt was made to obtain experimentally a comparative estimation of lung cancer risks due to atmospheric concentrations, actually occurring in population centres, of BP and fly ash released from coal-fired power plants.

MATERIAL AND METHODS

The study involved 1000 white mongrel female mice. Mongrel mice, like man, are known to develop spontaneous lung tumours.

Chronic administration of ash or BP was carried out in special inhalation chambers. In the BP experiment, the mice spent in the chamber 6 hr a day 5 times a week for 3 months; in the coal ash experiment, the chamber residence time was 7 hr a day during 5 months, a total of 48 times. AMADs of coal ash and BP particles were 4.1 and $5.9 \mu\text{m}$, respectively. Experimental animals' lungs retained 25% of fly coal ash particles and 9% of BP dust.

The animals were followed up to their natural death. The dead were subjected to autopsy and post-mortem examination.

In mathematical data processing, the Student parameter criterion was used, and the cumulative probability of lung tumour incidence was estimated by an interval procedure.

RESULTS

The investigational patterns and lung tumour incidence in mice are summarized in Table 1.

Table 1

Lung tumour incidence related to coal ash
and BP intakes by inhalation

Item	Animal group			
	1(control)	2	3	4
1. COAL ASH				
Chamber-air concentration, mg/m ³	0	2.5	5.0	10.0
Retained in the lung, mg/g of tissue *)	0	1.0	2.0	4.0
Animals with lung tumours, % **)	28	37	61	78 ***)
Animals with ash-induced tumours, %	0	9	33	50
2. BENZO(A)PYRENE				
Chamber-air concentration, µg/m ³	0	0.2	6.3	78.0
Retained in the lung, µg/g of tissue	0	0.0025	0.8	9.0
Animals with lung tumours, %	14	23	37	40 ***)
Animals with BP-induced tumours, %	0	9	13	26

Notes: *) - The ash or BP dose (amount) retained in the lung was calculated by AMADs of respective aerosols.

***) - Using the interval procedure.

***) - P < 0.01 as compared with control.

The evidence from Table 1 suggests a positive carcinogenic effect of BP and fly coal ash in the study.

Table 2 gives average latent periods (ALPs) of tumours, time between the onset of administration and the first tumour appearance, and ALPs for the first 25% and 50% of murine tumours following the coal ash inhalation.

The data from Table 2 show a carcinogenic capacity of fly coal ash, thus supporting the results from Table 1. It is noteworthy that coal ash is considerably less carcinogenic than BP - by one to three orders for different concentrations. The dose-response curves for these agents differ: close to linearity for ash and far from it for BP.

Table 2

Average latent periods (ALP) of lung tumours
by coal ash concentrations inhaled

Item	Animal group			
	1(control)	2	3	4
	Ash concentration, mg/m ³			
	0	2.5	5.0	10.0
ALP	615±45	545±47	523±40	457±59 (**)
First tumour appearance	488	217	283	221
ALP 25%	490±3	402±47	349±47 (**)	228±9 (*)
ALP 50%	504±10	458±49	409±36 (**)	280±30 (*)

Notes: *) - P < 0.01 as compared with control;

***) - P < 0.05 as compared with control.

Mathematical data processing of both experiments gave the following dose-response equations:

$$\text{for coal ash} \quad Y = 5.2X + 28 \quad (1)$$

$$\text{for BP} \quad Y = 16.4 (Z)^{0.19}, \quad (2)$$

where Y is the percentage of animals with lung tumours;

X is the coal ash dose (mg/g of lung tissue);

Z is the BP dose (µg/g of lung tissue).

DISCUSSION

The findings from Table 1 and 2 should be discussed, above all, with respect to the question: if coal ash exhibits a carcinogenic capacity, why then this capacity has not been revealed in other similar studies, e.g. in a detailed one by S.Persson et al [1]?

An analysis of radionuclides, BP and some metals contained in ash showed that the carcinogenic effect of coal ash might result from chromium, nickel, cadmium, arsenic and other metals. Such metals as chromium, beryllium, etc., accumulated in the lung amounted to 10E17 molecules and more [2]. As for the latter part of the question, in the above mentioned [1] and other studies, BP and coal ash were administered to animals intratracheally in suspension, rather

than by natural inhalation. Very soon, the agents administered were rejected. In our study, the agent contact with the lung tissue was much longer, without any serious disturbance of the lung physiology.

Another issue of importance is a comparative risk estimation for BP and ash.

Does a low, as compared with BP, carcinogenic activity of coal ash mean no danger? Apparently not, given millions of tons annually released from solid fuel plants into the atmosphere. Moreover, a direct carcinogenic effect of ash was observed in our experiments at air concentrations very close to those actually encountered in the atmosphere. It should also be noted that the carcinogenic effect of ash, like other carcinogenes, e.g. BP, may have no threshold.

Table 1, equations (1), (2) and dose-response relationships known for ionizing radiation permit rough estimates of the radiobiological carcinogenicity equivalent for BP and fly coal ash. Similar death risks from induced cancer are caused by the whole-body exposure to a total gamma dose of 0.054 Sv and by the fly coal ash intake at a concentration of 0.05 mg/m³. For a BP concentration of 0.1 µg/100 m³, the radiobiological carcinogenicity equivalent is 1.98 Sv.

CONCLUSION

Earlier, the authors were the first to demonstrate experimentally the ability of fly coal ash inhaled with the air to induce lung cancer [2, 3]. It is also for the first time that the dose-carcinogenic response relationship has been studied for the coal ash and BP intake by inhalation.

The USSR current standards for coal ash and BP concentrations in the air do not prevent the population from a substantially higher risk than that caused by exposure to radiation within radiation protection limits.

METHODS AND PRINCIPLES FOR MAKING PRIORITIES IN RADIATION PROTECTION

J.O. Snihs

Swedish Radiation Protection Institute, Stockholm, Sweden

ABSTRACT

In making priorities one has to distinguish between the problems and the methods to solve them. They are both ranked on basis of aspects relevant for radiation protection and given different relative weight. The discussions in Sweden have concluded that the most important tasks in priority order are to prevent acute deaths, preclude stochastic effects in large populations, consider radiation problems related to high social and economical values and preclude stochastic effects in particularly exposed individuals. This leads to 8 areas of special concern.

INTRODUCTION

A first choice of priorities is found in the relative weight of questions on radiation protection as compared with other problems in the society. This choice is made on the political level on the basis of proposals presented by the competent authority. Factors involved are the available resources, the relative cost effectiveness of activities in various areas of concern and the political significance of the problems in a more wide political framework.

A recent modifying factor in the choice of priorities is the increasing interest by politicians, authorities and scientists to get a better balance and similarities in the judgement and handling of risks from various kind of environmental pollutants. These may be e.g. radioactive and non-radioactive releases from industries and from waste disposal facilities. Two recent symposia discuss these problems (1,2).

In the area of radiation protection there is also an ambition to balance the efforts in reducing radiation doses in order to make the radiation protection optimized. That means that improvements in protection should be reasonable in comparison with other efforts made in society to reduce risks. This is achieved by using economical valuation of risks and relating these to protection costs.

PRINCIPAL METHOD FOR CHOICE OF PRIORITIES

At the authority level the decision on priorities is reflected in the budgetary process. This is made by choosing priorities of the marginal changes in the existing program i.e. using the so called incrementalistic approach in the decision making (3,4) or by using a more rigorous approach by questioning the whole programme on radiation protection and choosing priorities more thoroughly. Both methods have their benefits and drawbacks (5).

The first method is normally less cumbersome and therefore more often used. The second method is by definition more time consuming and needs more manpower. How it can be accomplished is described below on the basis of Swedish experience.

The activity of the authority is characterized by its programmes, working methods, organisation and resources. The choice of priorities is made on the problems to be solved i.e. the programmes, and on the working methods. The degree of priority of a problem decides its timetable and resources to be allocated. The degree of priority of various working methods decides inter alia the efficiency and profile of the authority. It is necessary before making priorities to structure the problems (and working methods) in a systematic way to make them comparable.

The various possible working methods are defined as e.g. international work, inspections, own measurements and control, check others' measurements, standardize, give lectures, give criteria, etc.

The basis for forming an estimate of the relative importance of the various problems (i) is a set of factors (aspects) (j), which are more or less important from the radiation point of view and for which we need to assess their relevance for each problem, (i).

Examples of these factors are political decisions, international decisions, requirements by the public, public concern, legal requirements, controllability, benefit of the practice where the problem occurs, cost-effectiveness of an action, collective doses, individual doses, risk of accidents, prognosis of development etc.

The importance of these factors (aspects) for each of the various problems gives a basis for choice of priorities. It can be found in three steps.

The first step means a ranking of the problems (i) with regard to the factors (j), one by one. This can be made by comparison of pairs of (i) in a matrix in such a way that the problems (i) will be ranked in order of importance for each factor (j). There is therefore one matrix for each (j). The ranking is made by answering the question: how important is factor (j) for a given problem (i) in the judgement of the overall importance of the problem, assuming that something can be made reasonably to solve/decrease/control the problem in respect to aspect (j). The ranking of problems in each matrix should reflect the relative importance of each aspect (j). In all matrices the condition of symmetry must be fulfilled i.e. if $a > b$ and $b > c$ then also $a > c$. This procedure yields a weighting factor w_{ij} for importance.

The second step means a ranking of the factors (j) irrespective of problem but just considering the overriding objectives of the authority and the general valuations in the society having in mind the actual state of conditions of the

radiation protection in the country. The ranking can also here be made in a matrix by a pair-ranking method, with condition of symmetry. The basis for judgements should in principle be made by interviews of various groups in the society. This yields a weighting factor q_j .

The two ranking procedures lead to a set of weighting factors of the problems (i) for each aspect (j). The third step is to multiply each factor w_{ij} with corresponding factor q_j and add all these products for each (i). The numerical value of the sum $\sum_j q_j w_{ij}$ indicates the relative priority of each programme. The reliability of the method is checked by a sensitivity analysis by having several people making the same analysis independently.

The choice of priorities for the working methods can in principle be made similarly. The factors (aspects) may be efficiency, cost, speed, competence, development, attracting and keeping personnel, good reliability, etc.

PRACTICAL RESULTS

In the discussions of priorities for the next 3-year radiation protection programme of the Swedish Radiation Protection Institute the presented methods and ideas were leading the thoughts even though we did not proceed along the mathematical formalism described above. It was concluded inter alia that the most important tasks of the Institute are in priority order the following

1. to prevent acute deaths and other serious damage caused by radiation
2. to preclude or decrease the stochastic effects of radiation in large populations
3. to pay attention to radiation protection problems related to conditions in society with high social and economical values
4. to further preclude or decrease the stochastic effects of radiation in particularly exposed individuals.

Using these bases of judgment in combination with some others, eight programmes (problems) were identified as those of highest priority. They are given below with special explanation in Fig.1 why they are justified. Their relative position is not in order of priority.

1. Radon in houses
2. Sun radiation
3. X-ray examinations of patients
4. Emergency preparedness for nuclear accidents in Sweden or abroad
5. Data screens
6. Strong sealed radioactive sources and large accelerators
7. Normal operation of nuclear power
8. Radioactive waste of nuclear power.

Fig. 1

Qualification/Programme	1	2	3	4	5	6	7	8
Number of cancer deaths per year prevented by protection effort	>100	>100	-	>10 ³	2)	-	-	-
Number of Swedes running a risk >1% to die in cancer caused by radiation	>10 ⁶	~10 ⁶	>10 ³	1)	-	-	>10 ³	-
The protection efforts are cost-effective.								
Number of lives saveable for less than 0.2 M US dollars per life	>10	>100	>10	-	-	-	-	-
The radiation problems are connected to high social and economical values	yes	yes	-	yes	yes	-	yes	yes
There is a risk of acute deaths	-	-	-	yes	-	yes	-	-
The problem is increasing.								
A protection effort now is more efficient than later	-	yes	-	-	yes	-	-	yes
Need of good control	-	-	-	-	-	yes	yes	-

Notes. 1. Means unnecessary deaths
 2. In total after a very serious accident

CONCLUSION

The discussion on priorities has been well received at the political level since it has been possible for board members and ministry officials to understand the main arguments behind the priorities suggested. In times of budget cuts it helps the politicians to get the best value for the money spent.

NEW SETTING-UP OF THE CRITERION OF ACCEPTABILITY OF RISK IN
RADIOPROTECTION SECTOR

L. Failla

I.N.P.R.A.T.

(National Institute for Risk Prevention in Technological
Activities)

ABSTRACT

The method presently used for choosing the values of "acceptability" of the risk of damage from i.r. is based on the comparison with other risks in human life, it divides the persons exposed to the risk into groups and establishes for each of them the values of doses considered "acceptable". Taking into account that the damage involves the single person, the risk-benefit relation is evaluated on him, putting aside the distinction in groups and the general method of comparison.

The relation $B > R > 0$ where B =benefits and R =risks. Applied to the single person enables us to identify the "acceptable" doses for him, through an appropriate selection of B and R .

INTRODUCTION

As we know, ionising radiations (i.r.) can cause damages to the man who absorbs them. The probability of damage becomes lower whenever the absorbed dose of i.r. decreases; but it is not possible to establish a threshold under which this probability is zero. It is assumed as a working hypothesis in order to establish the fundamental criteria of radioprotection for those doses which produce "stochastic" effects. This hypothesis derives from the proportionality between the risk (probability) of damage and the absorbed dose, represented by a straight line which passes through the origin of the cartesian axis.

A large literature on this topic and mainly the ICRP itself, have examined and are examining the issue resulting from this lack of threshold; this involves the need to establish a value of "acceptability" of the risk which corresponds to a certain value of dose in order to make the use of i.r. possible. Therefore, it is necessary to choose and eventually indicate and recommend such value of "acceptability" based on appropriate methods or criteria to establish.

At this stage, this issue shifts obviously from the scientific field towards the moral, political and social ones.

DISCUSSION

The ICRP No.9 (sept.1965), but also others of its publications, states the principle "that all doses be kept as low as is readily achievable" but it also adds "economic and social consideration being taken into account", briefly indicated as ALARA. Apart from this, it is pointed out that this principle states the opportunity to keep doses as low as possible in order to expose people concerned to the minimum risk which is considered "acceptable", although the introduction in the second part: "economic.." makes its application more flexible.

The criteria and methods used by the ICRP to recommend the

values of "acceptability" are inspired by this principle and are based on the system of comparison with the risks the man runs during every-day life. Based on these criteria and on the above principle (ALARA), the ICRP has identified the maximum values for those doses which cause a risk considered "acceptable" by mankind. These values are divided into three groups of exposed people: 1) workers; 2) people exposed for medical reasons; and 3) population. Therefore they do not take into account the single person but they stick to general considerations. Moreover, they do not make a distinction between those people who are the object of the risks and those who get the benefits.

But the damages we are discussing have their effects on the single person exposed to i.r., causing considerable pain to the individual himself and to his relatives.

The proposed method for choosing the criteria of acceptability differs from the present method used, which has been explained earlier, as it examines the single individual exposed to i.r. developing a risk-benefit analysis which is personalized even though it utilizes, as we will see later, objective and general parameters. The above method consists of moving the risk-benefit analysis from a general interest for the society to the specific one for the single individual. The value of "acceptable" risk and, therefore, the maximum dose accepted for the stochastic damages is chosen on the basis of this individual analysis. According to the above, the objects of the risks and benefits respectively can be inserted automatically, being the individual the object of this relation, while the proposed three categories of the ICRP No.60 are no longer valid.

Let us indicate with "R" the risk of damage resulting from the absorption of i.r. and with "B" the benefits originated by the activity involving such risk; the "acceptable" dose for each single individual should be: $B-R > 0$ (1).

The value of risk (probability) of damage to the single person, according to the absorbed dose, can be obtained from the straight line, used in the working hypothesis explained above, which indicates the proportionality between the dose and the risk. Therefore this value can easily be quantified for each person on the basis of the received dose, by using the above considerations; it will be possible to identify the value of maximum dose for each single person in order to make the risk-benefit relation more advantageous to him, hence to consider such value "acceptable".

The benefits deriving to man from the use of i.r. are numerous and of a different kind. They can, however, be summarized in two main benefits:

A) reduction, as a result of the use of i.r., of the risk of damage due to those activities differing from the ones which expose man to i.r. (B_d); if we know the type of activity exposing a person to i.r., we can evaluate this reduction (B_d), by considering those tables and statistics which are used for insurance purposes and are indicated by the competent national and international organizations. B) The improvement of welfare (living conditions) of the exposed person (B_m). The fundamental elements on which man physical welfare is based can be divided into the following two groups: $B_{m,1}$, those elements involving man directly; and $B_{m,2}$, those ele-

ments which act through the social organization. Hence we will have the relation: $B_m = B_{m,1} + B_{m,2}$. For the first elements ($B_{m,1}$) a further classification can be made into the following groups that are the fundamental elements for the human life: $B_{m,1,1}$: food; $B_{m,1,2}$: clothes; $B_{m,1,3}$: house; $B_{m,1,4}$: Health.

The quantitative choice of the various $B_{m,1}$ depends on the different individual and social situations and each country should establish these values giving them a "weight" on the basis of particular social and environmental circumstances. We will have: $B_{m,1} = B_{m,1,1} + B_{m,1,2} + B_{m,1,3} + B_{m,1,4}$.

For the second group ($B_{m,2}$: the social organization) to improve the conditions in the above sector, utilizes the elements which can be summarized as follows:

$B_{m,2,1}$: goods production; $B_{m,2,2}$: goods exchange;
 $B_{m,2,3}$: health.

The above sectors are a synthesis of various activities. Like for $B_{m,1}$ also for $B_{m,2}$ we have to give a "weight" to each sector. Hence we will have: $B_{m,2} = B_{m,2,1} + B_{m,2,2} + B_{m,2,3}$.

Once $B_{m,1}$ and $B_{m,2}$ are evaluated in this particular situation, we will be able to calculate B_m keeping in mind that the "weights" to be given to $B_{m,1}$ and $B_{m,2}$ have a minimum value = 0 and a maximum value reflecting a particular environmental condition.

The choice of the above elements ($B_{m,1}$ and $B_{m,2}$) is only indicative; it can be substituted and extended. Our purpose is to present a working method necessary to introduce the proposed principle: "of the application of the risk-benefit relation to the single individual exposed to i.r."

CONCLUSIONS

We have already shown how to evaluate B_d ; with the above, we can evaluate B_m . Therefore we have $B = B_d + B_m$ (2) replacing on (1) we have $(B_d + B_m) - R > 0$.

The evaluation of R can be easily made using the hypothesis of the straight line which shows the relationship between the absorbed dose and the probability of damage. This will give the possibility to choose the maximum value of dose of i.r. considered "acceptable" for the single individual exposed. Keeping unchanged the relation $B - R > 0$ (1). However, if we take into account the ALARA principle, we will notice that the relation (1) indicates those values of R which are not to exceed but, if possible, they must be further reduced.

L'INFORMATION DE LA POPULATION DE L'ISERE EN MATIERE DE RISQUES
TECHNOLOGIQUES MAJEURS ET PLUS PARTICULIEREMENT DE RISQUE NUCLEAIRE

H. de CHOUDENS, Adjoint au Directeur du Centre d'Etudes Nucléaires de
Grenoble - Commissariat à l'Energie Atomique - FRANCE

POPULATION INFORMATION ON MAJOR TECHNOLOGICAL RISKS AND SPECIALLY ON
NUCLEAR RISK.

Following Tchernobyl accident which has revealed in France a strong need for information on technological risks among population and a lack in its organisation, the Mayor of Grenoble City who was also at this time, Environment Minister in French Government had initiated in Isère Région an important opération of consideration of actions which has to be undertaken to correct these lacks.

Among ten actions retained one of them was the creation of an Association for Information of the public for Prevention of major risks.

This Association has first initiated a consultation on the perception by the population of the different major risks (Industrial and Natural) in view of the results of this consultation, Medical Professions were the first concerned and a publication "Medecine and Nuclear risk" has been elaborated and distributed to all doctors of the Region.

A Memento on Nuclear risk has then been written and largely distributed in the region, specially in the medias.

A booklet on Nuclear risk and behavior in case of Nuclear accident has then been realised and distributed to all people around Electronuclear Reactors of the Region and to children in the schools. In complement, public meetings have been organised in these sectors to inform and discuss with the population.

INTRODUCTION :

Entre autres réactions pleines d'enseignements, l'accident de Tchernobyl a mis à jour en France un besoin pressant d'information de la population dans le domaine des risques majeurs qu'ils soient industriels (risque chimique, risque nucléaire...) ou qu'ils soient naturels (tremblement de terre, éruptions volcaniques, glissements de terrains...).

Parallèlement, il est apparu que tous les organismes officiels capables de fournir en cas de crise les informations nécessaires ainsi que dans une certaine mesure, les médias chargés de diffuser l'information, étaient finalement mal préparés à jouer ce rôle.

Dans le Département de l'Isère, le Maire de Grenoble qui était alors Ministre de l'Environnement dans le Gouvernement Français a donc lancé durant l'été 1986 une grande opération de réflexion sur les moyens de prévention et de gestion des Risques Technologiques et Naturels Majeurs. Au cours de cette opération, entre autres, une commission spécialisée s'était penchée sur les problèmes d'information des populations, avant, pendant et après une catastrophe.

Dix actions prioritaires avaient été retenues dans le rapport final rédigé à la fin de l'opération. Parmi celles-ci, l'une préconisait la création au niveau départemental d'une structure permanente chargée d'organiser et de diffuser l'information. Ainsi fut créée l'Association d'Information pour la Prévention des Risques Majeurs (AIPRM) regroupant les organismes publics, les collectivités locales, les industriels, les scientifiques, les associations de défense de l'environnement, les syndicats. L'Association est présidée par une journaliste, Noële ROY.

LA PERCEPTION DES RISQUES PAR LA POPULATION

S'agissant d'informer un public aussi hétérogène qu'une population, il est apparu nécessaire à l'Association de déterminer quels étaient les comportements de celle-ci en matière de risques majeurs et quels étaient les relais qui possédaient le plus de crédibilité auprès du public et pourraient être utilisés. Une enquête auprès de la population de l'Isère fut donc confiée à une équipe de l'Université des Sciences Sociales de Grenoble dirigée par un de ses professeurs Anne LALO.

Les résultats en furent, sur certains points surprenants. Ainsi dans un département très nucléarisé tel que l'Isère (deux sites de Centrales Electronucléaires dont un surgénérateur, deux centres de recherche avec deux réacteurs, une usine de fabrication de combustibles nucléaires), l'accident grave dans une installation nucléaire n'arrive qu'en sixième position dans les préoccupations de la population avec 20 % de personnes inquiètes (le souci majeur du public est le risque d'accident de la route, voir Fig.1).

Quant aux personnes ou organismes à qui le public fait confiance pour avoir des informations, ce sont les gens ou organismes considérés comme indépendants des enjeux économiques et politiques qui sont les plus crédibles ; à l'autre extrémité, pouvoirs publics, élus, journalistes, industriels sont peu, voire très peu crédibles (fig.2).

INFORMATION DES PROFESSIONS MEDICALES

Les résultats de l'enquête citée au précédent paragraphe montrent que les médecins sont parmi les catégories considérées par la population, comme les plus crédibles pour donner des informations sur les risques. D'autre part, en cas d'accident radiologique, les personnes inquiètes de ses conséquences pour leur santé, s'adressent tout naturellement à leur médecin pour être informées. En France, l'accident de TCHERNOBYL a bien mis en évidence ce recours aux médecins des personnes les plus anxieuses sur les conséquences de retombées radioactives. Corrélativement, les médecins se sont trouvés tout à fait démunis pour répondre aux interrogations du public et ont manifesté par la suite une forte demande de formation et d'information sur les problèmes des risques radiologiques et sur leur rôle vis à vis du public lors d'un accident nucléaire majeur.

La Faculté de Médecine de Grenoble, sous l'impulsion de son doyen le Professeur G. VROUSOS et avec le soutien de l'Association d'Information pour la Prévention des Risques Majeurs a donc très rapidement entrepris la réalisation d'une plaquette "Médecins et Risques Nucléaires" donnant la conduite pratique pour les médecins en cas d'accident nucléaire (fig.3).

Cette brochure (fig4) donne en particulier sous forme de fiche style "check list" les conduites à tenir en présence de différentes situations : personne irradiée et/ou contaminée, blessée et contaminée...

Cette plaquette a donc été distribuée à tous les médecins de l'Isère en 1988. Deux ans après sa publication en 1990 pour essayer de déterminer son efficacité, une étude d'impact a été réalisée par un cabinet spécialisé auprès des médecins qui en avaient été destinataires. Les résultats ont montré l'intérêt soulevé par une telle publication. En effet, 61 % des médecins interrogés se souviennent avoir reçu la plaquette et parmi ceux-ci 80 % l'ont conservée dont 65 % après l'avoir lue (pour les spécialistes en communication, ces résultats à deux ans, pour ce type de support, sont à considérer comme très bons).

Après sa diffusion dans l'Isère, une demande s'est manifestée de la part d'autres départements français ce qui conduit à une diffusion nationale et à un tirage important (à ce jour à 50.000 exemplaires). L'initiative de distribuer une telle brochure aux médecins a été soulignée comme excellent par les inspecteurs de l'AIEA venu faire une évaluation des mesures prévues pour faire face à un accident autour de la Centrale Electronucléaire de St ALBAN, - St MAURICE L'EXIL, en Isère. L'AIEA a d'ailleurs demandé l'autorisation de la traduire en anglais. Par ailleurs cette plaquette a reçu en 1988 le Prix de la Société Française d'Energie Nucléaire récompensant une action remarquable effectuée par l'information du public.

L'action d'information du monde médical n'est pas considérée comme terminée par la distribution de cette plaquette. En effet, l'étude d'impact indiquée ci-dessus a aussi montré que 89 % des médecins désiraient que des initiatives continuent à être prises pour leur information dont la rédaction d'une nouvelle brochure leur donnant des renseignements complémentaires.

Prenant acte de ce besoin, de nouvelles actions sont donc d'ores et déjà lancées :

- . Actions de formation post universitaire sur le risque radiologique.
- . Edition d'une version améliorée et complétée de la plaquette
- . Publication d'une revue périodique : "Médecins et Rayonnements Ionisants".

LES MEDIAS, LES ELUS, LES "DECIDEURS":

A l'occasion d'un incident nucléaire, les personnes chargées de recevoir puis retransmettre l'information : journalistes, responsables des pouvoirs publics, élus, se trouvent confrontés à une communication utilisant des notions et un vocabulaire loin de leur être familier. Pour leur fournir un document auquel ils pourraient se référer facilement, s'ils éprouvent la nécessité de se remémorer la signification de certains éléments qui leurs sont transmis, un "Mémento du Risque Nucléaire" a été rédigé et diffusé (Fig 5 - Mémento du Risque Nucléaire).

Au-delà de la cible concernée par ce mémento, celui-ci a suscité l'intérêt des responsables de la Sécurité Radiologique de quelques organismes qui ont obligation de fournir à leurs travailleurs et particulièrement aux travailleurs occasionnels ou intérimaires, une information sur le risque radiologique et les moyens de s'en protéger. Ainsi à Grenoble, l'Institut Laue Langevin, organisme européen de recherche exploitant un réacteur à Haut Flux de Neutrons, et à l'échelon national Electricité de France, utilisent ce mémento pour certaines catégories de leurs personnels. A ce jour, le tirage de cet ouvrage s'élève à 15000 exemplaires. Toute personne du public intéressée par les problèmes de

risques radiologiques mais peu familier avec ce domaine, peut d'ailleurs utiliser un tel document qui cherche à présenter de façon simple et compréhensible par tous les éléments de Radioprotection.

L'EDUCATION NATIONALE

Les enfants et adolescents constituent une catégorie du public qu'il est primordial de sensibiliser aux problèmes des risques majeurs et d'éduquer quant aux conduites à tenir en cas d'accident. Ce sont en effet les adultes de demain et qui plus est, un excellent relai de l'information vis à vis de leurs parents. L'Education Nationale est pour ce public, l'intermédiaire le plus efficace et quasiment obligé pour faire passer les messages. L'Association a donc entrepris un travail en profondeur avec un Groupe de Travail formé d'enseignants. Ce groupe s'est attaché en premier lieu à définir et organiser sous forme de stages une formation des enseignants qui seront ensuite amenés à intégrer dans leurs enseignement une partie consacrée aux risques et aux manières de s'en protéger. En second lieu, les outils pédagogiques nécessaires ont été élaborés sous forme d'une mallette pédagogique contenant les éléments nécessaires au professeur pour préparer ses cours et en présenter les éléments à ses élèves. Cette mallette concerne actuellement le risque chimique et il est bien entendu de faire de même pour le risque nucléaire.

LA POPULATION

Cible ultime de l'information, des actions directes ont été menées à son égard.

Tout d'abord compte tenu de l'obligation faite aux pouvoirs publics et aux exploitants d'Installations Nucléaires, d'informer la population des communes avoisinantes, l'Association a apporté son concours aux exploitants des Centrales Electronucléaires de l'Isère pour réaliser une plaquette qui a donc été diffusée à tous les foyers concernés et aux enfants des écoles (Fig.6). D'autre part, dans le cadre d'une grande campagne d'information étalée sur plusieurs mois et comportant, en plus de conférences diverses, d'informations à la radio et à la télévision et des réunions publiques de discussions dans les zones entourant les contrôles, une brochure traitant de tous les risques technologiques et industriels dont bien entendu le nucléaire a été rédigée et mise en vente (pour une somme modique) chez les distributeurs habituels de journaux.

CONCLUSIONS

L'information du public qui ne peut être dissociée d'une formation nécessite un effort soutenu de longue haleine. Dans le passé, elle a trop souvent été négligée ou n'a fait l'objet que de campagnes utilisant parfois de gros moyens mais de durées brèves, style "coup de poing". Les résultats ont montré que leur impact était souvent faible et toujours éphémère. Jusqu'à un passé récent et dans une certaine mesure, maintenant encore, la population ignore souvent comment elle serait avertie d'un accident et la conduite qu'elle aurait à tenir. SEVESO, BHOPAL puis TCHERNOBYL ont en France, mis en lumière, ces besoins.

Au niveau des Pouvoirs Publics et des Industriels, de gros efforts ont été consentis pour améliorer la situation en matière d'information. Dans l'Isère, la création de l'Association d'Information pour la Prévention des Risques Majeurs (AIPRM) soutenue matériellement par le Conseil Général du Département a été un élément important de cet effort. En près de quatre ans, après une phase d'organisation, l'AIPRM peut mettre à son actif des réalisations qui ont rencontré un excellent accueil auprès de la population et qui, point le plus important, s'inscrivent dans un programme continu qui en fait n'est est qu'à son début. L'action de l'AIPRM s'inscrit donc dans le long terme.

Paris, France

CHERNOBYL : ANALYSIS OF THE INFORMATION GIVEN BY THE MEDIA

Alarmist information was given by the media after Chernobyl, causing public concern on nuclear energy. Electricité de France published a document "Chernobyl, truth and falsehood" in March 1991, in order to give elements of critical analysis to the staff of the company. The information given was grouped in three parts : what is true, what is wrong and what is uncertain. This classification was established and explained on the basis of scientific and medical knowledge on the effects of ionising radiation, the scanty international scientific publications about Chernobyl, the reports by international organisations and eyewitness accounts of western people who worked in humanitarian organizations.

INTRODUCTION

A la suite de l'accident de Tchernobyl, les médias ont donné des informations diverses, parfois contradictoires et difficiles à vérifier, souvent alarmistes. Ce fut le cas à nouveau lors du quatrième anniversaire.

Face à ce flux d'informations, il est apparu nécessaire et important que l'ensemble du personnel d'Electricité de France dispose des moyens de porter un regard critique sur cet événement et ses conséquences. C'est l'objet du document "Tchernobyl : le vrai, le faux et l'incertain".

MODALITES

Dans ce but, nous avons répertorié tous les articles et toutes les émissions diffusés en France au cours de l'année 1990. Nous les avons analysés et classés par thèmes en distinguant trois types d'informations : celles dont nous pouvons confirmer la véracité, celles à l'évidence erronées et celles pour lesquelles nous ne disposons pas de données suffisantes.

Pour ce faire, nous nous sommes appuyés :

- sur les connaissances médicales et scientifiques concernant les effets des rayonnements ionisants ;
- sur les rares publications soviétiques dans des journaux scientifiques internationaux ;
- surtout sur les rapports des organismes internationaux à propos de Tchernobyl et ses conséquences (AIEA, UNSCEAR, OMS, Communautés Européennes,...) ;
- et enfin, sur les témoignages des personnes ayant séjourné en URSS au cours des dernières années, notamment dans le cadre d'organismes d'aide humanitaire (Croix Rouge, Médecins du Monde,...).

DANS LE CHAPITRE "CE QUI EST VRAI", nous avons retenu les informations sur :

- les causes de l'accident, en général bien analysées par la presse et liées à l'incompétence des exploitants, la vétusté du matériel et la conception des réacteurs soviétiques RBMK ;
- le retard à l'information de la population et les évacuations après l'accident ;
- l'étendue des zones contaminées et les décisions d'évacuations de populations dans les années suivant l'accident ;
- l'impact de l'accident sur la végétation et en particulier la forêt autour de la centrale accidentée ;
- l'état archaïque de la médecine soviétique dans la région concernée se traduisant par un manque de médecins et de matériel, ainsi que l'absence de données épidémiologiques correctes sur l'incidence des maladies avant l'accident (notamment des anomalies thyroïdiennes et des cancers) ;
- l'importance de l'irradiation thyroïdienne reçue par de nombreux enfants et le retard apporté à une prévention efficace par l'iode stable ;
- l'apparition de nombreux troubles psychologiques et maladies psychosomatiques dans la population ;
- et enfin, l'insuffisance de l'information donnée en France après l'accident.

DANS LE CHAPITRE "CE QUI EST FAUX", nous avons classé principalement des descriptions fantaisistes et erronées des effets des rayonnements ionisants, auxquels on attribue souvent les effets du stress induit par l'accident. Il est également abusif d'attribuer aux rayonnements toute maladie constatée après Tchernobyl en ne considérant ni le taux de base des maladies, ni les autres causes possibles (comme le traumatisme causé par l'accident ou les perturbations dans l'alimentation). De même les effets tardifs des rayonnements ionisants sont en général mal connus par les journalistes, qui ignorent bien souvent la nécessité d'un temps de latence après l'irradiation pour qu'un cancer puisse être considéré comme radioinduit. Ainsi peut-on catégoriquement réfuter les déclarations faisant état de "milliers de victimes soviétiques déjà emportées par des cancers dus aux radiations".

D'autre part, les médias assimilent volontiers la limite réglementaire de dose, établie dans un but de radioprotection des travailleurs et des populations, à la notion de dose dangereuse pouvant provoquer un syndrome aigu d'irradiation, voire le décès. La présentation des risques de cancer est encore plus confuse.

De nombreuses informations ayant trait aux normes alimentaires, aux contre-mesures à prendre pour la distribution et la consommation des aliments sont également fausses.

Enfin nous avons rassemblé **DANS LE CHAPITRE "CE QUI EST INCERTAIN"**, toutes les informations pour lesquelles nous n'avons pas suffisamment d'éléments pour juger ou non de leur exactitude. Ainsi en est-il :

- des doses reçues par la population puisqu'on ne dispose d'aucune dosimétrie précise ;
- du nombre exact de morts entraînés par Tchernobyl ; on ne peut exclure, qu'en plus des 31 décès officiels chez les pompiers et les employés de la centrale, quelques décès soient survenus chez les militaires et/ou des décontamineurs, dont certains ont pu recevoir des doses élevées ;
- du nombre de cancers qui sera dû à l'accident de Tchernobyl ;
- des anomalies de la thyroïde liées à l'accident puisque le taux de base n'était pas connu de façon précise auparavant ;
- du nombre d'avortements liés à l'accident ;
- du coût économique.

CONCLUSION

Ce document a largement répondu à l'attente du personnel. Certains auraient souhaité qu'il soit simplifié dans son contenu. Nous avons préféré lui conserver un bon niveau intellectuel pour éviter la simplification et la caricature. En plus du personnel, il a été très demandé à l'extérieur de notre entreprise, notamment par les journalistes, les élus et d'autres entreprises concernées par l'énergie nucléaire.

Soulignons le besoin d'une information aussi objective que possible sur les risques liés aux rayonnements ionisants, ce qui nécessite que les spécialistes de radioprotection et de santé puissent donner leur avis.

**PERCEPTION DES RISQUES ET DE LA SÉCURITÉ

HOW EMPLOYEES PERCEIVE RISKS AND SAFETY IN NUCLEAR INSTALLATIONS

ABSTRACT

Employees of the French centre of Saclay have been interviewed twice in November 1984 and March 1987 about their risks at the workplace, their views on safety, their protective attitudes, and also about the Chernobyl accident in the second survey. Perceived risks are compared, safety measures and protection teams are judged, importance of the Chernobyl accident is appreciated. Differences in perception between the various professional groups are pointed out. The main results are briefly presented hereafter.

LE CONTEXTE ET LES OBJECTIFS DES ENQUÊTES SUR LA SÉCURITÉ

Avec des installations de recherche fondamentale et appliquée et un effectif de plus de 6000 personnes, le Centre d'Études Nucléaires de Saclay est le plus grand centre de recherche nucléaire d'Europe. Face à la diversité des activités et des risques, la sécurité du personnel est gérée par de nombreux intervenants qui comprennent la formation de sécurité (gardiennage et incendie), les ingénieurs centraux de sécurité, le Service médical du travail, le Service de Protection contre les Rayonnements (SPR) et un Comité d'Hygiène, de Sécurité et des Conditions de Travail. Cette structure lourde et pyramidale se heurte à un certain manque de communication avec les travailleurs du Centre. Rien ne permet de connaître la façon dont le personnel voit l'organisation de la sécurité ni de prévoir les effets des messages diffusés ou de cerner le degré d'investissement du personnel dans l'application des mesures de sécurité.

Les deux enquêtes réalisées sur le Centre tentent de pallier ce manque en permettant l'expression libre du personnel et en apportant aux instances de sécurité une meilleure connaissance de ses demandes. Les questionnaires ont été envoyés individuellement aux agents. Ces envois ont été précédés d'une note du Directeur du Centre au personnel l'invitant à bien accueillir ces initiatives. Le questionnaire aborde la perception des risques et de la sécurité, et traite des comportements face aux risques. Dans la première enquête [1], en Novembre 1984, 5560 travailleurs ont été contactés et 3000 ont répondu, ce fort taux de réponse (56%) constituant déjà en soi un premier succès. L'échantillon obtenu était représentatif selon l'âge, le sexe et le statut professionnel (ouvriers, techniciens, ingénieurs et cadres administratifs). Dans la seconde enquête [2], qui s'est déroulée en Mars 1987 soit 10 mois après l'accident de la centrale nucléaire de Tchernobyl, un groupe représentatif de 2500 personnes avait été contacté. 945 personnes ont répondu qui, après vérification, peuvent être considérées comme constituant encore un échantillon représentatif.

Il existe peu de travaux publiés sur les opinions et comportements des travailleurs des installations nucléaires. Les attitudes psychologiques vis-à-vis des risques nucléaires ont été étudiés dans [3] ; trois types d'attitude avaient été dégagés : l'inquiétude (pour 15% des individus),

l'assurance (pour 5%), et la "neutralité" (pour 80%). Dans [4], connaissance du risque et perception ont été mis en relation pour diverses activités.

Les seuls résultats de la première enquête apparaissent ci-après, la seconde enquête n'ayant fait que les confirmer.

LA PERCEPTION DES SITUATIONS À RISQUES

Il s'agit du danger perçu pour un ensemble de 27 situations rencontrées tant dans l'entreprise que dans la vie courante, dans le domaine nucléaire et dans les autres domaines.

Résultats : "Brancher un appareil électrique près d'un point d'eau" (72% d'accord) est considéré comme la situation la plus dangereuse suivie par l'acte de "Fumer" (57%). Les risques de nature industrielle principalement cités sont "Vivre à proximité d'un centre de stockage de déchets chimiques" (56%) et "Travailler dans une usine de charbon" (54%) comparables avec "Boire de l'alcool pendant la journée" (54%). Il faut noter que "Travailler dans une centrale nucléaire" et "Vivre près d'une centrale nucléaire" sont considérés comme dangereux par seulement 6% et 8% des personnes interrogées, soit au même niveau que "Prendre l'avion" (4%).

LE COMPORTEMENT EN MATIÈRE DE SÉCURITÉ

Il s'agit, à travers différentes affirmations, de mieux connaître l'opinion des agents sur certains de leurs comportements sécuritaires.

Résultats : Les travailleurs demandent à être associés à la gestion de la sécurité car pour 96% "La sécurité est l'affaire de tous". Les pourcentages aux deux questions "Je ne connais rien à la sécurité" (71% de désaccord) et "Ce n'est pas à moi mais à mes supérieurs de s'occuper des problèmes de sécurité" (80 % de désaccord) confirment l'intérêt général porté à la sécurité. De plus, 76% sont d'accord pour participer à des exercices de sécurité (5% sont contre). Ils sont moyennement satisfaits de leurs conditions de sécurité, 51% seulement affirmant "Je suis satisfait de mes conditions de sécurité" (18% déclarent le contraire).

LA PERCEPTION DES MESURES PRISES

C'est la mesure de l'accord plus ou moins fort du personnel vis à-vis d'obligations (au nombre de 20) rencontrées tant dans le domaine du travail que dans la "vie privée".

Résultats : Le fait de rendre toujours les mesures de sécurité proposées toujours obligatoires est en général approuvé (taux d'accord compris entre 52% et 96%). Si la visite médicale fait presque l'unanimité (1 % seulement de désaccord), par contre, le fait d'être habilité pour pouvoir intervenir sur un circuit électrique, le contrôle des accès dans les bâtiments sont des mesures qui ne semblent pas convaincre l'ensemble du personnel.

LA PERCEPTION DES INTERVENANTS

Les positions prises sur les deux affirmations "Je vois quelle est sa fonction en ce qui concerne la sécurité" et "Je pense que j'irais le voir pour des problèmes de sécurité" permettent de mieux appréhender l'image de chacun des 13 intervenants en sécurité.

Résultats : Pour la première question, deux groupes apparaissent : les acteurs présents sur le Centre et ceux extérieurs au Centre. Le SPR est, de loin, le plus connu. Avec le plus faible score, on trouve les délégués syndicaux dont la fonction en ce qui concerne la sécurité

n'est pas très explicite. La réponse à la deuxième question dépend étroitement de l'importance de l'intervenant sur le lieu même de travail.

• **Le signalétique** des personnes interrogées, permet d'étudier les réponses faites aux rubriques précédentes en fonction du sexe, de l'âge de la situation dans l'entreprise (ancienneté, classement hiérarchique,...).

Résultats :

- Les plus jeunes aspirent à participer plus. Ils sont en général moins informés et approuvent de façon moins systématique les mesures prises.

Les femmes manifestent, en général, plus d'inquiétude. Elles sont moins impliquées dans la gestion de la sécurité. Elles ont plus tendance que les hommes à approuver les mesures de sécurité.

- Les cadres administratifs et les ingénieurs expriment en général moins leur inquiétude que les ouvriers et les techniciens.

UNE COMPARAISON ENTRE LES SECTEURS CHIMIQUE ET NUCLÉAIRE

Ces deux secteurs mettent en jeu des matières dangereuses, des installations qui peuvent être impressionnantes, des produits de haute technicité et des personnels plutôt qualifiés. Le secteur de la chimie a pour lui l'antériorité, la dissémination géographique et il fait partie de la vie de tous les jours ; le secteur nucléaire est plus récent, il se réduit à quelques grandes installations et ses produits échappent souvent au perceptible. Avec la question "La chimie, c'est plus dangereux que le nucléaire", il est possible d'évaluer les différences de perception pour ces deux domaines.

			oui	non
1982	National	- France	19 %	37 %
Novembre 1984	Travailleurs	- Saclay	42 %	20 %
Février 1986	National	- France	23 %	28 %
Juin 1986	National	- France	20 %	39 %

Dans le grand public, la chimie est considérée comme moins dangereuse que le nucléaire. Par contre, les travailleurs du Centre donnent des réponses totalement inversées. Ceci peut être dû au fait de connaître les deux types de risque, à moins qu'il ne s'agisse d'un effet de dissonance cognitive, à savoir une minimisation du risque auquel on est exposé pour pouvoir mieux supporter sa condition.

L'ACCIDENT DE TCHERNOBYL

Dans la consultation de Mars 1987, une partie du questionnaire traitait de l'accident de Tchernobyl. Les points à retenir dans les réponses sont les suivants :

L'accident de la centrale nucléaire de Tchernobyl n'a pas modifié l'opinion que les agents du Centre avaient sur la proposition "La chimie c'est plus dangereux que le nucléaire" : il y a toujours environ 45 % de oui pour 20 % de non. Il n'y a pas non plus de changements importants dans la perception des situations à risque. En moins de quatre ans, les opinions favorables aux deux propositions suivantes : "J'ai été informé des risques que je cours sur mon lieu de travail" et "Je suis satisfait de mes conditions de sécurité à Saclay" sont passées de 50% d'accord à plus de 60 % en 1987. Les femmes montrent malgré tout plus de réticence que les hommes.

Concernant l'accident plus particulièrement, un agent sur deux a été sollicité par ses proches pour répondre à des questions sur Tchernobyl. Dans leurs avis, les agents du Centre sont généralement plus modérés que les individus du public : ils croient moins à

l'éventualité d'un tel accident en France (32 % au lieu de 54 % environ dans le public), la confiance est plus grande chez les cadres (62 % d'entre eux n'envisagent pas cette éventualité) que chez les agents techniques ou employés (où ils sont seulement 40 %). Les explications des experts sont plus compréhensibles pour eux que pour le public : cela est vrai pour un travailleur sur trois à Saclay mais seulement pour un individu sur cinq dans le public. Il apparaît que les travailleurs de Saclay n'ont pas grande confiance en l'organisation de la sécurité : 58 % estiment que la protection des populations ne peut être assurée en cas d'accident dans une centrale nucléaire en France (et 21% seulement le pensent). Par contre, ils répondent beaucoup plus positivement, à plus de 70 %, en ce qui concerne leur protection en cas d'accident sur le Centre.

CONCLUSION

Dans les résultats présentés, on constate une grande diversité dans les perceptions tant des risques que de la sécurité. Cette diversité résulte bien entendu de l'expérience de chacun mais aussi de son rôle dans l'organisation du travail. Le fait d'appartenir à une collectivité transparait lorsque l'on compare les réponses ici obtenues à celles du grand public. Certaines catégories de travailleurs (par exemple, les personnels de bureau) ont sur les activités à risque des conceptions déformées et souvent excessives qui nécessitent des responsables de l'entreprise un effort d'information et même de formation. Cet effort s'impose d'autant plus que tout travailleur du secteur nucléaire, dans ses relations avec ses proches, a un rôle plus ou moins important de communication externe. Au delà des résultats, l'enquête a provoqué une dynamique entre les différents intervenants, permis une expression du personnel dégagée du cadre institutionnel, donné l'occasion de réunions au cours desquelles les travailleurs ont pu réfléchir sur les quatre thèmes proposés dans le questionnaire. La consultation est ainsi devenue un des outils d'animation de la sécurité à un échelon aussi proche que possible du poste de travail.

**EVALUATION DES CONSEQUENCES RADIOLOGIQUES
DES REJETS GAZEUX EN SITUATION
ACCIDENTELLE**

Y.H. BOUGET

Electricite de France
Service de la Production Thermique
Paris - La Défense

**METHOD AND TOOLS FOR ASSESSING THE
OFF-SITE CONSEQUENCES OF A NUCLEAR
ACCIDENT**

When an accident, with possible gaseous release, occurs in a nuclear power plant, the utilities must be capable of providing the Authorities with information about release radiological consequences and this in a very short time. The difficulties encountered in assessing radiological consequences during crisis exercises (lack of time for doing manual calculation, difficulty in getting useful information about the accident ...) have led Electricité de France, in collaboration with the Commissariat à l'Energie Atomique, to settle a simple method and efficient tools for local crisis teams.

INTRODUCTION

Lorsque survient, dans une centrale nucléaire, un accident susceptible d'engendrer des rejets radioactifs dans l'environnement, l'exploitant doit être en mesure de fournir à l'Administration, dans des délais courts, des informations relatives aux conséquences radiologiques des rejets prévisibles ou en cours.

Ces informations sont capitales pour permettre à l'Administration de décider des éventuelles mesures de protection à prendre vis-à-vis des populations avoisinantes.

Les exercices réalisés dans le cadre de l'organisation de crise ont montré que les responsables chargés d'évaluer les rejets dans l'environnement (terme-source) ne disposaient pas des moyens suffisants pour réaliser les prévisions. Ces dernières étaient en effet établies à partir des résultats très pessimistes issus des études d'accident figurant dans les rapports de sûreté des centrales. D'autre part, les calculs des conséquences radiologiques (équivalents de dose reçus par le public), effectués manuellement à l'aide d'abaques opérationnels, nécessitaient beaucoup de temps et étaient cause d'erreurs.

Ces difficultés ont conduit Electricité de France à développer, avec la collaboration du Commissariat à l'Energie Atomique (C.E.A), une méthode et des moyens simples permettant aux équipes de crise des centrales d'effectuer plus facilement et plus rapidement les évaluations des rejets gazeux.

METHODE ET OUTILS DE CRISE POUR L'EVALUATION DES REJETS GAZEUX

La méthode d'évaluation s'appuie sur les recommandations de la publication n° 40 de la C.I.P.R. [1] et sur les éléments de doctrine énoncés dans le Plan Sanitaire d'Urgence [2].

Celle-ci est structurée en 3 parties et permet :

- de suivre à tout moment l'évolution des rejets en cours et d'en calculer les conséquences radiologiques à l'aide d'un outil informatique,
- d'évaluer de façon réaliste, dès le début de l'accident, l'enveloppe des rejets prévisibles en considérant non plus les résultats des scénarios d'accident, mais un ensemble de données pré-établies en fonction de l'état du combustible et du confinement,
- d'interpréter les premiers résultats des mesures de radioactivité pratiquées dans l'environnement pendant les rejets.

Les moyens ou outils élaborés à partir de cette méthode se composent :

- d'un document "papier" fournissant tous les éléments nécessaires à la détermination de l'activité rejetée ou susceptible d'être rejetée (prévisions),
- d'un logiciel fonctionnant sur un micro-ordinateur PC pour le calcul des conséquences radiologiques des rejets.

Le document "papier" (Fig. 1) fournit les données relatives :

- aux activités contenues dans les circuits et dans le combustible,
- aux rejets potentiels, pré-calculés pour différents cas de figure en fonction de l'état du combustible, du confinement et de la disponibilité de certains matériels tels que le circuit d'aspersion de l'enceinte et les pièges à iode des circuits de ventilation (9 états ont été définis, couvrant toutes les

situations accidentelles, de la petite brèche primaire jusqu'aux accidents avec fusion du coeur). Cet ensemble de données permet de réaliser des prévisions sans faire de calcul,

- aux ordres de grandeur des activités mesurables dans l'environnement selon la gravité de l'accident.

De plus, ce document comprend un logigramme de surveillance de certains paramètres-clés caractérisant l'état des 3 barrières (gainage du combustible, circuit primaire, enceinte de confinement). La scrutation de ce logigramme permet aux équipes de crise locales d'être averties de tout événement pouvant conduire à des rejets importants.

Le logiciel de calcul utilise un modèle de diffusion atmosphérique développé par le CEA. Ce modèle calcule en fonction de la distance et de la météorologie locale :

- la dose organisme entier due au passage du nuage,
- la dose à la thyroïde due à l'inhalation d'iode radioactif,
- les débits de dose dus aux dépôts.

CONCLUSION

Cette méthode et ces outils ont été testés lors des exercices de crise. Ils ont révélé leur efficacité pour faire des évaluations précoces (jusqu'à 24 heures après l'accident).

Ces outils essentiellement conçus pour les techniciens des centrales ne prétendent pas remplacer le travail des experts, en particulier ceux qui seraient présents dans les centres de crise et qui disposeraient d'outils informatiques plus précis pour déterminer l'impact réel de l'accident.

PUBLIC EXPOSURE RESULTING FROM DISCHARGES TO ATMOSPHERE FROM THE NUCLEAR FUEL REPROCESSING PLANT AT SELLAFIELD IN THE UNITED KINGDOM

S R Jones and M J Fulker

British Nuclear Fuels plc,
Sellafield, Seascale, Cumbria, UK.

ABSTRACT

Discharges of radionuclides to atmosphere from the Sellafield reprocessing plant include noble gases, volatile species, and particulates.

Doses to the critical group estimated by environmental monitoring in 1990 were about $160 \mu\text{Sv y}^{-1}$ committed effective dose equivalent (CEDE), making conservative assumptions regarding critical group habits. Doses calculated from a pessimistic generic predictive model were similar.

However detailed studies have allowed more accurate and site specific parameters to be adopted for atmospheric dispersion, foodchain transfer of key radionuclides, and critical group habits. This model indicates that the critical group doses from 1990 discharges would have been substantially lower, at $45 \mu\text{Sv y}^{-1}$ or less.

INTRODUCTION

The Sellafield site, operated by British Nuclear Fuels plc, is located in Cumbria, NW England. A variety of nuclear process plants are situated on the site, including reprocessing and associated chemical plants, high and intermediate level waste conditioning and storage facilities, and four nuclear power reactors of the Magnox type.

Discharges to the atmosphere are made via seven major discharge stacks and numerous minor roof level outlets. Radionuclides discharged include the noble gases 85Kr and 41Ar ; other gases and volatiles including 3H , 14C , 131I and 129I ; and particulates contaminated with fission products and actinides such as 90Sr , 106Ru , 137Cs , 238Pu , $239/240\text{Pu}$, 241Pu , and 241Am . Details of the quantities discharged are reported elsewhere (1). Public radiation exposure resulting from the discharges is estimated in two ways.

A routine environmental monitoring programme is carried out, which enables radiation exposure to be estimated from concentrations in the environment and assumptions regarding habits. Current (1990) levels of dose to the public, estimated in this way, are about $160 \mu\text{Sv y}^{-1}$ (CEDE).

However environmental monitoring in itself is not sufficient; not all components of dose can be adequately assessed by monitoring, and there is a need to predict the radiation doses which will result from future discharges. This need is met by models. A simple and conservative model is used as the basis for discharge planning (2); this uses a conventional Gaussian atmospheric dispersion model (3), an empirical method of assessing the effective height of releases (4) and a generic foodchain transfer model (5). The model calculates the sum of doses to the limiting age group for each nuclide. The predicted doses from 1990 discharges are given in Table 1, and agree quite well with the estimates from environmental monitoring.

This overall agreement is however fortuitous, and conceals a number of discrepancies in the doses arising from specific radionuclides. These discrepancies reflect inadequacies in the generic equilibrium models applied, and have been addressed in a number of research projects aimed at producing a more reliable site specific environmental model. The main areas of investigation are summarised below.

ATMOSPHERIC DISPERSION

The Gaussian plume model (3) assumes an isolated release stack situated on a uniform flat plane with a uniform wind rose, the effective height of release being modified to take some account of the structure on which the stack is situated (4). However the Sellafield site is complex, and it is necessary to also take account of the effects on dispersion of surrounding buildings. Dispersion behaviour has been investigated for a range of outlets using models from 1/200 to 1/500 scale in a wind tunnel, and at full-scale for ground level outlets by releasing the tracer gas SF₆ (5).

The results indicate that most tall stacks have a lower effective height than the empirical rule suggests; however dispersion from ground level releases is somewhat greater than indicated by the Gaussian plume model. These findings are attributed to the effects of downwash and the effect of turbulence from buildings on plume mixing, which appears to increase the horizontal and vertical standard deviations (σ_y and σ_z) of the Gaussian plume.

For the present, these effects have been allowed for in the model by assigning effective heights to each release point so that the correct dispersion factor is predicted at the distance relevant to the critical group; more sophisticated treatments may be developed. The net effect is to somewhat increase the predicted critical group doses for most radionuclides.

CARBON 14

The concentration of carbon 14 incorporated in biota is usually calculated by a specific activity model, which assumes that the 14C content is determined by the value of the ratio of 14C to stable carbon in air; the latter can be estimated directly from the atmospheric dispersion model, as an annual average.

Measurements of 14C in vegetables and milk near Sellafield showed higher 14C: stable carbon ratios than predicted; moreover, the ratio varied significantly from one sample type to another, suggesting that the specific activity model was inapplicable. Pending further investigation, an arbitrary factor of pessimism (x10) was incorporated into the model.

Investigations have now confirmed that the effect is caused by systematic variations in the dispersion pattern through the course of the year (7,8). Plants incorporate 14C by photosynthesis only during daylight hours during their growing season; the average 14C: stable carbon ratio over this specific period correlated well with the ratio in biota, and differs from the annual average ratio principally because of sea breeze effects.

Understanding this effect has allowed the factor of pessimism in the model to be reduced.

IODINE 129

The routine environmental monitoring programme for I291 covers only milk. Regulators had expressed concern that alternative foodchain models indicated the possibility of significant uptake of this long lived nuclide from soil to root crops; however a special measurement campaign has confirmed that milk is indeed that most important exposure route, consistent with findings elsewhere (9). These studies also permitted the adoption of a lower transfer factor for I291 from grass to milk, although the new value is still believed to be conservative.

ARGON 41

Direct radiation from the ⁴¹Ar released in shield cooling air from the Magnox reactors remains the single most significant source of radiation exposure consequent on discharges to atmosphere from the site. These doses are currently calculated purely from the dispersion model, direct measurement being difficult in the presence of natural radiation. Studies at Magnox power stations operated in the UK by Nuclear Electric plc have shown that the doses so calculated are pessimistic; this is currently under investigation.

CRITICAL GROUP HABITS

Previously, pessimistic assumptions have been made concerning the habits of the critical group. A hypothetical group has been defined, living 700 m from the point of discharge (or at the point of maximum concentration); residing permanently at that location; and subsisting entirely on food grown at 1.5 km from the point of discharge (with the exception of grain products) consumed at rates typical of a high rate consumer.

This situation clearly did not exist in practice; accordingly a survey was carried out to determine actual food consumption and other exposure-related habits (12). This showed that, while the maximum consumption rates for individuals and for particular food groups were not dissimilar to the assumed values for the critical group, that no individual simultaneously consumed all foods at the maximum rates. Of course, distances to places of residence and food production generally exceeded the values assumed.

Using data from this habit survey, a dose distribution for the survey population has been calculated, using the predictive environmental model, which shows that the average dose for the population living on farms or isolated households around the site is about a factor of four lower than that for the pessimistic critical group; whereas the dose to the highest exposed individual is about two thirds of that for the pessimistic critical group (13).

There was only one infant in the survey population, so it was not possible to derive realistic group average habits for this critical age group. Nonetheless the survey results have been used to define more realistic critical group average consumption habits for other age groups (10 year old and adult).

Using these more realistic critical group parameters has a major impact on calculated doses.

IMPROVED DOSE ESTIMATES

The amendments described above have been incorporated into the predictive model and revised doses can be calculated, as indicated in Table 1. These are substantially lower than the earlier estimates.

The revised doses from 1990 discharges are also lower than the doses estimated from environmental monitoring. This partly reflects the fact that environmental monitoring data relate to the areas of highest concentration, rather than the locations where people actually live; in addition, the predictive model is an equilibrium model which calculates doses resulting from equilibration of the environment with discharges at 1990 levels whereas the monitoring data reflects some residual effects of higher discharges in the past.

CONCLUSIONS

Refinement of the predictive model for discharges to atmosphere from the Sellafield site has led to some changes which increase calculated doses (atmospheric dispersion) and some which reduce calculated doses (foodchain transfer and critical group habits). Overall, refinement of the model has led to substantial reductions in calculated doses.

Such model refinement is essential if radiological input to effluent management decisions is to be useful, since decisions on effluent treatment options require accurate information as to both absolute levels of radiation dose to be expected, and the relative significance of individual discharge sources and radionuclides.

THE HISTORY OF CRITICAL GROUP DOSES FROM THE CONSUMPTION OF FRESHWATER FISH AT
TRAWSFYNYDD, NORTH WALES

D R P Leonard
Fisheries Radiological Inspectorate,
Ministry of Agriculture, Fisheries and Food
Directorate of Fisheries Research, Fisheries Laboratory,
LOWESTOFT, Suffolk, UK

ABSTRACT

Radionuclides discharged into the aquatic environment from Trawsfynydd power station are, as for all UK facilities, subject to statutory controls to ensure that the resulting public radiation exposure complies with nationally-accepted criteria. Environmental monitoring by MAFF has shown that near this facility the consumption of freshwater fish is radiologically the most important pathway with Cs-137 the dominant radionuclide. Information gathered from consumers over a twenty-five year period has been interpreted so as to derive doses to the public. Committed effective doses (CEDs) are presented using ICRP 1990 methodology and compared with the recommended dose limit of 1 mSv year⁻¹. Doses to the critical group are shown to have exceeded 1 mSv year⁻¹ for two years but do not exceed this limit when averaged over a period of 5 years. Because of the changing habits of the consumers it is suggested that the average annual CED over the lifetime of any member of the public will not exceed 1 mSv year⁻¹ during the operation of the station.

INTRODUCTION

The 390 MW(e) (nominal) twin gas cooled Magnox type reactors presently operated by Nuclear Electric plc at Trawsfynydd, North Wales commenced commercial operation in 1965. An authorisation was granted to discharge small quantities of low level liquid radioactive waste into the adjacent freshwater lake. Such authorisations are granted by Government Departments under the Radioactive Substances Act (1960) and kept under review. In setting and reviewing these limits, full consideration is given to the environmental implications of discharging this waste and particular attention is paid to the exposure pathways of the public. This paper considers public exposure from the consumption of fish from the lake between 1962 and 1990 and especially those people who are potentially the most exposed, the so called critical group.

METHODS

Post-hoc (ie non-predictive) assessment of dose to a critical group of fish consumers makes use of results from an appropriate environmental monitoring programme (Leonard and Hall, 1989), information about peoples consumption rates and suitable dose per unit intake data. At Trawsfynydd, consumption rate data are primarily derived from interviews with anglers and people whom they supply (Leonard et al., 1982). Enthusiastic anglers usually possess season tickets and belong to the lake's angling association, which has been a valuable source of information throughout the life of the power station and lists of members have formed a basis from which habits surveys could be conducted. The first major habits survey took place in 1962 and has been carried out at approximately five-yearly intervals ever since. Lake bailiffs and potential critical group members were regularly consulted between surveys to ascertain if consumption habits had changed. Some high rate consumers were asked to keep a diary of their catch and consumption rates. During the survey, each family was asked to estimate their individual consumption rates, the number, size and species of fish caught during a calendar year as well as seasonal preferences and cooking methods. Consumption of children was considered (Leonard and Hunt 1985). Interviews were also conducted with anglers who purchase day tickets. The surveys were specifically designed to try and identify high rate consumers rather than being targeted randomly. The data were collated to provide individual consumption rates for each species of fish expressed in kg year⁻¹. It was found that the following

factors limit consumption rates of the indigenous trout: only six trout can be taken on any one day and stocked rainbow trout (*Salmo gairdneri*) now outnumber brown trout (*Salmo trutta*) by a ratio of about 6:1. The former contain low concentrations of lake derived radionuclides, usually being caught within three weeks of release. The indigenous brown trout are preferred by many consumers but are relatively more difficult to catch. Some consumers may prefer perch or a combination of species. Analysis of individual consumption and interview data showed that high rate consumers were either skilled anglers themselves or a relative or friend of such anglers. Because of the amount of time required to catch large quantities of fish, critical group consumers tend to be either retired or associated with the management of the fishery.

The initial study showed that Cs-137 was the most dominant radionuclide. Fish sampling commenced in 1961 with the collection of brown trout when concentrations of Cs-137 averaged 17 Bq kg^{-1} (wet) due to nuclear weapons test fallout. In 1962 mean concentrations increased to 53 Bq kg^{-1} and reached 164 Bq kg^{-1} at the end of 1964, prior to power station operation (Preston et al., 1967). Perch (*Perca fluviatilis*) were sampled for comparison from 1965. Angling increased in popularity because the warm water discharges promoted fish growth; however, the indigenous brown trout population could not support the number of anglers who wished to fish at Trawsfynydd and thus rainbow trout were introduced to the lake from 1973, and sampling of this species commenced at this time. Other species such as rudd (*Scardinius eryththalmus*) and eel (*Anguilla anguilla*) have also been monitored although they are not regularly eaten. Ideally, a sample of each species has consisted of six to ten fish which was caught by MAFF staff using gill nets or purchased by MAFF from rod and line anglers using a wide range of baits. These anglers were asked to provide monthly or quarterly samples during the fishing season which extends from March to September for brown trout, February to December for rainbow trout and for perch. Usually quarterly samples were collected by MAFF staff.

Cs-137 was detected in all species of fish with the highest concentrations usually occurring in perch, followed by brown trout, rudd, eel and finally rainbow trout. Other radionuclides were also detected and these included Cs-134, Sr-90, S-35, Co-60, Mn-54, Ru-106, Pu-238, Pu-239+240, Pu-241, Am-241, Cm-242 and Cm-234+244.

Assessment of dose

The International Commission on Radiological Protection (ICRP) has made a series of recommendations that now embody three fundamental principles of justification, optimisation and dose limitation. In recent years, UK practice has been based on the recommendations of Publication 26 (ICRP 1977); the effects of Publication 60 (ICRP 1990) are currently being considered. This study examines the effect of ICRP 60 recommendations, noting that while the limit for the CED to members of the public is the same as the previous principal limit at 1 mSv year^{-1} , the new limit is slightly more stringent because it refers to a five year limit rather than a lifetime. A higher effective dose than 1 mSv is permissible in a single year provided that the annual CED averaged over 5 years does not exceed 1 mSv year^{-1} . The ICRP recommendations apply to doses to appropriate critical groups. In this study, the approach of Hunt and Shepherd (1980) was used from 1973 onwards. However, during the 1962 and 1968 survey the concept of a maximum consumer and a mean for all consumers was used. Using such means is likely to underestimate the dose to the high rate consumers and therefore a nominal consumption rate derived from the early data of $36.5 \text{ kg year}^{-1}$ of brown trout has been used in this study. For comparative purposes, results based on this consumption rate have also been calculated from 1965 when discharges commenced to the end of 1990. Using environmental monitoring data from the MAFF annual monitoring reports (eg. Hunt 1989) the CED was calculated utilising dose per unit intake data (Phipps et al., 1991). Cs-137, Cs-134 and Sr-90 were found to be the radiologically most significant nuclides. The other radionuclides typically contribute about 1% of the total annual dose. Figure 1 shows a plot of the total

annual dose from Cs-137, Cs-134 and Sr-90 in mSv year^{-1} plotted against time for the critical groups of consumers identified during the habits surveys and a hypothetical group consuming $36.5 \text{ kg year}^{-1}$. Neither group has exceeded 2 mSv year^{-1} but both groups have exceeded the 1 mSv year^{-1} limit in 1976 and 1977.

Figure 1. A graph showing the CED from Cs-137, Cs-134 and Sr-90 (mSv year^{-1}) to the critical group of fish consumers from 1963 to 1990 compared to a hypothetical group consuming $36.5 \text{ kg year}^{-1}$ of brown trout.

DISCUSSION

The cumulative CED for the critical group of fish consumers from 1965 to 1990 is approximately 12 mSv . This includes the contribution from the major and minor radionuclides, due to the power station's discharges as well as a small contribution from nuclear bomb test fallout and the Chernobyl reactor accident. On the basis of a hypothetical critical group of brown trout consumers eating at $36.5 \text{ kg year}^{-1}$, for the same period the comparative dose would only have been 10 mSv . Assessment of individuals who are or who have been members of the critical group and other consumers for whom several years data were available, showed that nobody was likely to have exceeded 10 mSv from the consumption of freshwater fish from Trawsfynydd over the twenty-five years that the power station has been operating. The dose from the ICRP model for Cs-137 is likely to be cautious based on the whole body monitoring of consumers near Sellafield which suggested that the parameters in the model for caesium retention would be unlikely to underestimate body content (Hunt et al 1989). When the authorised limits for discharges are reviewed, a predictive assessment is made to consider the maximum CED that could occur; thus it is now unlikely that the average annual CED over the life time of any member of the public will exceed 1 mSv year^{-1} . It is to be noted that dose assessments also need to consider other exposure pathways such as external exposure from lake bank occupancy, consumption of terrestrial foodstuffs, inhalation and immersion from Ar-41. MAFF have published such assessments (Hunt 1989, Tarrant 1991) and considered that the additional dose to high rate fish consumers is likely to be small. The additivity of dose from different pathways continues to be reviewed.

CONCLUSIONS

Monitoring and assessment of critical group fish consumers at Trawsfynydd for almost thirty years has demonstrated that the annual CED has exceeded 1 mSv for two of those years but not exceeded 1 mSv year^{-1} when averaged over a period of five years. ICRP recommendations, even applied retrospectively, have therefore been met.

ACKNOWLEDGEMENTS

The data used in this paper could not have been obtained without the cooperation of the Prysor Angling Association and its members. Particular thanks are given to the late Mr M Lewis, Mr D G Williams and Mr M Atherton. The help of a large number of MAFF staff with the interviews and environmental monitoring are also gratefully acknowledged especially Mr C J Hewett, Dr P G W Jones, Miss L M Thurston and Mr J R J Tipple.

B-2400 MOL

ABSTRACT

The behaviour of caesium and strontium deposited by the Chernobyl fallout in the region of Mol (Belgium) has been investigated in permanent pastures established on sandy soils. Their distribution within the soil and the changes of their concentration in grass were followed up to February 90. Their transfer from grass to cow's milk was investigated under field and controlled conditions. The behaviour of these two Chernobyl radionuclides is compared with that of the same nuclides from other source terms.

INTRODUCTION

In the region of Mol, the radioactive plume released from the damaged reactor in Chernobyl was detected on May 2. The peak of radioactivity in air was observed round about 11 a.m. on the same day. The radiocontamination in air decreased rapidly thereafter and was, on May 7, three orders of magnitude less than the peak concentration [2].

The highest deposits (more than 90% of the caesium and about 60% of the strontium deposit) were associated with rainfalls on May 3, 4 and 6. On May 10, the total fallout at Mol, in $\text{Bq}\cdot\text{m}^{-2}$, collected in stainless steel tanks, amounted to 35 for ^{90}Sr , 248 for ^{89}Sr , 1052 for ^{134}Cs and 2076 for ^{137}Cs [2]. Considering the residual contamination in our soils from weapons-testing fallout (WTF), respectively about 1.3 and 2.1 $\text{kBq}\cdot\text{m}^{-2}$ for ^{90}Sr and ^{137}Cs in spring 1986, the Chernobyl accident doubled the ^{137}Cs level in soil while it added but a few percent of ^{90}Sr to the still present pool.

RESULTS AND DISCUSSION

The interception of radiocaesium by grass on two pastures with mean fresh herbage densities of 1.4 and 0.3 $\text{kg}\cdot\text{m}^{-2}$, averaged over three samples collected on May 5 and 6, was respectively 22% and 13%. These values are in the range of that obtained for ionic forms under controlled conditions [3]. The interception of ^{89}Sr was estimated on one sample collected on May 6 and amounted to about 23% (herbage density = 1.7 kg

fresh weight.m⁻²). Taking into account the ratio ⁸⁹Sr/⁹⁰Sr in the deposit (7.1), one can estimate that 82% of the ⁹⁰Sr activity in this grass was due to the Chernobyl fallout while 18% originated from the old WTF deposit.

The changes over four years of the ¹³⁴-¹³⁷Cs contents in grass could be described by a two-compartments model. The ecological half-time estimated for the first compartment is about 10 days, while that of the long-term component is about 2 years. Because of the much lower amount deposited, the evolution of the ⁹⁰Sr concentration in herbage did not exhibit a clear exponential decrease like ¹³⁴-¹³⁷Cs. But systematic increases of the ⁹⁰Sr content were observed at each new start of vegetation growth after mowing (data not shown).

Six consecutive 5cm thick layers of our sandy soil were sampled at regular intervals in an ungrazed permanent pasture for radiocaesium and -strontium analyses [4]. Based on the ¹³⁷Cs/¹³⁴Cs ratio (1.8) in the Chernobyl deposit, the contribution of the WTF to the overall concentration in the different layers could be distinguished from that of Chernobyl. The concentrations averaged over 6 samples taken between May 13 and July 28 are given in table I.

SOIL LAYER (cm)	⁹⁰ Sr	¹³⁴ Cs	¹³⁷ Cs total	¹³⁷ Cs Chernobyl	¹³⁷ Cs WTF
0- 5	302 ± 13	1414 ± 311	3638 ± 525	2606	1032
5-10	284 ± 136	≤ DL	917 ± 310	na	917
10-15	157 ± 62	≤ DL	233 ± 86	na	233
15-20	≤ 85 ± 44	≤ DL	≤ 81 ± 22	na	≤ 81
20-25	≤ 89 ± 62	≤ DL	≤ DL	na	na
25-30	≤ 98 ± 58	≤ DL	≤ DL	na	na

DL = detection limit (≈ 65 Bq.m⁻²) ; na = not applicable.

Table I. Distribution of ⁹⁰Sr and ¹³⁴-¹³⁷Cs in the sandy soil of a permanent pasture (in Bq.m⁻² ± std. dev.).

During the first months after the accident, all ¹³⁴Cs in the soil remained confined in the top layer (mat horizon). Even four years later (data not shown), no migration to deeper layers could be observed. Most of the ¹³⁷Cs was also present in the mat horizon (72% from the Chernobyl fallout and 28% imputable to the WTF), but it was found deeper too, at least in the two next layers (up to -15 cm), due to the slow migration of the activity deposited in the sixties. Similar inference was not possible for strontium since when the samples were processed for strontium analysis, the ⁹⁰Sr had already decayed below its detection limit. However, as the contribution of the Chernobyl ⁹⁰Sr is less than 12% of the cumulated activity in the mat, the picture presented

corresponds essentially to the distribution of the strontium from the sixties. The sum of the ^{137}Cs activities attributed to the WTF in the different soil layers ($2.2 \text{ kBq}\cdot\text{m}^{-2}$) corresponds quite well to the amount expected to be still there from that source term while the sum of the ^{90}Sr activities represents but about 60% of the expected value. This can be explained by the higher mobility of strontium in soils, compared to caesium, leading to a higher exportation by vegetation harvesting or by lixiviation with the soil water.

Cow's milk is a good bio-indicator that integrates the upstream variations of the environmental behaviour of the radionuclides. Milk transfer factors (F_m) for the Chernobyl radiocaesium were estimated both under field and controlled conditions [5]. A value of $1.2 \cdot 10^{-2} \text{ d}\cdot\text{l}^{-1}$ was derived for freely grazing cows in the period between May and July 1986. A controlled experiment with cows fed over 30 days with hay harvested in June 1986 or in 1987 provided F_m values of $6 \cdot 10^{-3}$ and $1.1 \cdot 10^{-2} \text{ d}\cdot\text{l}^{-1}$ for the two respective harvests. The F_m estimated for strontium in field in May 1986 amounted to $1.6 \cdot 10^{-3}$ and $1.3 \cdot 10^{-3} \text{ d}\cdot\text{l}^{-1}$ for ^{90}Sr and ^{89}Sr respectively. A mean value of $1.7 \cdot 10^{-3} \text{ d}\cdot\text{l}^{-1}$ for ^{90}Sr has been estimated, still in field, for the period from June to September 1986. These transfer factors to milk, based on measurements performed in the region of Mol, are comprised in the range of the values reviewed by Coughtrey [1] for two other source terms (table II).

SOURCE TERM	CAESIUM	STRONTIUM
Chernobyl (pasture)	12 [5]	1.3 - 1.7 [this paper]
" (hay 86)	6 [5]	
" (hay 87)	11 [5]	
tracers studies	2 - 27 [1]	0.4 - 3.8 [1]
weapons testing	1.7 - 20 [1]	0.5 - 2.4 [1]

Table II. Transfer coefficients (F_m in $10^{-3} \text{ d}\cdot\text{l}^{-1}$) to cow's milk for radiocaesium and radiostrontium from different source terms.

CONCLUSION

The data obtained on the behaviour of the Chernobyl radiocaesium and -strontium in pasture ecosystems in the Mol region do not differ significantly from the data gathered in the past for these nuclides, from the WTF or used as ionic tracers. This suggests that most of the caesium and strontium from Chernobyl deposited in our region was readily soluble and largely available for plant and animal uptake.

A COMPUTER MODEL FOR THE CALCULATION OF DERIVED EMISSION LIMITS FOR
THE NORMAL OPERATION OF NUCLEAR FACILITIES

Bertrand Thériault

Atomic Energy Control Board
270 Albert St, Ottawa, Ont. Canada, K1P5S9

This paper presents a computer program for calculating derived emission limits for the normal operation of nuclear facilities. The environmental transfer model is discussed, in particular plume depletion effects, the effective height of release, sensitivity analysis, and the importance of the atmosphere to surface water pathway. When the receiving body of water receives only airborne effluent, this pathway has been found to be significant for long lived radionuclides and H₂O.

INTRODUCTION:

In order to ensure that no member of the public receives a dose higher than the regulatory limit, upper limits to the rate of release of radionuclides to the atmosphere and to surface waters must be known. This paper presents an overview of the computer program "DELPro" which has been developed to calculate such upper limits, usually known as derived emission limits (DEL), for the normal operation of nuclear facilities.

This paper is subdivided in two main sections. First, the methodology for calculating DELs is examined. The environmental transfer model (ETM), its applicability to other nuclear facilities as well as its limitations are discussed. In a second section, the program per se is described briefly, giving particular attention to modifications brought to the ETM¹; ie, the inclusion of atmospheric plume depletion effects, effects of building entrainment, and the addition of the atmosphere to surface water pathway. The sensitivity analysis routine is also discussed in this section.

METHODOLOGY:

The DEL is defined as the rate of release which is such that the group of maximally exposed individuals, the critical group, will not receive a dose higher than the regulatory dose limit. The critical group must also be relatively homogeneous with respect to those factors which affect doses received (eg, diet, age, behaviour). The methodology for determining DELs has three parts. First, the behaviour of the release must be known. Two modes of release are considered in the model¹; atmospheric and aquatic. A gaussian plume model is used for describing releases to the atmosphere. It assumes continuous release of radioactive material. A model² for reduction of the effective height of release due to plume entrainment in the wake of neighbouring buildings (downdraught) and in the wake of the stack itself (downwash) has been added to the initial model¹. Also added to the initial model is the effect of plume depletion (wet and dry deposition)^{2,3}.

Due to the high complexity of liquid dispersion in large bodies of water and its dependence on site-specific characteristics (eg, bottom topography, wind induced currents, seasonal variations in water

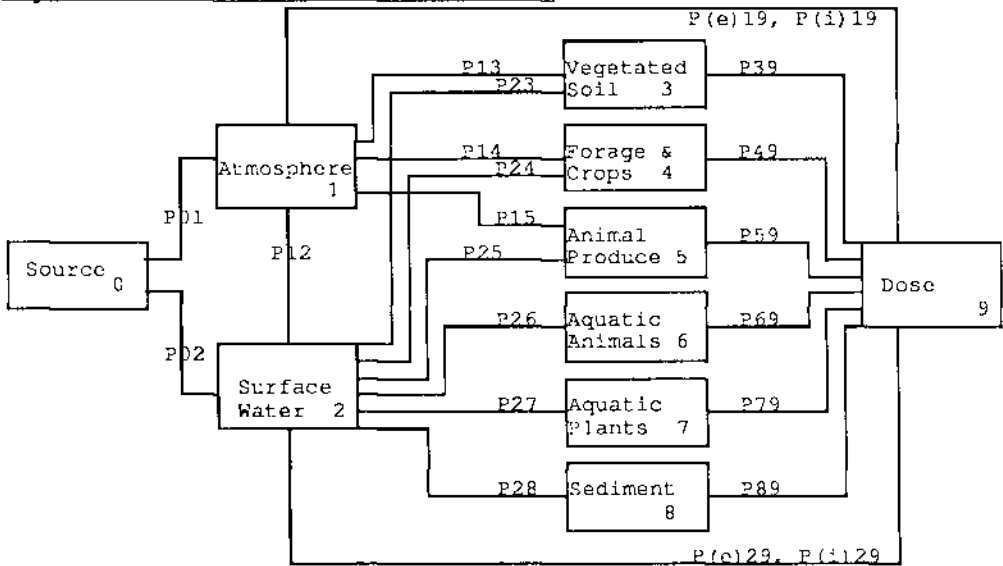

temperature) no general aquatic dilution model is used. Instead, site-specific concentrations are used. Also, since a DEL is calculated for each radionuclide released, the composition of the release must be known. This is achieved through effluent monitoring.

Second, the passage of radioactive material from the source through the environment to man must be analyzed. The environmental transfer model (ETM) used for this purpose is presented by the Canadian Standards Association¹, and can be seen in figure 1. Each compartment in the ETM is numbered. The quantity of radioactive material in compartment i is denoted X_i . A transfer parameter P_{ij} characterizes the transfer of material from compartment i to a compartment j such that

$$X_j = \sum_i P_{ij} X_i \quad (1)$$

All P_{ij} assume the system (ETM) to be in steady state, and are preferably calculated from site-specific data rather than from Canadian averages.

Figure 1: Environmental Transfer Model:

The atmosphere to water pathway (P_{12}) is not included in CSA¹ but it is in the Gorman⁴ model. In fig.1 the atmosphere to dose (P_{19}) and surface to dose (P_{29}) pathways both have two components. The external exposure component is denoted by (e) and the inhalation/ingestion component by (i). The DEL is defined as:

$$DEL = ADL / (X_9 / X_0) \quad (2)$$

where ADL is the annual dose limit for members of the public. DELs must be calculated separately for the stochastic and deterministic

dose limits, the most restrictive value being retained as the DEL for that radionuclide. X_g/X_c is determined from equation 1, for the pathways and radionuclides significant to the critical group in question. To ensure that the critical group is not exposed beyond the ADL, for a multi-facility site, when more than one radionuclide is released, or when more than one mode of release exists (air or water), the following criterion must be satisfied:

$$\sum_i \sum_j \sum_k Q_{ijk} / DEL_{ijk} \leq 1 \quad (3)$$

where Q_{ijk} is the actual release of radionuclide i from release mode j (air or water), and source facility k ; DEL_{ijk} is the DEL for radionuclide i , release mode j , and facility k .

The model applies to many facilities such as research reactors, incinerators, and radioisotope-processing facilities. The model does not apply to facilities involving area sources and releases to the ground (eg, uranium mine tailings and mills, fuel fabrication plants and refineries, and in-ground waste storage facilities).

THE PROGRAM:

DELPro is a 207 KB Microsoft Excel macro which can run on PC or MAC type microcomputers. It uses pull down menus to select actions (eg, select emission type, etc...) and dialogue boxes allow the user to enter site-specific information about the critical group. Doses to the critical group may also be calculated. Results of the calculations can be saved and printed.

When released from a stack, some of the material may be drawn downward into the low pressure region on the lee side of the stack. This process, known as downwash, causes the height of release to be lower than the stack height. This effect is usually present when the efflux velocity is similar or smaller than the mean windspeed at the stack height^{2,4}. The effective stack height may be further reduced if the emitted material is entrained in the wake of a nearby building. This effect, known as downdraught, occurs when the downwash corrected stack height is between 1 and 2.5 times the height of the nearby building, and when the mean windspeed is above 5 m/s^(2, 4).

Although the air to water pathway (P_{12}) is negligible when the receiving body of water also receives liquid emissions⁴, it may be important when radioactive material deposits onto standing ponds. These land ponds, receiving no liquid emissions, may be used for irrigation of crops and/or drinking water for livestock. To examine the importance of P_{12} , DELs were calculated using Canadian averages for all transfer parameters, with all realistic pathways selected. DELs for about 31 out of a total of 78 radionuclides decreased by a factor of two or more when P_{12} was selected. The most significant decrease was for ²³⁸U; when the pond was used for drinking by livestock the ²³⁸U DEL went down 9 orders of magnitude. Such a decrease was predictable since P_{12} is proportional to the half-life of the radionuclide¹ (²³⁸U half-life = 4.5E+9 years). The DEL for HTO went down by a factor of 6. A sensitivity analysis has shown that the atmosphere-pond-livestock-man pathway contributes 99% of the dose to

man for ^{135}Cs , ^{234}U , ^{235}U , ^{238}U , ^{237}Np , and ^{244}Pu when all airborne emission pathways are present. This same pathway contributed 79% of the dose for HTO.

The effect of dry deposition on plume depletion is accounted for by multiplying the atmospheric dispersion coefficient by the ratio of concentration of activity in the air taking into account dry deposition to the concentration of activity ignoring deposition³. Dry deposition reduces plume concentration significantly in stable conditions and at long distances from the source ($> 10\text{km}$). To account for wet deposition the atmospheric dispersion coefficient is multiplied by the factor $e^{-\Lambda t_1}$. Values of the washout coefficient, Λ , for rain and snow, and for various precipitation rates are suggested in reference 2; t_1 is the time during which the plume is being depleted by precipitation.

Each pathway's contribution, C_{ijk} , to the critical group dose is evaluated for each pathway i , radiation effect j (eg, stochastic dose to adults), and radionuclide k , and can be written as:

$$C_{ijk} = (X_9/X_0)_{ijk} / \sum_n (X_9/X_0)_{njk} \quad (4)$$

where m is the total number of significant pathways, $1 \leq n \leq m$, and X_0 and X_9 are from equation (2).

CONCLUSION:

The addition of the air to water pathway, accounting for downdraught and downwash, and the inclusion of plume depletion effects increase the versatility of DELPro. The next task now is to obtain a better understanding of the uncertainties associated with DELs and doses calculated using this model. Also, increasing the processing speed of the program by upgrading it to a compiled version would make it easier to run complex simulations.

ABSTRACT

An experimental programme concerning the behaviour of UF₆ released in gaseous phase in the atmosphere has been conducted in the years 1986-1989 by the french Atomic Energy Commission and Eurodif. Three field tests have been performed on the CEA/CESTA experimental site. These experiments permitted to get informations about the kinetics of the hydrolysis reaction of the UF₆, the behaviour of the hydrolysis products in the atmosphere and the granulometry of the solid particles.

RESUME

Un programme d'expérimentation sur site a été mené entre 1986 et 1989 par le Commissariat à l'Energie Atomique et Eurodif afin de mieux évaluer les risques pour l'environnement auxquels conduirait un rejet accidentel d'UF₆ sous forme gazeuse dans l'atmosphère. Trois essais ont été réalisés sur le terrain d'expérimentation extérieur du CEA/CESTA. Ces essais ont permis d'obtenir des informations sur la cinétique de la réaction d'hydrolyse de l'UF₆, sur la diffusion des produits d'hydrolyse dans l'atmosphère et la granulométrie des particules formées.

1. Introduction

The UF₆, used in the nuclear fuel processing, reacts with the water vapour of the air to give a solid product UO₂F₂ and a toxic gas, HF:

The numerical prediction of the consequences of an accidental release of UF₆ in the atmosphere needs therefore the following points to be considered :

- . what is the kinetics of the hydrolysis reaction,
- . how do UO₂F₂ and HF diffuse in the air, what are their chemical-physical forms and how do they deposit on the ground.

In order to answer to these questions, EURODIF, the operator of the uranium enrichment plant of Tricastin in the Rhône Valley, and the Institute for Protection and Nuclear Safety of the CEA, in cooperation with the U.S. Department of Energy (D.O.E.), decided some years ago to undertake an in-field experimental programme on UF_6 atmospheric dispersion. Three releases of gaseous UF_6 have been accomplished in 1986, 1987 and 1989 on the CEA/CESTA test site, near Bordeaux. This paper summarizes the main results obtained in these experiments.

2. Results and interpretation

2.1 - Concentrations in the atmosphere

The figure 1 presents the maximum values of the Atmospheric Transfer Coefficient (ATC, i.e., the ratio of the time integrated concentration at a given point over the released quantity) versus distance. It is observed that the ATC values in U and F are very close to each other. On the same figure, are also reported the SF_6 results (SF_6 is used in these experiments as a reference tracer). It can be observed that these values are very near to the previous ones, except at short distance from the source (it is difficult to attribute this discrepancy to a particular behaviour of the UF_6 plume in the first meters or only to the differences, even small, in the release conditions). It can be concluded that U and F diffuse similarly, and diffuse like a passive contaminant. Particularly, a major finding of these experiments is that no detectable depletion of the aerosols of UO_2F_2 in the plume due to the ground deposition occurs.

For analysis of the kinetics of the hydrolysis reaction, the atmospheric concentrations of U trapped on the particle filters in the first test have been measured : they were found to be close to the values collected at the same points in the bubblers, meaning that, after some seconds of travel time, all uranium was in form of particles UO_2F_2 and that the hydrolysis reaction had already ended. A confirmation of this fact is brought hereafter.

2.2 - Ground deposition

The figure 2 presents the deposition velocity of the uranium versus distance, on the points where the measured atmospheric concentrations were maximum on each cross-section. In both experiments, the velocity lies between 10^{-4} and 4.10^{-4} ms^{-1} , in good agreement with the sedimentation velocity which can be expected according to the measured particle sizes (see § 2.3). The velocity does not increase with the distance (on the contrary, it decreases), confirming that the hydrolysis is complete after a few seconds : if it was not the case, the creation of particles of UO_2F_2 during the transfer would increase the deposition velocity.

The mass ratio U/F measured in the deposits is presented on the figure 3 for the points in the wind axis. In the second test, this ratio is near by 6.3, which is the theoretical ratio in the UO_2F_2 compound. It means that only UO_2F_2 deposits on the ground, and indicates that no mixed compound UO_2F_2, HF is present in significant proportion in the plume. However, in the third test, a lower ratio is observed, particularly at distances greater than 40 m. These measurements do not seem significant as sand was found in important quantity in several of the Petri boxes where samples were collected, disturbing the analysis (a clear correlation is observed between the boxes where sand was found and the low value of the ratio). The sand could be easily transported by the wind due to the relatively low air humidity during this experiment.

2.3 - Granulometry

The granulometric distribution (aerodynamic diameters) in uranium is presented on the figure 4. The results in both experiments are very similar : they show a major mass fraction between 1 and 3 μm at all distances. Moreover, the distributions in F is very comparable to the one in U (which is not a surprise according to the preceding results concerning the solid compound formed during the transfer).

3. Conclusion

The experimental programme carried out in France in the years 1986-1989 allowed to get several important informations on the behaviour of UF_6 released in gaseous phase in the atmosphere :

- the hydrolysis reaction of the UF_6 is rapid, probably complete after some seconds;
- U and F diffuse similarly, without significant differences compared to the reference tracer;
- only, UO_2F_2 aerosols deposit on the ground;
- the major mass fraction of aerosols is observed for aerodynamic diameters between 1 and 3 μm ;
- the deposition velocity of the aerosols lies between 1 and $4.10^{-4} ms^{-1}$, values which are coherent with the expected sedimentation velocity for such particles.

Care must be taken not to extrapolate without caution all these conclusions to the cases of UF_6 released in liquid phase, for which, as it has been observed in different incidents, other and more complex phenomena may occur.

EXPERIMENTAL STUDIES ABOUT THE DISTRIBUTION BETWEEN SOIL AND CROPS
OF SMALL PARTICLES FALLOUT.

These studies are performed to quantify the distribution between soil and crops of the micronic particles generated during a major accidental release. Works are done in open fields. We have chosen the size of the particles to simulate the situation of the environment like in the not immediately near field. The results are very dispersed, function of the vegetals types and of the season.

At first, we expose some generalities about the experimental techniques; then the results and finally we comment and specify the limits of use of that kind of data.

INTRODUCTION

Nous présentons ici l'état récapitulatif des travaux entrepris par l'Institut de Protection et de Sureté Nucléaire dans le cadre du programme RESSAC¹ et relatifs à la répartition du dépôt entre le sol et la végétation cultivée sus-jacente.

L'expérimentation se subdivise en une phase de marquage des parcelles cultivées par un aérosol micronique; puis en une phase d'analyse du marqueur déposé sur les végétaux et les surfaces de sol correspondantes.

Nous présenterons en premier lieu les grandes lignes des techniques expérimentales employées, puis les résultats obtenus. Enfin, nous commenterons et indiquerons les principales conclusions et limites dans lesquelles il convient d'employer ces données.

1: MATERIELS ET METHODES

1-1: L'AEROSOL

La granularité doit être comparable à celle de l'aérosol de Tchernobyl. La substance active doit être facilement mesurable, non-toxique et de désactivation rapide (nécessité de pouvoir réutiliser rapidement le site d'essais).

Le produit qui nous est apparu comme le plus approprié a été l'uranine en solution aqueuse à 25 g.l⁻¹, dispersable à partir d'un générateur ultra-sonique à fort débit (5 l.h⁻¹), et mesurable avec une sensibilité satisfaisante par fluorimétrie (10⁻⁷ g.l⁻¹).

L'aérosol produit présente un diamètre median en masse de 1,5 µm avec un écart-type géométrique de 2,2.

¹ Réhabilitation des Soils et des Surfaces après un Accident.

1-2: LE MARQAGE

Les essais conduits dans le cadre de ce programme n'ont concerné que le dépôt sec.

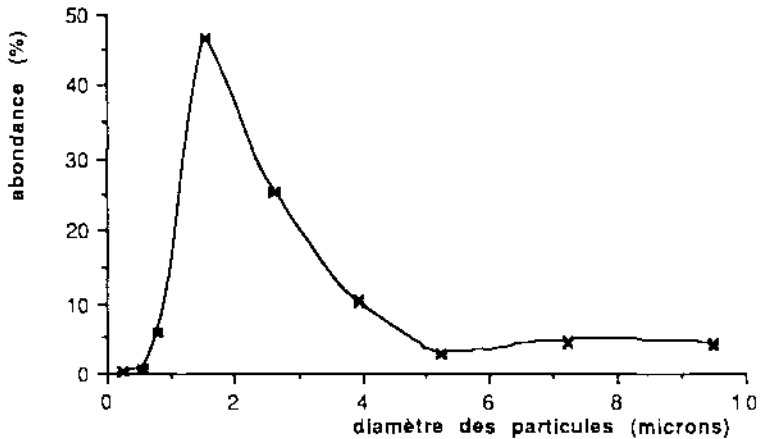

Le dispositif consiste à disposer les générateurs d'aérosol dans le vent des parcelles cultivées, et de les déplacer le long de celles-ci à l'aide d'un chariot mobile.

Les essais ainsi réalisés ont permis d'obtenir une homogénéité verticale de concentration dans les trois premiers mètres au dessus du sol, à condition toutefois que le générateur soit placé à un minimum de trente mètres en amont au vent des cultures.

GRADIENTS VERTICAUX DE CONCENTRATION

GRANULOMETRIE DE L'AEROSOL D'URANINE

1-3: LES PRELEVEMENTS

L'évaluation du dépôt sur la végétation se fait à partir de plantes entières.

L'évaluation du dépôt au sol est réalisée à partir de jauges de dépôt (disques d'acier inoxydable, $\Phi = 20$ cm, déposés directement sur le terrain. Cette méthode présente l'avantage de permettre la mesure de l'uramine avec un rendement proche de l'unité. Une mesure effectuée à partir d'échantillons de terre a un rendement fluctuant entre 0,4 et 0,6, imprévisible a priori, et est donc inutilisable dans notre cas. Des essais préalables nous ont permis d'établir que le dépôt sur nos jauges était représentatif du dépôt sur sol cultivé. Les échantillons sont lavés dans une quantité connue de solution tampon (pH 9,4), filtrés à 0,45 μm et finalement mesurés par fluorescence (513 nm).

1-4: LES VEGETAUX ETUDIES

Nous avons déterminé l'ensemble des cultures les plus abondantes en surface dans les pays européens. Nous avons étudié: des céréales (blé et maïs), des plantes oléagineuses (colza et tournesol), des plantes textiles (lin), maraichères (épinards, salades), des légumes industriels (petits pois, haricots, pommes de terre) et des plantes fourragères (betteraves, luzerne et graminées).

2: RESULTATS & INTERPRETATION

Le tableau proposé en fin de ce texte présente l'ensemble des résultats obtenus, en fonction de la productivité (poids sec par mètre carré de culture) ou du stade végétatif des plantes. Remarquons que ces deux indications sont complémentaires: le stade végétatif ne donne pas une indication suffisamment précise, et les résultats sont très influencés par les différences morphologiques entre les variétés. La productivité est souvent fonction de la densité de semis et aussi de la variété étudiée.

Pour certaines espèces, nous disposons de résultats suffisamment nombreux et homogènes pour tracer les courbes d'évolution du coefficient de captation des plantes en fonction de la productivité.

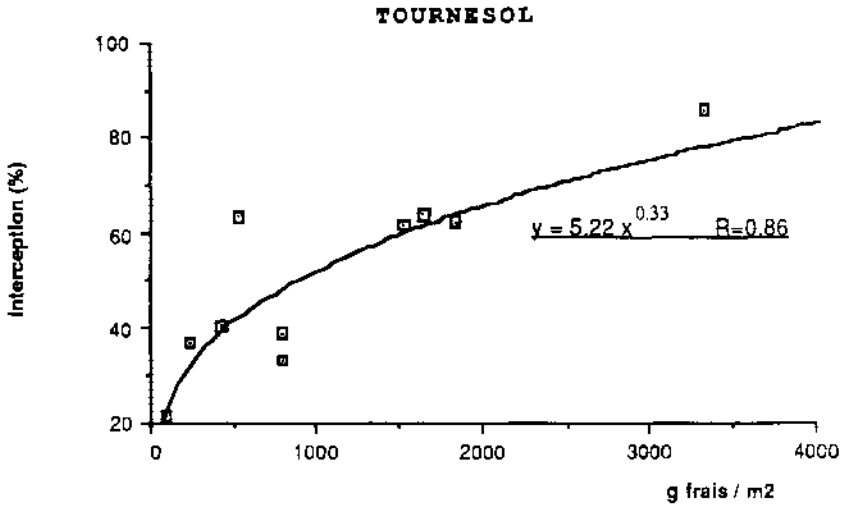

Nous ajustons les courbes de points à des courbes de la forme

$$y = ax^b.$$

Elles sont toujours bien corrélées avec le nuage des points expérimentaux, mais peuvent théoriquement donner des résultats de captation supérieurs à 100%...si on les emploie sans discernement hors de leur région de validation.

VEGETAUX	a	b
BLE (PAILLES COURTES)	26,22	0,12
BLE (PAILLES LONGUES)	15,62	0,215
CROU	1,60	0,48
HARICOT & POIS	4,09	0,41
HERBE	1,53	0,57
LIN	6,16	0,36
LUZERNE	17,56	0,21
MAIS	10,01	0,25
POMME DE TERRE	2,56	0,46
TOURNESOL	5,22	0,33

La figure ci-après illustre ce type de résultat.

Les données obtenues montrent de nettes variations dans le coefficient de captation, fonctions de l'espèce, du stade végétatif et de la densité culturale. En cas d'accident, on ne peut donc pas se satisfaire d'une seule courbe pour l'estimation des conséquences radiologiques et des mesures de protection à décider. Il faut pouvoir tenir compte des spécificités dues aux espèces cultivées, à leur stade de développement et aux pratiques culturales locales. Les données acquises lors de ces essais sont utilisables dans ce cadre.

HIGH TEMPERATURE PEAK CHARACTERISTICS OF THE READER-ANNEALED TLD-600
AND ITS APPLICATION TO PERSONNEL PROTECTION DOSIMETRY
IN MIXED NEUTRON-PHOTON FIELD

James C. Liu

Stanford Linear Accelerator Center, Stanford, CA 94309, USA

C. S. Sims

Oak Ridge National Laboratory, Oak Ridge, TN 37831-6379, USA

ABSTRACT

The high temperature peaks 6-7 of TLD-600 have higher responses to high LET radiation than to low LET radiation. This characteristic was studied for the automatic reader-annealed Harshaw albedo neutron TLD. The high temperature peaks response is linear for neutrons, but is supralinear above 20 mSv of ^{137}Cs photons. The peaks ratio (peaks 6-7/peaks 3-5) of TLD-600 is 0.15 for neutrons of any energy, 0.01 for ^{137}Cs gammas and 0.02 for M-150 x-rays. Based on the results, a personnel dosimetry using a single TLD-600 was developed and evaluated in mixed neutron-photon fields. The estimations for neutron, photon and total equivalent are better than 20% except in one case. However, an error analysis shows that the estimations are sensitive to the neutron and photon peaks ratios, depending on the neutron-photon dose equivalent ratio and the neutron source.

INTRODUCTION

The TL glow curve of the LiF-TLD (TLD-100, TLD-700, TLD-600) has several peaks, among which peaks 3-5 are main dosimetric peaks (peak 5 at $\sim 200^\circ\text{C}$), and peaks 6-7 are high temperature peaks (peak 7 at $\sim 260^\circ\text{C}$). Other peaks are usually not important for dosimetric purposes. The high temperature peaks have higher responses to high LET radiation than to low LET radiation and this characteristics can be influenced by many factors, e.g., TLD material, annealing, cooling, readout method, etc. Conventional long and high temperature oven annealing for LiF-TLD is usually not used for automatic TLD systems. This paper presents the high temperature peak characterization results for the Harshaw automatic reader-annealed TLD-600. Based on the results, a mixed field neutron-photon dosimetry using a single TLD-600 element was developed and evaluated in mixed fields. A few factors which may affect the accuracy of the dosimetric method are discussed.

MATERIALS AND METHODS

Harshaw albedo neutron TLDs (two pair of TLD-600/TLD-700; one pair is shielded in front by a $28 \times 13 \times 0.46 \text{ mm}^3$ cadmium sheet) were used in this study. The sensitivities of all TLD chips ($3.2 \times 3.2 \times 0.9 \text{ mm}^3$) were individually calibrated with free-in-air ^{137}Cs irradiations. The TL signals were normalized to a constant ^{137}Cs exposure and were in units of μGy . The Harshaw 8800 automatic TLD reader was used to readout and anneal the TLDs. The digitized 200-channel TL glow curves of the TLD-600 exposed to neutrons or photons from the Harshaw 8800 reader are shown in Figure 1. Neutrons produce much higher peaks 6-7 and slightly lower peaks 3-4 than photons. The linear heating profile (no preheat, a heating rate of 25°C s^{-1} from 50°C to 300°C , and a hold time of 6.7 s at 300°C) using hot N_2 gas in this study is also shown in Figure 1. The Computerized Glow Curve Deconvolution (CGCD) program⁽¹⁾ was used to separate the glow curve into individual peaks, but the deconvolution result was not satisfactory. This might be due to the first-order TL kinetic model in the CGCD program being inappropriate to describe the TL response of a neutron-exposed TLD-600.

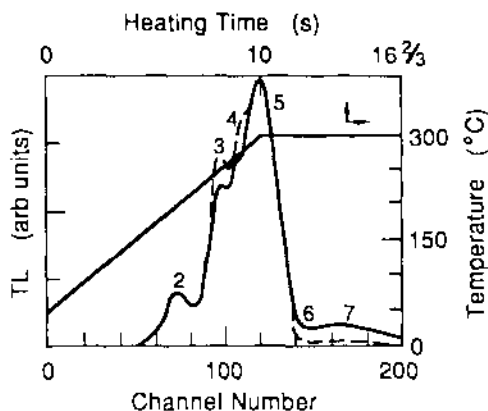

Figure 1. TL glow curves induced by neutrons (—) or photons (---) for TLD-600. Peaks 3-5 cover channels 96-145 and peaks 6-7 cover channels 146-200. The heating profile used is also shown.

Therefore, in this study (see Figure 1), the TL signal between channels 96-145 is regarded as peaks 3-5 and the TL signal between channels 146-200 is regarded as peaks 6-7. It has been found⁽²⁾ that these channel settings can achieve a satisfactory sensitivity and response stability over reuse, and minimize the fading influence from peaks 2 and 3. The TLDs were reader-annealed using the same heating profile just prior to irradiation. However, repeated annealings or annealing using a longer hold time (20 s) at 300°C was used sometimes for highly dosed TLDs in order to reduce the residual TL signal to an acceptable level. No pre-irradiation or post-irradiation, low temperature annealing was used.

Four radioisotopic neutron sources [²⁵²Cf(D₂O), ²⁵²Cf(PE), ²⁵²Cf and ²³⁸PuBe], eight monoenergetic neutrons (0.1, 0.25, 0.565, 1.2, 2.6, 3.2, 5.0 and 14.8 MeV), ¹³⁷Cs and the M150 x-rays were used for the TLD irradiations⁽³⁾. The ²⁵²Cf(PE) source is a ²⁵²Cf moderated by a 15 cm radius polyethylene sphere. The errors associated with neutron fluences were 10-15% for monoenergetic neutrons and 5-10% for radioisotopic neutron sources. All TLDs were irradiated perpendicularly with dosimeters mounted on the front face of a 40×40×15 cm³ Lucite phantom, except the M150 x-rays irradiations which were made using a 30×30×15 cm³ phantom. The dose equivalent quantity used is the ICRP 21 neutron dose equivalent quantity⁽⁴⁾ for neutrons and is the deep dose equivalent quantity⁽⁴⁾ for photons. The photon contribution from the neutron source to the TLD-600 signal was estimated by the paired TLD-700 element.

CHARACTERIZATION RESULTS

LINEARITY

The TL response for the Cd-covered TLD-600 exposed to ²⁵²Cf(PE) are shown in Figure 2. The linear response level for peaks 6-7 is up to ~2.56 mGy at 3 mSv neutron exposure. Since both peaks 6-7 and peaks 3-5 have linear responses over the range of 0.05-3 mSv, the total TL response (peaks 3-7 = the sum of peaks 3-5 and peaks 6-7) is also linear. The peaks ratio, peaks 6-7/peaks 3-5, is equal to the slope ratio in Figure 2. Therefore, the neutron peaks ratio for ²⁵²Cf(PE) is a constant of $(0.854/5.921)=0.144$ ($1\sigma=2\%$) over the dose range. The neutron sensitivity of the Cd-covered TLD-600, defined as the peaks 3-7 response, for ²⁵²Cf(PE) is $(0.854+5.921)=6.78$ mGy mSv⁻¹. Figure 3 shows the linear response curves of the Cd-covered

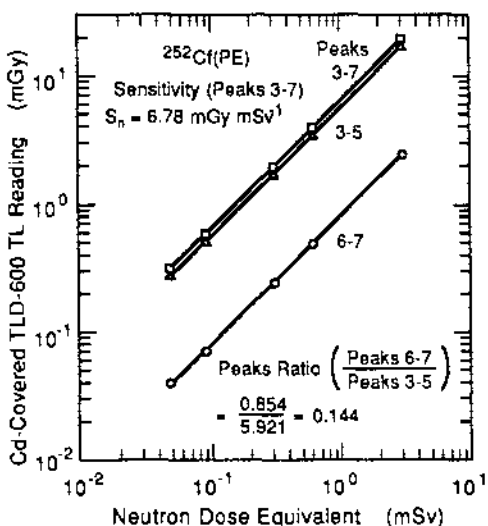

Figure 2. TL response linearities of the peaks 3-5, peaks 6-7, and total peaks 3-7 for the Cd-covered TLD-600 exposed to the $^{252}\text{Cf(PE)}$ neutrons.

Figure 3. TL response linearities of the peaks 3-5 and peaks 6-7 for the Cd-covered TLD-600 exposed to $^{238}\text{PuBe}$ neutrons. The supralinearity of the peaks 6-7 response for bare TLD-600 exposed to ^{137}Cs photons is also shown.

TLD-600 for $^{238}\text{PuBe}$. The neutron peaks ratio is $(0.113/0.789)=0.143$ ($1\sigma=3\%$), which is very close to that of $^{252}\text{Cf(PE)}$, but the neutron sensitivity is only $(0.113+0.789)=0.902$ mGy mSv^{-1} , due to the albedo neutron detection principle.

Figure 3 also shows the peaks 6-7 response of the bare TLD-600 exposed to ^{137}Cs free-in-air. The linear response level for peaks 6-7 is up to only 0.23 mGy at 20 mSv gamma exposure and the linear region has a slope of 0.012 mGy mSv^{-1} . The deviation from linearity (see dashed line in Figure 3) is $\sim 15\%$ overresponse at 103 mSv. The peaks 3-5 response of the TLD-600 exposed to ^{137}Cs , which is not shown in Figure 3, is linear up to 100 mSv with a slope of 1.045 mGy mSv^{-1} . Therefore, the photon peaks ratio of the TLD-600 for ^{137}Cs is a constant of $(0.012/1.045)=0.01$ ($1\sigma=10\%$) only up to the level of 20 mSv, due to the supralinear response of peaks 6-7.

Since the peaks 6-7 response is only $\sim 1\%$ of the peaks 3-5 response for a gamma-exposed TLD-600, the supralinearity of peaks 6-7 response is masked by the linearity of peaks 3-5 response. Therefore, the total peaks 3-7 response for a gamma-exposed TLD-600 is treated as linear in most personnel protection dosimetric practices.

The finding that the supralinearity of peaks 6-7 is LET-dependent (the lower the LET, the lower the TL response level at which supralinearity occurs) is consistent with results previously reported in Refs. 5 and 6. However, the gamma dose levels at which the supralinearity occurs are

different between our results and others (~100 mGy for TLD-100 in Ref. 5, 2.5 mGy for TLD-700 in Ref. 6, and ~20 mGy for TLD-600 in this work). It is also demonstrated that the peaks 6-7 have a higher response to neutrons than to photons; a factor of $(0.113/0.012)=9.4$ between $^{238}\text{PuBe}$ and ^{137}Cs , and a factor of $(0.854/0.012)=71$ between $^{252}\text{Cf(PE)}$ and ^{137}Cs .

PEAKS RATIO AND SENSITIVITY

Since the Cd-covered TLD-600 responds mainly to the albedo thermal neutrons, the peaks ratio is expected to be the same for all incident neutron energies. The peaks ratios of the Cd-covered TLD-600 for the monoenergetic and radioisotopic neutron sources ranged from 0.143 to 0.163 and the mean neutron peaks ratio was 0.15 ($1\sigma=7\%$). The neutron sensitivity (S_n) follows the typical energy-dependent curve of an albedo-type TLD (the response is high at low energies and is low at high energies).

Contrary to the neutron results, the photon peaks ratio is energy-dependent; 0.01 ($1\sigma=10\%$) for ^{137}Cs 662 keV gammas and 0.02 ($1\sigma=3\%$) for M150 x-rays. The photon sensitivity (S_p) of the Cd-covered TLD-600 is slightly energy-dependent (0.872 mGy mSv $^{-1}$ for ^{137}Cs gammas and 0.916 mGy mSv $^{-1}$ for M150 x-rays), due to the tissue-equivalence of the TLD-600 to photons.

Budd et al.⁽⁷⁾ studied the peaks ratios of the TLD-600 to x-rays and their peaks ratio values are a factor of five higher than ours, probably due to the slow cooling they used. However, a comparison on the relative peaks ratio as a function of photon energy (the peaks ratio at a given energy divided by the peaks ratio for ^{137}Cs gammas) between their results and ours shows good agreement (see Figure 4). The peaks ratios for neutrons and photons in this work are close to those of Doles et al.⁽⁸⁾ who used TLD-100 with different readout and annealing techniques.

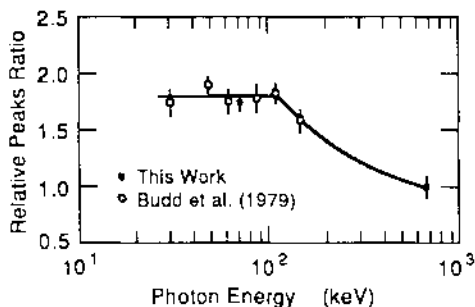

Figure 4. Relative peaks ratios as a function of photon energy (peaks ratio at a given energy divided by that of ^{137}Cs photons) for the Cd-covered TLD-600.

MIXED NEUTRON-PHOTON FIELD DOSIMETRY

A neutron-photon dosimetry using a single Cd-covered TLD-600 element in mixed fields can be developed by using the peaks ratio and sensitivity values. A Cd-covered TLD-600, irradiated to a neutron dose equivalent (H_n mSv) and a photon dose equivalent (H_p mSv), has a total peaks 3-7 signal of T mGy. Let the peaks ratio be PR (i.e., $PR = \text{peaks 6-7}/\text{peaks 3-5}$) and $K = PR/(1+PR)$ (i.e., $K = \text{peaks 6-7}/\text{peaks 3-7}$). The following two equations can be established.

$$T_H = H_n S_n K_n + H_p S_p K_p \quad (1)$$

$$T_I = H_n S_n (1 - K_n) + H_p S_p (1 - K_p) \quad (2)$$

T_H, T_I = measured peaks 6-7 and peaks 3-5 TL signals in units of mGy, respectively, and $T = T_H + T_I$

K_n, K_p = K values for neutron and photon radiations, respectively

S_n, S_p = neutron and photon sensitivities (peaks 3-7), respectively, of the Cd-covered TLD-600 in units of mGy mSv⁻¹

$H_n S_n K_n$ = TL signal component of peaks 6-7 contributed by neutrons.

Since PR is 0.15 for all neutrons, K_n is 0.13 for all neutrons. The value K_p is dependent on photon energy and can be determined from Figure 4. If neutron and photon energies are known, there are only two unknowns, H_n and H_p , to be solved in equations 1 and 2.

A test of the above mixed field dosimetry was made by irradiating eight groups of albedo TLDs to two neutron dose equivalents (0.5 and 1.5 mSv) with four H_n/H_p ratios (2.6/1, 1/1, 1/3 and 1/10), using both $^{238}\text{PuBe}$ and ^{137}Cs sources. The small 4.43 MeV gamma dose equivalent component (~4%) of the $^{238}\text{PuBe}$ source⁽³⁾ was included in the photon dose equivalent. The test results presented in Table 1 show the bias (B), precision (P) and accuracy (A) values in percentage for the neutron, photon and total (neutron + photon) dose equivalent estimations in eight mixed fields by using the four Cd-covered TLD-600 elements per exposure group.

Table 1. Dose equivalent measurement performance of the Cd-covered TLD-600 in mixed $^{238}\text{PuBe} + ^{137}\text{Cs}$ fields, using the high temperature peaks method.^(a) The values for B , P , and A are in percentage.

$H_n^{(b)}$	H_n/H_p	$H_p^{(b)}$	Neutron			Photon			Total ^(f)		
			$B^{(c)}$	$P^{(d)}$	$A^{(e)}$	B	P	A	B	P	A
0.5	2.6/1	0.19	-22.0	6.6	28.6	28.9	4.1	33.0	-7.2	3.3	10.5
	1/1	0.52	-14.0	3.3	17.3	7.7	3.0	10.7	-2.9	1.0	3.9
	1/3	1.52	-10.0	3.1	13.1	2.6	1.1	3.7	-0.5	1.3	1.8
	1/10	5.02	0	9.8	9.8	1.4	1.3	2.7	1.3	1.8	3.1
1.5	2.6/1	0.57	-12.0	5.9	17.9	7.0	6.2	13.2	-6.8	4.8	11.6
	1/1	1.57	-10.0	4.0	14.0	1.9	3.2	5.1	-3.9	2.7	6.6
	1/3	4.57	-7.3	3.5	10.8	1.3	1.6	2.9	-0.8	2.0	2.8
	1/10	15.07	4.0	4.3	8.3	-1.3	0.9	2.2	-0.9	1.1	2.0

(a) Peaks ratio is 0.15 for neutrons and 0.01 for ^{137}Cs photons.

(b) H_n is the neutron dose equivalent from $^{238}\text{PuBe}$, H_p is the photon dose equivalent from both ^{137}Cs and the 4.43 MeV gamma component of $^{238}\text{PuBe}$ (~4% of its neutron dose equivalent)⁽³⁾ in mSv units.

(c) Bias (B) is $(H - H_0)/H_0$, where H is the mean dose equivalent estimated from the four Cd-covered TLD-600 elements per exposure group and H_0 is the reference value.

(d) Precision (P) is one relative standard deviation per group.

(e) Accuracy (A) is the sum of the absolute value of bias and precision.

(f) Total dose equivalent (neutron + photon) estimation.

The neutron or photon bias is small when the H_n/H_p is small, and the bias is also smaller at the higher neutron dose equivalent level. The largest bias (-22% for neutrons and 29% for photons) occurs in the mixed field with $H_n = 0.5$ mSv and $H_n/H_p = 2.6/1$. The photon precision is better when the H_n/H_p is smaller (<7% in all cases). The neutron precision is better in the fields with $H_n/H_p = 1/1$ or $1/3$ (<10% in all cases).

Since the precision values are smaller than the corresponding bias values in most fields, the accuracy values show the same trend as the bias values. The worst accuracy is 29% for neutrons and 33% for photons in the field of $H_n=0.5$ mSv and $H_n/H_p=2.6/1$, while in the other fields the accuracy values are better than 18%. The total dose equivalent estimation is very good (accuracy is better than 12% in all cases) due to the opposite bias in the neutron and photon dose equivalent estimations. The opposite bias result is expected due to the use of a single TLD element to estimate both neutron and photon dose equivalents in our methodology.

ERROR ANALYSIS

The good dose equivalent measurement performance shown in Table 1 is an ideal case in which the neutron and photon sources are known (so peaks ratios and sensitivities are both known with small errors). In real fields, the photon and neutron spectra may be known only to a limited extent. In that case, although photon sensitivity has a small error due to the small energy-dependence of TLD-600 to photons, the photon peaks ratio may have a large error (peaks ratio varies from 0.01 to 0.02). In contrast to the case for photons, the neutron sensitivity may have a large error if the neutron energy is not well known, while the neutron peaks ratio is still a constant of 0.15. In either case, the uncertainty in photon or neutron energy can result in error to the neutron and photon dose equivalent estimations.

An error analysis can be performed by calculating the variations of the neutron and photon dose equivalent estimations as a function of the variation of the neutron or photon peaks ratio. Figure 5 shows the fractional changes in the neutron and photon dose equivalent estimations, if the photon peaks ratio is changed from 0.01 to 0.02. For this increase in the photon peaks ratio, the fractional change in the photon dose equivalent estimation is increased, but the fractional change in the neutron dose equivalent estimation is decreased. The fraction increase in the photon dose equivalent estimation is 9-11% in any field, regardless of neutron source type and the H_n/H_p ratio. The fractional decrease in the neutron dose equivalent estimation, however, shows strong dependence on both the neutron source type and the H_n/H_p ratio. Extreme results in the ^{137}Cs fields mixed with $^{252}\text{Cf}(\text{D}_2\text{O})$ or $^{238}\text{PuBe}$ are shown in Figure 5. The fractional decrease is higher when H_n/H_p is lower; it is <10% in the mixed fields with $^{252}\text{Cf}(\text{D}_2\text{O})$ in any H_n/H_p ratio; the decrease can be as high as 90% in a $^{238}\text{PuBe}$ mixed field with a H_n/H_p of 0.1. Fortunately, the fractional change of total dose equivalent, which can also be estimated from Figure 5, is less than 8% in any mixed field with $^{252}\text{Cf}(\text{D}_2\text{O})$ and less than 1% in any mixed field with $^{238}\text{PuBe}$.

Figure 6 shows the fractional changes in the neutron and photon dose equivalent estimations, if the neutron peaks ratio is changed from 0.15 to 0.14 (i.e., changed by 1%). The situation in Figure 6 is reversed from that in Figure 5. The fractional increase in the neutron dose equivalent estimation is 9-10% in any mixed field, regardless of neutron source type and the H_n/H_p ratio. The fractional decrease in the photon dose equivalent estimation has strong dependence on both the neutron source and the H_n/H_p ratio. The fractional decrease is higher when H_n/H_p is higher; it is as high as 95% in a $^{238}\text{PuBe}$ mixed field with a H_n/H_p of 10. The fractional decrease in the photon dose equivalent estimation in a $^{252}\text{Cf}(\text{D}_2\text{O})$ mixed

Figure 5. Fractional changes in the neutron and photon dose equivalent estimations in mixed neutron-photon fields, if the peaks ratio for photons is changed from 0.01 to 0.02. Extreme results in the mixed fields with two different neutron sources are shown.

Figure 6. Fractional changes in the neutron and photon dose equivalent estimations in mixed neutron-photon fields, if the peaks ratio for neutrons is changed from 0.15 to 0.14. Extreme results in the mixed fields with two different neutron sources are shown.

field could be larger than -100%, but this is only a calculated value and is physically impossible. The fractional change in the total dose equivalent estimation in a mixed field with $^{238}\text{PuBe}$ is <1% in all cases. The fractional decrease in the total dose equivalent estimation in a $^{252}\text{Cf}(\text{D}_2\text{O})$ mixed field with a $H_n/H_p = 1$ could be as high as 50%.

DISCUSSION

The upper linear response level of the peaks 6-7 in our study is ~3 mSv for neutrons and ~20 mSv for gammas. Using a three-month dosimeter exchange period, the maximum neutron and gamma dose equivalent limits per year with no supralinear peaks 6-7 response are 12 mSv and 80 mSv, respectively. Therefore, the high temperature peak dosimetry is suitable for most protection dosimetry situations, but not for accident dosimetry.

Low sensitivity of peaks 6-7 to photons (only 0.012 mGy mSv⁻¹) might lead to an impression of insufficient photon sensitivity of this method for use in protection dosimetry. Key points in the high temperature peak methodology are: using the high peaks 3-7 sensitivities of the TLD-600 for photons and neutrons to detect both photons and neutrons, and using the very different peaks 6-7 sensitivities for photons and neutrons to differentiate the photons and neutrons. Therefore, the photon and neutron peaks ratios should be accurately determined, so that the photon and neutron signals can be well separated. The good test results in Table 1 also prove that the method is appropriate for protection dosimetry.

Other concerns are the reproducibility of the peaks ratio during reuse and the variation of the peaks ratios within a group of TLDs. For example, the fading of peaks 2-3 would affect the peaks ratio value if the fading effect is not properly accounted for. A more stable peaks ratio value can be obtained, at the expense of total sensitivity, by using a narrower region of interest (e.g., covering only peaks 4-5). Our experience shows that the current settings of the two regions of interest and the heating profile can achieve a satisfactory result for at least a one-month fading period. The peaks ratio may not be chip-dependent, but it can be batch-dependent. A simpler solution is to use the mean peaks ratio for a batch, if the variation of the peaks ratios within a batch is acceptable. A more complicated solution is to generate individual neutron and photon peaks ratio values for every TLD-600 element. This is a tedious but not difficult procedure, and the mass data manipulation associated with it is easy in a computer-aided TLD system.

CONCLUSION

The high temperature peaks characteristics of the reader-annealed TLD-600 have been studied. The high temperature peaks have linear responses for neutrons, but supralinearity starts at about 20 mSv for gammas. The peaks ratio is 0.15 for neutrons of any energy, and is energy-dependent for photons (0.01 for ^{137}Cs , and up to 0.02 for x-rays below 100 keV). A mixed field neutron-photon protection dosimetry using a single Cd-covered TLD-600 element was developed and evaluated in different mixed field conditions. The results and an error analysis show that such mixed-field dosimetry would work well if both the neutron and photon sources are known. Otherwise, the neutron and photon dose equivalent estimations may have large errors, depending on the peaks ratio error, the neutron source type, and the neutron/photon dose equivalent ratio in the mixed field.

ABSTRACT

An area monitoring network system, RMSAFE, has been developed at NIFS for the application to the LHD fusion plasma experiment. Radiation emissions of intermittent burst-like pulses will be detected and measured in a passive monitoring way. Preliminary operations have been made.

INTRODUCTION

In order to monitor the radiations (X-rays and neutrons) emitted from high temperature plasma experiments for fusion studies, a system network of detectors named the Radiation Monitoring System Applicable to Fusion Experiments (RMSAFE) has been considered and developed. This is an area monitoring system of passive nature and is going to be applied to the experimental site of the National Institute for Fusion Science in Toki, Japan, where a new toroidal plasma machine called Large Helical Device (LHD) will come to operation within several years.¹ Although no tritium will be introduced into the machine, a certain amount of neutron yields together with X-rays will be given in deuterium plasma operations. These radiations should be monitored and controlled in a reliable way.

In the course of preparing the RMSAFE system it is needed to carry out considerable R & D work and for that purpose a prototype system (proto-RMSAFE) has been constructed at the present campus of NIFS in Higashiyama (30km from Toki), where plasma experiments with smaller sized devices, CHS and JIPP T-II U, are going on.²

SCOPE AND CONCEPT OF RMSAFE

The detailed operational conditions in the coming LHD experiments are still under discussion, but in typical modes of operation plasma discharges will take place with 0.5 ~ 10 sec in duration and 5 ~ 10 min of repetition cycle. The radiations are to associate with plasma shots and therefore they may appear as intermittent burst-like pulses. Some 1000 full shots are expected a year.

RMSAFE SYSTEM OUTLINE

In Fig. 1 is shown a schematic framework of RMSAFE now under construction. Since the main experimental building for LHD will not come out until a few years, here we are considering the sensors only in categories C and D, which are consisting of pressurized Ar-ion chambers and He-3 proportional counters, to detect environmental levels of gamma rays and neutrons, respectively. For the time being, seven monitoring points (two in the site and five on the borders) have been selected. Signals from these detectors are transmitted through optical cable lines to three 4-channel scalers. These scalers are interfaced with a GPIB box, and are connected with an engineering workstation playing as the central data processor of the system. The raw signals from each sensor are digitalized and counted by the scaler according to the mode selected. The observed data are analysed and recorded in the central data processor. The system is in connection with an Ethernet line to other experimental systems, for instance, alarm or interlock systems of the machine operation.

There are three modes of data counting function, Background (BG) Mode, Burst (BS) Mode and Time-profile (TP) Mode. In BG Mode, the sensor signals are sampled in a time width T are consecutively recorded, irrespectively of occurrence of burst-like events. $T = 30$ s is typically taken. A burst-like event is identified, if a rapid increase beyond a preset value is noticed in signals from a sensor during a short time span, say 50 ms, by means of an installed burst-detecting circuit. In case the system is in BS Mode or TP Mode, the counting status of all the sensors are immediately switched into the time profile counting one, where fine structures of signal evolution are counted for a period of 105τ , where τ denotes a preset time of sampling resolution and usually $10 \sim 200$ ms. In BS Mode the total signal intensities during the burst event together with the onset time are dealt with, while in TP Mode the detailed time profile records will be given as output. Unless a burst-like pulse event is encountered, the system remains in the background counting status, just the same as in BG Mode, so that the background components during the burst are extrapolated from the preceeding periods and subtracted to give the net burst contributions in BS and TP Modes.

DATA EXAMPLES

Figure 2 shows an example of Background Mode data obtained from an ionization chamber placed at a site border region in Toki. The output current from the chamber is given as counts/30sec, and is converted to the gamma dose rate in nSv/h. The observed data will give a mean level of (57.42 ± 2.45) nSv/h, which value is quite consistent with other environmental measurements made in this place, say, TLD giving 60.7 nSv/h.

In the Toki site it is strongly required that the radiational impacts on the environments should be kept as small as possible, and as a guideline it is given for an annual amount of dose contributions of experimental origin not to exceed $50\mu\text{ Sv}$ on the site boundaries.³

It is rather severe task to hold this amount reliably monitored, if we consider a natural background level of environmental radiations, typically $0.5 \sim 1\text{ mSv/y}$ in this area, with usual fluctuation of $\sim 10\%$, so that the net integrated dose limit $50\mu\text{ Sv/y}$ would be below the natural fluctuation levels. But it might be possible to catch them up, if the pulsed nature of experiments is taken into account. Suppose that 1000 full shots of radiation emitting plasma experiments are given in a year, then a single shot could share 50 nSv/shot in average, or a level of dose rate 5 nSv/s for 10-s duration, which value is well higher than the background rate of $15 \sim 30\text{ pSv/s}$.

The monitoring system is required to identify such pulses apart from the background level and to accumulate their dose contributions. So, this implies the dosimetry work to respond nSv/s range with 0.1 s time resolution. It is, however, not very easy to detect such faint pulses by use of a single detector. In order not to miss the pulse events as well as to find out the spatial distribution of emitted radiations, a number of sensors should be distributed over the site area, the Toki site being 47 ha in area, to form a network system.

The concept of RMSAFE has been developed to meet these requirements. Its characteristics are summarised as follows:

- (a) It is a sensor network system covering the whole area of the site to make the continuous monitoring of radiation fields (usually gamma rays and neutrons).
- (b) All the signals from the sensors are directly connected to a central monitoring data processor to find out the real time situation over the whole site area throughout the year round.
- (c) A burst-like pulse event of radiations can be detected and identified by sensor signals themselves, the system being operative in a passive way.
- (d) Once a burst is noticed by any one of the sensors, the whole system is turned into burst analysing status to make detailed observations and recordings.
- (e) In the period of no bursts, the background radiation levels are monitored continuously.
- (f) Sensors may be categorized in accordance with the radiation species and levels locally expected. For the time being, following 4 zones of monitoring position are considered:
 - A. Inside the shielded experimental hall
 - B. Indoor monitoring points out of the shielded area
 - C. Outdoor monitoring points in the site
 - D. On the site boundaries
- (g) The system would easily be extensible, in case of additional sensors and points needed.

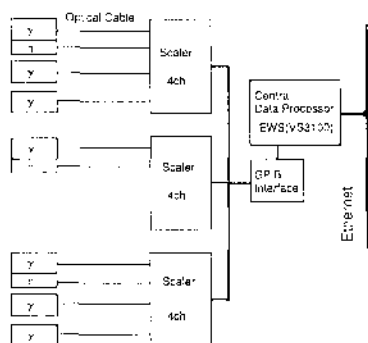

Fig.1 RMSAFE system.

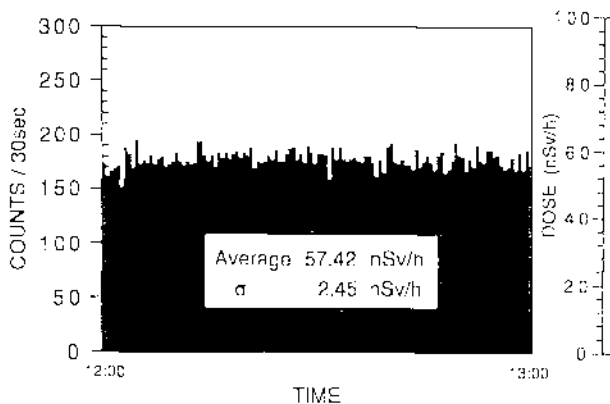

Fig.2 Background data for gamma rays in Toki.

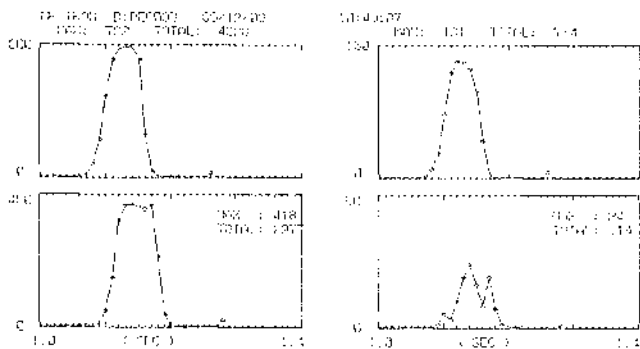

Fig.3 Time-profile data for neutrons from JIPP T-II U.

In Fig.3, another example taken with proto-RMSAFE is given. Here neutron observations with four detectors of different type were carried out around JIPP T-II U tokamak. The system is operated in Time-Profile Mode, and the data outputs are well representing the characteristics of neutron emissions associated with the plasma discharge.

CONCLUDING REMARKS

The idea of RMSAFE has been found useful in monitoring operations, though it may be necessary to make further R and D investigations for higher reliability. In parallel to the actual system construction of RMSAFE in Toki, studies with proto-RMSAFE will be made on the practical issues around the existing plasma experiments.

**HIGH LEVEL DOSIMETRY AT
THE STANFORD LINEAR ACCELERATOR CENTER***

N. E. Ipe and J. C. Liu

Stanford Linear Accelerator Center,
Stanford University, Stanford, CA 94309, USA

The Stanford Linear Accelerator Center (SLAC) operates a high energy electron accelerator (capable of energies up to 50 GeV). During operation the instantaneous dose rates in the vicinity of the beam pipe due to beam losses can be extremely high. This results in large accumulated doses to beamline components and nearby devices. Since these large doses can cause damage to some of these components and devices, there is always a need for high level dosimetry at SLAC.

Several types of high level dosimeters are used in order to cover a wide range of doses extending from about 10 Gy to 1 MGy. These are optichromic, radiachromic, red perspex, cinemoid (bright rose film #48), and Lexan dosimeters. The response curve for each of these dosimeters is presented. Some practical difficulties associated with their use in the field will also be reported.

INTRODUCTION

The Stanford Linear Accelerator Center (SLAC) operates a high energy electron accelerator (capable of energies up to 50 GeV). During operation the instantaneous dose rates in the vicinity of the beam pipe, due to beam losses, can be extremely high. This results in large accumulated doses (from electrons, photons and neutrons) to beamline components and nearby devices. In addition synchrotron radiation from storage rings can deliver very high doses. Since these large doses can cause damage to some of these components and devices, there is a need for high level dosimetry at SLAC.

Radiation damage depends on both integrated dose as well as the dose rate, in addition to environmental factors such as temperature and humidity. Equal doses from different types of radiation do not necessarily produce equal damage⁽¹⁾. For instance, for electronics and semiconductor devices, the displacement of atoms by neutrons is more damaging than ionization by electrons or photons. Whereas for organic insulating materials, the damage depends mainly on the dose and is independent of the type of radiation.

Exposure of plastics and films to electrons and photons results in a number of temporary and permanent changes, such as in appearance, chemical and physical states and in mechanical properties. Some substances undergo a change in color upon irradiation, which affects their light transmission. The change in transmission (T) or optical density (OD = log 1/T) of a material at a suitable wavelength can be used as an index for dose. This is essentially the principle behind the high level dosimeters used at SLAC.

Several types of high level dosimeters are used to cover a wide range of doses extending from about 10 Gy to 1 MGy. These

* Work supported by Department of Energy contract DE-AC03-76SF00515.

are optichromic, red perspex, radiachromic, cinemoid and lexan dosimeters.

EXPERIMENTAL METHODS

The opti-chromic (FWT 70-40M, Batch C-1 and FWT 70-83M, Batch C-3) and radiachromic dosimeters were obtained from Far West Technology, Inc.^a

The opti-chromic dosimeters were exposed in holders which provided protection from stray light. The radiachromic dosimeters were sealed in aluminum laminate pouches for protection from humidity changes and stray light during exposure. The radiachromic dosimeters were about 0.05 mm thick. The red perspex^b, cinemoid^c (bright rose film #48), and lexan^b dosimeters were about 0.32, 0.023, and 0.32 cm. thick.

The perspex and Lexan dosimeters were wrapped in black opaque plastic and together with cinemoid were held in a plastic badge whose front surface was about 0.5 mm thick.

Gamma Irradiation

Dosimeters were exposed to gamma radiation using the ⁶⁰Co sources (Hotrod Model U, Nuclear Systems) at U.C. Santa Cruz, California and Lawrence Berkeley Laboratory, California. Build-up materials consisting of plexiglass or polycarbonate were used to achieve electronic equilibrium. The dose rates range from 74-81 MGy/s and 0.6 mGy/s to 0.4 Gy/s (exposure rates were converted to dose rates using a conversion factor of 0.95). The opti-chromic, red perspex, cinemoid and lexan dosimeters were exposed to doses ranging between about 0.15 kGy and 90 kGy. All irradiations were performed at room temperature.

Electron Irradiation

The electron irradiations were performed using an electron beam accelerator (energy = 4.5 MeV).^c

The surface doses were monitored using radiachromic films which were calibrated by the National Institute of Standards, Washington D.C. The dose rates ranged between 6.7 and 8 kGy/s. All irradiations were performed at room temperature. All dosimeter types were exposed to electrons.

Dosimeter Readout

The Macbeth quantalog densitometer (TD-102) was used to determine the optical density for red perspex (using gold/visual and red filters) cinemoid (green filter) radiachromic (green filter) and lexan (gold and blue filters).

The Far West Technology Opti-chromic (FWT-98) and Radiachromic (FWT-91R) readers were used to read the opti-chromic and radiachromic dosimeters, respectively. Wavelengths of 600, 656 and 680 nm were used for the opti-chromic and 510 nm for the radiachromic dosimeters (the 610 nm wavelength was not useful for this study).

Fig. 1: Response of Opti-chromic Dosimeters.

Two dosimeters were used per irradiation condition and at least four readings were taken per dosimeter (except radiachromic, for which only one reading was taken). Two controls were used for each dosimeter. The difference in the average optical density between the irradiated dosimeter and the control (ΔOD) was then determined.

RESULTS

Opti-chromic and radiachromic dosimeters

The response of the opti-chromic dosimeters for gammas (γ) and electrons (e^-) is shown in Figure 1. The data provided by the manufacturer for ^{60}Co irradiation is also shown (γ'). The curves have been drawn only to aid the eye.

For both FWT 70 40M and 70 83M, the manufacturer data agrees reasonably well with the data obtained in this study at 600 and 656 nm. At these two wavelengths, the gamma and electron responses are fairly equivalent. However, at 680 nm, the electron response is much lower than the gamma response. At doses of about 75 KGy, the dosimeters started disintegrating.

Opti-chromic dosimeters consist of the liquid form of a radiachromic material in an optical waveguide⁽²⁾. Radiachromic materials are so-called because they exhibit a change in color upon irradiation. The optical properties of the waveguide change with the formation of color centers and hence these dosimeters are called opti-chromic.

The response of radiachromic dosimeters is shown in Figure 2. The response to electrons obtained with the densitometer (green) is higher than the response obtained with the

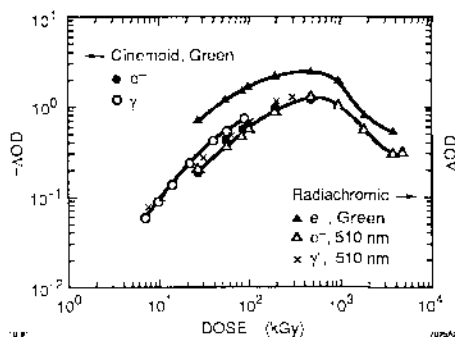

Fig. 2: Response of Radiachromic and Cinemoid Dosimeters.

reader, though the shape of the curves are very similar. The data provided by the manufacturer for ^{60}Co gamma irradiation (γ') is also shown. The response for gammas and electrons appears to be fairly equivalent. The response decreases for doses greater than 500 kGy. The radiachromic dosimeters change from a clear colorless film to a deep blue with increasing radiation doses. These dosimeters are dose-rate independent to 10^{13} Gy/s, have an equivalent response to x-rays, gammas and electrons, small temperature dependence and a long shelf life⁽³⁾.

Red Perspex

The response of red perspex is shown in Figure 3. The response to electrons (e^-) and gammas (γ) is almost the same. The response obtained with the gold filter is similar to that obtained with the red filter. The response begins to decrease for doses greater than 50 kGy. Red perspex changes from a deep red to a dark red and then to brown with increasing doses. The material begins to become opaque as doses approach 1 MGy, and disintegrates thereafter.

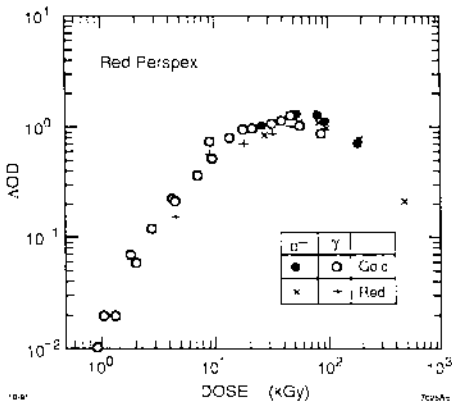

Fig. 3: Response of Red Perspex.

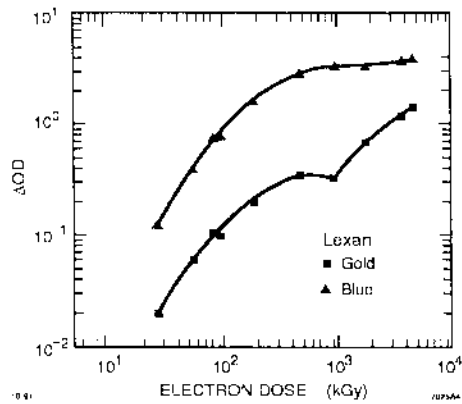

Fig. 4: Response of Lexan.

Red perspex (polymethyl methacrylate) is sensitive to temperature and humidity effects and suffers from fading⁽⁴⁾. Studies in progress indicate a 20% decrease in response for a storage period of about two weeks for doses greater than 50 kGy⁽⁵⁾. The response of red perspex is dose rate dependent for doses greater than 10^5 Gy/sec⁽⁴⁾.

Cinemoid

The response ($-\Delta\text{OD}$) of cinemoid (using green filter) is shown in Figure 2. The response for gammas is slightly higher than the response for electrons. The optical density of cinemoid decreases with increasing doses. Cinemoid changes from a bright rose to paler shades of salmon with increasing doses. The response decreases (optical density increases) for doses greater than 500 kGy. At doses approaching 500 kGy, the cinemoid becomes brownish yellow and very brittle. At higher doses, the cinemoid disintegrates. Cinemoid stored at room temperature for two weeks after irradiation did not show any significant fading⁽⁵⁾. The response of cinemoid (dyed cellulose nitrate) is independent of

dose rate for dose rates up to 10^{12} Gy/s⁽⁶⁾. Temperature rises of more than 80° destroys the dosimeter.

Lexan

The response of Lexan using blue and gold filters is shown in Figure 4. A higher response is obtained with the blue filter, for which the response levels off at doses greater than 1 MGy. The response with the blue filter decreases at doses greater than 600 kGy and then sharply increases with increasing doses. Lexan changes from a clear plastic to yellow and then dark brown with increasing radiation doses. Lexan also suffers from fading⁽⁵⁾. For doses between 25 and 100 kGy, there was a 40% reduction in response after storage for about two weeks.

CONCLUSIONS

Table 1 lists the useful ranges of the various high level dosimeters used at SLAC. Since most of these dosimeters have responses that decrease at very high doses, the use of a single dosimeter type can lead to erroneous results at high doses. Hence, a combination of dosimeter types should be used to determine doses. There are some practical difficulties associated with the use of these dosimeters in the field. Fading, sensitivity to temperature, light, humidity and dose-rate dependence can sometimes lead to large uncertainties. A typical accelerator operating run may last for months and the exact time at which the beam losses take place is not known. Hence it is difficult to correct for fading during the run. In addition, mixed fields of photons and neutrons exist in the vicinity of the accelerator, and the responses of these dosimeters to neutrons is not known. All these factors can lead to uncertainties that range from factors of about 2 to 5 in dose determination.

Dosimeter	Wavelength (nm) or Filter	Range (kGy)
Opti-chromic FWT 70-40 M	600 656 680*	0.01 - 1 0.1 - 10 30 (γ)
Opti-chromic FWT 70-83 M	600 656 680*	0.07 - 4 0.4 - 100 30 (γ)
Red Perspex	Gold Red	1 - 50 1 - 50
Radiachromic	600 510 Green	1 - 40 5 - 500 - 500
Cinemoid	Green	7 - 500
Lexan	Gold Blue	25 - 600 25 - 1000

SILENE, A SOURCE OF REFERENCE RADIATION FIELDS

The Silène reactor is an experimental facility designed to investigate the sequence of events and the consequences of criticality accident from both physical and radiological standpoints.

The small core volume, the use of shields of various sizes and materials, the properties of the leakage radiation and particularly the neutron/gamma dose ratios, the wide range of dose rate values, and the variety of operating modes make the unit a powerful research tool to meet the requirements of physicists, neutronics or dosimetry specialists and biologists.

I - INTRODUCTION -

Dans le but d'étudier le déroulement et les conséquences des accidents de criticité tant du point de vue physique que radiologique, l'Institut de Protection et de Sûreté Nucléaire du CEA a conçu et réalisé un dispositif expérimental sur le site de Valduc [1].

La source SILENE est un réacteur à combustible liquide qui présente à la fois une grande souplesse d'utilisation et une sûreté intrinsèque de haut niveau.

Le faible volume du coeur, l'utilisation d'écrans de nature et de dimensions diverses, l'intensité des rayonnements gamma et neutron émis ainsi que les divers modes de fonctionnement possibles en font un outil très puissant, susceptible de répondre à l'attente de nombreux expérimentateurs qu'ils soient physiciens, neutroniciens, dosimétristes ou biologistes.

II - LE REACTEUR SILENE - SES POSSIBILITES -

1 - Le coeur : c'est une cuve annulaire de 36 cm de diamètre traversée en son axe par un canal de 7 cm de diamètre. L'ensemble est placé au centre d'une cellule en béton de grandes dimensions (19 x 12 x 10 m).

Le réacteur utilise comme combustible une solution fissile de nitrate d'uranyle. Il en résulte deux avantages :

- une sûreté intrinsèque grâce à deux mécanismes de contre-réaction (échauffement de la solution et effet de vide dû à l'apparition de gaz de radiolyse).

- une grande souplesse d'exploitation (adaptation des caractéristiques du coeur à toute configuration expérimentale).

Le fonctionnement est obtenu en introduisant la solution fissile dans la cuve du coeur. L'excursion de puissance est réalisée par extraction d'une barre de réactivité se déplaçant dans le canal central.

En fin d'expérience la solution fissile irradiée est vidangée dans une cuve spéciale placée dans un local blindé ce qui autorise un accès rapide dans la cellule.

2 - Les modes de fonctionnement : Silène est conçu pour fonctionner selon trois modes :

- . en "salve" : l'excursion de puissance est brève (quelques millisecondes) mais très énergétique (jusqu'à 1000 mégawatts),
- . en "libre évolution" : on laisse évoluer librement l'excursion de puissance pour simuler un accident de criticité,
- . en "palier" : le réacteur fonctionne à une puissance stable prédéterminée (niveau compris entre 10^{-2} watt et 10^4 watts) pendant le temps désiré. Dans ce mode, le débit de dose due aux neutrons peut varier, suivant la puissance choisie de 5.10^{-9} à 5.10^{-3} Gy.s⁻¹ (à une distance de 4 m du réacteur nu).

3 - Les écrans :

Des écrans cylindriques peuvent être disposés autour de la source de manière à modifier les caractéristiques des rayonnements de fuite, par exemple dégrader le spectre des neutrons et modifier le rapport de la dose γ à la dose neutron. A cet effet deux écrans, l'un en plomb, l'autre en polyéthylène ont été réalisés et étudiés. Un écran d'acier sera qualifié prochainement.

Le vaste espace environnant le coeur du réacteur (230 m² au sol) permet l'irradiation de fantômes ou d'objets volumineux sur des arcs correspondant à des isodoses. Des écrans supplémentaires (murs de béton) peuvent être disposés dans la salle d'irradiation pour simuler des situations particulières.

III - CARACTERISTIQUES DES RAYONNEMENTS EMIS [2] -

Grâce aux différents modes de fonctionnement possibles, Silène offre une large gamme de débits de dose (10^{-8} Gy.s⁻¹ à 300 Gy.s⁻¹ pour la dose neutron à 4 mètres du réacteur nu). Cette large dynamique permet l'utilisation de détecteurs ou d'appareils de mesure de sensibilités très différentes.

La caractérisation du champ de rayonnement a été effectuée à l'aide de différentes techniques :

- . pour le spectre des neutrons : détecteurs à activation, chambres à fission, spectrométrie par protons de recul,
- . pour les doses neutrons : chambres d'ionisation (équivalent tissu et aluminium) et diodes avec comparaison des valeurs déduites de la spectrométrie,
- . pour les doses gamma : thermoluminescence, compteur Geiger Muller compensé en énergie.

Le tableau 1 indique les principales caractéristiques du champ mixte émis à 4 m de l'axe du réacteur nu ou muni d'écran pour une puissance de 4.10^{17} fissions développées dans le réacteur (énergie maximale pour une expérience).

Ecran	Dose neutron (Gy)	Dose gamma (Gy)	Dose gamma ----- Dose neutron
Sans	6,0	8,0	1,3
Plomb	5,2	1,1	0,2
Polyéthylène	~ 0,4	5,2	> 10

Tableau 1 : Caractéristiques du champ de rayonnement à 4 m du réacteur pour 4.10^{17} fissions.

Le tableau 2 donne la distribution relative en fluence et en kerma selon cinq bandes d'énergie de neutrons. On constate l'effet de déplacement du spectre dû aux écrans (plomb ou polyéthylène) par rapport à la configuration source nue.

Bande d'énergie	Source nue		Ecran de plomb		Ecran de polyéthylène	
	Fluence	Kerma	Fluence	Kerma	Fluence	Kerma
$E_n < 0,5 \text{ eV}$	20,1	0,3	18,0	0,3	23,3	0,3
$0,5 \text{ eV} < E_n < 50 \text{ keV}$	35,4	1,1	33,4	1,2	33,4	1,0
$50 \text{ keV} < E_n < 1 \text{ MeV}$	19,8	24,6	29,4	40,2	14,3	15,4
$1 \text{ MeV} < E_n < 5 \text{ MeV}$	23,0	66,7	18,6	55,4	25,0	67,1
$5 \text{ MeV} < E_n < 15,5 \text{ MeV}$	1,6	7,3	0,6	2,9	4,0	16,2

Tableau 2 : Distribution relative de la fluence et du kerma exprimée en pour cent.

IV - EXEMPLES D'APPLICATIONS -

Les caractéristiques de la source (forme des spectres, rapport γ/n) et les grandes dimensions de l'espace libre environnant le coeur permettent des applications extrêmement nombreuses dans les programmes liés à la protection de l'homme. On peut citer :

1 - Dosimétrie :

- réalisation d'exercices pour l'entraînement des équipes chargées de la dosimétrie d'accident de criticité,
- étude et développement de nouveaux moyens de mesure,
- étalonnage d'instruments de radioprotection.

2 - Intervention :

- étude de la stratégie à appliquer en matière d'intervention après un accident de criticité,
- réponse et qualification de détecteurs d'alarme de criticité.

3 - Activation du sodium :

- étude de l'activation du sodium du sang et détermination de coefficients permettant l'évaluation des doses reçues par des individus en cas d'accident (influence de la forme du spectre et de l'orientation).

4 - Radiobiologie :

- étude de l'efficacité biologique des neutrons sur différents systèmes, induction de cancer, anomalies chromosomiques etc...,
- irradiation d'animaux de grande taille.

V - CONCLUSION -

Les possibilités d'irradiation simultanée de nombreux objets sur une même isodose, les spectres variés disponibles, la souplesse de l'installation permettent de proposer Silène comme source de référence au niveau international.

Actuellement, dans le cadre d'un groupe de travail de la Commission des Communautés Européennes (Eurados W.G 9) la source Silène a été retenue pour l'organisation d'une intercomparaison internationale des systèmes de dosimétrie utilisés en cas d'accident de criticité [3]. Cette intercomparaison est également cautionnée par l'AIEA et se déroulera au Centre d'Etudes de Valduc en 1993.

SOME DOSIMETRIC CHARACTERISTICS OF THE RESIDUAL
DOSE AND THE PTTL FOR LiF:Ti,Mg

B. Ben-Shachar, U. German and E. Naim

Department of Health Physics and Safety
NRC-Negev, P.O.B. 9001, Beer-Sheva, 84190, Israel.

ABSTRACT

LiF:Ti,Mg TLD cards (G-1 and G-7) were irradiated in the range of 0.15 - 7.5 Gy and the residual dose and the PTTL were measured, in order to reassess the initial dose. We obtained a constant fraction of the initial dose (0.13% and 2.73% respectively) in the dose range 0.15 - 5.0 Gy for both the residual dose and the PTTL.

We evaluated the minimum exposure that can be reassessed, as well, when using both methods. We found that the minimum detectable exposure is ~13 mGy measured by the PTTL and ~380 mGy measured by the residual dose.

INTRODUCTION

The thermoluminescent dosimeter has become increasingly important in all aspects of personal and environmental monitoring. The main limiting factor that has prevented even a wider use is the loosing of the information accumulated in the crystal during the readout process.

LiF:Ti,Mg, proposed by Cameron (1), has been extensively used in dosimetry and it is a good compromise between the various desired characteristics. It is not as sensitive as certain other materials, but allows doses of 0.1 mGy to be measured with high performance equipment. The absence of thermal and optical fading (when different annealings are used) and almost tissue equivalence makes it the most useful TL material in radioprotection (2). There are two ways of reassessing high doses: by measuring the residual dose (second reading) or by the photo-transferred thermoluminescence (PTTL). The PTTL is the thermoluminescence after u.v. light exposure in a phosphor (3) which has been earlier exposed to ionizing radiation, then annealed and readout, leaving some TL as residual (RTL). The LiF:Ti,Mg has deep traps that can be significantly populated by high doses of ionizing radiation. Because normal readout procedures (heating to about 300°C) usually do not depopulate these traps, a second u.v. irradiation followed by the conventional readout can produce a response which is proportional to the original high dose. These "memory effects" in the TL materials can be employed for the re-estimation of doses and have been reported in several works (4,5,6).

The aim of the present work was to measure the residual dose and the PTTL for high doses (to 7.5 Gy) and to determine the accuracy and the minimum detectable level of the initial dose which can be determined by the two methods.

EXPERIMENTAL MEASUREMENTS

The measurements of the residual doses and the PTTL were performed with the standard LiF:Ti,Mg Harshaw manufactured G-1 or G-7 TLD cards. No annealing was performed. The cards were evaluated in an automatic Harshaw 2271 reader after being irradiated by a $^{90}\text{Sr}/^{90}\text{Y}$ source built in the system. The u.v. irradiation was performed by a 15 mw u.v. lamp (254 nm) at a distance of about 10 cm.

The TLD cards were irradiated to different doses between 0.15 and 7.5 Gy. The phosphors were evaluated immediately after the irradiation and a second reading was performed to measure the residual dose. After the second reading, the cards were irradiated by the u.v. lamp for 15 minutes and then read again (to measure the PTTL). The average results of the residual dose and the PTTL, obtained from the irradiation of 2 cards (four chips) for each dose, are presented in table 1.

Table 1: The average results of the residual doses and PTTL for exposures of 0.15 - 7.5 Gy.

Exposure (Gy)	Residual dose (mGy)	% of exposure	PTTL (mGy)	% of exposure
0.15	0.20±0.10	0.13	4.8± 0.5	3.20
0.30	0.35±0.06	0.12	7.5± 0.8	2.50
0.45	0.43±0.06	0.10	9.5± 1.0	2.11
0.60	0.75±0.07	0.13	12.1± 1.7	2.02
0.75	1.17±0.17	0.16	19.7± 1.7	2.63
1.00	1.24±0.27	0.12	31.6±10.3	3.16
1.85	2.38±0.56	0.13	55.3±12.2	2.99
3.00	3.67±0.85	0.12	77.9± 8.4	2.60
4.24	4.90±1.60	0.12	139.3± 8.5	3.29
5.66	10.16±2.18	0.18	156.2±27.0	2.76
6.60	14.77±0.66	0.22	256.1±61.8	3.91
7.50	17.87±4.07	0.24	318.5±23.2	4.25

The minimum measurable dose (MMD) of the initial dose when using the PTTL and the residual dose methods were determined by plotting the relative standard deviation of the PTTL (figure 1) and residual dose (figure 2) vs. the exposure and fitting to them the expression given by Zarand and Polgar (7,8). The MMD is defined as the dose value where the relative standard deviation is 20%. The values obtained are about 13 mGy for the PTTL and about 360 mGy for the residual dose.

CONCLUSIONS

From the results presented in table 1 and in the figures, the followings can be concluded:

A. For the dose range 0.15 to about 5.0 Gy, the value of the residual dose is a constant fraction of the first reading - $0.13 \pm 0.03\%$. There seems to be an increase of the residual dose for doses above 5.0 Gy, probably due to the supralinearity effect (3).

B. The values of the PTTL in the dose range 0.15 to about 5.0 Gy are a constant fraction of the first reading too ($2.73 \pm 0.44\%$), and the value of the PTTL seems also to increase for higher doses.

C. The PTTL is higher than the residual dose by more than an order of magnitude and its accuracy is better than that of the residual dose.

D. When employing the PTTL method, the MMD of the initial dose is about 13 mGy and for the residual dose method the MMD of the initial dose is about 0.36 Gy.

MEASUREMENT OF LOW PHOTON EXPOSURES USING A FULL AUTOMATIC PHOSPHATE GLASS DOSIMETRY SYSTEM WITH UV LASER EXCITATION

E. Piesch, B. Burgkhardt, M. Vilgis

Karlsruhe Nuclear Research Centre, 7500 Karlsruhe, Postfach 3640, FRG

ABSTRACT

The full automatic PLD system, to be PTB type tested in 1992, turned out to be superior to TLD systems mainly due to the intrinsic pre-dose suppression which provides dose measurements of 0.1 mSv with a variation coefficient of better than 5%. The results of consecutively irradiated and measured glasses demonstrate linearity and low random uncertainty of dose measurement in the low dose range.

INTRODUCTION

Retrospectively, the high pre-dose and the energy dependence of phosphate glass dosimeters prevented a large scale application of glass dosimetry so far. The most important progress of the last years have been found in the pulsed UV laser excitation of glasses which reduced the pre-dose dramatically (1). In the mean time, the modern, commercially available, full automatic Toshiba read-out systems FGD-10 and FGD-20 are expected to be reliable dosimetry systems for a large scale application in personnel and environmental monitoring (2,3).

With respect to the capability of measuring low doses within routine monitoring, it was of special interest to investigate linearity and random uncertainty of dose measurement in the low dose range.

DOSIMETRY SYSTEM

The flat glass dosimeter consists of a plastic encapsulation ($4 \times 3 \times 0.8$ cm³) with energy compensation filters on both sides and a glass element ($16 \times 16 \times 1.5$ mm³) fixed in a stainless steel card. The dosimeter is locked magnetically. In the PLD system Toshiba FGD-10 the automatic read-out includes: (a) opening and closing of the dosimeter, (b) reading of ID-No for capsules and cards, respectively, (c) exchange of high dosed by annealed glass cards during read-out, (d) the continuous reading of up to 500 dosimeters, (e) the calibration of the reader and (f) the print-out of the results.

Pulsed UV laser excitation reduces the pre-dose down to 30 μ Sv. The energy response of the flat glass dosimeter in Table 1 are recent results of an IAEA inter-comparison experiment using frontal irradiations on a slab phantom and the read-out in terms of $H'(10)$. After the PTB type test in 1992, the commercially available PLD system will be introduced in Germany as a governmental dosimeter within routine personnel monitoring.

The PLD system, now comparable with the best TLD systems regarding the lowest detectable dose, the dose range (0.03 mSv to 3 Sv) and the energy and angular response (10 keV to 3 MeV), is, however, superior with respect to the capability of repeated read-outs, the simultaneous indication of different dose quantities (exposure X or $H'(10)$) using the same irradiated dosimeter, and with respect to the interpretation of the read-out in terms of radiation quality and radiation incidence.

PRE-DOSE SUPPRESSION AND RANDOM UNCERTAINTY IN THE LOW DOSE RANGE

Fig. 1 illustrates the read-out after UV pulse excitation of an unirradiated and irradiated glass. During the read-out, the time dependent PL intensity $I(t)$ is integrated in two different periods, namely the short-term component (total reading) in the period between 2 - 7 μsec , and the irradiation independent, long-term component of the residual reading in the period between 40-45 μsec . A multiple f_{ps} of the measured residual reading is subtracted from the total reading resulting in the radiation induced reading M . The "pre-dose suppression factor" f_{ps} is measured only once after the initial annealing.

The internal pre-dose suppression during each read-out reduces the pre-dose value of the conventional UV excitation of 1 mSv by two order of magnitudes to about 0.03 mSv and also renders glass cleaning unnecessary.

Fig. 2 compares the frequency distribution of the variation coefficient, (a) for the pre-dose of dosimeter batches (mean value 25-35 μSv) after 15 times of re-use immediately after oven annealing at 400°C, and (b) for a 10 times daily reading at 6 mSv. The mean value of the variation coefficient was found to be 6.7 % (2 μSv) for the pre-dose of 30 μSv of annealed glasses and 0.46% (28 μSv) for a dose of 6 mSv of an irradiated calibration glass. On the basis of these data, the variation coefficient for the dose reading was calculated and presented in Fig. 3 as a function of the uncorrected dose reading $H_U = H + H_0$ as well as after subtraction of the individual pre-dose H_0 of about 0.03 mSv or of an accumulated "pre-dose" of 3 mSv as a function of the dose accumulated in the actual monitoring period. Using an annealed glass dosimeter, the variation coefficient for a dose measurement at 0.1 mSv was found to be 3%, at 3 mSv only 0.5%.

CONSECUTIVE MEASUREMENTS IN INDIVIDUAL MONITORING

The glass dosimeter reading is the total dose accumulated since the last annealing. During routine monitoring, personal dosimeters accumulate the natural radiation background and additional contributions of occupational exposures.

Tab. 1 Glass dosimeter results, 1990 IAEA intercomparison for Individual Monitoring

E (keV)	H / H'(10,0°)
20	0.94
37	0.98
57	1.01
104	0.97
205	0.93
374	0.96
662	1.04
1250	0.99
mean ± max/min	0.985 ± 5.5%

Fig. 1 Subtraction of the residual dose reading of PL dosimeters using pulsed UV laser excitation

Fig. 2 Frequency distribution of the variation coefficient for the pre-dose (mean value 0.03 mSv) of annealed glass dosimeter batches and the repeated readings of the calibration glass.

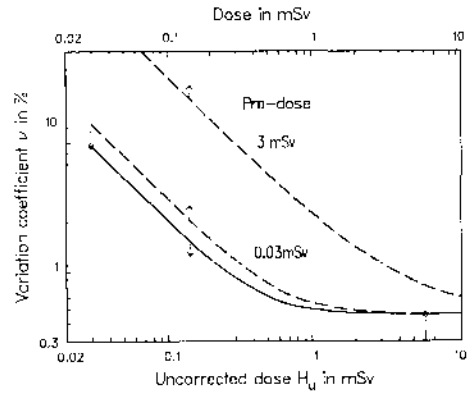

Fig. 3 Variation coefficient of the dose measurement using the same glass dosimeter vs. the uncorrected dose H_u and the measured dose $H = H_u - H_0$ at pre-doses of 0.03 and 3 mSv.

The actual dose contribution of the last monitoring period is given by the difference of two consecutive measurements at the beginning and the end of the monitoring period of usually 1 month.

Batches of glass dosimeters have been irradiated and measured consecutively over periods of more than three months using low exposures in steps of 0.05 mSv and 0.1 mSv, respectively. Fig. 4 shows for the consecutive measurements the ratio of the actual dose and the reference dose. For all exposures the mean values have been found to be within $\pm 1.3\%$. This scatter can be interpreted as the long-term

Fig. 4 Ratio of the actual dose reading and the reference dose for repeated irradiations of a batch vs. dose. Mean value of 8 dosimeters.

Fig. 5 Variation coefficient of the dose measurement using a batch of 10 dosimeters within vs. dose.

instability of the dosimeter system, including errors of the consecutive irradiations of the batches and the repeated reader calibrations using the calibration glass. In the upper dose range, the variation coefficients for dosimeter batches (Fig.5) are slightly higher by about 0.4% to those for one glass only (Fig.3), because of the small scatter in the photon response of individual glass detectors within the batch. In the case that the total accumulated "pre-dose" is 3 mSv, a contribution of 0.1 mSv of the last monitoring period can be measured with a variation coefficient of 25%.

MEASUREMENT OF THE NATURAL RADIATION BACKGROUND

In a similar experiment, a dosimeter batch was exposed to the natural radiation background and measured consecutively over a period of 3 months starting with a pre-exposure of 0.1 mSv. For all read-outs, the variation coefficient for the mean value of 8 detectors was smaller than 2% (4% for two detectors). Within environmental monitoring, the dosimeter pair usually used may indicate the natural radiation background already after 10 days with a random uncertainty of about 25%. Because annealed glasses are used for environmental monitoring, only the intrinsic pre-dose of 0.03 mSv will be subtracted. The corresponding variation coefficient for a single detector reading is shown in Fig. 3 as a function of the accumulated dose.

CONCLUSION

PLD systems, unlike other systems, do have the capability of combining, on the one hand, repeated read-outs at any time during the monitoring period by the user and, on the other hand, control measurements after long-term monitoring periods by independent services of the authorities with a relatively high precision of 1% as already demonstrated for the UV excitation with Hg lamps (4).

The full automatic PLD system, now improved and commercially available offers an unexpected new approach in routine monitoring and the breakthrough of a technique, so far neglected but now a potential alternative in personnel and environmental monitoring.

PROTECTION CONTRE LE BREMSSTRAHLUNG
SUR MOLECULES RESIDUELLES DE LA CHAMBRE A VIDE
D'UN ANNEAU DE STOCKAGE D'ELECTRONS OU DE POSITONS
DANS UN CENTRE PRODUCTEUR DE RAYONNEMENT SYNCHROTRON

J.C. FRANCK

Laboratoire pour l'Utilisation du Rayonnement
Electro-magnétique (LURE)
Université Paris-Sud
91405 ORSAY (France)

PROTECTION AGAINST BREMSSTRAHLUNG
DUE TO OCCURENCE OF RESIDUAL MOLECULES
IN THE VACUUM CHAMBER OF AN ELECTRON-OR-POSITRON
STORAGE RING IN A SYNCHROTRON RADIATION FACILITY

This parasitic phenomenon, which produces an important absorbed dose rates (more than ten milligrays per hour at the distance of 10 meters from the point-source emitter) is disturbing because it takes the same way as the synchrotron radiation produced by the insertion device.

This Bremsstrahlung develops itself in a very narrow cone downwards the insertion device and along its axis; its maximum energy is similar to the energy of the stored electrons or positrons (at LURE : 800 and 1850 MeV) and its absorbed dose rate is proportionnal to the stored particles (350 mA) and the pressure in the vacuum chamber (10^{-8} Pa).

Besides the calculations of this absorbed dose rate, we describe the way to calculate the beam catchers which thickness is always important (more than 10 cm of lead blocks), as well as the mode of elaboration of these shieldings within the very peculiar framework on the use of a synchrotron radiation.

INTRODUCTION

Le Bremsstrahlung créé par l'interaction entre les électrons ou positons stockés et les molécules résiduelles de la chambre à vide d'un anneau de stockage est un phénomène parasite préoccupant pour les expérimentateurs qui utilisent le rayonnement synchrotron issu d'un élément d'insertion (onduleur ou wiggler) installé dans une section droite de l'anneau.

Dans ce cas, en effet, le cheminement du rayonnement synchrotron est le même que celui du Bremsstrahlung; celui-ci se développe dans un cône très étroit en aval et dans l'axe de l'élément d'insertion et a pour énergie maxima l'énergie des particules stockées (à LURE, DCI: 1850 MeV; SUPER ACO: 800 MeV). (Figure 1)

Le débit de dose qu'il crée est important (un à plusieurs dizaines de milligrays par heure à 10 mètres du point source); il est proportionnel, notamment, aux particules stockées (350 mA à LURE) et à la pression régnant dans la chambre à vide de l'anneau (10^{-8} Pa).

La protection des expérimentateurs contre ce phénomène est particulièrement délicate : elle doit être efficace et ne gêner en rien l'expérimentateur qui utilise le rayonnement

synchrotron. Lorsqu'il s'agit de blocs d'arrêt, ils ont toujours une épaisseur importante (une ou plusieurs dizaines de centimètres de plomb par exemple).

Après un rappel du calcul du débit de dose maximum D_0 à ce Bremsstrahlung, nous présenterons les protections que nous avons mises en place à LURE autour des anneaux DCI et SUPER ACO et nous commenterons leur efficacité.

CALCUL DU DEBIT DE DOSE ABSORBEE MAXIMUM

Ce débit de dose maximum (D en $Gy\cdot h^{-1}$) au point cible peut être estimé à partir de l'équation suivante :

$$D = \frac{fN}{\pi\alpha^2 X_0} \frac{x}{L(x+L)}$$

où

f : débit de dose par unité de débit de fluence photonique à l'énergie maxima du Bremsstrahlung (mesure conservatoire) $Gy\cdot h^{-1} \gamma^{-1} cm^2 s$ (ICRP publication 21)
à 1850 MeV, $f = 2,2 \cdot 10^{-6}$ à 800 MeV, $f = 2 \cdot 10^{-6}$

N : débit d'électrons ou de positons en un point de l'anneau de stockage ($e^+ s^{-1}$ ou $e^- s^{-1}$)
pour 350 mA $N = 2,2 \cdot 10^{18}$

α : $\frac{0,511}{E_0}$ rd (E_0 : énergie (MeV) des particules stockées)
à 1850 MeV $\alpha = 2,8 \cdot 10^{-4}$ à 800 MeV $\alpha = 6,4 \cdot 10^{-4}$

X_0 : longueur de radiation dans l'air (cm)
à 10^{-8} Pa $X_0 = 3 \cdot 10^{17}$

x : longueur d'une section droite d'un anneau (cm)
DCI (1850 MeV) $x = 650$ SUPER ACO (800 MeV) $x = 770$

L : distance fin de section droite - point cible (cm)
DCI, $L = 1600$ SUPER ACO, $L = 1000$ (exemple)

A LURE ce débit de dose maximum estimé est de l'ordre de :
DCI : $1,2 \cdot 10^{-2} Gy\cdot h^{-1}$ SUPER ACO : $5,2 \cdot 10^{-3} Gy\cdot h^{-1}$

PROTECTIONS MISES EN PLACE A LURE CONTRE LE BREMSSTRAHLUNG

Elles reposent sur la mise en place de blocs d'arrêt au plus près de la source dès lors qu'elles ne gênent pas le cheminement utile du rayonnement synchrotron.

Les dimensions de ces blocs sont déterminées par mesure conservatoire en ne retenant que le débit de dose maximum au point-cible pour un stockage maximum de particules dans l'anneau et une exposition maxima de personnes du public au point le plus critique: Elles sont calculées longitudinalement en utilisant exclusivement le libre parcours moyen maximum des photons dans le matériau utilisé (Béton:21; Plomb:2,1; Tungstène:1,3 (en cm)) et transversalement les longueurs de Molière (Béton:13; Plomb:1,6; Tungstène:0,93 (en cm)); si nécessaire un puits est aménagé sur la face avant du bloc d'arrêt pour limiter les problèmes de rétrodiffusion.

Premier cas (DCI): nombre pair de lignes de rayonnement synchrotron (RS) issues du même élément d'insertion

Dans ce cas un bloc d'arrêt mobile nommé "Piège à gamma neutrons (PGN)" situé à l'intérieur de l'enceinte de protection qui contient l'anneau et dont la fonction est d'obturer le passage des lignes RS à travers cette enceinte lors du remplissage de l'anneau est muni d'une pièce rapportée en tungstène; lorsque le PGN s'efface pour l'utilisation du rayonnement synchrotron, cette pièce fait obstacle au Bremsstrahlung (figure 2). Des mesures de débit de dose ont montré l'efficacité de ce dispositif ($D < 1 \mu\text{Gyh}^{-1}$).

Deuxième cas (SUPER ACO): nombre impair de lignes de rayonnement synchrotron issues du même élément d'insertion

Dans ce cas un bloc d'arrêt fixe est installé hors de l'enceinte de protection juste en aval d'un dispositif de déviation du rayonnement synchrotron (miroir ou monochromateur) (figure 3). Des mesures du débit de dose à l'aide d'une chambre d'ionisation juste en amont et en aval d'un tel bloc d'arrêt ont montré son efficacité (source-point cible:12m; E_0 :800 MeV; I:350 nA; plomb:25 cm; $D=8000$ (juste en amont), $D < 1 \mu\text{Gyh}^{-1}$ (juste en aval) du bloc d'arrêt).

CONCLUSIONS

La maîtrise de la protection contre ce Bremsstrahlung n'est parfaite que dans le cas d'un nombre pair de lignes de rayonnement synchrotron issues d'un même élément d'insertion: pièce rapportée sur PGN situé dans l'enceinte de protection.

Elle est satisfaisante dans le cas contraire si la rétrodiffusion au niveau du bloc d'arrêt et la diffusion le long de la ligne centrale RS ne donnent pas de débits de dose inacceptables pour des personnes du public; si tel est le cas, des mesures complémentaires de protection s'imposent (ex: obstacles empêchant l'approche de la ligne RS).

Enfin le protocole de calcul des blocs d'arrêt utilisé à LURE et qui est conservatoire est parfaitement validé par les mesures de débit de dose effectuées autour des points-cible.

THE URINALYSIS INTERCOMPARISONS ADMINISTERED BY CANADA'S NATIONAL REFERENCE CENTRE FOR RADIOBIOASSAY - HAVE THEY MADE A DIFFERENCE?

M. LIMSON ZAMORA, M. GODDARD, R. FALCOMER, W. HUNT AND G. MOODIE

BUREAU OF RADIATION AND MEDICAL DEVICES
DEPARTMENT OF NATIONAL HEALTH AND WELFARE

ABSTRACT

The Bureau of Radiation and Medical Devices has acted as Canada's National Reference Centre for Bioassay and *in vivo* Monitoring since 1983. The Centre provides quality assurance to organizations performing *in vitro* radiobioassay, including urinalysis intercomparisons for uranium, tritium, and carbon-14. Evaluation of results has shown that regular participation has resulted in a steady improvement in analytical performance. Bias between the true value and reported results has been reduced, and precision enhanced.

BACKGROUND

The assessment of the dose from the intake of radionuclides is a two-step process. The first step involves either directly measuring the individual suspected of over-exposure, or measuring his excreta, the matrix of choice usually being a urine specimen. The second step is the conversion of the measurement to a dose through the use of an appropriate metabolic model. It follows then that, given a good metabolic model, the quality of a dose estimate would depend ultimately on the quality of the measurements used for its calculation.

Licensees of the Atomic Energy Control Board (AECB), Canada's regulatory agency, are distributed across the country. To ensure comparability of the measurement data generated by these organizations, the AECB in 1982 approved a policy requiring all its licensees to calibrate, on a regular basis, devices and systems used in estimating radiation dose, and to demonstrate the traceability of such calibrations to AECB-approved national standards. While suitable standards existed in Canada at the time to meet these requirements for some licensed operations, e.g., those which made use of gamma-radiation, there were other operations and areas for which no suitable practical standards existed. These areas included bioassay, for which the AECB in 1983 designated the Bureau's Bioassay Section and Human Monitoring Laboratory to act as the National Reference Centre with a mandate to develop and provide programs and practical reference standards for measurements used in the assessment of internal dose. The working group, organized to address the technical questions associated with the development of such standards, recommended [1] that "measurement traceability" which includes instrument performance, analyst proficiency and the procedures used, be the mechanism by which bioassay laboratories demonstrate their capabilities on a continuing basis to the AECB.

EXISTING PROGRAMS

With these recommendations in mind, the Bureau has established and administers three urinalysis intercomparisons: (1) Uranium, which has been in place since 1978, and was re-structured in 1983 to allow the assessment of precision as well as the bias of submitted results, (2) Tritium and (3) Carbon-14 which were established in 1985 and 1986, respectively. The Uranium and Tritium Programs have been available semi-annually, while the Carbon-14 Program is offered annually. Urine standards are prepared in-house containing radionuclides in the range commonly encountered in specimens measured by participating laboratories, as well as concentrations cited as "Derived Investigation or Action Levels" in the criteria documents [2,3] published by the Federal-Provincial Working Group for Bioassay and *in vivo* Monitoring Criteria. Performance is tested at three radionuclide concentrations which are unknown to the participants. To determine a laboratory's ability to reproduce results, five aliquots of each concentration are sent to each participant. As noted above, samples are distributed on a regular basis, since satisfactory performance cannot be reasonably guaranteed over an indefinite length of time. Participants are asked to return their analytical results to the Reference Centre within thirty days of receipt of samples. Results are evaluated with respect to bias and precision, and a final report is sent to all participants regarding their performance. Anonymity is maintained by assigning a code to each laboratory. The AECB is in the process of setting performance criteria for bioassay measurements. In the interim, the Centre uses the following limits for the acceptability of results:

- 1 to 10 AMDA: $-.50 \leq \text{Relative bias} \leq .25$
Relative precision $\leq .40$
- 10 to 100 AMDA: $-.25 \leq \text{Relative bias} \leq .25$
Relative precision $\leq .25$

Acceptable Minimum Detectable Amount (AMDA) values are those cited in the Bioassay Guidelines [2,3].

BENEFITS DERIVED FROM PARTICIPATION

A primary benefit derived from participation is the opportunity to obtain external verification of one's results. This is illustrated in Table 1 below. The participant obtained excellent precision for the measurement of the intercomparison standards distributed in December 1983. However, the measurement bias was large and for the 79 μg spike, exceeded the acceptable relative bias limit. The problem was not the instrument or the analytical procedures in use, but the laboratory standard. After changing to a certified standard, accuracy improved tremendously, as shown by the July 1984 results.

Some laboratories have also used the sample sets that we provide to compare the performance of analysts on their staff. Because we ensure the homogeneity of the samples that we distribute, these laboratories can be sure that they are making a valid comparison between analysts who are measuring the same radionuclide concentrations in the same sample matrix. At times, as many as three analysts have participated in the intra-laboratory intercomparison exercise.

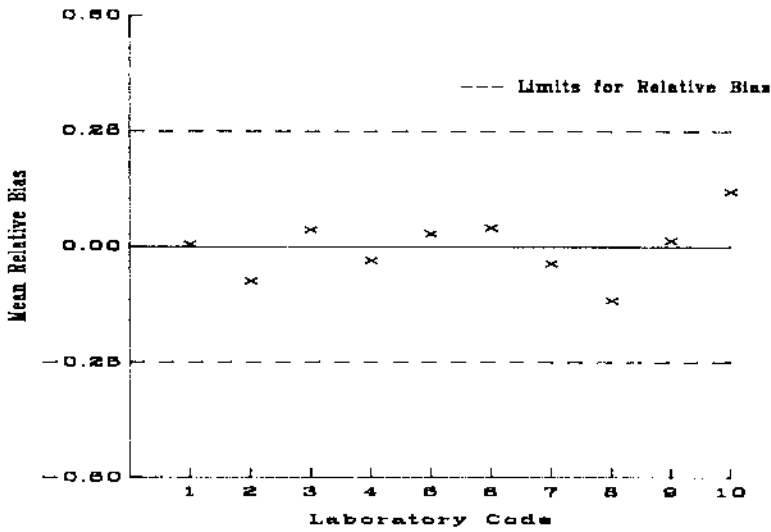

Fig. 1. Tritium in Urine Intercomparison mean relative bias chart.
Spike Level = 9.29×10^4 Bq/L

Fig. 2. Improvement and sustained good performance of a Uranium Urinalysis Intercomparison participant.

TABLE 1
Uranium in Urine Intercomparison Results for Participant A

Date	Spike ($\mu\text{g/L}$)	Mean Relative Bias	Relative Precision
December 1983	47.62	-.404	.039
	79.00	-.408	.024
July 1984	51.35	-.040	.030
	75.27	.071	.031

Of particular interest to the AECB is the validity of results and their comparability between licensees. Figure 1 is a chart taken from the report for the September 1991 Tritium Intercomparison. It provides a quick appraisal of how each licensee compares to other laboratories who have analyzed identical radionuclide levels, as well as whether or not the mean relative bias of submitted results are within acceptable limits. Final reports include similar charts for precision.

All intercomparison results submitted to the Centre to date, as well as data on the evaluation of measurement performance have been stored in a historical data base. The performance of a Uranium Intercomparison participant over a three-year period is charted in Figure 2. The concentrations measured were equal to or greater than the Derived Investigation Level cited in the Uranium Bioassay Guideline [3] for Class D uranium. This laboratory had close to unacceptable negative bias in July 1983, but after several consultations with Reference Centre staff regarding analytical techniques, showed dramatic improvement in accuracy in the December 1983 intercomparison, which was maintained through 1986, and thereafter.

This trend of improvement and sustained good performance with regular participation has been demonstrated with almost all participants. Any observed lapses usually occur when new staff are hired, or new measurement procedures are implemented. Generally, however, bias and precision are well within the acceptable limits. Feedback provided in the reports has given the participants confidence in their measurement capabilities and bolstered their credibility in the eyes of the employees that they monitor.

EVALUATION OF SURFACE CONTAMINATION BASED ON CERTIFIABLY
TRACEABLE, INTERNATIONALLY ACCREDITABLE MEASUREMENTS

Mr. G. D. Whitlock

Hughes Whitlock Ltd.
PO Box 22, Malvern, Worcs.
England WR13 6SL

ABSTRACT

National Accreditation and Measurement Service (NAMAS) adopted by the EUROMET agreement requires that the calibration of monitoring instruments be traceable internationally with the objective that radiation hazard assessment be improved. This objective is achieved for Tritium surface contamination by employing calibration sources and evaluation methods which comply with ISO standards including the measurement of activity removable by volatilisation as well as dust. Consideration should be given to organic binding of Tritium in the skin with its implications in the event of litigation.

INTRODUCTION

The basis of Radiological Protection is currently in a state of change. A requirement of the new ICRP regulation relates hazard to individuals instead of collective dose. Most European countries have signed the EUROMET agreement, by which the calibration of Monitoring Instruments has to be traceable to NAMAS accredited calibration laboratories with the objective that radiation hazard assessment be improved as a consequence of being based upon creditable measurements. Independently, standards organisations pursue the same logic and have produced ISO 8769-"Reference Sources" and ISO 7503-"Evaluation of Surface Contamination", which describe the calibration and the method.

Individually and collectively this calls for a review of radiological protection practices to meet these new demands if only to show evidence of competence in the event of litigation. Current legislation requiring the measurement of activity removable (which detaches) from the surface in normal use can not be satisfied by measuring only active dust. Many forms of Tritium contamination are volatile, and removal by volatilisation has to be accounted for particularly as it presents a greater hazard than removable dust. Research has shown localised organic binding of Tritium in organs of the skin¹, and the implications of this should be considered.

Using the evaluation of surface contamination by Tritium as an example, the practical application of the regulations, national objectives, and associated international standards are covered in the following protocol.

THE REFERENCE SOURCE

A reference source with a certified emission rate traceable to measurements by a national standards laboratory has to be of a form which accords to ISO 8769 "Reference Sources".

A Tritium source constructed to this standard is available. Its size is 100 mm x 150 mm, and the activity has been deposited by the Langmuir-Blodgett technique in the form of a homogeneous monolayer of tritiated molecules². There is therefore, no self absorption, and the classic spectrum of energies of the emitted beta particles is unmodified other than by backscattered betas the effect of which can be calculated. Figure 1.

Fig. 1. Monolayer Tritium Beta Emission Spectra

Fig. 2. Tritium Beta Absorption in Air

The source has to be suitable for calibrating all manner of Tritium surface contamination measuring instruments, and should not introduce distance variation errors into the calibration. This calls for a surface flatness of ± 0.025 mm because, even though the maximum range in air of the measuring energy Tritium beta (18.6 KeV) is approximately 4 mm, the mean range of Tritium betas is only 0.25 mm (approximately half the thickness of a finger nail). Figure 2. This source is used to establish a valid calibration of the measuring instrument.

THE SURFACE MEASURING INSTRUMENT

The instrument must be so constructed that the conditions and geometry for calibration measurements can be reproduced identically or within a predictable approximation when taking measurements of the surface.

Essentially, the detector must be sensitive to the low energy Tritium betas. This means that no protective or gas retaining "window" can be incorporated because even the maximum energy beta (18.6 KeV) is absorbed in 8 microns (10^{-6} M) of unit density material, and the mean range of the beta emission is 0.2 microns.

In addition, the International Standard ISO 7503 "Evaluation of Surface Contamination Part 2 Tritium" shows a

detector with a minimum area of 100 cm² is preferred. An instrument, which meets all these requirements is the Hughes Whitlock Ltd. Vacuum Scintillation Counter (VSC).

ACTIVITY PER UNIT AREA

Estimating the surface contamination level, in terms of activity in Bq cm⁻² from the number of emissions recorded as counts by the measuring instrument, requires careful consideration.

Prior to decontamination, the source may be infinitely thick in terms of Tritium contamination. The method used for decontamination might itself have caused the formation of thick sources because dissolving the activity in a solvent could change its form to one likely to be absorbed by the surface.

Although in these circumstances, direct measurements do not enable the calculation of activity cm⁻², they do indicate activity build up and reveal the need to decontaminate the surface as well as promote more diligent and or alternative decontamination techniques. Normally, after decontamination, the form of the contamination remaining on surfaces acceptable for radiological purposes then approximates to the monolayer calibration source³ and the measurements are traceable.

EVALUATION BY WIPE ASSAY

Where the surface is not flat enough to make direct measurements, wipe assay is used but they should be made according to ISO 7503, which requires that a wipe collection factor be established.

The 10% collection factor can only be applied to indicate the presence of active dust on smooth, non-porous surfaces. It cannot be assumed to apply to all removable activity, and certainly not to total activity assessment. Care should be taken that the collected dust does not produce a thick source on the wipe or be absorbed into it as these states can cause gross measurements errors.

When an acceptably flat area for direct measurement can not be found, wipe collection factors can still be obtained by preparing a facsimile of the surface, and applying experimental quantities of activity for direct measurement and wipe assay.

REMOVABLE ACTIVITY-DUST AND VOLATILES

'Removable' activity is that which can be caused to be detached from the surface by any working practice. This does not allow the evaluation of 'removable' to be confined to the evaluation of only dust particles. Dust is a form of activity that is 'removable' but a form of 'removable' that should be of greater concern is volatile activity. Volatile fractions can be released (removed) by a change in temperature or

pressure e.g. the heat from a hand placed on the surface. Inhalation and ingestion routes are the same as for dust. In addition, in the case of Tritium, it can be absorbed through the skin over the whole body surface.

It has been shown that organic binding of Tritium takes place in the skin particularly in the region of the glands e.g. hair follicles¹. Tritium betas emitted from these sites >8 microns from the surface are not detectable externally, and would not show in urine measurements because any slow exchange would be masked by the rapid excretion rate of the majority of inhaled or absorbed activity. The regulatory requirement to monitor 'removable' activity automatically embraces volatiles as well as dust as a removable form. Making the measurements to meet the regulations is the licensee's responsibility.

DETECTING VOLATILE ACTIVITY

During measurement, the VSC creates a partial vacuum (500 millibars) in the measuring chamber, one part of which is the surface being measured. If a volatile form of Tritium is present, the reduced pressure causes volatilisation to take place, and diffusion to occur in the contamination and surface materials. Air absorption is reduced, and the change in geometry is detected by the instrument to differentiate volatiles from other surface contamination.

CONCLUSIONS

Current practices in Radiation Protection do not satisfy the legislative requirement to measure activity removable by all means. Accredited measurements using Certified Sources and International Standard methods not only satisfy legislation but create a less hazardous working environment supporting the ALARA principle. The means are available and there is no excuse in the case of litigation for not applying them.

APPLICATION OF THIN MEMBRANE SOURCES FOR PREPARATION OF β -RAY
DOSE CALIBRATION SOURCES IN SKIN CONTAMINATION MEASUREMENT

Makoto YOSHIDA, Hiroyuki MURAKAMI and Kazuyoshi BINGO

Japan Atomic Energy Research Institute
Tokai-mura, Naka-gun, Ibaraki-ken, Japan

ABSTRACT

The application of thin ion-exchange membrane sources was studied for preparation of β -dose calibration sources in skin contamination. The preparation method, the dose calibration method by an extrapolation chamber and the backscattering effect of backing materials were discussed. The membrane sources are suitable for preparing the calibration sources.

INTRODUCTION

In the nuclear facilities where unsealed radioactive materials are handled, skin contamination with β -ray emitting nuclides can happen to workers. It is very important in the practices of radiation protection to properly estimate the skin dose for the worker. The dose estimation has been so far carried out on the basis of both activity measurement of skin contamination sources and skin dose calculation from the activity¹⁾. This manner is complicated and sometimes includes large errors for the estimation.

It is very convenient that the skin dose can be directly estimated through the β -ray measurement over skin surface with the instruments sensitive to β -rays. Then, it is demanded that the readings of instruments are well related to skin doses. For the purpose, proper calibration sources are needed to deal with routine calibration works.

In the β -dose calibration of personal monitors and surveymeters, in general, the dose is determined by keeping some distance between β -ray sources and instruments. However, in determination of the dose for skin contamination, the source surface must be directly in contact with a window of extrapolation chamber. This situation makes some requirements for preparation of the calibration sources for dose evaluation in skin contamination.

We have already reported a preparation method of relatively thin sources with ion-exchange membranes^{2,3)}. This method can provide large film-like plastic sources whose characteristics are able to meet the requirements mentioned above. In the present paper, the application of the membrane sources to the dose calibration sources has been studied.

EXPERIMENTS

(Preparation of membrane sources)

When skin tissue exposes to the β -rays from skin contamination sources, there is no backing material for the sources but air. For the reason, the skin dose from the sources need be determined without backing materials as well. On the other hand, when

the β -rays are measured outside the tissue with β -ray sensitive instruments, the backscattered β -rays by the tissue should be taken into account. In order to develop the dose calibration sources satisfying these conditions, a thin self-supported source is necessary and can be prepared with ion-exchange membranes.

The membrane sources were prepared with homogeneous polyethylene cation-exchange membranes whose thickness was 3 to 5 mg/cm². These ion-exchange membranes uniformly adsorb radioactive ions under the optimum conditions of carrier concentration, soaking time, hydrogen ion concentration (Ph) and temperature.⁴⁾ Two radioactive nuclides of ²³⁴Tl and ⁹⁰Sr-⁹⁰Y were used for this experiment. The initial size of the membranes on soaking was 20cm x 20cm.

The membranes were soaked for 2 days in radioactive solutions at the temperature of 29°C. On removal from the solution, they were rinsed several times with distilled water to wash off unfixed activity from the surface and dried at room temperature between filter papers. Finally they were mounted in drum-like shape on a brass ring. This way easily provided a flat source without corrugation.

(Uniformity of membrane sources)

Radioactivity distribution of the membrane sources was estimated by autoradiography with industrial X-ray film. The membrane source on the mount ring was directly in contact with X-ray film. The exposure time is about one day. The optical density of the exposed area of X-ray film was measured by a density-meter with a 2mm dia. aperture. The total number of measured positions is more than 50 (2 positions per cm²).

(Extrapolation chamber)

The extrapolation chamber used for determining 7 μ m dose equivalent rate to the membrane sources was designed in accordance with the recommendations of International Organization for Standardization (ISO)⁴⁾. The cross-sectional view of the extrapolation chamber is shown in Fig.1. The entrance window is a carbon coated polyester sheet of 6.37mg/cm² thick. The a collecting electrode is 30 mm in diameter. The more detailed structure is referred to a previous paper.⁵⁾ The membrane source was kept in contact with the entrance window by screwing the mount ring to the front frame of the extrapolation chamber. The absorbed dose rate of each source was several mGy·h⁻¹.

RESULTS AND DISCUSSION

When a source is calibrated by an extrapolation chamber in the geometric condition of surface-to-surface contact, good uniformity of activity distribution is required. Unless the activity distribution is sufficiently uniform, the resultant dose seriously depends on partial activity of the source facing to the small finite collecting electrode. This good uniformity is easily attained by using ion-exchange membrane sources. The standard deviation of activity distribution estimated by autoradiography was less than 4% for all ion-exchange membrane sources prepared with each radionuclide. Among them, the membrane sources with the deviation of 1 to 2% were selected especially for preparing the present calibration sources. In addition to the

uniformity, flatness of the membrane stretched on a mount ring and negligible removal of activity from the source enable the dose calibration by an extrapolation chamber.

The dependence of ionization currents on the electrode spacing was estimated for the membrane sources mounted on the rings with different diameters. The results for ^{90}Sr - ^{90}Y membrane sources are shown in Fig.2. The experimental points closely match a straight line for the 100 mm dia. source but do not for the 40 mm dia. source. Since a slope of the line determines the absorbed dose, the source diameter should be more than 50 mm at least for ^{90}Sr - ^{90}Y . The larger diameter is needed as the higher energy of β -rays because the tendency depends on the range of β -rays.

The membrane sources were cut into pieces 10mm in diameter for measurement of $4\pi\beta$ -emission rates. The emission rates were measured by $4\pi\beta$ -counting with a thin source backing (about 20 $\mu\text{g}/\text{cm}^2$ thick). The mean emission rate per unit area for each membrane source was derived from the average count rate for 5 pieces. For all tested sources with the same nuclide, the ratios of the dose determined by the extrapolation chamber to the mean emission rate show good agreement within the evaluated errors. On the basis of the emission rate measurement, the doses even for the sources with small size or any shape can be easily calibrated although it is impossible for them to be directly determined by an extrapolation chamber.

After calibrated by the extrapolation chamber, the membrane sources have to be stuck on a backing plate to obtain the proper supplement of backscattered β -rays. The influence of backscattered β -rays for the membrane sources of about 6 mg/cm^2 thick was estimated using a $2\pi\beta$ -counting system. The β -ray count rate for the ^{234}Tl membrane source increases by about 10% on a plastic backing and 20% on a stainless steel backing. However, the β -rays backscattered by a backing material can be absorbed by the membrane source itself. The influence is considered to remain slightly conservative if the layer of contamination source is too thin in comparison with the membrane source thickness. Therefore, it is much better to use as thin membrane sources as possible or to select the proper backing materials which compensate the loss of backscattered β -rays.

CONCLUSION

The ion-exchange membrane sources are suitable for preparing dose calibration sources in skin contamination by the following reasons.

The doses can be easily calibrated by the extrapolation chamber because of the uniformity of activity distribution, negligible removal of activity and flatness.

On the dose calibration by an extrapolation chamber, the membrane sources more than 50 mm in diameter need be used for ^{90}Sr - ^{90}Y . However, on the basis of the relation of the dose to the mean emission rate, the doses can be derived for the sources with any size and shape.

The influence of β -rays backscattered by skin tissue can be taken into account by selecting a proper backing material even

though the thickness of membrane source is not sufficiently thin in comparison with the layer of skin contamination source.

STANDARD TEST BENCH FOR CALIBRATING INSTRUMENTS USED
TO MEASURE NATURAL OR ARTIFICIAL RADIOACTIVE
AIRBORNE PARTICULATES

An aerodynamic calibration device, known as ICARE, has been set up in France at the Saclay Research Centre to certify instruments used to measure natural or artificial airborne radioactive particulate contamination or radon. ICARE can calibrate passive detectors and monitors with sampling air flow-rates of less than $60 \text{ m}^3/\text{h}$. The adjustment of such parameters as ^{222}Rn daughters volume activity, attached fraction and equilibrium factor, and the volume activity and size of α or β emitter carrying aerosols, allows realistic conditions to be obtained. ICARE complies with monitor test method standard currently under development by the International Electrotechnical Commission.

INTRODUCTION

L'installation ICARE /1/ répond au besoin de qualifier les instruments de mesure de la contamination atmosphérique dans des conditions réelles d'utilisation. Il est souhaitable de compléter les essais mécaniques, électriques et physiques (sources solides) par des essais dynamiques réalisés en présence d'aérosols radioactifs calibrés, émetteurs artificiels et/ou naturels.

Ainsi, les performances réelles des moniteurs de radioactivité artificielle pourront être connues (rendement de mesure, seuil de détection) en tenant compte des phénomènes liés à la granulométrie des aérosols : enfouissement dans les filtres, colmatage, autoabsorption α , rétention sur les parois, etc..., ainsi que de l'influence de la radioactivité naturelle (efficacité de la compensation radon). L'installation permet également d'étalonner les détecteurs de ^{222}Rn et/ou de ses descendants dans une large gamme d'activité volumique ; cette partie a été réalisée avec l'aide de la Commission des Communautés Européennes /2/.

DESCRIPTION ET PERFORMANCES

L'installation représentée par la figure ci-après, est constituée d'une veine gazeuse principale (0) dans laquelle circule un débit d'air filtré et régulé à $60 \text{ m}^3/\text{h}$; des aérosols radioactifs calibrés sont échantillonnés à des fins de contrôle, de mesure de référence et de prélèvement par les instruments à étalonner.

Radioactivité artificielle :

Des aérosols radioactifs artificiels, du type décrit dans /3/, sont produits par l'un des quatre pulvérisateurs liquides ultra-soniques (1) inclus dans une boîte à gants (2). Une solution aqueuse de CsCl contenant un traceur de ^{239}Pu ou de ^{137}Cs est pulvérisée en brouillard qui, entraîné par un débit d'air sec, crée un aérosol solide dont la taille est fonction de celle des gouttelettes de brouillard et de la concentration en sel. Un générateur de hautes fréquences (3) excite une céramique piézoélectrique qui émet des ondes ultra-sonores provoquant à la surface de la solution une fontaine au sommet de laquelle naît le brouillard dont la distribution granulométrique est peu dispersée. Le diamètre aérodynamique médian en activité des aérosols secs est $0,4 \mu\text{m}$ (aérosols fins) pour deux pulvérisateurs et $4 \mu\text{m}$ (gros aérosols) pour les deux autres. Ces deux valeurs encadrent bien la plage granulométrique des contaminations atmosphériques qui ont pu être mesurées dans l'environnement /4/ et dans des

installations nucléaires /5/. La mesure de référence de l'activité volumique, variable entre 8.10^{-2} et 12 Bq/m^3 pour ^{239}Pu et 10 à 10^5 Bq/m^3 pour ^{137}Cs , est obtenue à partir de prélèvements sur membrane filtrante des particules d'aérosol échantillonnées par une sonde isocinétique (9) ; le filtre est analysé par un Service de Métrologie habilité par le Bureau National de Métrologie. Des capteurs α et β (10) suivent en temps réel l'évolution de l'activité. Selon le débit de fonctionnement de l'instrument à étalonner, ce dernier est raccordé à l'une des sondes d'échantillonnage (11) prévues de 6.10^{-2} à $30 \text{ m}^3/\text{h}$; si le débit est celui de la veine gazeuse ($60 \text{ m}^3/\text{h}$), la veine est dérivée comme indiqué sur le schéma.

Radioactivité naturelle

Des aérosols radioactifs naturels issus des produits de filiation à vie courte du ^{222}Rn peuvent également être injectés dans la veine gazeuse principale, seuls ou en mélange avec les aérosols marqués artificiels, afin de mettre en situation réelle les instruments à étalonner. De plus, une chambre de test (14) permet d'étalonner les détecteurs de ^{222}Rn et/ou de ses descendants dans des conditions dynamiques, la vitesse de l'écoulement étant réglable jusqu'à $0,05 \text{ m/s}$.

Pour produire le radon, le système utilise un nouveau procédé breveté /6/ qui consiste en un dépôt solide de ^{226}Ra dans un feutre acrylique imprégné d'oxyde de manganèse ; le facteur d'émanation du radon dans l'air de balayage est voisin de 100%. Trois sources d'activité différentes permettent de faire varier l'activité volumique du radon dans la chambre de test de 4 à 4.000 Bq/m^3 . La mesure est faite en aval des sources par un conteneur normalisé utilisé pour les gaz radioactifs émetteurs de rayonnement γ . Selon un autre procédé breveté /7/, ce dispositif a été modifié par un arrangement du volume interne en des milliers d'alvéoles sur lesquelles se fixent les atomes des produits de filiation du radon. L'activité est mesurée par spectrométrie γ après le temps nécessaire à la mise à l'équilibre. Le dispositif a été préalablement étalonné avec un étalon gazeux multigamma $^{85}\text{Kr} + ^{127}\text{Xe}$.

Dans le volume de vieillissement (6) sont injectés le radon et des aérosols de CsCl produits par un nébuliseur pneumatique (5) dont la concentration est mesurée par un compteur de noyaux de condensation. Sa variation ainsi que celle du temps de séjour dans le volume permettent d'ajuster la valeur de la fraction attachée des descendants et de leur facteur d'équilibre. Le diamètre aérodynamique médian en activité : $0,2 \mu\text{m}$, est représentatif des valeurs moyennes mesurées dans les habitations. La détermination de l'activité volumique de chacun des descendants, de leur énergie α potentielle, de la

fraction attachée et du facteur d'équilibre est réalisée à partir des mesures de l'activité α de deux membranes filtrantes (7) ayant prélevé simultanément l'aérosol radioactif en aval du volume, la fraction libre ayant été piégée en amont de l'une des membranes. Ces informations sont données par un logiciel qui traite les signaux issus des ensembles de comptage par une méthode de déconvolution en fonction du temps ; la mesure est poursuivie jusqu'à ce que la précision donnée par le logiciel soit jugée satisfaisante.

CONCLUSIONS

L'installation d'étalonnage ICARE permet un réglage souple et reproductible des caractéristiques des aérosols radioactifs et du radon ; elles sont représentatives des conditions rencontrées dans l'environnement et dans les milieux industriels. Les mesures de référence sont reliées aux étalons nationaux, et les méthodes de test sont en voie d'être reconnues par la Commission Electrotechnique Internationale.

ABSTRACT

A dual-type ionization chamber using ^3He and ^4He has been proposed and developed for monitoring X-n mixed fields in the vicinity of nuclear fusion experiments and other radiation sources. Some response characteristics of the system have been checked in different conditions.

INTRODUCTION

In large-scale plasma experiments for controlled nuclear fusion, energetic neutrons and X-rays will be produced, so that it should be important to monitor these radiations in and around the experimental zone. They are usually giving rise to a mixed field of burst pulse associating with the plasma shot. It is, therefore, quite desirable to develop a monitoring sensor effective for real-time measurements of neutron components and X-rays separately.

In view of safety control applications to the neighbouring area of the coming Large Helical Device (LHD) of NIFS, a dual-type neutron monitor has been designed and developed. As the type of sensors, ionization chamber scheme is adopted because of its simplicity and applicability to a wide range of radiation intensities.

IONIZATION CHAMBER

A dual-chamber system is consisting of two cells of the same geometric shape, volume and wall material. One of them is filled with pressurised ^3He gas, being sensitive to both neutrons and X-rays, and the other filled with ^4He gas being sensitive only to X-rays. The difference in signals from these cells is to give the neutron contribution.

Each chamber cell is a cylindrical vessel (80mm ϕ \times 200mm) of stainless steel (3mm thick) to give a gas volume of 1

Fig. 1. Chamber cells.

litre. A rod-type electrode (5mm ϕ \times 150mm) is held coaxially inside the cell with an insulated gaurd ring structure installed at one end of the cylinder. (Fig.1) An electric potential is supplied to the cell wall, keeping the gaurd ring to the ground potential. The charge collected on the electrode is introduced to a capacitance vibrating electrometer to observe the current output. Measurable current range is $10^{-5} \sim 10^{-11}$ A with a moderate time constant. In the testing experiments, each cell of the chamber pair is connected with its own electrometer to avoid unexpected interference.

Chamber cells with ^3He and ^4He gases of different pressures (1~6 atm) are prepared, as well as the one with 1-atm air for comparison. If the neutron signals from ^3He are due to a thermal capture process ($n + ^3\text{He} \rightarrow t + p + 765 \text{ keV}$), the stopping range of the secondary p and t in 1-atm ^3He gas are estimated as 4.5 cm and 2.2 cm, respectively. Since we are interested in neutron energies up to a few MeV, a detachable polyethylene moderator (5 cm thick) is usually placed surrounding the chamber cells. The whole system is situated in a casing of 1 mm thick Cu plate to shield electromagnetic noise.

RESPONSES TO GAMMA-RAYS

As the first step of testing the chamber characteristics irradiation against ^{60}Co gamma rays has been carried out. A test field is available at the Co-60 Radiation Room, belonging to Dept. Synthetic Chemistry, Nagoya University, where a strong ^{60}Co source of $\sim 10^7$ TBq is installed.

When the applied potential is varied, the current output to the electrometer reveals itself as a saturation curve. In Fig.2 typical examples are shown, for 1-atm cells of air, ^3He , and ^4He , respectively, with outward positive potentials. The responses of ^3He and ^4He are quite similar to each other, while the air chamber gives much higher saturation current levels and potentials.

The saturation curves are dependent on the polarity of applied voltage, as well as on the gas species and pressures. The current increases in the outer positive potential case are slower than the negative case, and seems to reach somewhat lower levels in saturation. These features may reflect the

Fig. 2. Saturation curves.

possible space charge effects around the axial electrode as well as the recombinations efficient in the ion collection processes, and further detailed analysis is needed.²

In order to see the response-to-dose characteristics of these chambers for gamma rays, we have compared data of different field intensities. In the Co-60 Radiation Room, where high absorbed dose rates of $10 \sim 10^3$ Gy/h are attained and the typical response currents from 1-atm ^4He are ranging $10^{-7} \sim 10^{-6}$ A. In addition to the experiments in such a strong field, we have made another exposure test by use of many orders of magnitude weaker ^{60}Co (~ 10 MBq) in an open space. This gives absorbed dose rates $10^{-5} \sim 10^{-3}$ Gy/h, and the observed outputs are down in $10^{-14} \sim 10^{-12}$ A, which are almost the lowest detectable limit of the present system. The proportionality covering these two limits is well justified. (Fig.3)

Fig. 3. 1-atm ^4He responses to gamma rays.

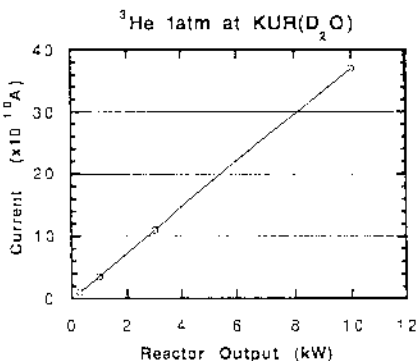

Fig. 4. Responses of ^3He and ^4He to KUR thermal neutrons.

RESPONSES TO THERMAL NEUTRONS

The neutron responses of ^3He chamber has been surveyed by means of D_2O -thermalised neutron irradiation at the KUR fission reactor of Research Reactor Institute, Kyoto University.

In Fig.4 are shown the results. Responses from ^3He and ^4He are plotted against the operated reactor powers. Both response currents give very good linearity, though the current ratio $^3\text{He}/^4\text{He}$ is as high as $\sim 10^3$. This implies that the small amount of gamma rays coexisting in the thermal neutron area can easily be separated with the dual-chamber. In reactor

operations at 3 kW and 10 kW, the air-absorbed gamma doses were known. The ^4He responses in these cases are plotted in Fig.4 together with ^{60}Co data, showing very good fitting to the line. The thermal neutron flux in the area is estimated by a different experiment³ as $9.6 \times 10^8 \text{ n cm}^{-2} \text{ s}^{-1}$ at 1 kW operation, so that the observed ^3He current $0.35 \times 10^{-9} \text{ A}$ should imply the thermal neutron sensitivity of the 1-atm ^3He chamber with moderator to be $3.6 \times 10^{-17} \text{ A/n cm}^{-2} \text{ s}^{-1}$.

TESTINGS WITH MIXED X- γ FIELD

A preliminary operation test of the dual-chamber system in ^{252}Cf has been done. An available source is estimated to contain some $0.067 \mu\text{g}$ of ^{252}Cf isotope, and a neutron emission rate of $1.55 \times 10^6 \text{ n/s}$ and a gamma exposure rate of $9.5 \times 10^{-4} \text{ Gy/h}$ at 1 m are expected. Using 1-atm ^3He and ^4He chambers, response to source distance characteristics have been examined. The ^3He responses reveal $r^{-1.5}$ decrease with distance r , and some 40 times higher than the ^4He ones, though the latter signals are very low and scattered in $10^{-10} \sim 10^{-11} \text{ A}$ regime. It would be desirable to make use of a stronger source to obtain a more definite results.

SUMMARY AND REMARKS

A dual-type cylindrical ionization chamber system has been developed for the dosimetry use of the neutrons and X(gamma)-rays. Several tests so far carried out in various field conditions seem to show good capability of the system.

Tasks and issues left for the future:

- (i) Tests in the burst-like pulse fields (use of existing accelerators or plasma devices)
- (ii) The method of practical data treatment, including the built-in data processing scheme (such as automatic ^3He - ^4He subtractions) and conversions to dose-equivalent quantities.
- (iii) The detailed considerations on the chamber characteristics, physical and/or simulational analyses to understand the general behaviours as well as better choice of materials and structures.

CALIBRATION OF PARALLEL PLATE IONIZATION CHAMBERS IN DIFFERENT KINDS OF RADIATION

Linda V.E. Caldas and Maria P.P. Albuquerque

Instituto de Pesquisas Energéticas e Nucleares
Comissão Nacional de Energia Nuclear
São Paulo, Brazil

ABSTRACT

Parallel plate ionization chambers designed and constructed for use in low energy X-radiation fields were tested in beta ($^{90}\text{Sr} + ^{90}\text{Y}$), gamma (^{60}Co and ^{137}Cs) and intermediate energy X-radiation, in order to verify the possibility of their usefulness for the detection of these kinds of radiation. The obtained calibration factors were compared with those of the secondary standards of each type of radiation.

INTRODUCTION

Different types of ionization chambers are normally used depending on the kind of radiation. The parallel plate ionization chambers are recommended for low energy X-radiation dosimetry^{1,2}. However some interest has been already shown in the use of such chambers in other kinds of radiations^{3,4}. The objective of this work was to verify how to use these chambers in beta, gamma and intermediate energy X-radiation, in order to avoid the necessity of acquisition of several chambers.

EXPERIMENTAL MEASUREMENTS

Two parallel plate ionization chambers A and B, of circular form, with Lucite bodies, active volumes of 0.6 cm^3 , graphite collecting electrodes and guard-rings, designed and manufactured at IPEN^{5,6}, were tested at three different laboratories. Chamber A was examined in Brazil, using the irradiation systems of the calibration laboratories of São Paulo (IPEN) and Rio de Janeiro (Instituto de Radioproteção e Dosimetria - IRD), and chamber B was calibrated at the Secondary Standard Dosimetry Laboratory of Neuherberg, GSF, Germany (Institut für Strahlenschutz). In each case the chamber response was compared with that of a corresponding secondary standard chamber. The standard deviation of all these measurements was lower than 0.20%.

For low energy X-radiation the obtained calibration factors for the chamber A can be seen in Table 1 in comparison to those of the secondary standard ionization chamber (P) for this

energy range. Both chambers A and P are of the superficial type. The energy dependence of chamber P presents a variation of 1.9%, while it is only 0.3% for chamber A.

In the case of intermediate energy X-radiation, the calibration factors for the chamber A are presented in Table 2. Chamber T is the secondary standard chamber (thimble type) recommended for this kind of radiation. It can be seen that chambers A and T show variations of 5.7 and 2.1% respectively for the energy dependence in the considered range.

In order to test the chamber A in gamma radiation fields, at the laboratory of São Paulo, a ^{60}Co Kelcoet Barnes Flexaray and a ^{137}Cs Cosapan-M, Generaly, were used. At the German laboratory GSF a Gammatron and a Theratron were employed with the chamber B. Initially the electronic equilibrium thickness had to be determined, taking measurements for different Lucite absorbers: 3.3 mm (^{60}Co) and 1.2 mm (^{137}Cs). The obtained results are shown in Table 3, normalized to ^{60}Co response (because different electronic equipments were used), in comparison to commercial chambers (superficial and thimble). All chambers were calibrated against the normally utilized secondary standard for gamma radiation. The greatest energy dependence was presented by the chamber C (1,2%); chambers A and B show similar behaviours to that of chamber D, which is of the recommended type (thimble) for gamma radiation.

In the case of beta radiation the $^{90}\text{Sr} + ^{90}\text{Y}$ sources of the secondary standards of the calibration laboratories of IPEN and GSF were utilized. The reference instrument for this kind of radiation is the extrapolation chamber (E). In Table 4 the calibration factors are presented.

CONCLUSION

The obtained results show the usefulness of the parallel plate ionization chambers developed at IPEN for X, gamma and beta radiation detection.

INTRODUCTION

The characteristics of CR-39 detectors have been investigated intensively during the last years in many laboratories. The enlargement of tracks by electrochemical etching made counting easier but, on the other hand, complicated the etching process. For routine application of CR-39 in neutron personal dosimetry neither etching nor reading should be complicated or time consuming.

Recently NE-Technology (formerly: Vinten) introduced an automatic reader for chemically etched CR-39 detectors. Along with this reader a new CR-39 Material, PN3, was made available. This system would allow for a routine application of CR-39.

The characteristics of PN3 detectors and possible batch constructions were investigated.

EXPERIMENTAL CONDITIONS

Detector material

The CR-39 material which we used was PN3 from NE-Technology, England. The detectors were 1,5 mm thick and 20 mm x 25 mm in size. All detectors were cut and coded by the supplier.

Etching conditions

The detectors were chemically etched using a two-step technic. This etching procedure is the standard procedure recommended by the manufacture [1]. During the first step, the pre-etch step, the detectors were immersed in a 60% methanol and 40% 6.25 N NaOH solution at 70°C for one hour. Under these conditions the bulk etching velocity is equal to the track etch velocity and therefore the surface of the detector is polished without etching the tracks in this surface layer [1]. About 30 µm of each detector surface is removed by this step.

During the second step the detectors are immersed in 6.25 N NaOH solution at 70°C for six hours.

Counting system

Since the automatic reader of NE Technology was available as a prototype instrument only, most detectors were counted with the Quantimet 920 in connection with an optical microscope under the magnification of 32x. For each detector 200 fields of view with the field size of $250 \mu\text{m} \times 250 \mu\text{m}$ each were analysed. The total analysed area was $1/8 \text{ cm}^2$. Tracks with a diameter smaller than $2,7 \mu\text{m}$ were discriminated.

ENERGY RESPONSE

Response to thermal neutrons

For thermal neutron irradiation a polyethylen moderated Am-Be source was used. For the detection of thermal neutrons the $\text{Li-6}(n,\alpha)\text{H-3}$ reaction was applied. The resulting α -particles have an energy of 2,04 MeV which corresponds to a range of about $10 \mu\text{m}$ in CR-39 [2]. Because of this short range, the α -particles do not penetrate the pre-etch layer and are therefore not detectable. The tritium particles of the same reaction have an energy of 2,74 MeV what results in a range of about $60 \mu\text{m}$ in CR-39 [3]. Therefore the H-3 particles are detectable.

For the irradiation with thermal neutrons we placed TLD-700 (LiF) on the detector surface. The response was found to be about 100 times as high as for bare Cf.

Response to Cf-252 and Am-Be neutron fields

Since over a wide range of neutron energies the elastic scattering on protons is the dominating reaction for the production of detectable particles, a radiator with a high hydrogen content is used to increase the response of the detector. As mentioned above, a $30 \mu\text{m}$ layer is removed during the pre-etch step. Since this thickness corresponds to the range of about 1,2 MeV protons [2], this pre-etch layer serves as an effective radiator for neutrons with energies below about 1,2 MeV. If the neutron energy exceeds this value the response can be increased by an external radiator.

To test this effect, the detector was divided in two different fields. One field was covered by 3 mm of polyethylen. The second had to be covered by a material with a low overall cross section for neutrons. For this purpose aluminium was chosen. Figure 1 shows the radiator stack that was applied during the irradiations. This stack was irradiated with bare Cf and Am-Be neutrons. The frontside of the detector, this is the side that is analysed later by track counting, faced the source. The stack was mounted on a 15 cm thick 30 cm x 30 cm plexiglass slab phantom. Table 1 shows the results of this experiment.

The ratio of the responses of the aluminium covered detector field to the polyethylen covered detector field for the Am-Be irradiation is lower compared to the Cf

irradiation. This shows that this ratio can serve as a rough figure for spectrometric information. If the main dose contribution derives from neutrons with energies up to 1,2 MeV this ratio should be close to 1. If the percentage of higher energy neutrons increases, the ratio decreases.

Table 1: Response for Various Neutron Energies

Neutron field	Radiator	Response \pm SD [Tracks * cm ² * mSv ⁻¹]
Thermal	Li-6 (TLD-100)	31500 \pm 7040
Bare Cf	3 mm polyethylen	250 \pm 61
Bare Cf	2 mm Al	164 \pm 46
Am-Be	3 mm polyethylen	295 \pm 57
Am-Be	2 mm Al	117 \pm 32
50 MeV	air	165 \pm 20
50 MeV	3 cm plexiglass	179 \pm 45
70 MeV	air	160 \pm 23
70 MeV	3 cm plexiglass	167 \pm 25

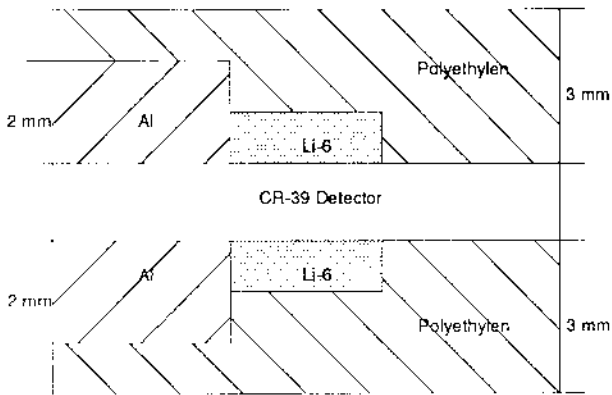

In order to look at the effect of the wearing direction of the dosimeter, we turned the radiator stack by 180° towards the phantom. Now the front side of the detector faced the phantom. As expected, both fields showed a similar response, since in this case the 1,5 mm thick detector serves as a radiator. The overall response (210 \pm 31 tracks * cm⁻² * mSv⁻¹) decreased because the relative hydrogen content of CR-39 (48.6 %) is lower than that for polyethylen (66.6 %).

In order to be able to receive some spectrometric information from the comparison of the two fields, the dosimeter should be worn in the proper direction.

Response to 50 MeV and 70 MeV Neutrons

Different CR-39 materials, including PN3 were irradiated with 50 MeV and 70 MeV neutrons at the Paul Scherrer Institute. For a more detailed description of the experiment and the results see ref. [4]. For the irradiation one detector was placed in front of a 3 cm plexiglass slab and a stack of 5 detectors was fixed behind the slab. The results show that the plexiglass had practically no influence on the response of the detectors. The results are also shown in Table 1. In general the sensitivity is about 2/3 of that for bare Cf.

Fig. 1: Detector stack

APPLICATION IN ROUTINE DOSIMETRY

For routine application a first reading could be restricted to the fields covered by polyethylen and Li-6. The reading of the field behind aluminium is thought to be applied for detectors only which show a dose above a certain investigation level. The feasibility of the system is being investigated in an extended field test in accelerator and reactor environments.

ABSTRACT

We developed a real time personal neutron dosimeter by using two types of silicon p-n junction detectors, thermal neutron sensor and fast neutron sensor. The thermal neutron sensor which is ^{10}B doped n-type silicon with a polyethylene radiator mainly counts neutrons of energy from thermal to 1 MeV, and the fast neutron sensor which is p-type silicon with a polyethylene radiator is sensitive to neutrons above 1 MeV. The neutron sensitivity measurements revealed that the dosimeter has a rather flat response for dose equivalent from thermal to 15 MeV, excluding a drop from 50 keV to 1 MeV. In order to get the conversion factor from counts to dose equivalent as accurately as possible, we performed the field test of the dosimeter calibration in several neutron-generating fields. By introducing the two-group dose estimation method, this dosimeter can give the neutron dose equivalent within about 50% errors.

I. INTRODUCTION

The development of personal neutron dosimeters that indicate the dose equivalent in real time becomes important with the increased number of people working in high intensity, high energy accelerator facilities and nuclear fuel reprocessing plants. To produce an instrument that is small and light, and has enough sensitivity to neutrons is a difficult task.

Recently, two types of direct-reading personal neutron dosimeters have newly been developed. One is a bubble-damage polymer detector which uses tiny, superheated droplets of a detector liquid uniformly dispersed in a firm elastic polymer developed separately by Ing et al.¹ and Apfel et al.² The other is a silicon dosimeter developed by Nakamura et al.³ which uses two types of silicon p-n junction detectors fabricated by Fuji Electric Co. Ltd. This dosimeter had low neutron sensitivity and we further realized the dosimeter of higher sensitivity by using larger silicon detector of 1 cm x 1 cm. One type, thermal neutron sensor, is an n-

type silicon crystal on which a p' layer of elementary boron enriched 94% ^{10}B is deposited in about 1 mm thickness and the other type, fast neutron sensor, is an p-type silicon crystal without boron coating. Both crystals are contacted with 0.08 mm thick polyethylene radiators and in some cases only the thermal neutron sensor is covered with a polyethylene moderator of 10 mm thickness. Figure 1 shows a schematic cross sectional view of the dosimeter.

II. NEUTRON SENSITIVITY MEASUREMENT

A. Experimental

The neutron detection efficiencies of these two sensors were measured in the monoenergetic fast neutron field at the Fast Neutron Laboratory of Tohoku University. Monoenergetic neutrons of five discrete energies of 200 keV and 550 keV by the Li(p,n) reaction, 1 MeV by the T(p,n) reaction, 5 MeV by the D(d,n) reaction and 15 MeV by the T(d,n) reaction were produced using

Thermal neutron sensor

Fast neutron sensor

Fig. 1 Schematic cross sectional view of two silicon sensors

the Dynamitron accelerator. The dosimeter was placed in the forward direction to the beam axis. The neutron fluence incident on the dosimeter was measured with a ^{235}U fission chamber placed in front of the dosimeter. Since the ^{235}U fission chamber is sensitive to low energy neutrons scattered from the surrounding objects, a hydrogen proportional counter which was adjusted to count neutrons above several tens of keV was also placed at about 45 deg to the beam axis as a subsidiary neutron fluence monitor. The efficiency measurement of the thermal neutron sensor to thermal neutrons was done in the experimental hole of the TRIGA-II type reactor of Rikkyo University and in the thermal neutron field leaked from a graphite pile of Institute of Radiation Measurements. Thermal neutron fluence incident on the dosimeter was measured with a gold activation foil. The dosimeter encapsulated two silicon sensors was placed in front of a commercially available ellipsoidal water phantom, 45 cm high and 30 cm wide. The output pulses due to alpha particles produced by the $^{10}\text{B}(n,\alpha)$ reaction and protons recoiled from the elastic collision in the polyethylene radiator were measured with a multichannel analyser.

B. Results

Figure 2 shows the neutron detection efficiency of the dosimeter as a function of neutron energy. The measured results are the sum of the integrated counts given by the thermal neutron sensor and the integrated counts of the fast neutron sensor multiplied by a factor of 40, in order to get the detection efficiency as close as possible to the fluence-to-dose-equivalent conversion factor given by ICRP-51 which is drawn in a dotted line. In Fig. 2, the results calculated with the MORSE-CG code are also shown to compare with the results measured by the thermal sensor. Since the recoil proton pulses from the radiator were not included in the MORSE calculation, this comparison is valid only in the energy range below 1 MeV, where it shows good agreement between experiment and calculation.

This dosimeter which combines two silicon sensors has neutron sensitivity over a wide energy range from thermal to 15 MeV and also has good energy response, excluding a large deviation from the ICRP-51 response curve in the energy range from 50 keV to 1 MeV, as seen in Fig. 2.

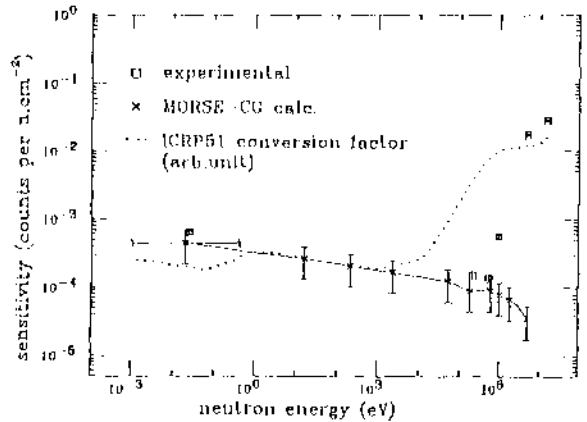

Fig. 2 Comparison of measured and calculated neutron detection efficiencies of the dosimeter, together with the ICRP-51 fluence-to-dose-equivalent conversion factor

III. FIELD TEST OF DOSIMETER RESPONSE

Because of the deviation of the dosimeter energy response from ICRP-51, it is necessary to determine the conversion factor from counts to dose equivalent values to be fitted in various spectral fields necessary for neutron monitoring. For getting this conversion factor, we have been doing the field test of the dosimeter calibration in the following typical neutron fields having known neutron energy spectra; 1) moderated ^{252}Cf neutron source calibration field, 2) a beam extraction hole of the fast neutron source reactor of University of Tokyo, 3) labyrinth from the 40 MeV cyclotron room of Tohoku University, 4) MOX (Mixed Oxide) fuel handling room of Power Reactor and Nuclear Fuel Development Corporation and so on.

In these field tests, the dosimeter was fixed on the water phantom faced to the neutron beam direction. The measured counts were compared with the dose equivalent values obtained from the dose equivalent counters (rem counters) of Studsvik 2202D and Fuji Electric NSN1 which were used as neutron dose monitors. Considering the energy response of the dosimeter shown in Fig. 2, we propose the following two-group dose estimation method which divides neutrons into two energy groups of thermal to 1 MeV and above 1 MeV. The total neutron dose equivalent H is given by adding the neutron dose equivalent of energy higher than 1 MeV, H_1 and that of energy lower than 1 MeV, H_2 . H_1 and H_2 are given by

$$H_1 = K_1 C_1 \quad \text{for } E_n \geq 1 \text{ MeV,}$$

$$H_2 = K_2 (C_2 - R C_1) \quad \text{for } E_n \leq 1 \text{ MeV,}$$

where C_1 , C_2 are the respective counts measured with fast sensor and thermal sensor, K_1 , K_2 are the respective conversion factor in units of $\mu\text{Sv}/\text{count}$,

R is the correction factor which subtracts the contribution of fast neutrons above 1 MeV counted in thermal sensor. From the results of these field tests, the K_1 and R values were found to be fixed as 2.0 and 0.5, while on the other hand, K_2 had to be three different values corresponding to the neutron energy spectra.

Table 1 summarizes typical examples. The K_2 value becomes smaller with decreasing the mean neutron energy in the test neutron fields. Figures 3 to 5 show the neutron energy spectra in lethargy units. The K_2 value of 2.0 in Table 1 corresponds to the field close to fission neutron spectrum which is appeared in bare ^{252}Cf neutron source field in Fig. 3⁴ and in PuO_2 - UO_2 mixed fuel field in Fig. 4.⁵ The K_2 value of 0.075 corresponds to the field close to 1/E slowing-down neutron spectra which is seen in polyethylene-moderated ^{252}Cf neutron source field in Fig. 3 and at the point 2 in the entrance of the labyrinth connected to the accelerator room in Fig. 5,⁶ and that of 0.015 to the well-thermalized neutron field at the point 7 near the exit of labyrinth in Fig. 5. Table 1 also gives the ratio of dose equivalent values given by this dosimeter and those by the rem counters. By using the conversion factors of K_1 , K_2 and R shown in Table 1, it was revealed that this dosimeter can give the neutron dose equivalent within about 50% difference at maximum.

IV. CONCLUSION

The characteristics of our newly-developed real-time personal neutron dosimeter based on the present study can be summarized as follows; (1) From these field experiments, this dosimeter will be possible to give the neutron dose equivalent within about 50% errors in the energy range from thermal to 15 MeV.

Table 1 Summary of field test of dosimeter calibration

Field	Mean Neutron Energy (MeV)	K_1 ($\mu\text{Sv}/\text{count}$)	K_2 ($\mu\text{Sv}/\text{count}$)	Ratio ¹
^{252}Cf (bare)	2.11	2.0	2.0	1.11
PuO_2 - UO_2	1.8	2.0	2.0	1.09
^{252}Cf (polyethylene)	1.0	2.0	0.075	1.40
Labyrinth No. 2	0.026	2.0	0.075	0.71
Labyrinth No. 7	0.012	2.0	0.015	1.32

¹ Ratio of dose equivalent values given by this dosimeter to those by rem counter

(2) The dosimeter is insensitive to gamma rays up to about 100 mSv/h.

(3) The size and weight of the dosimeter is about 100 mm x 60 mm x 20 mm and about 150 g, respectively, which is small and light enough for personal dosimeter.

DETERMINATION OF AMBIENT DOSE EQUIVALENT IN MIXED RADIATION FIELDS BY MEANS OF RECOMBINATION CHAMBER

Institute of Atomic Energy, Swierk, Poland
(Work partly supported by International Atomic Energy Agency under Research Contract 6353/RB)

N. Golnik and M. Zielczynski

ABSTRACT

The response of the REM2 recombination chamber to $H^*(10)$ was determined for some photon and neutron radiation fields (X-rays with effective energy 111 keV, gamma radiation of ^{137}Cs and ^{60}Co sources, the radiation of isotopic neutron sources $^{241}\text{Am-Be}$ and ^{252}Cf , monoenergetic neutrons in energy range from thermal to 19 MeV). For mixed gamma-neutron radiation with broad neutron energy spectrum the response of the chamber to $H^*(10)$ is constant within 20%, so the chamber can be used as a good detector for monitoring of the ambient dose equivalent.

INTRODUCTION

The recombination chamber it is a high-pressure ionization chamber operated in non-saturated mode. In this mode the initial recombination of ions is significant, so the sensitivity of the chamber depends on LET of incident radiation and provides information about the quality of this radiation. Therefore the chamber can be used for determination of the dose equivalent.

Recently, the ambient dose equivalent $H^*(10)$ is recommended as an operational radiation protection quantity for external radiation. The aim of this work was to estimate, whether the recombination chamber can be used for determination of this quantity in mixed neutron - gamma fields.

INSTRUMENT

For present investigation the REM2 recombination chamber was chosen. The chamber was manufactured in Poland by POLON. Now it is no longer commercially available, but it is still routinely used in some laboratories over the world for monitoring of the dose equivalent. REM2 is a parallel-plate ionization chamber with 25 tissue-equivalent plates, the volume of 2 dm³, the mass of 6 kg and the effective wall thickness of about 2 g/cm². The chamber is filled with methane and nitrogen (4%) at pressure of about 1 MPa. The chamber was operated in differential mode [1]. In this mode the collecting voltage in one half of the chamber is high and the ionization current is close to saturation. In the second half of the chamber the collecting voltage has a lower value, specially chosen so that the ionization current depends on the initial recombination of ions. The signal from the chamber is equal to the difference between this two currents and is proportional to the dose equivalent rate. For the purpose of this work the response of the chamber was defined as the ratio of the signal to $H^*(10)$.

METHOD

Response of the chamber to $H^*(10)$ was experimentally determined in three photon and two neutron fields: X-rays with effective energy 111 keV, gamma radiation of ^{137}Cs and ^{60}Co sources, the radiation of isotopic neutron sources $^{241}\text{Am-Be}$ and ^{252}Cf . The radiation fields were established in calibration room at the Radiation Protection Department of IAE Swierk. Exposure for photons and fluence for neutrons were well defined for all irradiation conditions. Ambient dose equivalent for photons was calculated by multiplying the exposure with the conversion factors for monoenergetic photons, given in the ICRP Publication 51 [2]. For isotopic neutron sources the conversion factors given by Bartlett were used [3].

The current of the ionization chamber was measured with a Keithley 642 electrometer connected to an automated system for the experiment control and data acquisition. Response of the chamber for some monoenergetic neutrons, over a neutron energy range from thermal to 19 MeV, was estimated on the basis of experimental results by Höfert and Raffnsøe [4]. Since the results had been expressed by authors in terms of MADE (according to ICRP 21 [5]), so the recalculation to the $H^*(10)$ was made. The conversion factors given in ICRP Publication 51 [2] and spline interpolation between given points were used for the recalculation.

PHOTON AND NEUTRON RESPONSES

Experimental results for photons and for neutrons from isotopic sources are given in Table 1. The relative response quoted in the Table is defined as the ratio of the chamber response for the radiation considered to the response for ^{137}Cs .

TABLE 1. Response of the REM2 recombination chamber to $H^*(10)$ for photons and for isotopic sources of neutrons.

Photon source	Neutron source	Correct. to photon emission	Effective energy E_T (keV)	Response to $H^*(10)$ ($\mu\text{C}\cdot\text{Sv}^{-1}$)	Relative response R/R_{Cs}
X-rays ^{137}Cs ^{60}Co			111	10.12	0.992
			662	10.2	1.000
			1250	10.51	1.03
	$^{241}\text{Am-Be}$ ^{252}Cf ^{252}Cf	no		10.2	1.0
		no		11.0	1.08
		yes		11.08	1.086

Uncertainties of the relative response values are of about 4% for photons and of about 8% for neutrons. This include the uncertainties of the exposure or fluence determination and stochastic uncertainty (expressed as one standard deviation) of measured ionization currents. Conversion factors are taken without uncertainties, however it should be noted that for neutrons this uncertainties may be as great as 10%.

It can be seen that for photons of energies considered the differences in responses of the chamber are very small. The second practically important fact is, that the response for $^{241}\text{Am-Be}$ neutron source is the same as for ^{137}Cs photon source. It was the reason, why the correction of response for photon emission was not needed in case of $^{241}\text{Am-Be}$ source.

The values of the response for monoenergetic neutrons, related to the response for $^{241}\text{Am-Be}$ source, are given in Table 2 and in Fig. 1. As it was mentioned above, the values were obtained by recalculation of earlier published results [4]. No assessment of uncertainties has been made for this case; the results are not considered to be unequivocal, but they can help to assess the applicability of the recombination chamber as an instrument for the ambient dose equivalent determination.

TABLE 2. Relative response of the REM2 chamber to $H^*(10)$ for neutrons (recalculated from data given in [4]).

Neutron source or energy (MeV)	Relative response $R/R_{\text{Am-Be}}$
Thermal	1.15
0.0245	2.46
0.1	1.19
0.25	1.19
0.57	0.94
1.0	1.14
2.5	1.22
5.0	0.89
15.5	0.53
19.0	0.64
^{252}Cf	1.096

Fig.1 Relative response of the REM2 chamber to $H^*(10)$ versus neutron energy (related to $^{241}\text{Am-Be}$ source).

DISCUSSION AND CONCLUSIONS

As it was expected from general considerations, only minor differences in the response of the chamber were found for the photon radiations investigated. The experimental results are too poor to exclude that somewhat larger differences may appear for photons of other energies. Even though, this should not have any significant influence on the determination of $H^*(10)$ for mixed radiation fields, because the photon contribution to the dose equivalent is usually low.

A serious advantage of the chamber is the almost equal response for gamma radiation and for neutrons of $^{241}\text{Am-Be}$ source. Therefore, for determination of $H^*(10)$ in mixed neutron-gamma fields, the chamber may be calibrated either with $^{241}\text{Am-Be}$ source, or with ^{137}Cs source.

There is a number of factors which cause that the sensitivity of the commonly used T.E. chambers is lower for neutrons than for photons. In the REM2 chamber influence of these factors is compensated by an excess of the hydrogen content in the filling gas with respect to the T.E.-gas.

The usefulness of the recombination chamber in monitoring of the $H^*(10)$ depends primarily on the neutron energy dependence of the chamber response. Such a dependence for the REM2 chamber is given in Fig.1. It can be seen, that with respect to calibration with $^{241}\text{Am-Be}$ source, there is an overestimation of the $H^*(10)$ for neutron energies lower than 5 MeV and underestimation for higher energies. The overestimation for lower neutron energies, caused by the excess of hydrogen, does not exceed 20%, except of the 24.5 keV neutrons, where the relative response of almost 2.5 was observed. We are not able to find any explanation for so high overestimation at this neutron energy. With increasing energy of neutrons the effectiveness of the compensation decreases and $H^*(10)$ becomes to be underestimated down to the value of 0.53 for neutrons of energy 15.5 MeV. Taking into account the operating principle of the recombination chamber and the differences of the chamber construction comparing to the ICRU sphere, we expect that the relative response of the chamber will not decrease more, even for high energy neutrons. However this prediction needs further investigations.

For a broad neutron energy spectrum, which is the usual case in radiation protection practice, one can expect that the relative response of the chamber is sufficiently constant. Therefore a large recombination chamber, like the REM2, may be considered as a good detector of the ambient dose equivalent of mixed radiation in vicinity of isotopic sources and nuclear installations.

Frequency Sweep ESR Spectrometer for Dosimetry and Dating

Hidemoto Hara*, H. Morishima**, H. Kawai**and Y. Nishiwaki**.

3-4-1 Kowakae, Higashi-Osaka City, Osaka 577, Japan

For the study of radiation damage in matter, ESR (Electron Spin Resonance) is widely used these days and much progress has been achieved in the method of measuring ESR signals. However, with the standard type ESR equipment, a large electromagnet and regulated power supply are set up and quite a large area is required in the laboratory. Therefore, it is impossible to conduct an experiment on site outside the laboratory with such a large equipment. For dosimetry with such a large ESR equipment it is required that the samples to be used for ESR-dosimetry have to be brought back to the laboratory for measurement. In order to facilitate the ESR measurement on site outside the laboratory in nuclear accident or emergency or for the purpose of dating of ancient natural samples at remote places, we are trying to build an experimental, small-sized ESR equipment, which is capable of transforming into a battery powered portable version.

With the first type of portable ESR spectrometer which was developed, the feasibility as a reader of alanine dosimeter was studied. The developed ESR spectrometer was designed to be small enough that it can be placed on a two-feet-square desk, however it has the functions of high magnetic field modulation, high frequency modulation, variable amplitude and AFC(Automatic Frequency Control)function in order not to sacrifice sensitivity, stability and reproducibility. The spectrometer has

two main components of a permanent rare-earth metal magnet and resonator part, and a unit box with a microwave circuit, an AFC circuit, a sweep controller of magnetic field, an oscilloscope, etc. Sensitivity was improved by using FET (Field Effect Transistor) amplifier in a resonance detector circuit.

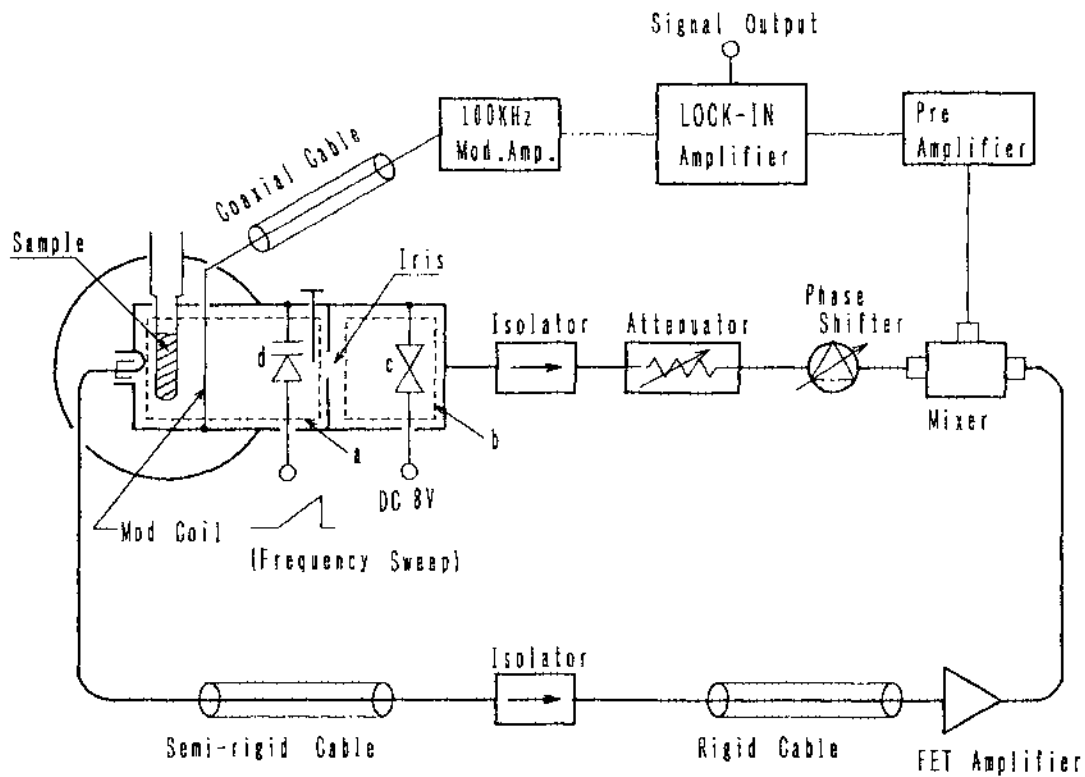

With the second type of portable ESR spectrometer, it is intended to measure ESR signals of shell goods such as button and human teeth which were irradiated by nuclear radiation accidentally. For this purpose we are trying to develop ESR equipment using a strong permanent magnet and microwave modulation. Conventional ESR equipment consists of a system whereby resonance is detected by fixing the microwave frequency and sweeping the magnetic field, while the equipment we are trying to develop uses the method whereby ESR signal is detected by fixing the magnetic field and sweeping the microwave frequency. The high Q-value sample cavity has been coupled with the low Q-value oscillation cavity through the iris hole. Voltage impressed to the tuning diode inside the sample cavity gives shift to the resonance frequency, simultaneously controlling the oscillation frequency. About 100 megahertz frequency sweepings have been used by giving trapezoidal modulation. Magnetic field has been fixed to an adequate value by controlling the gap of the permanent magnet.

At present, the sensitivity of this equipment is too low to be used for the measurement of low radiation dose range for routine radiation protection purposes. Therefore, it is now intended to develop an equipment to be used to screen the persons who would have received unusually high dose of radiation accidentally in case of nuclear accident or emergency. In such cases, ordinary dosimeter designed for measurement of low dose of radiation for routine radiation protection purposes may not be usable. Under such emergency cases, ESR equipment must be brought as close to the site of accident as possible, in order to facilitate the

prompt screening of the persons who are exposed to unusually high dose of radiation, using ESR signals of shell button, sugar coating of the medicine carried by the person or human teeth if available. We are now trying to improve the sensitivity and reproducibility of this type of portable equipment.

MERLINS vs BNFL : A CLAIM FOR DAMAGE TO PROPERTY BY RADIOACTIVITY

S R Jones and J A Coote

British Nuclear Fuels plc,
Sellafield, Seascale, Cumbria, UK.

A J Shuttleworth

British Nuclear Fuels plc,
Risley, Warrington, Cheshire, UK.

ABSTRACT

A case heard in the High Court, London in 1989 tested the provision for strict liability imposed by the Nuclear Installations Act 1965, in respect of damage caused by radioactivity emanating from a nuclear licensed site. Plaintiffs were Mr and Mrs Merlin of Moutain Ash, Ravenglass, Cumbria; defendants were British Nuclear Fuels plc, nuclear site licensees for the Sellafield reprocessing plant.

Both sides agreed that housedust in the property contained about 350 Bq kg⁻¹ actinides, attributable to discharges from the Sellafield plant; assessments of consequent dose and risk to the occupants diverged considerably.

The judge concluded that, since physical damage to the property had not occurred, the claim, made pursuant to the provisions of the Nuclear Installations Act 1965, must fail. Moreover, he indicated a strong preference for the defendant's assessment of resulting dose and risk, at no more than about 100 μ Sv yr⁻¹ (effective dose equivalent) or a risk of about 10⁻⁶ per year.

LEGISLATIVE BACKGROUND

In the United Kingdom, the Nuclear Installations Act 1965 is the primary legal instrument for regulating the operation of large nuclear installations. In addition to defining the regulatory framework, it also places a strict liability on the site licensee for any damage caused by nuclear matter (ie radioactive materials) handled on the site.

This strict liability had been tested in civil proceedings relating to damage to the health of employees (cancer cases), but prior to 1989 there had been no test of this provision in respect of off-site effects.

THE CLAIM

The plaintiffs in this case had lived in the village of Ravenglass, about 15 km south of the Sellafield nuclear fuel reprocessing site, since the early 1970s. Their house immediately overlooked the Ravenglass estuary, the sediments of which contained enhanced levels of fission products and actinides as a consequence of discharges from the Sellafield plant.

On two occasions, once in the late 1970s and subsequently in the early 1980s, the plaintiffs had samples of their housedust analysed for radioactivity. These measurements clearly showed the presence of radionuclides emanating from Sellafield, including the actinides plutonium and americium at combined concentrations of around 350 Bq kg⁻¹.

The plaintiffs expressed concern at these findings and decided to move from the village. They found their house difficult to sell and it did not realise the price they expected; the situation was complicated by the screening of a television documentary which raised a number of concerns regarding emissions from Sellafield, and which featured the plaintiffs and the issue of radioactivity in their housedust.

The plaintiffs then embarked on proceedings in the civil courts, citing the levels of radioactivity in their house and its alleged low value on the market as justification for a claim of damage to property under the absolute liability provision of the Nuclear Installations Act 1965.

The defendants conceded that concentrations of radionuclides in the housedust were at the levels pleaded by the plaintiffs, and that the fission product and actinide component resulted almost wholly from discharges from the Sellafield plant. They however contended that the property had not been damaged, nor had there been a significant risk to the health of the occupants. Surveys of radioactivity in housedust in the area, together with assessments of resulting doses (1,2) were cited; these showed that radionuclide concentrations in the plaintiffs property were at the high end of, but within, the range for other properties in the area.

The case was heard in the High Court in London during the autumn and early winter of 1989, taking some three months.

COURT EVIDENCE AND ARGUMENTS

The case involved argument both about points of law and about radiological protection science.

In regard to the law, the plaintiffs argued that any contamination of their property amounted to damage, that due to the contamination the premises ceased to be of any use or value as a home, and/or that they were obliged to sell the property at an under-value. In the alternative, they argued that there was a significant risk to health presented by radioactivity in the housedust and the property must thereby be damaged. The defendants contended that loss of value by itself was as pure economic loss not actionable; that no demonstrable physical damage to property had occurred and that there was therefore no basis for a claims. In the alternative, they contended that the risk to health from radioactivity in the house was so low as to be insignificant.

Much of the court's time was taken by considering the arguments regarding health risks. Experts for the plaintiffs and defendants had assessed the likely radiation doses and consequent risks to the occupants of the property; these assessments were a long way apart.

The plaintiffs suggested that doses as high as $10-20 \text{ mSv y}^{-1}$ to the lung could result, leading to a doubling of the lung cancer risk for a non-smoker spending a lifetime in the property; the defendants concluded that lung dose would not be the limiting factor, that doses were likely to be 0.1 mSv y^{-1} (effective dose equivalent) at most; and that lifetime risks were unlikely to exceed 1 in 10^4 . The only area of agreement was that intake of actinides, by inhalation or ingestion, was the most significant factor.

The technical arguments were structured by considering separately the intake of radionuclides; estimation of doses to organs and effective dose equivalent; and estimation of consequent risks.

The defendants estimates of intake rested on a simple model which supposed that the air in the house might contain $100 \mu\text{g m}^{-3}$ of suspended housedust and that a person might inadvertently ingest 100 mg d^{-1} of housedust. These figures emerged as reasonable from the earlier mentioned studies (1,2) and from other literature (eg 3,4). The plaintiffs adopted a quite different approach but their assumptions on intake were shown to depend on the dust suspended in air consisting almost entirely of fine estuarine sediment, with a specific activity many times that of housedust, and at a mass loading substantially in excess of $100 \mu\text{g m}^{-3}$. These assumptions produced erroneously high values for the activity concentration in air for houses in which both housedust activities and air concentrations had been measured (1,2); moreover studies specially commissioned by the defendants (5) provided support for the loading figure of $100 \mu\text{g m}^{-3}$, and showed that even the finest component of housedust ($<1.5 \mu\text{m AMAD}$) had a specific activity only twice that of the bulk sample.

For dosimetric calculations, the defendant's experts depended on standard dosimetric models (6,7). By contrast, the plaintiff's expert focused on the estimation of doses to lung. In particular, the plaintiffs expert argued that the current ICRP lung model is inadequate, particularly for alpha emitters, in that it calculates dose to the lung as a whole; since (it was argued) the bronchial epithelium, and in particular the epithelium at bronchial bifurcations, is the tissue in which lung cancers arise then the dose to this component must be estimated specifically. Much debate centred on this point, and the defendants commissioned an expert's report from the Task Group on Lung Dynamics, which has recently proposed a revised lung model to ICRP (8). The defendants conceded that the present lung model is too simple, but noted that much of the dose in their expert's calculations resulted from transfer of actinides out of the lung since class W behaviour (most conservative in ICRP 30 dosimetry) had been assumed. Moreover several aspects the plaintiff's non-standard estimate of dose to the bronchial epithelium were questioned and compared unfavourably with calculations carried out by the Task Group.

In assessing risks, the plaintiff's expert took their estimate of radiation dose to lung and derived a dose/risks relationship largely from a single study of Swedish iron ore miners (9), claimed to be more complete in terms of follow-up than other studies.

By contrast, the defendants experts took their lower estimates of dose (including dose to organs other than lung) and derived dose/risk relationships from the usual, much wider, range of epidemiological studies (eg 11,12).

THE JUDGEMENT

On the points of law, the judge concluded that the strict liability provisions of the Nuclear Installations Act apply only to personal injury or to physical damage to tangible property; they do not apply to economic loss or to the imposition of a risk to health, that is an enhanced probability of future personal injury. On that basis alone the judge concluded that he must find for the defendants.

However, lest his judgement on law should be reversed on appeal he gave an assessment of both the magnitude of damages, which he concluded to be substantially less than the plaintiffs claimed, and the scientific evidence. He concluded that the defendant's assessments of dose and risk were to be

much preferred and that the plaintiffs had failed to establish that the risk to health was anything other than trivial.

The plaintiffs did not appeal against the judgement.

CONCLUSION

It is impossible in a short paper to describe adequately the complex technical arguments in this case. It seems, on the face of it, incredible that a radiological assessment of the significance to be attached to two measurements of radioactivity in housedust could occupy two months in a court of law.

One of the reasons is that apparently simple assessments of this type are underpinned by an extensive structure of assumptions and models dealing with methods of assessing intake, dosimetry, and dose/risk relationships. Experts from both sides would agree that the examination of scientific evidence was thorough and thought-provoking.

In this case conventional radiological protection methodology carried the day, but significant questions were only partially answered, particularly in regard to the details of lung dosimetry and lung cancer aetiology.

M. CHRISTIAN BATAILLE

LA GESTION DES DÉCHETS NUCLÉAIRES À HAUTE ACTIVITÉ *LES RESPONSABLES POLITIQUES FACE AUX RISQUES DES RAYONNEMENTS IONISANTS*

L'étude des effets des rayonnements ionisants sur les êtres vivants a commencé il y a près d'un siècle et les premières normes internationales en ce domaine ont été édictées il y a plus de 60 ans.

Il ne s'agit donc pas d'un problème nouveau. Malgré tout, les responsables politiques qui sont en permanence en contact avec la population constatent régulièrement que la perception de ces risques par le public repose toujours en grande partie sur des éléments irrationnels.

Alors que le monde moderne vit de plus en plus au milieu des rayonnements ionisants, de la production d'énergie nucléaire, de la médecine ou de l'industrie, il apparaît toujours aussi difficile de communiquer sur ces sujets.

Or, les responsables politiques ont de plus en plus souvent à prendre des décisions, ou parfois à supporter les conséquences de décisions, que le public considère, à tort ou à raison, comme susceptibles d'entraîner des risques liés aux rayonnements ionisants.

Il faut d'ailleurs remarquer que cette situation n'est pas propre au nucléaire. Sur de nombreux points, nos sociétés contemporaines pourtant largement imprégnées par la science et la technique apparaissent à beaucoup de nos concitoyens comme moins sûres que les sociétés traditionnelles où les risques objectifs étaient pourtant plus nombreux et plus graves.

L'évolution des sciences et des techniques n'a pas comme on l'espérait encore dans les premières années de ce siècle, rendu le monde plus intelligible et moins inquiétant à la majorité des hommes.

Il existe même dans nos sociétés une étrange dissymétrie entre les dangers réels et la perception des risques pour la population.

Ce qui inquiète nos concitoyens, ce ne sont pas les accidents de voiture ou les maladies liées à l'alcoolisme ou au tabagisme qui font cependant des dizaines de milliers de morts chaque année, mais plutôt des menaces imprécises et mal identifiées liées à des techniques dont ils ne comprennent pas bien les tenants et les aboutissants.

Il y a des discours que la société est prête à entendre et d'autres pas.

Si nous nions - lors de la prise de décisions politiques - tous les aspects irrationnels qui déclenchent ces peurs et ces rejets, les réactions de nos mandants nous obligent alors souvent à réviser brutalement nos positions antérieures.

Il faut bien admettre que, dans l'ensemble, de ces peurs et de ces rejets les risques liés à la radioactivité tiennent une place à part quels que soient les efforts que déploient les autorités pour tenter de banaliser le nucléaire.

Dans un pays qui, comme la France, a relativement bien accepté le développement d'un programme nucléaire ambitieux, il est assez curieux de constater que tout ce qui concerne les rayonnements ionisants continue à susciter une inquiétude tout à fait particulière bien souvent totalement irréductible aux arguments et aux démonstrations des spécialistes et des experts.

Cela tient peut-être aux caractères spécifiques des rayonnements ionisants impossibles à voir et même à détecter avec des moyens ordinaires.

L'utilisation militaire de l'atome n'est certainement pas non plus étrangère à cette défiance envers des techniques qui peuvent aussi servir à des destructions massives.

Nous avons été, en France, confrontés il y a quelques mois à une réaction de rejet de la population qui a d'autant plus surpris qu'elle n'était pas conforme à l'attitude que nos concitoyens avaient en général adoptée jusque là, face au nucléaire.

Alors que le programme nucléaire français s'était développé pratiquement sans opposition, les tentatives d'implantation des laboratoires souterrains destinés à étudier le comportement des déchets nucléaires à haute activité en couches géologiques profondes ont été violemment contestés par une importante partie de la population.

Malgré de notables efforts de communication, ni les experts scientifiques, ni les dirigeants des organismes chargés de la gestion des déchets nucléaires n'ont réussi à convaincre les populations concernées du peu de dangers objectifs que présenterait l'enfouissement des déchets nucléaires et le gouvernement a dû se résoudre à suspendre les travaux de recherche.

Les responsables politiques français se sont donc retrouvés tout à coup confrontés, sans y être véritablement préparés, aux problèmes posés par la perception des risques des rayonnements par le public.

Or, ces problèmes posent un véritable dilemme à ceux qui sont en charge de la conduite des affaires de l'Etat :

- faut-il tenir compte des craintes, même irrationnelles de la population ?
- ou faut-il au contraire privilégier la poursuite du développement de l'industrie nucléaire ?

Même si elles ne sont pas toujours scientifiquement justifiées, les craintes de la population face aux risques des rayonnements sont un fait qui s'imposera de plus en plus aux responsables politiques d'autant que les experts sont pour le moment incapables de fournir une explication simple et rassurante sur les effets stochastiques des faibles doses de radioactivité.

Quelle serait en effet la responsabilité des gouvernants s'il s'avérait un jour que les faibles doses de rayonnement qu'ils ont autorisé avaient des effets pathogènes irréversibles ?

Mais d'un côté, il faut bien, à partir du moment où l'on accepte le recours à l'énergie nucléaire, tolérer certains rejets radioactifs dans l'environnement.

Les responsables politiques doivent donc en permanence arbitrer entre ces deux contraintes tout en s'efforçant d'améliorer l'information du public.

Placé dans une situation de blocage pour lesquels les mécanismes habituels de négociations se révélaient inopérants, le Gouvernement a alors exprimé le souhait que l'Office parlementaire d'évaluation, organisme qui dépend uniquement du Parlement, procède à une étude et recherche les solutions susceptibles de permettre la reprise du dialogue avec les populations concernées.

Au cours de cette enquête qui a duré sept mois, toutes les opinions ont été entendues sans exclusive et sans limitation.

Il ne s'agissait pas pour le rapporteur de l'Office de tenter de refaire les multiples travaux scientifiques existants mais plutôt d'essayer de comprendre pourquoi la peur de la radioactivité pouvait conduire au rejet d'un projet présenté comme sûr par pratiquement tous les experts.

Il est très rapidement apparu qu'une des causes de cette attitude négative tenait à l'ignorance dans laquelle on avait tenu nos concitoyens vis-à-vis des problèmes de radioprotection.

Je connais bien les efforts que des organismes comme l'Association Internationale de radioprotection ou comme la Société française de radioprotection font depuis plusieurs décennies pour informer le public sur les notions de base de la protection contre les rayonnements ionisants mais les contacts que j'ai pu avoir sur le terrain m'ont démontré que l'information en général ne passait pas.

Selon moi, cet échec ne doit pas être imputé aux spécialistes, qui un peu partout dans le monde font correctement leur travail, mais aux responsables politiques qui n'ont pas pris les dispositions nécessaires pour que l'information sur la radioactivité puisse effectivement atteindre le grand public et être acceptée par lui.

Pour qu'une information passe dans une population, il faut en effet que celle-ci soit apte à la recevoir et qu'elle ait confiance dans ceux qui la délivrent.

Comme le notait l'Académie des sciences française : "De tous les agents potentiellement toxiques de notre environnement, les rayonnements ionisants sont sans doute ceux dont les effets sont les mieux connus et qui font l'objet du plus grand nombre de travaux expérimentaux et d'enquêtes épidémiologiques".

Cela est parfaitement exact mais il n'en demeure pas moins que la perception des risques éventuels pour la population ne correspond pas aux messages que les autorités et les experts souhaitaient faire passer.

La première raison tient certainement à l'insuffisance de la formation initiale des individus sur tout ce qui concerne la radioactivité. Alors que nous vivons et que nous vivrons dans un monde de plus en plus nucléarisé, la majorité

d'entre nous ignore jusqu'aux bases mêmes de la radioactivité, d'où une exclusion de fait des débats et un rejet en bloc des arguments des experts.

Un sondage effectué en France il y a quelques années a d'ailleurs montré que l'inquiétude vis-à-vis du nucléaire diminuait à mesure que l'on se rapprochait d'une installation nucléaire, certainement parce que les habitants sont alors mieux informés de la réalité des risques.

La deuxième raison qui est peut-être en grande partie spécifique à la France c'est que toutes les questions qui concernent les risques des rayonnements ionisants n'ont pas été traitées avec suffisamment de transparence et de démocratie.

Les questions ont longtemps été considérées comme un problème purement technique qui devait donc être traité entre spécialistes dans la discrétion, voire la dissimulation.

Les faits ont montré que c'était une erreur et qu'elles étaient devenues en peu de temps un problème de société.

Très fréquemment désormais, en France et dans les autres pays économiquement développés, des choix que l'on considérerait d'ordre technique donnent tout à coup naissance à des controverses d'ampleur nationale.

Les administrations en charge du dossier constatent souvent avec retard que certains problèmes ne peuvent être résolus par la seule approche technique et qu'il faut solliciter le niveau institutionnel et politique pour prendre position, ou au besoin pour arbitrer.

Dans les démocraties modernes, certaines dispositions contraignantes ne peuvent être imposées, s'il n'existe pas de consensus, qu'après un large débat où tous les intérêts, toutes les opinions ont pu se faire entendre.

Cela ne veut pas dire que les scientifiques et les techniciens, tous ceux qui savent doivent être écartés du débat mais simplement que d'autres arguments que les leurs doivent aussi se faire entendre.

Le débat entre hommes de science ne peut prendre en compte que des analyses rationnelles construites à partir de faits prouvés. En sont donc exclus les risques hypothétiques ou non démontrables, les peurs irrationnelles, et même l'éthique et la morale.

Le monde change, le citoyen ne reste plus passif devant les choix faits par d'autres qu'on voudrait lui imposer. S'il est mal informé des enjeux véritables, il se réfugie dans une opposition aveugle et souvent violente.

Parmi les problèmes de civilisation qui vont se poser de façon cruciale dans les années qui viennent, le nucléaire tiendra certainement la première place.

Le mystère qui entoure encore cette forme d'énergie mais aussi le goût du secret qui a été cultivé pendant trop longtemps par ses responsables font qu'aujourd'hui la France, après la plupart des autres pays développés, risque de se trouver dans une impasse.

Il n'y aura pas de poursuite du programme nucléaire sans une très large acceptation de la population.

En conclusion, je reprendrai les observations que j'ai présentées au Parlement français dans mon rapport sur les déchets nucléaires à haute activité.

Responsabilité, transparence et démocratie sont les mots qui doivent désormais guider notre démarche pour tout ce qui concerne la radioactivité et en particulier dans le domaine de la radioprotection.

RESPONSABILITÉ : car les responsables politiques doivent réellement s'impliquer dans ces questions qu'ils avaient par trop tendance à abandonner aux spécialistes. Ces derniers bien entendu doivent pouvoir continuer à déterminer librement les critères scientifiques de la protection des populations et de l'environnement mais c'est aux hommes politiques de fixer les règles qui sépareront clairement ce qui est interdit de ce qui peut être toléré.

Une politique de radioprotection doit s'appuyer sur des données techniquement et scientifiquement fiables et rigoureuses mais elle doit aussi s'attacher à ne mettre en oeuvre que des solutions socialement et politiquement acceptées.

TRANSPARENCE : les années 90 doivent marquer la fin de la culture du secret en matière nucléaire, les origines militaires de cette industrie expliquent peut-être cette persistance agaçante d'une culture du secret qui ne se justifie plus quand la quasi totalité des habitants du pays développé bénéficie déjà de l'énergie nucléaire. Nous avons besoin désormais d'une approche transparente.

DÉMOCRATIE : car jusqu'alors une méthode autoritaire et administrative a souvent prévalu. Elle a pu correspondre au début du développement de l'énergie nucléaire. Sans remettre en doute la capacité des chercheurs et techniciens, elle a comporté le risque de céder à un vertige technologique et scientiste. Aujourd'hui les choses sont différentes, le public exige des informations et demande à contribuer aux décisions. **IL FAUT DONC DÉSORMAIS EMPRUNTER UN CHEMIN DIFFÉRENT** faisant appel aux ressources de la démocratie et de l'information. A cette forme sophistiquée de production d'énergie qu'est le nucléaire doit correspondre un processus ouvert de décision.

L'avenir de l'énergie nucléaire dépend de notre capacité à développer la Démocratie.

**Information for the public on nuclear safety in the
European Community: Regulations and Practices**

**H. ERISKAT – D. TEUNEN
Commission of the European Communities
DG XI-A-1 Radiation Protection**

La Commission Européenne est active dans le domaine de l'information en radioprotection pour le public:

- par un instrument légal, contraignant pour les Etats Membres, c'est à dire la directive information en cas d'une urgence radiologique (89/618/EUR),
- par des actions de support, comme des vidéos, brochures, etc.

* * *

This paper describes the work of the Commission of the European Communities in training and information in radiation protection.

The radiation protection has a long European pedigree.

In 1957 the Euratom Treaty established the European Atomic Energy Community, and one of the principal tasks attributed to the Community in the field of radiation protection was the preparation of uniform safety standards for protection of the population and of workers, and the monitoring of their application.

Training and information have remained and will continue to remain an integral component of the Standards. This Community precedent has led to radiation protection being taken as a model in other sectors.

Since 1975 the Commission has also organized conferences on training and information, attended by radiation protection specialists, and by representatives of the competent authorities and of the trade unions.

At the same time opinion polls on the risk perception by the population on the degree of satisfaction with information on radiation protection was performed in 1988 and 1989.

These consultations resulted in several support actions, such as the informative booklet "Radiation and You", videotapes, etc.

The Commission's action as regards public information is likewise based on the Euratom Treaty and on a legal instrument, responsibility for the matter having been conferred on the Commission by the Council Directive of 27 November 1989 on informing the general public about health protection measures to be applied and steps to be taken in the event of a radiological emergency (89/618/EUR). This directive seeks to define common objectives for informing the general public about health protection measures to be applied and steps to be taken in the event of a radiological emergency, and is partially based on the experience gained by the Commission with the so-called Seveso directive of 24 June 1982 on the major accident hazards of certain industrial activities (82/501/EEC). The deadline for implementing was 27 November 1991.

This public information obligation is specified in articles 5 and 6 of this Directive.

Article 5.1 reads,

Member States shall ensure that the population likely to be affected in the event of a radiological emergency is given information about the health-protection measures applicable to it and about the action it should take in the event of such an emergency.

The purpose of this provision is clearly not to define the geographical areas concerned, but to ensure that information is provided only if the authorities can assure the population that adequate measures have been planned. The population should be informed only if it is covered by an intervention plan.

Article 6 reads:

Member States shall ensure that, when a radiological emergency occurs, the population actually affected is informed without delay of the facts of the emergency, of the steps to be taken and, as appropriate to the case in point, and of the health-protection measures applicable to it.

In the event of a real radiological emergency, information must be provided systematically, rapidly and openly in order to encourage the population actually affected to adopt the appropriate behaviour. This cannot be achieved without obtaining the confidence of the population.

As laid down in Article 6(1), the information must be provided without delay, since lack of information and ignorance of the facts may produce anxiety and unforeseeable reactions on the part of the general public. The Member States can therefore, if appropriate, begin informing the population at the pre-alarm phase.

The most direct sources of information should be used (national, regional and local press and radio, television, direct answers by telephone and, if appropriate, computerized magazines such as teletexts).

Every step should be taken to ensure that sources of information are not giving contradictory information, e.g. by creating or appointing a national information dissemination agency with a coordinating function.

Overview of the implementation of the Directive 89/618/EURATOM.

Here we summarize, as an example, the situation in some E.C. countries:

Federal Republic of Germany

The legislation on planning for emergencies states that the Länder are responsible for establishing emergency plans. In 1975 (an updated version appeared in 1988) they negotiated with the Federal Government the "framework recommendations for contingency planning in the neighbourhood of nuclear installations", which set out the criteria to be met by emergency plans, as well as the warnings and information to be given to the public in the event of an accident.

Belgium:

The province governors are the competent authorities in the event of emergencies.

A national emergency plan which has been adopted on..... serves as a model for the various existing provincial emergency plans. Since the national emergency plan has been published, the population is able to familiarize itself with the broad outlines of the emergency plan. The national plan provides for both prior information and information in the event of an accident.

France:

Article 5 (prior information)

Information brochures have been distributed in the region of the 25 nuclear sites. The authorities think that this information campaign should be repeated every five years in view of the mobility of the population.

Since 6 May 1988 all the intervention plans specific to given installations are available for consultation at the relevant Prefectures and town halls. Information in schools in certain regions of France with nuclear installations can constitute an example of prior information, since the process must start with the very youngest children.

Article 6 (information in the event of an emergency)

By virtue of a decree adopted in mid-May 1990, the authorities can use the radio stations on the basis of agreements concluded with them.

A nuclear event scale has been adopted to facilitate relations with the media. It applied to power plants and has been extended to other fuel-cycle installations.

Ireland:

A non-regulatory, administrative emergency plan has been drawn up setting out the responsibilities of each ministry. This will be published and made available to the public.

In the event of an accident, an inter-ministerial expert committee would be convened to draw up communiqués to the Government on the question of information.

Portugal:

The Emergency plan is the responsibility of the National Service for Civil Protection. Public information is the responsibility of the Committee on Protection against Ionizing Radiation and the regional health authorities.

The Ministry of Environment is responsible for information on transfrontier emergencies.

United Kingdom:

The Department of the Environment is responsible for emergency measures in the event of an accident outside British territory, while the Department of Energy is the responsible body in the event of an accident occurring on British territory.

Conclusions

From this brief overview it can be concluded that:

- in the majority of Member States specific regulations are being drafted governing information for the public on radiation protection; this should result in a better coordination between national and local authorities involved;
- the communication technology necessary for achieving the aims of the Directive has to be established or developed;
- a suitable terminology has to be developed to ensure both transparency of information and an understanding of the various levels of risk, without over-dramatizing the situation.

The initiatives already taken included such appropriate measures as agreements with the media, the establishment of a nuclear event scale and the publication of emergency plans.

Ref: Council Directive of 27 November 1989 on informing the general public about health protection measures to be applied and steps to be taken in the event of a radiological emergency (89/618/EUR).

L'intégration des valeurs sociales et éthiques dans la gestion du risque radiologique

Thème n° 2 : La perception des risques des rayonnements

Présentation : orale

Les modalités de gestion du risque radiologique à une époque donnée traduisent à la fois l'état des connaissances sur les effets des rayonnements mais également les idées dominantes concernant la perception et les pratiques sociales en matière de contrôle des risques en général. Ainsi, après avoir été dominé pendant plusieurs décennies par le modèle du seuil, une évolution profonde s'est opérée avec l'adoption du paradigme de l'optimum à la fin des années soixante-dix. Les développements les plus récents montrent cependant la nécessité de dépasser le strict plan de la rationalité économique pour inscrire la gestion du risque radiologique dans le cadre plus large de l'acceptabilité sociale des risques industriels et technologiques.

De ce point de vue, l'expérience montre qu'au-delà d'une réelle complexité, les phénomènes d'aversion au risque, ainsi que les attitudes sociales face au temps et à l'équité se retrouvent dans de nombreuses situations auxquelles les responsables de la radioprotection doivent faire face. Bien qu'il apparaisse indispensable de traduire en termes pratiques ces facteurs, à ce jour, les tentatives d'intégration dans la gestion du risque radiologique restent limitées et peu probantes.

L'objectif de la communication est de proposer une démarche, pour essayer de remédier à cette situation, qui s'appuie sur les travaux entrepris au CEPN dans le cadre d'un contrat de recherche supporté par la Commission des Communautés Européennes (DG XII). Bien qu'encore parcellaires, les premiers résultats permettent de dégager quelques principes généraux quant à la démarche méthodologique. Des exemples relatifs au traitement de l'aversion et au temps sont présentés à titre d'illustration.

'AT-A-GLANCE' BROADSHEETS, AN APPROACH TO PUBLIC INFORMATION

M J Gaines

National Radiological Protection Board,
Chilton, Oxfordshire, UK

ABSTRACT

The At-a-Glance series of broadsheets uses illustrations as the main information carrier but is underpinned by the results of scientific work. The clarity of the presentation, together with attractive design and printing and the association with science, has produced publications with great appeal to laymen. Some 500,000 broadsheets have been produced, many to meet the demand for bulk supplies for other organisations.

INTRODUCTION

NRPB has a well-established system of publications but most of them are far too technical for laymen. Even the booklet, 'Living with Radiation', is too advanced for the non-scientist, although it does provide a useful introduction for other technical, non-radiation protection, professionals. To avoid the jargon of radiation protection, NRPB therefore created the 'At-a-Glance' series of broadsheets in which illustrations are used to communicate most of the information - they are not just used to support text.

A major means of communicating the scientific output of NRPB is often a conference paper or a journal article, and therefore the organisation is very experienced in the use of visual aids. When we were considering how best to improve our communications with laymen, particularly people such as elected representatives on local authorities, we determined how best to use the skills we already had in presenting quantitative information visually. The idea of a series of broadsheets, in which visual materials dominate, was developed in 1989 and the first in the series was published towards the end of that year. Since then, over 500,000 have been produced.

THE MAIN SERIES

The series has developed over this time but the illustrations remain the principal means of telling the story, with the captions supporting them; and - equally important - each one is underpinned by the science.

Initially, four broadsheets were produced. Two of these are about broad aspects of radiation protection and two are about NRPB.

With the title 'Radiation Protection', one leaflet summarises the basic ideas of radiation protection as a starting point for other leaflets in the series. The ideas are grouped under sequential headings: atoms, radiation and radioactivity, radiation and tissue, radiation effects, harm and sensitivity, radiation protection principles, radiation protection in the UK, and how effective?

'Radiation Doses - Maps and Magnitudes' shows visually the main sources of radiation exposure, natural and man-made, and the average and the range of doses. The enormous variation in doses across the country is lucidly set out - indeed, one of the aims of the leaflet is to help lay readers to appreciate just how great the variation is. The graphics are based mostly on data contained in an NRPB report⁽¹⁾.

In 'NRPB at a Glance', pictures of NRPB staff at work are arranged under a linked series of scientific ideas: source of radiation exposure, environmental transfer, doses to people, dose distribution, and estimation of health effects; NRPB's role in standards is summarised.

'Partners in Protection' illustrates the way NRPB works with the

European Communities, industry, local authorities, central government, other professionals, etc. It is a striking characteristic of NRPB that it acts as a focal point for a large and varied number of organisations.

In 1990 a fifth broadsheet, 'Radon', was published. It describes the characteristics of radon, the means by which it builds up in homes, the nature and level of the risks, the remedies and preventative measures, and the problems posed by and solutions to radon in the workplace.

In 1991, four more broadsheets, were published.

'Transport of Radioactive Materials' summarises the use of radioactive materials to explain why transport is essential. It then describes the types of packages and containers used, outlines the modes of transport, and illustrates with pie diagrams and bar charts the radiation doses received during routine transport operations and those arising from accidents; these illustrations are again based on data in NRPB and other publications^{(1),(2),(3)}.

'Non-ionising Radiations' illustrates the types of sources of these radiations across the electromagnetic spectrum, the biological effects and the protection measures available, and the magnitude of the emissions and exposures produced.

'Nuclear Emergencies' summarises the types of accidents that can occur, the countermeasures that can be introduced, the standards that apply and the monitoring and detection techniques available. Emergency plans are outlined and the responsibilities of the various Government bodies listed. The National Arrangements for Incidents Involving Radioactivity are described.

'Medical Radiations' starts with a cover illustration that illustrates the caring face of radiation in medicine. It summarises the way in which x-rays are used, how staff are protected, how x-rays help in diagnosis, how patients are protected, how radioactive materials are used in diagnosis, and how radiotherapy is used; it also describes magnetic resonance imaging and summarises the role of NRPB. The bar charts are based on various NRPB studies^{(1),(4),(5)}.

Although not in exactly the same mould, the 'Radiation Atlas of Western Europe' (published 1992) is an atlas of natural radiation levels - cosmic, indoor gamma, outdoor gamma and radon. It contains maps derived from a report⁽⁶⁾ prepared by NRPB for the CEC from data produced by various researchers in western Europe. Others in the series are in production.

'RADIATION AT WORK' SERIES

A broadsheet, 'Low Specific Activity Scale in the Oil Industry', has been produced. It is intended for workers in the industry and deals with the problem of 'LSA scale' which collects in parts of oil installations. The new publication is the first in a new series dealing with the problems of radiation at work, and was suggested by staff of an oil company who had seen some of the NRPB's 'At-a-Glance' series.

The publication describes the hazards of LSA scale, shows how it can be detected and measured, and indicates the sort of precautions and procedures necessary. It also shows that radiation doses to workers close to LSA scale are much lower than doses to other workers such as industrial radiographers, nuclear industry workers and air crew. Indeed, the average off-shore worker receives a lower radiation dose than the average person in the UK because he does not inhale so much of the naturally occurring radioactive gas radon while he is on the oil rig.

One more in this series is in production and others are planned.

SLIDE SETS

The popularity of the 'At-a-Glance' series, and the requests we have had for slides based on them, has encouraged the Board to mass-produce standard sets of slides based on the series. Generally, they are supplied in batches of twenty, with a copy of the broadsheet and captions for the slides. In this way, slide sets are being produced for 'Maps and Magnitudes', 'Radon' and 'Non-Ionising Radiations' broadsheets.

GRAPHICAL TECHNIQUES AND BELIEVABILITY

A recent publication has pulled together the expertise of social scientists, scientists and public relations professionals to provide a practical guide to communicating with the public⁽¹⁾. With this publication in mind, and assuming that the science is correct, it is instructive to examine how graphics should be used to encourage people to believe scientists in this cynical age.

Firstly, the illustrations should communicate; if possible they should have impact, like the three-dimensional radon map, but that is not always possible. However, we have the data to relate a topic like radon to everyday life and this is shown in the three graphs showing how radon levels vary from season to season, from day to day, and from hour to hour as windows and doors are opened and some escapes from the house. These graphs are average values of several hundred houses and there are no false zeros - radon concentration really does vary to this degree, day to day.

The illustrations should clearly inform. Hopefully they all do - the broadsheets have been described as 'information-packed'.

The illustrations should also explain, and this they seem to do in relation to a variety of topics. They are also used to separate assumption (the linear relationship) from fact (which it is not) and they are used to show a practical item such as the ease of introducing remedial measures for radon.

The illustrations should also clarify, and an example is the 'Nuclear Emergencies' broadsheet which clarifies important, complex situations.

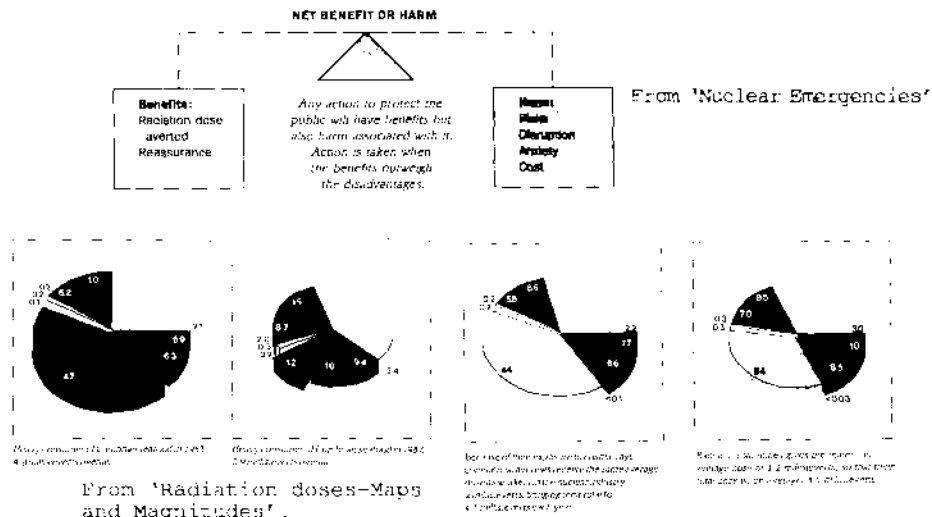

The illustrations should also tell the truth, as far as that can be determined, and a particularly good example is the 'Transport of Radioactive Materials' broadsheet; the charts on accidents hide nothing.

The illustrations should also compare like with like, for instance the pie diagrams in 'Maps and Magnitudes', or the bar charts of doses to workers in that publication and in 'Medical Radiation'.

All of this is important for the 'believability' of the broadsheets.

From 'Radon'

Have they been successful? The public takes into account many factors in relation to risks. For instance it is less concerned about those that are familiar and understood; and it is also less concerned when the institution is responsible for controlling the risk is seen as trustworthy. Scientists as a group are held in high regard and clear explanations are appreciated. In using the At-a-Glance series to explain radiation protection NRPB hopes it has helped the public to become at least interested and informed, and possibly enabled it to form its own opinion. The demand for the broadsheets - 50% of them have been sold to local authorities, nuclear industries, research institutes, etc, and the feedback that we have had from them and other organisations, schools, health authorities, regulatory bodies and the general public - indicates some success; but we continue to learn and we will continue to improve the series.

CRITERIA FOR THE COMPENSATION OF RADIATION INDUCED
HEALTH DISORDERS IN CZECHOSLOVAKIA

V. Klener, + J. Ševc, V. Plaček¹

Centre of Radiation Hygiene
Institute of Hygiene and Epidemiology, Prague
Institute of Occupational Hygiene in Uranium Industry, Píbram¹

ABSTRACT

Radiation-induced health disorders and specifically lung cancer due to radioactive substances are included in the enumerative list of occupational diseases in Czechoslovakia. A compensation for the deterministic effect is based on the evidence that the threshold dose in target organ was exceeded. For the judgment on the compensation for cancer the calculation of the causation probability is adopted as a helpful tool. It is shown on the example of lung cancer in uranium miners how the criteria changed during decades depending on new biological and epidemiological data.

INTRODUCTION

According to Czechoslovak laws only such health disorders can be compensated which are included in the official list of occupational diseases. Two items of this list are related to radiation effects, namely the lung cancer due to inhalation of radioactive substances and another rather broadly defined affection: radiation induced health disorder. Compensation in Czechoslovakia is administratively based on the certificate issued by a regional clinic (department) of occupational medicine, while the evaluation of working conditions is carried out by an officer of national hygienic service.

DETERMINISTIC EFFECTS

The criteria for granting the status of an occupational disease and a compensation can be rather clearly defined for the deterministic type of health disorders as e.g. the cataract of the eye or chronic radiation dermatitis, which from time to time are claimed for as a conjunctural results of previous occupational exposure. If an authorized expert can give evidence that under specific working conditions of the claimant the threshold dose in the target organ could have been reached, then the status of an occupational disease could be sanctioned.

STOCHASTIC EFFECTS

Quite different approach should be applied in litigations for malignant diseases in radiation workers. In Czechoslovakia we gained a longlasting

experience with lung cancers in uranium miners. In the review of Ševc et.al. (1988) 484 lung cancers were found within a well defined cohort of about 4000 miners exposed to high levels of radon daughter products between 1948-1957 and followed up systematically up to now. From the sixties many claims for compensation for lung cancer began to be submitted for expert judgement each year and the setting of unified criteria became urgent. In the course of years the approach to the assessment of a possible relationship between lung cancer and working conditions changed and the history of this development seems to be rather illustrative.

The recommended criteria for granting a compensation were first agreed upon on a seminary of experts in occupational medicine in 1961 and were based on the duration of work in uranium mines. The condition for qualifying a lung cancer as an occupational disease set at four years of underground work was derived empirically from the results of a pilot study evaluating in retrospective the causes of death in earlier miners from the area of Joachimstal within 1918-1938. In this group of miners the shortest exposure period of eight years was found, and using the arbitrary safety coefficient of two the four-year minimum exposure was settled.

In the middle of sixties a substantial reconstruction of ventilation systems in uranium mines was started and the concentrations of radon daughters decreased systematically during the following years. It appeared that the criterion bound to the duration of exposure does not mean a comparable additional risk to workers exposed in different calendar periods. It became apparent that a new criterion bound to cumulative exposure should be looked for. This idea was connected with the fact that in these times a new registration system of individual exposures of uranium workers was introduced. On the basis of this registration system the individual cumulative exposure to radon daughters in working level month (WLM) units could be identified together with the external gamma doses and served as a source for the assessment of exposure. In this period of time it seemed to be appropriate to determine, from epidemiological data, such a level of cumulative exposure below which the incidence of lung cancer was not significantly different from the spontaneous one. Such analysis resulted first in a tentative criterion of 100 WLM of cumulative exposure, later 25 WLM. The latter value reflected the findings in the youngest age group as to the start of work in uranium industry.

Another approach was adopted in the transient period in the late sixties, when the maximum yearly exposure was limited to 3 WLM and when the cumulative exposure of uranium miners began to decrease. In this situation a worker could hardly reach the critical value of 25 WLM. With the idea to mitigate the decreasing chance for compensation a combined criterion was introduced taking into account both the WLMs and the duration of underground work. A scoring system was implemented where the points for exposure (one point for each 3 WLM) and the points for the period of work (one point for one year) were summed up. Depending on the age, the critical values of the score for granting compensation were 11, 14 and 16 points for the ages up to 40, 41-50 and above 50 respectively.

In the course of eighties many new quantitative data on dose-effect relationship for radiation-induced lung cancer were collected leading to the calculation of absolute and relative risk coefficients. Thus a way has been opened for probabilistic approach in litigations for malignant diseases. We tried to follow this way, but at first we could not find any partner for the discussion on this matter. On the international scale this topic appeared first in 1983 at the 7. International Congress of Radiation Research in Amsterdam (Bond, V.P., Jablon, S., Catlin, P.J.). In the meantime the U.S. experts elaborated very valuable radioepidemiological tables (Rall, J.E., 1985) commented in the publication of an Oversight Committee (Mosteller, F., 1984).

In the Czech Republic a new procedure of eligibility for compensation was adopted which uses the new data from Czechoslovak epidemiological studies, and is based on probabilistic approach (Ševc et. al. 1989). The granting of social privileges connected with occupational disease is based on the estimate of causation probabilities given by the formula

$$PC = \frac{R}{O + R} ,$$

where R is the relative risk of cancer induction, O the spontaneous risk (O=100%). For the calculation of PC age-related relative risk coefficients are used which resulted from the epidemiological data. Three values of the relative risk coefficient are used as follows:

- age at start of work up to 29 years 5.7% per 1 WLM
- 30-39 years 3.5% per 1 WLM
- 40 y and above.. 2.1% per 1 WLM

The value of R for input into the formula is calculated as a multiple from these relative risk coefficients and the data of individual exposure in WLM. In accord with the findings of many epidemiological studies the registered cumulative exposure is lagged as follows: the exposure accumulated during the last five years before the manifestation of a cancer is omitted, and for the exposures received earlier than 15 years ago only a half of the registered value is taken in the calculation. The calculated value of PC is used as a criterion for granting compensation. With the value of $PC > 0.5$ the compensation is unequivocally allocated. In the range of $0.4 < PC < 0.5$ some supporting factors, such as the duration of underground work or the violation of the safety rules from the part of the organization, can qualify the worker for compensation. The claimants not reaching the value of $PC = 0.4$ are excluded from the benefits connected with the status of an occupational disease. This approach is applied not only to the uranium workers, but also to the workers in non-uranium mines with high concentrations of radon daughters in the air.

We are aware of that a perfect and fully just system could not be developed for the social security of workers suffering from occupational induced cancer. Our review should document how the approaches changed during the time in the effort to found an optimized way reflecting the new radiobiological and epidemiological data. In principle we use a similar, i.e. probabilistic, approach for the analysis of other types of cancer submitted for expert judgement as occupational diseases.

PERCEPTION DU NUCLEAIRE ET COMMUNICATION.

Alain MOREAU

Assistant Communication.
Direction du Centre d'Etudes de Saclay.
CEA - FRANCE.

NUCLEAR PERCEPTION AND COMMUNICATION.

Summary : There are three types of interrogation in nuclear communication.

The first type concerns hygiene : "what risks are you making me run ?"

The second concerns the perception of research and industrial activities, which corresponds to the categories : **Mystery, Magic, Power**, expressed in the following way : "You are mysterious", "aren't you sorcerer's apprentices ?", "You decide everything, you are party and judge".

The third concerns the choice of society in Nuclear Energy.

In all of this, technical reasoning alone is insufficient. It's the way it's done that counts. It's the way of **listening**. Our tools of communication must be forged with this in view.

La communication dans le domaine du risque radiologique est réputée difficile.

Elle est pourtant essentielle, en situation normale pour aborder le domaine de la perception du risque et celui des comportements, et, en situation de crise, pour éviter les phénomènes de rumeur ou de panique.

La communication est un véritable outil de sécurité.

Dans ce domaine, l'accident de Tchernobyl a été une leçon en France. L'impression majoritaire dans la population a été de ne pas avoir été informée, bien que les données concernant les niveaux de retombées aient été fournies.

En avril 1987, le Premier Ministre du Gouvernement français a énoncé le principe de "la transparence de l'information sur la radioactivité dans l'environnement" en soulignant que "toute l'information en ce domaine doit être accessible".

Mais c'est la façon avec laquelle nous communiquons, l'attitude que nous adoptons dans les relations que nous établissons avec le public qui sont à préciser et qui ont conduit à des réflexions ainsi qu'à des orientations au CEA et au Centre de Saclay.

COMMUNICATION ET INFORMATION

Communiquer et informer constituent deux démarches différentes. Etymologiquement, communiquer, c'est "rendre commun" : cela suppose un échange, lors d'une mise en relation ; informer, en revanche, est une démarche unidirectionnelle qui ne suppose pas de retour.

Nous avons, en général, de bons outils d'information : plaquettes, journaux, expositions, émissions de télévision... et cela est indispensable.

Mais nous sommes moins préparés pour les échanges que suppose la communication.

Très souvent, devant les difficultés, nous nous limitons à la question "Comment faire pour que le public nous comprenne ?" "Comment faire pour qu'il nous écoute ?" "Comment faire pour passer notre message ?"

Mais nous-mêmes, sommes-nous prêts à écouter ? à recevoir le message ? à comprendre ?

L'**attitude d'écoute** est d'autant plus importante dans le domaine de la perception du risque radiologique que nous quittons le domaine de la technique, de l'objectif et du rationnel, pour entrer dans celui de l'**émotion** et de l'affectif. Fondamentalement, nos interlocuteurs n'ont pas tant besoin d'acquérir des connaissances, des données, des chiffres, que d'être déchargés, débarrassés des tensions qu'ils peuvent ressentir, centrées sur l'émotion fondamentale qui est la peur.

Même si cette émotion est objectivement injustifiée de notre point de vue, elle n'en est pas moins présente avec ses raisons d'être, et il nous faut l'accepter et la reconnaître.

L'état de tension, l'état émotionnel entraînent le besoin de s'exprimer, d'être écouté. C'est l'expression, c'est-à-dire donc, **notre** écoute, qui permet la détente, condition d'une vision plus juste de la situation et d'une perception du risque plus équilibrée.

LES THEMES D'ECHANGES

Au CEA Saclay, l'expérience nous a montré que les échanges en sécurité radiologique, dans une situation relationnelle avec le public, se rapportaient à trois grandes familles d'interrogations :

Le premier niveau d'interrogations, le plus immédiatement abordé, se rapporte aux questions sanitaires : "Quels risques me faites-vous encourir ?"

Le second niveau se rapporte à la perception des activités de recherche et des activités industrielles du nucléaire. Cette perception est marquée par les catégories : **Mystère, Magie, Pouvoir**, qui s'expriment respectivement sous les formes suivantes : "Vous êtes mystérieux". "N'êtes-vous pas des apprentis sorciers ?". "Vous décidez de tout, vous êtes juge et partie."

Le troisième niveau concerne le "choix de société" sur le thème de l'énergie nucléaire.

Le premier niveau est le niveau "prise de contact" et doit, bien évidemment, être traité. Il doit conduire à l'apport d'informations sur le risque radiologique, sans chercher à convaincre, à rassurer à tout prix.

Il est indispensable de traiter le second niveau, même s'il paraît nous éloigner des sujets sanitaires. Nous le faisons surtout par le choix de notre attitude : des affirmations péremptoires, des certitudes assénées, une certaine exaltation de réalisations techniques peuvent induire, par réaction, le doute et, sinon la méfiance, du moins la réserve ainsi qu'un sentiment d'un monde différent et mystérieux.

Le troisième niveau, celui du choix du Nucléaire, nous dépasse en tant qu'experts puisqu'il concerne le citoyen, mais il nous faut garder à la conscience que cette question demeure présente.

DES OUTILS DE COMMUNICATION

C'est dans une logique d'écoute concernant ces familles d'interrogations qu'ont été réalisés des montages vidéo relatifs à la perception du risque, la protection de l'environnement, les plans de crise et les déchets nucléaires.

La parole est donnée aux habitants voisins, à nos partenaires administratifs, aux organisations écologistes ... Ce n'est pas seulement le CEA qui parle.

Ces outils sont faits pour aider aux échanges dans les réunions, pour jouer un rôle débridant en levant les inhibitions, en nous présentant prêts à recevoir toutes les remarques, y compris les remarques désagréables ou mettant en cause notre point de vue.

L'attitude d'écoute peut être symbolisée par le schéma ci-dessous :

A

B

Il ne s'agit pas d'approuver forcément les propos de l'interlocuteur, mais de lui montrer que son point de vue est pris en considération au même titre que le nôtre.

C'est l'attitude indispensable pour créer l'**indispensable climat de confiance et être, à son tour, écouté.**

ABSTRACT

An additional handbook for determining tissue doses from the upper gastrointestinal (GI) fluoroscopy examination is now available and a similar handbook addressing computed tomography (CT) examinations is being developed. Also, a complete recomputation of tissue-air-ratios is underway for revising the handbook currently available for common radiographic projections. All three efforts utilize a Monte Carlo radiation transport code and current anthropomorphic reference adult male and female phantoms.

COMPLETED HANDBOOK ON UPPER GI FLUOROSCOPY EXAMINATION

The handbook of tissue doses for the upper gastrointestinal fluoroscopic examination contains data for a set of discrete x-ray fields that can be used to simulate a dynamic upper GI examination. The handbook presents the absorbed dose to various tissues per unit entrance exposure (free-in-air) as a function of the x-ray fields and x-ray beam qualities typically used for the upper GI examination with BaSO₄ contrast material in the GI tract.

The dynamic upper GI fluoroscopic examination can be approximated with a set of discrete x-ray fields (1). The protocol for this involved videotaping the examination, while fluoroscopic technique factors, tube current and tube potential were simultaneously recorded on the audio track of the videotape. Subsequent analysis allowed the dynamic examination to be segmented into a series of discrete x-ray fields uniquely defined by field size, projection, and anatomical region. The anatomical regions associated with the upper GI examination were observed to be the upper, middle and lower esophagus, the gastroesophageal junction, the stomach, and the duodenum. The projections associated with each anatomical region are the left posterior oblique (LPO) and the right anterior oblique (RAO).

Once the discrete x-ray fields were identified, the technical specifications of each field could be used with mathematical anthropomorphic phantoms and a Monte Carlo radiation transport code to obtain tables of conversion factors (i.e. tissues doses per unit of entrance exposure, free-in-air). These phantoms and codes have evolved for use in medical x-ray dosimetry over a number of years. The conversion factors can then be used to estimate tissue doses for upper GI fluoroscopy.

The mathematical phantom used to represent the reference male patient was the ADAM phantom, developed at the Gesellschaft für Strahlen-und Umweltforschung (GSF) (2) by modification of the original MIRD-5 phantom of the Internal Radiation Dose Committee (3). The reference female patient was represented by GSF's EVA phantom (2).

Each table contains entries for male and female reference patients, giving the selected tissue doses per unit of entrance exposure, free-in-air. The values tabulated are for the average absorbed dose in the tissue (weighted over its entire mass). The user must take into consideration the actual entrance exposure at a give facility to estimate the absorbed dose for that facility.

An example of the type of data in the handbook is given in Table 1 for the duodenum anatomical region, LPO projection.

Table 1. Duodenum, LPO - tissue dose (mGy) per 1 mC/kg entrance exposure, free-in-air

Description of projection: The patient is oriented with the back to the x-ray table, the left posterior side against the table, angled at a nominal 30 degrees from a true posterior-anterior central ray. The distinguishing characteristic of the anatomical region is that it is centered on the duodenum. Field size: 11.4 cm x 11.4 cm at the image receptor. SID = 80 cm; SSD = 50 cm.

Note: Data entries apply to both single and double barium contrast procedures.

kVp	80		100		120	
HVL(mm Al)	4.0		5.0		5.5

+ Less than 0.01 mGy per mC/kg.

The tissues for which data are tabulated are those for which the International Commission on Radiological Protection (ICRP) has provided risk coefficients for cancer mortality, genetic effects and in utero effects (4). For both the male and female patient these include: thyroid, esophagus, lung, active bone marrow, stomach, colon, bladder, liver and trunk tissue. The average absorbed dose in the trunk tissue is used as an indicator for the other tissues in the trunk of the body not specifically named. Trunk tissue excludes the lungs and skeletal tissues in the trunk. In addition, testis tissue is included for the male patient, and breast, uterus and ovary tissues are included for the female patient. The average absorbed dose in the uterus is used as the absorbed dose in the embryo, and is strictly applicable only in the first two months of pregnancy.

Data are given for the following three kVp and HVL combinations: 80 kVp, 4.0 mm Al HVL; 100 kVp, 5.0 mm Al HVL; 120 kVp, 5.5 mm Al HVL.

PLANNED HANDBOOK ON COMPUTED TOMOGRAPHY EXAMINATIONS

The handbook of tissue doses in computed tomography will contain data for the range of CT examinations observed in practice. The phantoms will be adapted to the geometrical and radiation exposure complexities of CT examinations. The handbook will present the absorbed dose to tissues from CT examinations per unit of computed tomography dose index (CTDI), a measurement manufacturers are required to provide to clinical users under the United States federal performance standard for CT equipment (5).

First, absorbed doses to tissues per unit CTDI will be calculated for contiguous one-centimeter slices of both the male (ADAM) and the female (EVA) phantoms, from the apex of the head to the base of the torso. (i.e. 24 head slices and 70 torso slices). The data will encompass kVp and filtration conditions that cover the range of design for current CT systems.

From the basic set of data for the contiguous one-centimeter slices, tissues doses per unit of CTDI will be computed and presented for specific head and body CT examinations, by accumulating the tissue doses from the required slices for each examination. The handbook user will be able to select the relevant values from the handbook and apply the values of CTDI provided by the CT system manufacturer or determined locally to obtain tissue doses for the examination.

UPDATE OF HANDBOOK ON COMMON PROJECTIONS IN DIAGNOSTIC RADIOLOGY

The revised handbook of selected tissue doses for common projections in diagnostic radiology will contain a complete and expanded recomputation of the data published in December 1988 (6). The expansion will consist of separate entries for a reference adult male and a reference adult female patient, additional oblique projections, an expanded list of tissues, and reformulation of a radiation detriment index.

Approximately 17,700 separate computer runs are underway. Tissue-air-ratios will be generated for appropriate tissues in each of two phantoms. The anticipated computer runs include: up to 8 different clinical projections (i.e. PA, LPO, LL, LAO, AP, RAO, RL, RPO) for each phantom; 160 to 320 4 cm x 4 cm plane parallel beams (grids) per clinical projection; and 4 to 7 monoenergetic energies per grid.

The expanded set of tissue-air-ratios will permit a much greater range of clinical conditions to be addressed than previously available, and the expanded set of tissue-air-ratios will be incorporated into the computer program for tissue doses in diagnostic radiology (7) now widely distributed and in use throughout the world.

RADIOLOGICAL IMPACT OF DIAGNOSTIC NUCLEAR MEDICINE TECHNOLOGY
ON THE QUÉBEC POPULATION (PATIENTS AND WORKERS) IN 1989.

L. Renaud, J. Blanchette
Institut de Cardiologie de Montréal, Hôpital Laval de Québec,
Québec, Canada.

ABSTRACT

Using the results of a six month survey on the doses received by non-monitored hospital workers from diagnostic nuclear medicine patients (DNMP) in three hospitals and published statistics on Québec's workers and hospitals, an evaluation of the radiological impact of DNMP has been calculated on the Québec's population. In 1989, diagnostic nuclear medicine accounted for 6 % of the diagnostic imaging acts. The diagnostic nuclear medicine gave an average of 6.4 mSv/act or a total of 2,800 Sv-man. The diagnostic nuclear medicine technologists community received 0.4 Sv-man and the non-monitored hospital workers 1.7 Sv-man from the DNMP in the same year.

INTRODUCTION

The nuclear medicine technology is a very powerful diagnostic tool. However, its use brings a new radioexposure source and environmental contamination inside the hospital. In the late eighties, according to the Québec's Ministère de la Santé et des Services Sociaux[1], the diagnostic usage of nuclear medicine was growing at a rate of 10 to 13 % per year. In 1989, this technology was available into 44 Québec's hospitals[2] and generated 440,000 nuclear medicine acts[3] paid by the Régime d'Assurance Hospitalisation du Québec (RAHQ). The diagnostic nuclear medicine patients (DNMP) are ambulatory inside the hospital and may influence the environmental radiation level.

In this study, we estimate the monitored and non-monitored hospital workers collective dose in hospital environment from DNMP as well as the effective dose per nuclear medicine act in 1989 using three major sources of information: a survey[4] designed to measure and assess the radiological impact of DNMP on a selected group of non-monitored hospital workers, published[5] occupational doses in Québec and various statistics available on Canadian hospitals[2,6].

MATERIAL AND METHODS

A survey over 10 consecutive weekdays in three university hospitals (ICM: Institut de cardiologie de Montréal (171 beds), LAVAL: Hôpital Laval de Québec (340 beds), HDM: Hôtel-Dieu de Montréal (430 active beds)) succeeds to demonstrate that the nuclear medicine patients are highly ambulatory inside the hospital. Few minutes after their radioactive administration (RA), both in-patients and out-patients can go anywhere inside the hospital[4]. More than eighty-three percent (83%) of the patient movements occur in the first 24 hours. This time and motion study enabled us to identify hospital non-monitored groups (nurses, physicians, technologist, cleaners, secretary) who were likely to come regularly in the near environment of the DNMP.

Following this survey, we distributed 840 calibrated thermoluminescent² dosimeters (TLD) to selected workers in the three participating hospitals. Table I summarizes the distribution profile of TLD's holders in each hospital. TLD were worn during 6 consecutive months.

¹ This work was produced under contract to the Atomic Control Board and Supply and Services Canada; contract No. 87015-8-4099/01-55, project 6.105.1.

² Chalk River Nuclear Laboratories, Chalk River, Ontario, Canada, K0J 1P0

Concurrently, all RA were recorded: prescribed procedure, radioactivity administered, isotope, radiopharmaceutical, patient origin (in or outside hospital), date and hour of the RA.

RESULTS

Exposure to the patients

Table II summarizes the mean RA (MBq) per procedure for various nuclear medicine examinations and the average number of RA per week. During this six month survey which has recorded over 10,000 RA, we observed a large variation in RA between hospitals depending upon their activities and specialities.

The effective dose per unit of activity for normal adults [7,8,9] combined with the observed activity per RA and with the medical acts paid by RAHQ in 1989, leads to an overall estimate of 2800 Sv-man to the Québec's population by the diagnostic nuclear medicine technology or an average of 9.8 mSv for each of the 268,000 RA or 6.4 mSv per act. Table III summarizes the number of RA for each group of nuclear medicine procedures with the corresponding collective and individual effective dose (H_E). 75 % of nuclear medicine imaging devices is clustered in Montréal (55 %) and Québec (21 %) areas.

Exposure to the non-monitored workers

From the 840 distributed TLD, 805 were returned for reading and report. Table IV summarizes the statistics on exposures of surveyed personnel and the surveyed fraction of the whole hospital personnel. The average value of this fraction was sixteen (16) percent.

Merging the average of the annual occupational doses given in Table IV, with published statistics [2,6] on the hospitals with a nuclear medicine service, we then estimate a collective dose of 1.7 Sv-man to the non-monitored hospital workers population coming in the near environment of the DNMP. This estimate assumes that only 16 % of the workers might be exposed to the diagnostic nuclear medicine patients, a very conservative hypothesis.

Exposure to the diagnostic nuclear medicine technologists

As published by Sont and al. [5], the average body dose (including all doses) to the nuclear medicine technologist was 2.35 mSv in the province of Québec during 1988. We assume that the average dose to those workers remained the same during 1989. In 1989, the province of Québec had 170 registered nuclear medicine technologists leading to a collective dose of 0.4 Sv-man.

RA/week	92	108	160

DISCUSSION

The diagnostic nuclear medicine technology gives more effective dose per act to the patients and to the monitored and non-monitored hospital workers when compared to the radiological diagnostic imaging technology. The Québec's population received about 6200 Sv [10] or approximately 1 mSv per capita per diagnostic medical irradiation in 1989 or 0.5 mSv by radiodiagnostic act and 6.4 mSv per nuclear medicine act. The nuclear medicine technology accounts for only 6% of total medical acts paid by RAHQ and generated 45% of the

patient effective dose. This estimate excludes therapeutic procedures (angioplasty, I^{131} therapy), dental and chiropractor radiology and was not weighted for patient age at the irradiation time.

Sont reports that the radiological technologists are exposed at an average of 0.13 mSv/year or about 0.4 Sv-man. We have calculated a collective dose of 0.4 Sv-man to the nuclear medicine technologists. According to Table VI, this group contributes for 8 % of the collective occupational dose in Québec. These monitored workers are the most exposed workers in medical environment in the province of Québec.

Table V: Québec nuclear medicine profile in 1989.

# Hospitals:	44
# γ cameras/Hospital	2.7 ± 1.6
# workers/Hospital	1832 ± 960
# Nucl. Med. Tech.	170
Mean occupational dose of Nucl. Med. Tech.	2.35 mSv

Mobile or fixed X-Ray machines are visible and known sources of irradiation, the DNMP is *incognito* for the majority of the workers. The unknown character of this human radioactive source may explain the observable range of radiological exposures (upto 1.4 mSv/6 months) on more than 90 % of the 805 workers monitored during the six month survey. These workers had a dose detectable by the TLD technology. From those data, we conclude that on average at least 14 % (90 % x 16 %) of the hospital workers population may receive a quantifiable irradiation by the usage of the nuclear medicine technology into an hospital. We estimate that the collective dose to that personnel (nurses, orderlies, porters, cleaners, physicians...) working in this environment is 0.13 mSv per capita during 1989, a dose comparable to the one of radiological technologists. According to Sont, all

workers of Québec monitored by the dosimeters of Health and Welfare Canada share a collective dose of 5 Sv-man. According to this analysis, the non-monitored hospital workers exposed by DNMP share a collective dose of 1.7 Sv-man.

This estimate excluded the general population exposure from the DNMP. The individual estimate may be different from one hospital to another depending upon the number of nuclear medicine patients, the technology acceptance, the isotope and the activity administered, the management of the patient, the workers' duty and training.

CONCLUSION

When fully justified, the diagnostic nuclear medicine technology like any other technology using ionizing radiations has to be optimized in terms of the dose to the patient and to the workers' population. A slight decrease of the exposure rate at the origin, a better management of the radiation source or any adapted training may have a significant impact on the collective dose even if the average individual dose to the non-monitored personnel is low compared to the diagnostic nuclear medicine technologist. In the optimization process, doses to the diagnostic nuclear medicine technologists, to the patients as well as to the non-monitored hospital personnel has to be considered.

WORLD-WIDE VARIATIONS IN EXPOSURES OF PATIENTS
TO IONISING RADIATION

Jack Valentin

Swedish Radiation Protection Institute (SSI),
Box 60204, S-104 01 Stockholm, Sweden

ABSTRACT

X-ray examinations increase in developing and nuclear medicine examinations in all countries, but all are less frequent in developing countries. Children are not infrequently examined, more so in developing countries. Doses per x-ray examination can be lower in developing countries, but nuclear medicine doses are similar in all countries.

INTRODUCTION

UNSCEAR (The United Nations Scientific Committee on the Effects of Atomic Radiation) has estimated medical exposures to 0.4-1 mSv annually per caput (1). This refers mostly to the early 1980ies, and rests on extrapolation from few countries. Access to medical radiation increases in developing countries, and the pattern of investigations changes.

Hence UNSCEAR initiated a Survey of Medical Radiation Usage and Exposures in 1989. Some 40 very differing countries have responded so far. This paper describes some aspects of the answers. The paper states the author's personal views only and does not predict any future UNSCEAR conclusions.

The Survey contained questions on national conditions and numbers of patients, their age and sex, doses or activities for diagnostic and therapeutic uses of radiation. However, this paper deals with diagnostic radiation uses only. Many countries do not have the statistics requested. Still, even the relatively few answers obtained now extend our knowledge appreciably. These answers come from all inhabited continents, developing as well as industrialised countries, and small as well as large ones.

Countries are grouped in four levels of health care, according to the frequency of physicians. 22 answers come from level I countries (<1,000 population per physician), 7 from level II (1,000-3,000), 6 from level III (3,000-10,000) and 2 from level IV (>10,000 population per physician).

RESULTS: GENERAL CONDITIONS

The Survey provides national averages and ranges of individual values for the various quantities. Here, most results are given as ranges and medians of national averages.

Some countries could not answer all questions, so entries in subsequent tables do not always represent all countries.

Table 1 shows arithmetic mean frequencies of radiologists, diagnostic x-ray units and nuclear medicine clinics. For health care levels I and II, a time trend is indicated. Access to medical radiation increases quicker at level II, but is still lower than at level I (where access may be close to satisfying demand).

Table 1. Access to medical radiation by level of health care (number per 1,000 population)

Level of health care:	I	II	III	IV
Radiologists 1970-74	0.063	0.023	-	-
1985-89	0.076	0.038	0.009	0.0003
Diagnostic x-ray units 1970-74	0.45	0.026*	-	-
1985-89	0.39	0.11*	0.037	0.004
Nuclear medicine clinics 1970-74	0.005	0.0003	-	-
1985-89	0.008	0.0009	0.0004	0

* including dental units

RESULTS: DIAGNOSTIC X-RAY EXAMINATIONS

Table 2 shows that the frequency of x-ray examinations has increased only slightly at level I, but almost doubled at lower levels. At level I, both maximum and minimum national averages are actually lower in the 1980ies, reflecting substitutions of ultrasound, endoscopy etc for x rays.

Table 2. Number of x-ray examinations per 1,000 population (range and median of national averages)

Level of health care:	I	II, III, IV
1970-74 Range	369 - 2705	<8 - 26
Median	586	17
1985-89 Range	144 - 1157	14 - 81
Median	613	29

Table 3 shows patient age distributions for some x-ray examinations. Examination of children is not very infrequent and often more common at lower levels of health care, probably due partly to young populations of developing countries.

One could expect high doses per examination in developing countries. But as Table 4 shows, no such trend was reported. National ranges of individual doses are also narrower for developing countries. If this is correct and representa-

AN ANALYSIS OF THE SPATIAL DOSE DISTRIBUTION
AROUND THE PATIENT WITH THERAPEUTIC DOSE OF I-131

ABSTRACT

Spatial dose distribution curves based on the measurement of clinical cases, theoretical and experimental analyses were studied around the patients treated with I-131 for thyroid carcinoma. When the maximum activity in a patient was 555MBq, external exposure at 50cm from a side of the subject's was $76.4 \mu\text{Sv/hr}$ for theoretical value, $65 \mu\text{Sv/hr}$ for experimental value, and $32 \mu\text{Sv/hr}$ for clinical case. The total exposure at 1m from the side of the breast in clinical cases 1, 2 and 3 were obtained 7.75, 1.97 and 0.79mSv, respectively. The result of case 1 suggested that special restriction need be placed on the patient's proximity to other individual.

INTRODUCTION

When performing the treatment of various kinds of diseases using Radionuclide (RN) in the practice of nuclear medicine, the patient becomes a significant source of radiation. I-131 utilized for the RN treatment of thyroid disease is said to be only one RN presently used for therapy in Japan. The patient administered I-131 must be admitted in a RN ward. However, there are only a small number of data which can be used in investigating the criteria for permitting the patient to discharge the hospital or transferring the patient to a general ward. This time, in order to clarify these points, a theoretical analysis of the spatial dose distribution around the patient administered I-131 was conducted, a model experiment was performed and clinical examples were investigated.

MATERIAL and METHOD

The spatial dose distribution showing in Fig 1 calculated by using following formula.

n_i =means number of photons per disintegration

$$\Gamma = 0.459 \sum_i n_i E_i (\mu_{en} / \rho)_{air} \quad (\mu Gy \cdot m^2 \cdot MBq^{-1} \cdot h^{-1})$$

E_i -photon energ (MeV)

$(\mu_{en} / \rho)_{air}$: mass energy-absorption coefficient for air (m^2 / kg)

Actual measurement by phantoms was performed. The neck sections of Alderson Rand Phantoms No.7~11 were extracted and ORTNS-type neck phantoms were inserted in those areas. The measurement was performed using an ionization survey meter (Aloka TCS-151). Three clinical cases were investigated and they were administered 3.7(case 1), 3.26(case 2) and 3.3GBq of I-131 respectively. At the same time as the measurement of the spatial dose, Linear Scanning was carried out using Medical Universal Human Counter (Toshiba) in order to know the distribution of RN in the patient's body.

The spatial dose distribution within the RN ward and the RN distribution within the body were successively measured from immediately after the administration.

RESULT and DISCUSSION

Fig. 1 Theoretical spatial dose distribution curve around the Alderson Rand Phantom under the thyroid gland containing I-131 solution of 111MBq.

Fig. 2 Experimental spital dose distribution curve around the Alderson Rand Phantom under the thyroid gland containing I-131 solution of 111MBq.

Fig 1 shows the calculated spatial dose distribution assuring 111 MBq of I-131 contained in the thyroid of the neck. Fig 2 shows the actual measurement by phantoms. According to the results of the above three cases, the external exposure levels at 50cm and 80cm from the side of the patient's body were obtained one week and two

Table 3 Total exposure at 0.5, 1.0 and 2.5 m from the side of the breast of clinical case.

	Activity administered (GBq)	Exposure per treatment		
		at 0.5m (mSv)	at 0.5m (mSv)	at 0.5m (mSv)
Patient 1	3.7	31.0	7.75	1.24
Patient 2	3.26	3.12	0.78	0.125
Patient 3	3.3	3.71	1.72	0.315

weeks after the administration and the results indicated by the table were obtained. In case 2 showing a small uptake into the thyroid and a rapid discharge, external exposure levels observed one week after the administration for 50cm distance

and 80cm distance were 0.5μ Sv/hr and 0.2μ Sv/hr respectively. In case 1 showing a retarded discharge due to transfer, external exposure levels obtained for these distance were 66μ Sv/hr and 28μ Sv/hr respectively. As for the results obtained two weeks after, they were 28μ Sv/hr and 13μ Sv/hr for these distances in case 1 which dose rates indicating almost no existence of an external exposure source were observed in case 2. The spatial dose rate for the time when the intrabody residual level of I-131 becomes 555MBq was obtained at 50cm from the side of the patient's body for each of the theoretical analysis, the model experiment and the clinical cases there by obtaining the results shown in the table 2. The time when the intrabody residual level becomes 555MBq was about 12 days after the administration for case 1, about one day after for case 2 and about 3 days after for case 3. The spatial dose rate for the clinical cases was about 1/2 of that for theo-

retical analysis and that for the model experiment. This is considered to be due to the fact that I-131 was incorporated only into the thyroid in the latter cases while I-131 was distributed in the whole body of each clinical case. Therefore, when considering the criteria for the admittance of patients administered RN in a special ward while taking into consideration the external exposure level for a person beside the patient, the external exposure level will be overestimated if the calculation is performed on the basis of the supposition that the source of radiation consisting of a point source attenuates only according to the physical half life.

Accordingly, it is necessary to perform estimation according to the result of each clinical case in order to know accurate exposure levels. Total exposure levels for persons continuously staying at 0.5, 1.0 and 2.5m from the patient from immediately after administration of I-131 were calculated and the results shown in the Table 3 were obtained.

According to the definition by I.C.R.P, it is not necessary to provide a special restriction to another person staying near the patient for the radiation level with which the yearly dose limit at 1m from the patient is less than 5mSv. Cases 2 and 3 are those corresponding to this category while a special restriction is required for case 1. It has been found that the patient should be admitted in a RN treatment ward provided with a special measure for preventing adjacent persons from being exposed to radiation by taking into account the fact that the effective half life varies according to each case.

CONCLUSION

Spatial dose distribution curves based on the measurement of clinical cases, theoretical and experimental analyses were studied around the patients treated with I-131 for thyroid carcinoma. When the maximum activity in a patient was 555 MBq, external exposure at 50cm from a side of the subject was $76.4 \mu\text{Sv/hr}$ for theoretical value, $65 \mu\text{Sv/hr}$ for experimental value and $3.2 \mu\text{Sv/hr}$ for clinical case. The total exposure at 1m from side of the breast in clinical cases 1, 2 and 3 were obtained 7.75mSv, 0.78mSv and 1.72mSv respectively. The result of case 1 suggested that special restriction need be placed on the patient's proximity to other individual.

**ABSORBED DOSE TO TECHNICIANS WORKING AT ACCELERATORS FOR
RADIATION THERAPY**

A. Almén, L. Ahlgren and S. Mattsson

ABSTRACT

Absorbed dose to the trunk and the hands of technicians working at high-energy accelerators for radiotherapy have been measured for seven accelerator in different hospitals. Induced radioactivity and leakage radiation have been studied. The annual absorbed dose to the trunk was estimated to 2.0 mGy. Induced radioactivity contributed with 1/3 of the total absorbed dose. For one accelerator the variation of absorbed dose rate after an irradiation inside the treatment room was followed. Radionuclides with rather long halflives e.g. ^{187}W were identified.

INTRODUCTION

External radiotherapy is mainly carried out with photon or electron beams from electron accelerators. The technicians operating these accelerators will be irradiated from photons penetrating the radiation shield in the accelerator head and the walls of the treatment room. Photons scattered in the patient and in the treatment room before penetration of the walls will also contribute. If the photon energy exceeds 8-10 MeV the technicians when inside the treatment room will be irradiated by induced radioactivity produced by photonuclear reactions. The highest induced activity is expected in the parts of the accelerator exposed by the highest photon fluence. Depending on the photon energy and irradiated material a number of radionuclides will be produced with different halflives. Neutrons will also be produced.

The aim of this study was to estimate the absorbed dose to technicians working at accelerators producing high-energy photons due to induced radioactivity and leakage radiation.

MATERIALS AND METHODS

Absorbed dose to 24 technicians working at seven high energy accelerators in six different hospitals in Sweden was measured. The accelerators used accelerating potentials above 10 MV producing photon and electron beams of different energies.

Five TL-dosimeters (LiF, $3.2 \times 3.2 \times 0.9 \text{ mm}^3$) were carried on the trunk and five on a wrist bracelet. The dosimeters on the trunk were covered with 5 mm buildup material, the dosimeters on the wrist had no additional buildup except a thin plastic cover. The dosimeters were calibrated in a ^{60}Co -field. During the measuring period of ten working days the background radiation and the radiation at the control console was measured with TL-dosimeters. A pressurized ionisation chamber (Victoreen 450P) was also used to measure the absorbed dose rate due to leakage and scattered radiation at the control console when high-energy

photons were used. The leakage radiation inside the treatment room was measured with a ionizing chamber one meter from the isocenter perpendicular to the central beam axis. For the measurements a 50 mm buildup cap was used.

The time variation of the absorbed dose rate due to induced activity after a treatment with high-energy photons in one treatment room was measured with a NaI(Tl)-detector placed at the isocenter and at 1.3 m above the floor at a location beside the treatment couch. The measurement was carried out for one accelerator and started 0.5 min after the irradiation and went on for 48 h. The signal from the NaI(Tl)-detector was compared with readings from a plastic scintillation detector calibrated for absorbed dose measurements. The curves over count-rate versus time were analyzed and separated into several exponential functions.

RESULTS AND DISCUSSION

Absorbed dose rate outside the treatment room due to leakage radiation during a treatment with high-energy photons varied considerably between the accelerators (Table 1). Table 1 also shows the leakage radiation through the accelerator head in the treatment room. The leakage radiation is given per absorbed dose unit given to the patient. Inside the treatment room the average absorbed dose measured divided by absorbed dose maximum in water at isocenter is given in table 1.

Table 1. Leakage radiation inside the treatment room and at the control console, when irradiating with high-energy photons.

Designation	Manufacturer	Leak. rad. inside/ mGy/Gy	Leak. rad. control console/ μ Gy/h
Linac 1	Clinac 1800 Varian	0.134	4.4
Linac 2	SL 75/20 Philips	0.135	0.4
Linac 3	SL 75/20 Philips	0.347	1.0
Linac 4	Dynaray LA20 Brown Boveri	0.435	1.2
Linac 5	SL 25/20 Philips	0.459	0.2
Microtron 1	MM22 Scanditronix	0.513	1.4
Microtron 2 Race trac	MM50 Scanditronix	0.462	2.5

The annual dose was calculated by extrapolating the measured dose to one year assuming a workload of 45 week in a year. The natural background was subtracted from the TL-readings. The absorbed dose at the control console was calculated and was subtracted from the total absorbed dose. Estimation of the

contribution from induced radioactivity to the total absorbed dose was then obtained. The average absorbed dose to the trunk was estimated to 2.0 mGy per year. In figure 1 the mean absorbed dose to the technicians at each accelerator are given.

Figure 1 The measured absorbed dose to the trunk extrapolated to one year.

In the same way the absorbed dose to the hand was calculated for the different accelerators to 2.1 mGy. The dose to the hands varies from 0.7 to 3.3 mGy.

A similar investigation (LaRiviere P, 1985) has given comparable absorbed doses. His registered dose outside the treatment room is however lower. This could be due to different measuring techniques or due to that the control console is very distant from the accelerator.

At the control console the average dose rate was measured to 1.6 μ Gy/h. The average leakage dose rate inside the the room was 0.36 mGy/Gy.

A number of radionuclides was identified by examining the halflives. The identified nuclides were also compared with gamma spectroscopy measurments (Ahlgren et al, 1988). An example of the absorbed dose rate curve is given in figure 2.

Figure 2 Absorbed dose rate at isocenter in the treatment room 0.5 to 60 min after a termination of the treatment with high energy photons.

The contribution from ^{28}Al ($T_{1/2}=2.3$ min) and ^{62}Cu ($T_{1/2}=9.7$ min) dominates the dose-rate immediately after the treatment. Later the contribution from radionuclides with longer half-lives becomes important. E.g. ^{187}W ($T_{1/2}=24$ h) and ^{57}Ni ($T_{1/2}=36$ h) contributes to the absorbed dose rate in the treatment room due to their relatively long half-lives for several hours. At isocenter the absorbed dose rate is about two times higher than beside the treatment couch.

CONCLUSION

The total annual absorbed dose rate to the technicians was calculated to 2.0 mGy. The absorbed dose to the trunk and to the wrist are very similar. The dose to the hands are probably higher than to the wrist due to the β -particles emitting from the surface of accessories.

Induced radioactivity in the accelerator contributes with 1/3 and the radiation transmitted through the walls of the treatment room contributes with 2/3 to the absorbed dose to the technicians.

The contribution from induced radioactivity is rather constant for the different accelerators indicating the importance of radionuclides with long half-lives as a source of radiation. This also means that the technicians is irradiated every time they enter the treatment room, not solely after treatments with high-energy x-rays.

ACKNOWLEDGEMENTS

This work has been supported by the Swedish Radiation Protection Institute. We also wish to thank all the technicians, nurses and hospital physicists participating in this study.

Neutron Leakage from the Entrance Maze of Medical Electron Accelerators

H.-P. Weise

*Bundesanstalt für Materialforschung und -prüfung (BAM), Berlin,
Federal Republic of Germany*

For medical electron accelerators with photon energies above 15 MeV the shielding requirements in the entrance region of the treatment room are mainly determined by neutron streaming. The accelerator (especially the bremsstrahlung target and the collimator system) is the primary source of fast photoneutrons with an average energy of about 1 MeV. The neutrons are scattered from the walls of the maze resulting in a broad energy spectrum down to thermal energy. For calculating the attenuation factor of the entrance shielding door the neutron dose rate has to be determined using a reliable procedure. Several methods have been proposed for estimating neutron streaming through the maze, e.g.:

- the albedo method which is based on single scattering of fast neutrons from the maze walls,
- a semiempirical method developed by Nakamura et al. which was derived from transport calculations,
- an empirical procedure by Kersey based on measurements at various accelerator installations.

The accuracy of these three procedures was compared by calculating the neutron dose rates for various accelerator facilities for which sufficiently reliable measured data were available. Good agreement between calculated and measured values was generally obtained for the Nakamura method. The Kersey method overestimates the neutron component in some cases. The simple geometric albedo approach however severely underestimates the neutron dose rate at the entrance of the maze. This discrepancy is certainly due to the fact that the simple albedo concept does not take into account the buildup of thermal neutrons by multiple scattering. Measurements with a Bonner spectrometer indicate a considerable contribution of slow neutrons to the total dose rate at the entrance. For the design of the entrance maze the Nakamura method was found to be the most reliable one, the deviation between calculation and measurement for various representative geometries being less than a factor of two.

EXOTIC FILTER MATERIALS FOR DIAGNOSTIC X-RAY EQUIPMENT - ARE THEY SUPERIOR TO COMMONLY AVAILABLE MATERIALS?

P. Dvorak and C. Lavoie
Bureau of Radiation and Medical Devices
775 Brookfield Road
OTTAWA, Canada K1A 0C1

ABSTRACT

Measurements and computer simulations were carried out to evaluate the suitability of various elements for use in X-ray filters. Filter thicknesses were selected to give approximately identical absorbed doses to the image receptor for all elements under consideration. The results suggest that elements in the ranges of atomic numbers from approximately 22 to 42, and above 68 perform about equally well in terms of affecting the phantom dose and image contrast under the conditions used in measurements and simulations. In some specialized applications, exotic filters may have advantage in matching the X-ray spectrum to the image receptor response. These special cases are not considered here.

INTRODUCTION

In diagnostic radiography, filters are used to modify the spectral distribution of photons in an X-ray beam in order to reduce the number of photons that would contribute to the patient dose but not to the acquisition of diagnostic information. Aluminum and, less frequently, copper have been traditionally used in equipment designed for diagnostic procedures other than mammography. In recent years, several less common elements, typically metals from either the rare earth or the fifth period group, have been proposed and tested as filter materials. Adding such filters to the basic filtration, e.g. 2.5 mm Al, results in decreasing both the X-ray dose to the patient and image contrast. Filters tested by the Bureau of Radiation and Medical Devices performed as advertised. An obvious question is whether adding an equivalent thickness of other, more common and less expensive materials, would result in similar changes in the patient dose and image contrast as does adding a more exotic filter.

To evaluate the behaviour as X-ray filters of a large number of elements under various conditions, we developed a computer simulation of the basic X-ray imaging chain. We found good agreement between results of computations and data obtained by actual measurements of film densities and exposures.

COMPUTER SIMULATION AND COMPARISON WITH EXPERIMENT

Figure 1 shows the simulated arrangement. The spectrum calculated according to [1] is filtered through a 1 mm thick glass window and 2.5 mm Al basic filter before reaching the additional filter under evaluation. The filtered beam is attenuated by a phantom, simulating the patient, and two contrast test objects. It passes through the patient support and antiscatter grid, and is finally absorbed by the image receptor.

Mass attenuation coefficients are calculated from the parametrization method developed in Ref. [2], while mass energy absorption coefficients are interpolated from Ref. [3]. Attenuation calculation uses the standard exponential formula

$$E = \int \{E(e) * \exp(-\mu(e) * d)\} de \quad (1)$$

where E is the beam energy fluence, e is the photon energy, E(e) is the spectral distribution of the fluence, and $\mu(e) * d$ is the product of attenuation coefficient and attenuator thickness

while the integral dose uses the formula for thin absorbers [4],

$$D = \int \{E(e) * v(e) / \mu(e) * [1 - \exp(-\mu(e) * d)]\} de \quad (2)$$

where v(e) is the mass energy absorption coefficient, and the other symbols have the same meaning as in (1).

Derivation of Eq. (2) in Ref. [4] can be applied also to thick absorbers, such as phantoms, in a narrow beam geometry.

Since we use the model to compare the behaviour of different filters under identical conditions, we are interested only in relative values. In this case, it is not necessary to include any correction to account for the grid factor. Similarly, we have used the inverse square law to facilitate the comparison with experimental data, but its omission would not influence

the results of comparison of individual filter materials. The computer model does not take into account the scattered radiation. For comparisons between calculated and measured values, we corrected the measured values by subtracting the estimated contribution of scattered radiation from the reading of the probe used to measure the exposure at the phantom exit and image receptor entrance. We did not use any patient support or grid in this particular case.

Table 1 summarizes the results of comparison. The data are presented in pairs consisting of figures for the filter under consideration and an approximately equivalent copper filter.

40 Zr	0.042	68 Er	0.027	92 U	0.008

The filter thicknesses listed in Table 2 result in approximately identical doses absorbed in the image receptor under conditions shown for Table 1 and Figure 2. Calculations of the solid bone contrast (not shown) result in the same pattern of dependence on the atomic number of the filter as found for polymethylmethacrylate. Some of the elements listed in Table 2 may not be suitable for X-ray filters because of their mechanical or chemical properties, radioactivity, or cost.

CONCLUSION

The results of measurements and computations suggest that, under the conditions used in this work, there is no noticeable difference in performance as filter materials for elements in the ranges of atomic numbers from approximately 22 to 42, and above 68. Advantages of special filters designed for matching the X-ray spectrum with image receptor response are not treated in this paper.

ABSTRACT

A method for simultaneous determination of dose and image parameters in mammography is presented. A single exposure of a suitable phantom is needed, followed by the film analysis on a microdensitometer. The objective assessment of image quality is based on the image quality index, a global concept developed by the authors. The radiation risk to the patient is estimated by the mean glandular dose.

The procedure has been used in several evaluation tasks of radiological equipment, material and techniques : influence of anode and filter material, comparison of screen-film combinations, limitations of the magnification technique.

INTRODUCTION

Radiological examination is an effective method in the diagnostic of pathology of the female breast. The new radiological equipments allow to obtain a high image quality enabling the detection of microcalcifications of the order of 100 μm . On the other hand the absorbed dose to the breast must be controlled and held to the lowest possible value, owing to the high radiation sensitivity of this organ. The test of mammographic equipments has to take both aspects, image quality and dose, into account. Additionally, the assessment should be objective in order to convince both physicians and technicians.

In the case of image quality several approaches have been proposed for the objective assessment : signal-to-noise ratio, detective quantum efficiency, information capacity (1). However these parameters have no direct connection to the radiological task and are difficult to be perceived and correlated to clinically significant features. In our approach we developed as quality index the diameter of the smallest microcalcification which the system can detect. This quantity is derived from the measured basic quality parameters : contrast, noise and resolution. The mean glandular dose will be used to evaluate the radiological risk.

CONCEPT OF IMAGE QUALITY INDEX

The image quality index (IQI) is defined as the diameter of the smallest detectable spherical object with a high probability of correct decision. In a first approach (2), the IQI has been derived assuming a Gaussian MTF and a white noise; it was given by the following formula :

$$IQI = \frac{2}{m} \left(\sigma_h^2 + 2 \frac{G}{C \pi^{1/2}} \right)^{1/2}$$

where m is the object magnification, σ_h the width of the Gaussian line spread function, G the Selwyn granularity coefficient and C the image contrast.

The model was further improved using statistical decision theory for 'quasi-ideal' observer (3). In this case the signal-to-noise ratio (SNR) is given by the following expression :

$$SNR = \frac{C \int df_x \int df_y S^2(f_x, f_y) MTF^2(f_x, f_y)}{(\int df_x \int df_y S^2(f_x, f_y) MTF^2(f_x, f_y) W(f_x, f_y))^{1/2}}$$

Where $S(f_x, f_y)$ is the object form in the spatial frequency domain, MTF the modulation transfer function and W the Wiener spectrum.

The value of SNR is calculated for different object dimensions using the measured system parameters (C , MTF, W). The SNR value corresponding to visual detection has been derived by visibility tests (2). Their comparison yields the IQI value.

EXPERIMENTAL PROCEDURE

The image quality parameters and the dose are measured using a Lucite mammographic phantom 53 mm thick. Test objects, embedded in the phantom, allow the measurement of the image quality parameters on a radiograph :

- contrast, by measuring the transmission of an aluminium plate,
- resolution, by measuring the profile of a copper foil edge,
- noise, by scanning a uniformly exposed surface with a microdensitometer.

The surface dose is measured using thermoluminescent dosimeters; the mean glandular dose is calculated using conversion factors measured in a BR12 phantom.

The performance assessment of mammographic equipment needs a single exposure of the phantom and subsequently an analysis of the radiograph with a microdensitometer and a measurement of the thermoluminescent dosimeters.

APPLICATIONS

Influence of anode and filter material

The influence of anode and filter material on the image quality and dose has been measured using the procedure described above. The three following anode-filter combinations were used : W-Mo, W-Rh and Mo-Mo. The results obtained are given in figure 1.

The Mo-Mo and W-Mo combinations give similar results. The W-Rh combination at an IQI of 100 μ m implies a lower dose, but is not able, in the voltage range used, to produce IQI values as low as the molybdenum filtration.

Fig.1. Image quality index (IQI) versus mean glandular dose (MGD) for three anode-filter combinations

Comparison of screen-film combinations

A set of screen-film combination has been tested using our method. The list of the combinations and the results obtained are given in figure 2.

Fig.2. Performances of different film-screen combinations

The results are clustered around a hyperbolic curve, showing that each system corresponds to a compromise between image quality and dose.

Assessment of the magnification technique

The magnification technique using an air-gap between the breast support and the film has been tested. This method is claimed to

improve the quality compared to the classical system using a grid for scatter reduction. The results are presented in figure 3.

For thin breasts, owing to the low doses, the magnification technique is acceptable until a magnification factor of 2. For mean thickness breasts (around 35 mm), the magnification factor should not be greater than 1.5; for this value the dose is the same as for the classical method (without magnification and with grid), but the image quality is clearly improved. For thick breasts (~ 50 mm) magnification is critical because of the high dose involved.

Fig.3. Performance of the magnification technique (m:magnification)

CONCLUSIONS

The assessment method presented here has the following advantages:

- the method is objective avoiding the tedious ROC approach;
- it is global, giving simultaneous information about image quality and dose;
- it is easy to apply, a single exposure being needed.

The applications of the method have proved its efficiency and gave insights in the radiological procedures.

IMPLEMENTATION OF THE QUALITY ASSURANCE PROGRAMME
OF THE X RAY RADIATION IN SERBIA - YUGOSLAVIA

Tomasevic Miroslav, Kosutic Dusko, Marinkovic Olivera

Abstract : Under constant dosimetric control in Serbia there are 782 diagnostic X ray units with 969 X ray tubes. In 1990, 202 such units were subjected to the radiation dose reproducibility testings; 206 to measurement of high voltage and accuracy of exposure time. In 94.55% cases the said reproducibility amounted less than five percent and only 1.98% was higher than 10%. The exposure time was reliably determined in 78.15% X ray generators; deviations in excess of 10% were registered in 21.48%. Similar situation occurred in selection of high voltage. Of observed X ray generators in 10-12% cases deviations increased ten percent.

Introduction :

The scope of ionizing application, and particularly its medical use is controlled by the Federal laws and Regulations passed during the period from 1986 - 1989 (1.2.3.4). All ionizing irradiation sources are constantly subjected to the regular dosimetric control performed by specialized, highly qualified and adequately equipped institutions authorized by Republic i.e. Regional legal regulations. Owing to some changes in legal regulations, the dosimetric control of all ionizing irradiation sources is reestablished on the completely different base using Quality Assurance Program. The basic provisions of the Program, accepted in our country as well, (But not in all Republics) are given in revised and supplemented version of the aforementioned Legal Regulations from 1989 (3).

The results of performed testing :

In order to meet the proposed criteria related to the scanning of certain organs and the parts of the body selection of adequate high voltage (kV) values, X-ray tube current (mA) and duration of scannings is to be selected at the X-ray apparatus control panel, ranging within the permitted variation of 10%. Since these values directly influence the dose of X-ray irradiation exerted to the patient it means that it must not exceed the proposed limits. The results of irradiation doses reproducibility testing in 1990. are presented in Table 1.

Table 1 - DOSSES

The type of X-ray unit	Pcs	Measured deviations					
		< 5%		>5% and <10%		> 10%	
		Pcs	%	Pcs	%	Pcs	%
DENT	57	55	96.49	2	3.51	0	0.00
SELENOS 4	71	65	91.55	3	4.23	3	4.23
SUPERIX 800	25	24	96.00	1	4.00	0	0.00
SUPERIX 1000	39	38	97.44	0	0.00	1	2.56
SUPERIX 1250	10	9	90.00	1	10.00	0	0.00
TOTAL	202	191	94.55	7	3.47	4	1.98

According to the accepted criteria, among all tested X-ray units, irradiation doses deviation exceeding 10% was found only in 4: in 3 SELENOS 4 x-ray generators and 1 SUPERIX 1000 generator. Presented values revealed no significant difference of measured deviations in certain X-ray generators.

Following the accepted criterion that only those X-ray generators in which the accuracy and reproducibility of the exposure time range within the permitted variation of only 10% may be considered as satisfactory, it was found that a number of tested generators failed to meet the criterion. Among tested X-ray generators, 21.85% failed to meet the proposed criterion while remaining 78.15% revealed satisfactory testing results. (Table 2)

The accuracy and reproducibility of high voltage, on the basis of direct measurement of high voltage of 70kV, 80kV, 90kV and 100kV were evaluated in diagnostic X-ray units subjected to the testing. The results for 70kV are in Table 3.

Table 2 - TIME

SUPERIX 800	24	13	54.17	9	37.50	2	8.33
SUPERIX 1000	34	16	47.06	12	35.29	6	17.65
SUPERIX 1250	7	3	42.86	3	42.86	1	14.29
TOTAL	93	54	58.07	29	31.18	10	10.75

CONCLUSION AND SUGGESTED MEASURES

The results of our initial tests, performed at X-ray units manufactured in Yugoslavia justify the necessity of diagnostic X-ray units control as a routine procedure. In spite of the fact that measured values mostly ranged within the proposed limits, we believe that more detailed and more reliable results related to the diagnostic X-ray units performances are to be obtained through further investigations.

RADIOACTIVE CONTAMINATION DUE TO NUCLEAR
MEDICINE EXAMINATIONS IN LIQUID AND GASEOUS MAIRICES

G.Testoni*, T.Bernardi*, D.Berti*, O.Tubertini**, R.Zannoli*

* Servizio di Fisica Sanitaria dell'Università di Bologna

Measurements carried out since 1980 on the radioactivity of liquid wastes produced by the city of Bologna and due to the activity of Nuclear Medicine Departements.

Radioactivity was measured in the fumes produced by sewage sludge inceneration too.

INTRODUCTION

The "Servizio di Fisica Sanitaria" of the University of Bologna checks radioactive pollution and its environmental impact due to scientific research and industrial or medical activity.

Because of the past experience, we can conclude that the most important radioactive impact is due to the Nuclear Medicine Departements (Malpighi and Maggiore Hospitals).

Liquid wastes produced by the city of Bologna and surrounding areas are collected by a sewage system, leading to a depuration plant; the capacity of the sewage system is about 250,000 mc per day.

The samples (about 200 in June 1991) were taken at the entrance and exit of the city depurator. Radioactivity was measured in muds, ashes and fumes produced by treatment of the depuration.

Samples were gathered "in continuo" from the liquid at entrance by means of a fractions collector during all the week night and day.

The depuration cycle produces about 10,000 tons muds. The muds combustion yields 750 tons ashes and 10 million mc fumes per year.

The radioactivity in the fumes was collected on cellulose filters and active coal caps by means of a suction pump during 30 minutes (3 mc per min.).

Before letting into atmosphere, fumes were washed with depurated water that was tested too.

We did not regularly check the activity of beta-emitter radionuclides, since they are used only for analysis "in vitro" and liquid waste is not released into the sewage system, nevertheless some untreated samples (1 ml) were tested and no radioactivity was found.

MATERIALS AND METHODS

For beta-emitters radionuclides, to 1 ml sample 12 ml scintillation liquid HT Ready Solv. (Beckman) were added, and then the mixture was tested by a Beta-counter Beckman LS-100 during 8 hours

For gamma ray spectrometry we gathered samples of the liquids at entrance and exit of the depurator, of the ashes, of the fumes, and of the fumes washing water.

1 litre of untreated sample was counted in "Marinelli" beaker (anular geometry) by a high-purity Germanium coaxial detector (2 KeV resolution at 1330 KeV, relative efficiency 30%) or a 3"x3" NaI(Tl) crystal (6,5% resolution at 662 KeV). Minimum detectable activity was about 0,5 Bq/litre.

The cellulose filters and active coal caps were tested in the same counting-chaine, but in an other geometry.

The counting-chaine calibration was performed by a calibrated source QCY-44 (Amersham) in aqueous solution.

Quantitative valuations were carried out for Tc-99m, I-131, I-125, Tl-201, Ga-67, Xe-133, Cr-51, Co-57 with a counting time of 2000-5000 sec.

RESULTS

The results are explained in the following figures and tables.

Fig.1 illustrates input capacity of depurator during a day , and the quantity of Tc-99m measured in an hour.

Fig.2 Refers the weekly course of Tc-99m in entrance at the depurator.

In tab.1 are compared the activities administered to the patients in a week, with the activities in entrance at the depurator, in fumes, in ashes and in the fumes washing water.

 +---+ Activity measured in Bq/l

Fig.2

CONCLUSIONS

1) If H-3 and C-14 are present in the Bologna sewage system, they are not measurable by our equipment (in any case less than 1Bq/ml)

2) The radioactive impact due to the Nuclear Medicine Departments is not particularly important (till now!).

3) The transit through the sewage system and the depuration process strongly pull down the radioactivity of used nuclides, because of their low average-time.

4) The radioactivity in the gases leaving the depurator is completely negligible.

RADIOTHERAPIE METABOLIQUE PAR ^{131}I : RISQUES DE CONTAMINATION ET D'IRRADIATION DU PERSONNEL SOIGNANT

L' ^{131}I est utilisé en thérapeutique pour le traitement des hyperthyroïdies (111 à 1110 MBq), des nodules autonomes extinctifs (NA) (740 MBq) et des cancers thyroïdiens (C) (3700 MBq).

Chez quinze patients (10 C, 5 NA) ont été mesurés le taux de fixation en regard du parenchyme thyroïdien, l'élimination urinaire quotidienne de l' ^{131}I , l'activité résiduelle et la distance correspondant à un débit de dose de $2,5 \cdot 10^{-2}$ mSv/h à la sortie (J+4) :

- Taux de fixation moyen : C : 4,8 % - NA : 28,1 %
- L'élimination urinaire est représentée en pourcentage cumulé de l'activité administrée

(cf courbe)

- L'activité résiduelle du patient à la sortie : - C : 536 MBq - NA : 381 MBq
- Distance $2,5 \cdot 10^{-2}$ mSv/h : - C : 22 cm - NA : 84 cm

Elimination urinaire en pourcentage cumulé de l'activité administrée

CONCLUSION : L'hospitalisation en secteur radioprotégé est justifiée, surtout pour les cancers, par les risques de contamination du personnel par les urines (2035 MBq éliminés les douze premières heures pour les C contre 148 MBq pour les NA). A J+4, l'élimination urinaire devient relativement faible dans les deux pathologies (C : 37 MBq ; NA : 17 MBq).

Par contre, à J+4, le débit de dose Gamma est quatre fois plus important pour les NA que pour les C, ce qui pose le problème de l'irradiation du personnel en secteur non protégé.

Ionizing Radiation Sources Used in Medical Applications in Brazil

S.M.V. Oliveira, A.M.C. Araujo and G. Drexler*

Instituto de Radioproteção e Dosimetria - IRD,
Nat. Nuclear Energy Commission - CNEN, Rio de Janeiro, Brazil

*Institut für Strahlenschutz,
GSF - Forschungszentrum für Umwelt und Gesundheit GmbH,
D - 8042 Neuherberg

Abstract

Data about ionizing radiation sources used in medical applications in Brazil and obtained through a IRD/CNEN national programme together with Brazilian health authorities are presented. This study used the geographic country division into five regions. The results are analyzed for each region. Due to many demographic, social and economic differences among these regions, some modifications are proposed to the UNSCEAR collection data model, for developing countries with similar situations.

Introduction

This inventory began with an IRD programme in Rio de Janeiro state (Southeast Region) where radiation protection and quality control inspections were performed in 2,000 diagnostic and 4,000 odontological X-ray equipments. The programme was extended in 1987 to other states (table 1). In one of them - Espirito Santo state (also Southeast Region) - the inventory is already completed: in the last years neither the number of diagnostic radiology equipment increased nor was the broken equipment replaced. In other states where the inventory is presently continuously updated - Acre and Rondonia (North Region) Paraíba and Ceara (Northeast Region), Sao Paulo (Southeast Region), Parana (South Region) and Goias (West Region) - the X-ray equipment is increasing with population increment. In the remaining states available data is shown but should be analysed separately since the collecting methodology was quite different (table 2).

Main results

In an UNSCEAR classification (health care level I - IV) Brazil in total can be classified to be in health care level I/II (table 3) with significant variations between the geographical regions. Using the correlation of X-ray equipment per inhabitants the classification is II/III and indicators like odontological consultations or radiodiagnostic examinations show decreasing tendency with time (fig. 1). Thus the health care level in Brazil is comparable i.e. with India or China.

Regarding the radiological examinations distribution among the main types, it was observed that the frequency for preventive procedures is lower than for the corrective procedures (fig. 3). Furthermore, in developing countries like Brazil, the population distribution in cities and countrysides (table 1) must be considered separately, because the health resources in countrysides are much smaller.

Optimizing procedures in health care thus must utilize many indicators in order to identify the actual situation and to initiate necessary actions.

Conclusions

To describe the situation and estimate deficiency resp. the needs of a country as well as to assess population exposures, the relationship among more health indicators and socio-economic variables should be considered. The results obtained have also demonstrated that a data collection standardization is necessary and unique statistical methodology analysis should be elaborated and implemented.

Nuclear Medicine and Radiotherapy data in Brazil should be more detailed. According to UNSCEAR Report 1988 nuclear medicine and the therapeutic uses of radiation is increasing in developing countries and the need for quality control will arise.

THE INTERNATIONAL CHERNOBYL PROJECT

Abel J. González

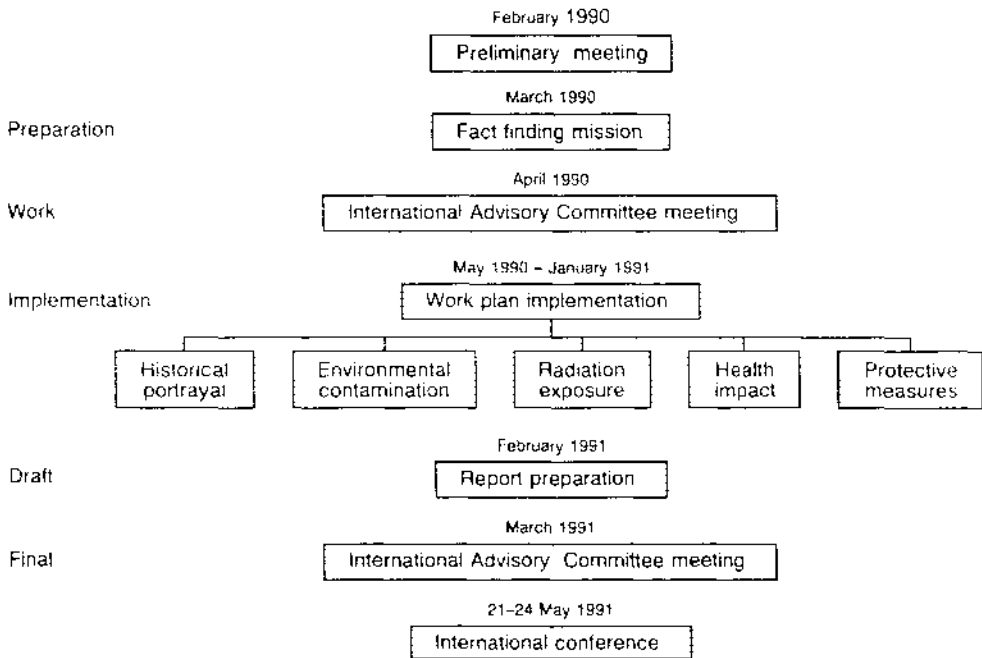

Deputy Director, Division of Nuclear Safety
International Atomic Energy Agency, Vienna, Austria

ABSTRACT

The findings of the International Chernobyl Project are summarized herewith. The project focused on four key issues related to the radiological consequences of the Chernobyl accident which are of concern to the population and policy makers: the true extent of the current contamination in inhabited areas of Belarus, Russia and the Ukraine; the past, current and future radiation exposure of the population; the actual and potential health effects; and the adequacy of measures being taken to protect the public. The project findings are expected to contribute towards alleviating the consequences of the accident by presenting factual information to allow future policy and worldwide assistance to be channelled to where it is most needed and where it can be best used.

INTRODUCTION

1. In response to a governmental request, the International Atomic Energy Agency (IAEA) organized a multinational team to assess the current radiological situation after the Chernobyl accident in the three more affected Republics, Belarus, Russia and the Ukraine. Seven international bodies participated: CEC, FAO, IAEA, ILO, UNSCEAR, WHO and WMO. Thus, the International Chernobyl Project was formalized in February 1990.
2. A group of ten scientists designed a strategic approach after a fact-finding mission in March 1990. This group met with officials in Moscow and the Republics' capitals, scientific organizations, hospitals, clinics and agricultural centres in the affected areas and in Kiev, Gomel and Moscow. They also discussed project plans with residents of seven settlements in the three Republics, who predominantly expressed anxieties about children's health and the adequacy of the Government's proposed measures for limiting radiation exposures within their lifetime, as well as mistrust against the authorities and against scientific and medical committees.
3. Subsequently, an International Advisory Committee (IAC), consisting of 21 members from 7 international organizations and 10 countries (including radiation specialists, medical practitioners and psychologists), was established to direct the project and assess findings. The IAC met 23-27 April 1990 in Kiev and Minsk to define the project structure and work plan to be completed in 1 year with limited resources. The task that evolved was to assess the quality and correctness of existing data and to conduct an independent study by means of laboratory analyses of field samples and internationally recognized assessment techniques. It focused on four key issues of concern to the population and policy makers: the true extent of the current contamination in the Republics' inhabited areas; the past, current and future radiation exposure of the population; the actual and potential health effects; and the adequacy of measures taken to protect the public. The project conclusions and recommendations were approved by the IAC in Vienna 18-22 March 1991 and presented for scrutiny to an international conference of experts in Vienna 21-24 May 1991. The findings are contained in a Technical Report which should be referred to for further technical details. (See Fig. 1.)

The International Chernobyl Project. The Project was organized in response to a governmental request for an international assessment of the radiological consequences of the Chernobyl accident. The multinational effort was directed by the International Advisory Committee and included the participation of the CEC, FAO, IAEA, ILO, UNSCEAR, WHO and WMO. Five tasks defined the Project implementation: historical portrayal of the events leading to the current radiological situation, the evaluation of the environmental contamination, the evaluation of the radiation exposure of the population, the assessment of the health impact from radiation exposures and the evaluation of the protective measures.

Figure 1

GOALS AND SCOPE

4. The project dealt exclusively with the radiological consequences for the inhabitants of affected areas: approx. 25,000 km² with ground concentration levels of Cs over 5 Ci/km² (58% located in Belarus, 32% in Russia and 9% in the Ukraine), covering a population of 825,000 (45% live in Belarus, 24% in Russia and 31% in the Ukraine) residing in over 2,000 settlements in the three Republics. The project did not cover the prohibited region (approximately 30 km in radius around the damaged reactor) or the emergency personnel ("liquidators") who carried out recovery operations after the accident.

WORK PLAN

5. Surveys were performed on 27 "surveyed contaminated settlements", some with relatively high soil surface contamination, others with relatively low soil surface contamination but with the potential for high radiation doses to the population through the food chain. For comparison, surveys were also conducted on 7 "surveyed control settlements" outside the contaminated areas. In addition, a number of information exchange activities were carried out to enhance the level of understanding of the problems involved among the local scientific community.

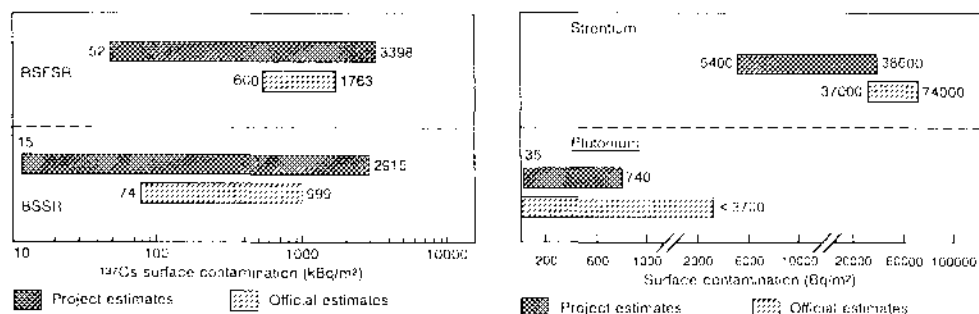

PARTICIPATION

6. Some 200 experts from research institutes, universities and organizations in 25 countries and 7 multinational organizations participated in the assessment. Approximately 50 missions were undertaken between March 1990 and January 1991. The IAEA Seibersdorf Laboratory together with 13 laboratories in 6 countries collected and analysed samples and conducted an intercomparison exercise with laboratories in Belarus,

Russia and the Ukraine. Governmental authorities and commercial companies in 5 countries donated equipment, supplies, radiation monitors and computing time. Project teams made 2,000 measurements of external gamma dose rates, ecosystem and milk, monitored almost 22,000 inhabitants for external and internal exposures and performed approximately 1,500 medical examinations. Overall efforts concentrated on assessing the reliability and accuracy of data, techniques and methodologies used to estimate contamination levels, doses and health effects and evaluating radiological protection policies.

MAJOR FINDINGS

7. From the radiological point of view, the relevant radioactive contaminant still remaining in the area is Cs-137, Sr 90 and Pu-239 being potentially interesting. The contamination values in available maps for Cs-137 and Pu-239 were generally corroborated, while Sr 90 results were lower than reported. (See Fig. 2.) Water and food contamination was below Codex Alimentarius levels.

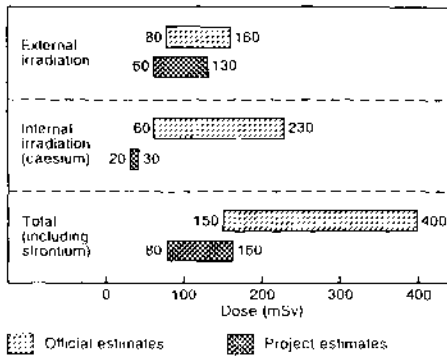

Comparison of Project measurements of caesium soil contamination with official values of caesium surface contamination for settlements of Belarus and Russia. Limited Project sampling of caesium contamination in top soils in five settlements of Belarus and four settlements of Russia indicated values that were consistent with the range of the official values based on comprehensive surveys carried out since the accident and reported for these settlements by the State Committee on Hydrometeorology and Environmental Monitoring, Moscow.

Comparison of Project measurements of strontium and plutonium soil contamination with official values for surface contamination in the Bragin region, Belarus. The Project concluded that analytical results for a limited set of soil samples corresponded to the reported estimates for plutonium but were lower than those for strontium. As illustrated here for settlements in the Bragin region, the measurements of strontium contamination suggest the potential for overestimation in the official values reported by the State Committee on Hydrometeorology and Environmental Monitoring, Moscow.

Figure 2

8. The official procedures for estimating doses were scientifically sound and the methodologies used were intended to provide results that would not underestimate the doses. However, independent project estimates were lower than the officially reported dose estimates. (See Fig. 3.)

9. No health disorders were found that could be attributed directly to radiation exposure; however, significant non-radiation-related health disorders do exist in the affected area. (See Fig. 4.) There are also substantial psychological consequences in terms of anxiety and uncertainty. No current increase in the incidence of leukemia or cancer could be substantiated and future potential increases in cancer would be difficult to discern. These general conclusions on the health situation were followed by a number of detailed conclusions, some related to neoplasms, in particular to the many reported increases in cancer and to the potential future cancer increase, as follows: USSR data indicated that reported cancer incidence had been rising for the last decade and has continued to rise at the same rate since the accident; the project team considered that there had been incomplete reporting in the past and could not assess whether the rise is due to increased incidence, methodological differences, better detection and diagnosis or other causes; the data did not reveal a marked increase in leukemia or thyroid tumours since the accident; on the basis of estimated project doses and currently accepted radiation risk estimates, future increases over the natural incidence of all cancers or hereditary effects would be difficult to discern, even with large and well designed long term epidemiological studies; however, reported estimates of absorbed thyroid dose in children are such that there may be a statisti-

Comparison of Project estimates and officially reported estimates for radiation dose to the population in selected settlements. Project dose estimates derived independently were compared with the official values for the population in the selected settlements as reported by the Institute of Biophysics, Moscow. As illustrated here, the Project estimates were lower than the officially reported dose estimates. Overall, there is general agreement within a factor of 2-3.

Figure 3

Project assessment of the general health of the population in selected settlements. The Project assessment of reported increases in illness attributed to the Chernobyl accident included an investigation of the general health of the population in selected settlements. Independent medical examinations of inhabitants of both surveyed contaminated and surveyed control settlements revealed no health disorders that could be attributed directly to radiation exposure, but did indicate significant non-radiation-related health disorders among the adult population. As illustrated here, Project results indicated that 10-15 per cent of the adult population examined in both surveyed contaminated and surveyed control settlements should be referred to a physician for follow-up medical care.

Figure 4

ably detectable increase in the incidence of thyroid tumours in the future. Examination of nearly 800 children showed no difference in height and weight between those living in contaminated settlements and those in control settlements with no contamination. Comparison with growth pattern norms in the USA indicate that children are generally healthy and their diet is adequate. Medical examinations showed that thyroid size and size distribution, as well as thyroid nodules, were similar to those reported in other countries.

10. With regard to protective measures, it was found that measures taken or planned exceed what is strictly necessary on radiological grounds. Relocation and foodstuff restrictions should have been less extensive. However, the project concluded that relaxing current policy could be counter-productive (although more restricted criteria should not be adopted) and social and political factors must be considered. (See Figs. 5 and 6.)

Criteria for evacuation of the population in the early phase of the Chernobyl accident. While the Project team was not able to investigate in detail many of the early protective actions taken by the responsible authorities, it was judged that the general response of the authorities was broadly reasonable. As illustrated here, the intervention levels of absorbed dose for evacuation applied in the early phase of the post-accident response by the authorities were consistent with general guidance prevailing at the time of the accident (the vertical columns indicate the upper and lower levels of the guidance values.) Absorbed dose is defined as the energy absorbed per unit mass of tissue.

Figure 5

LONG TERM RELOCATION CRITERIA

Long term relocation concepts were established at first on the basis of a lifetime dose of 350 mSv (35 rem) as the intervention level for relocation, the so-called 'lifetime dose limit'. Subsequently, a surface contamination of 40 Ci/km² (1480 kBq/m²) was introduced as the intervention level for relocation. The bases on which the criteria for relocation were derived were not wholly consistent with the principles currently recommended internationally. However, the International Advisory Committee concluded that "The protective measures taken or planned for the longer term, albeit

well intentioned, generally exceed what would have been strictly necessary from a radiological protection viewpoint." The table gives estimates of dose averted for the various intervention concepts. The Committee concluded that "measures are not justified on radiological protection grounds; however, any relaxation of the current policy would almost certainly be counter-productive in view of the present high levels of stress and anxiety amongst inhabitants of the contaminated areas of concern and people's present expectations."

Criterion	Year of application	Level	Lifetime dose averted from external radiation (mSv)	Lifetime dose averted from external radiation and residual ingestion dose (mSv)
Temporary annual dose limit	1986	100 mSv per annum		
	1987	30 mSv per annum	~ 140	< 240
	1988	25 mSv per annum	~ 130	< 230
	1989	25 mSv per annum	~ 150	< 260
Lifetime dose limit	1990	350 mSv lifetime	~ 60	< 130
Surface contamination	1990	> 40 Ci/km ² surface	~ 80	< 160
	1990	< 15 Ci/km ² surface	~ 30	< 80

Figure 6

SUMMARY

11. The major conclusions of the International Chernobyl Project can be summarized as follows: the official surface contamination levels were generally corroborated; the radiation doses incurred and expected future doses are lower than originally estimated; significant non-radiation related health disorders and negative psychological consequences in terms of stress and anxiety were found, but no health disorders were detected that could be directly attributed to radiation exposure; early protective measures were reasonable and consistent with international guidelines, measures taken or planned for the long term (relocations and foodstuff restrictions) exceed those which would be necessary on radiological grounds.

12. The findings have been published in an Overview for policy makers and the scientific audience and a comprehensive Technical Report for the scientific audience, both available in English and Russian. Several brochures for the general public have also been published in English and Russian. The full proceedings of the international conference that scrutinized the project are also available.

13. The International Chernobyl Project results as presented by the IAC represent an important contribution to alleviate the consequences of the Chernobyl accident. Factual information will allow future policy as well as worldwide assistance to be channelled to where it is most needed and to where it can be best used.

SOME GENERAL CONCLUSIONS FROM SIX YEARS OF CHERNOBYL-RELATED RESEARCH IN SWEDEN

Ulf Bäverstam and Leif Moberg

Swedish Radiation Protection Institute
Box 60 204, S-104 01 Stockholm, Sweden

ABSTRACT

A large research programme has been carried through by Swedish scientists as a follow-up of the Chernobyl accident. The long-term behaviour of cesium in the agricultural and aquatic ecosystems shows many similarities with previous experience. This is also true for the reindeer ecosystem. The effects of the cesium fallout on cultivated soils can be substantially decreased by various actions. Large-scale mitigating actions show only minor effects on effective half-times of cesium in fresh-water fish. The contamination of radionuclides in the forest ecosystem is even more difficult to influence. Measurements of resuspension show lower values than earlier findings. Shielding factors for houses generally confirm earlier theoretical estimates. The average radiation doses to people in Sweden are dominated by the external radiation, while the internal doses can potentially be very large and dominate for some individuals. On average the doses after Chernobyl are about the same as those after the nuclear bomb tests.

INTRODUCTION

An extensive research programme has been carried through in Sweden, motivated by the fallout from the nuclear accident in Chernobyl. A major part of this research has been financed and co-ordinated by the Swedish Radiation Protection Institute (SSI). An extensive summary of the results has recently been published (Moberg, ed). Results presented in this article are taken from that book. The programme has encompassed studies of the transport of radioactive elements to Sweden, deposition mechanisms, fallout characterization and deposition measurements. It has been estimated that 5 percent of the released amount of Cs-137 was deposited in Sweden. The deposition was, however, very uneven, with larger areas obtaining a Cs-137 contamination of more than 100 kBq/m², and in extreme cases more than 200 kBq/m².

Extensive measurements with air-borne detectors, and *in situ* gamma spectrometry allowed the deposition pattern to be determined. This knowledge has then constituted valuable background information for a number of measurements as well as for the action taken by the authorities.

Research in the long time perspective has been focussed on the behaviour and effects of the only long-lived gamma-emitters, Cs-134 and Cs-137, and especially on the transport and accumulation in the terrestrial and aquatic environments, activity measurements on man and dose calculations.

RADIATION DOSES

The average fifty-year dose for individuals in Sweden is about the same as that received as a consequence of the atmospheric bomb tests. The variation in doses between individuals is, however, much larger after Chernobyl,

due both to the non-uniform deposition and to the large variation in intake. The resulting total effective dose commitment to man in Sweden is summarized in this table.

<u>Collective dose (manSv)</u>		<u>Individual dose (mSv)</u>	
External	Internal	External	Internal
		(ratio max/min)	
5000	1000	0.6 (50-100)	0.1 (10 ³ -10 ⁴)

Of special interest are groups living in high-deposition areas with diets including large amounts of game meat, reindeer and freshwater fish, for example reindeer-breeding Sami families. Whole-body measurements show that individuals from this group receive average internal doses 100 times that of the average Swede. On the other hand, people who buy their food and live in low-deposition areas receive a dose equal to one tenth of the average value.

The external dose follows more closely the deposition pattern and constitutes the larger part of the collective dose commitment after Chernobyl, in average five times larger than the dose commitment from intake.

TERRESTRIAL RADIOECOLOGY

The high levels of cesium concentration in lichens, the predominant fodder for reindeer during the winter season, subsequent to fallout are well known since the sixties. This time, however, the maximum values were more than ten times higher than after the bomb tests. The effective half-time of Cs-137 in lichen was found to be 8-14 years during the sixties and recently repeated measurements on residual bomb-caesium give values of 8-10 years. Even if the time elapsed since the Chernobyl accident is short, preliminary results indicate half-times in the range 6-15 years, i.e. similar to earlier experience. A number of actions have been taken to decrease the consequences. Moving reindeer to areas with lower deposition, use of bentonite to decrease uptake in the reindeer, adding cesium-free food to the diet prior to slaughter, and the use of zeolites are methods that have been tested with varying degrees of success.

In spite of these actions a large number of slaughtered reindeer have been discarded for selling in the open market. For reindeer in some areas the long half-time of cesium in lichen will be a problem for some decades.

Studies of the radioactive contamination of the forest ecosystem in Sweden were limited during and after the sixties. Results from post-Chernobyl observations of the amount of Cs-137 remaining in different parts of the boreal ecosystem, the fraction lost by run-off, the concentration prevailing in plants in important food-chains and concentrations in moose indicate that changes in levels about one-year after the initial deposition will be exceptionally slow. In fact, it will probably be governed by the physical decay of the radioactive cesium. One consequence of this is that

the collective dose from forest products might be of the same order as that from agricultural products. However, this will be clarified by further studies. The concentrations of cesium in moose and roedeer, in particular, are also high. The variations between individual animals, years etc are large.

Radioecological questions related to agriculture have been studied right from the end of the fifties. A basis of knowledge existed prior to the Chernobyl accident. However, even though the pre-Chernobyl studies were in progress over a long period, the aims were restricted. The studies after Chernobyl have opened up a wider scope. On a large number of sites the cesium transfer both to grass and grain crops has been measured. The results have increased the experience on the effect of soil composition on cesium transfer to crops, on the importance of the nuclide depth distribution and variations due to differences in the agricultural systems used. Results from experiments with different levels of potassium fertilization are generally in agreement with earlier findings. Transfer coefficients of radioactive cesium to cow's milk show a large range of values, but are similar to those which were generally accepted before the accident.

AQUATIC RADIOECOLOGY

A number of radionuclides originating from the accident were detected in the marine biota of the Baltic Sea. The only ones frequently observed in fish were Cs-134 and Cs-137. A major fraction of the total load of Cs-137 to the Baltic Sea was transferred to the sediments already during the first year. The accumulation of cesium in fish in the Baltic Sea is much smaller than in freshwater fish, and the radiological consequences from the contamination of the Baltic Sea were quite small.

In lake ecosystems a rapid incorporation of Cs-137 resulted in high concentrations. Organisms at lower trophic levels reached their maximal activity concentrations already during 1986. The predator fish reached maximum values the following years, the exact time depending on the type of lake and species. A major part of the Cs-input was relatively early deposited on the bottom sediments. Resuspension of cesium from the sediments has been found to be an important reason for delayed recovery in some lakes. Fish that consume macro invertebrates which feed on the contaminated sediment layer can cause sustained accumulation of cesium. In particular, this has been demonstrated in oligotrophic high-altitude lakes.

The apparent half-time of cesium in fish varies considerably (0.6-13 years) depending on the type of lake, species, age of the fish etc. However, the half-times for large perch and large pike seem to be similar to those found during the sixties.

It is known that the content of stable potassium in the water is negatively correlated to the concentration of Cs-137 in fish but potash treatment of lakes after the deposition does not seem to be a very effective way to speed up recovery. The treatment performed in oligotrophic lakes imply that the recovery can never be more than 5% faster compared with no treatment. This result is supported also by recent Swedish laboratory experiments on Chernobyl contaminated fish and water. Once the lake is contaminated with cesium, a subsequent addition of potassium has little effect on the half-time. Liming of lakes shows the same negative results.

MODEL TESTING

The Chernobyl databases have been utilized to test environmental transfer models primarily within the international BIOMOV5 study. Two main cases, based on lake and vegetation-milk data, were investigated. The accuracy of the predictions for water and sediment was found to be satisfactory for most radioecological assessments. The discrepancies were higher for fish. For the milk pathway about half of the predicted time-integrated concentrations of I-131 and Cs-137 in vegetation were within a factor of two from the observed values, while for the time-integrated predictions of I-131 and Cs-137 in milk the discrepancies were higher.

The available data sets, prolonged in time, will be available for future model testing and analyses.

THE FALLOUT

As a result of the relatively high deposition in some parts of Sweden it has been possible to perform field measurements of a number of parameters (dry and wet deposition velocities, resuspension, shielding factors for houses) which earlier had to be estimated from small-scale experiments or measured in environments different from those in Sweden. The measured shielding factors for houses confirm earlier theoretical estimates based on experiments. Measurements of resuspension show lower values than those often used prior to the Chernobyl accident.

GENERAL CONCLUSIONS

It would appear that many of the results and many conclusions after Chernobyl support corresponding earlier data. The very slow recovery in the forest ecosystem had not previously been fully appreciated.

The average doses in Sweden are low, and comparable to the doses obtained from the atmospheric testing of nuclear weapons. However, the variation in doses between individuals is much larger after Chernobyl. It is important that the deposition took place before the growing season, and that the major farming areas of Sweden received a very low contamination which contributed to the fact that there were such low doses from agricultural products.

The results are very similar to those from the sixties. There is, however, an important difference between the research in the eighties and that in the sixties. Today a more ecological approach is encountered. This fact, which at least in part is explained by the larger number of scientists trained in ecology and taking part in radioecological research, contributes to the fact that the present-day results have a higher credibility than those of former years.

This paper presents a first estimation, performed in 1990, of the cost and averted collective exposure of the potential relocation of the population from the affected territories of Russia, Byelorussia and Ukraine, to improve their living conditions following the Chernobyl accident. A general and simplified modelling approach was adopted in the evaluation. Results suggest that from a strict radiological protection viewpoint, it would have been very difficult to justify any allocation of resources to relocate the population living in areas with less than 40 Ci/km². The study has also indicated the need for further investigations on various points.

1. INTRODUCTION

Following the Chernobyl accident a variety of measures were taken to protect those affected from exposure to radiation. Once the immediate effects of the accident were dealt with, attention turned to longer term considerations, in particular how to ensure "safe" living conditions for those living beyond the evacuated zone. In 1989, criteria were proposed to restore "normal" living conditions. In those settlements where the criterion was exceeded people would be relocated; in the remaining settlements normal living conditions, with no restrictions on food nor people's habits, would resume. Considerable debate and argument arose over the appropriateness of this criterion. In an attempt to resolve some of these disagreements, the Soviet Government requested the International Atomic Energy Agency (IAEA) to organise an international group of experts to review and evaluate the measures being taken to assure "safe" living conditions for those people continuing to live in the affected areas. This paper presents a first estimate of the effectiveness of the measures adopted within the so-called "State All-Union and Republican Programme for Urgent Measures for Eliminating the Consequences of the Chernobyl Accident for 1990-1992" by the Soviet Supreme of the USSR in April 1990 [1]. This study has been performed under contract for the Commission of the European Communities within the framework of the IAEA International Chernobyl Project [2].

2. METHODOLOGY AND DATA

Based on dosimetric and economic data collected in USSR during summer 1990, a general and simplified modelling approach was adopted in the evaluation. The basic input to the model is the distribution of the population living in the affected areas as a function of the level of ground contamination expressed in Ci/km² of Cs-137 [3]. The corresponding total population was about 705,600 people for the three Republics (Russia, Ukraine, and Byelorussia), and was considered to be representative of those living in these areas at the beginning of 1990, for levels above 5 Ci/km².

The doses corresponding to a given contamination level have been derived from a generic dosimetric model developed at the Institute of Biophysics in Moscow. The model is based on simple expressions, which are used to derive the external and internal doses in a given year, as a function of the surface Cs-137 contamination, when no restrictions exist. The average relationships between the dose and contamination level are presented in Table 1.

Table 1: Average relationships between surface contamination, individual annual dose (for 1990) and individual lifetime dose (1990-2060)^a

Surface contamination Cs-137 (Ci/km ²)	Annual effective dose equivalent in 1990 (mSv)	Lifetime effective dose equivalent (1990-2060) (mSv)
5	≈ 2	≈ 40
15	≈ 5	≈ 90
40	≈ 13	≈ 210
80	≈ 25	≈ 410

a) Doses were estimated in the absence of any protective measures

In the absence of any protective measures, the total collective dose for the 1990-2060 period, for people living in the zones with more than 5 Ci/km² (500,000 people between 5 to 15 Ci/km², 200,000 between 15 to 40 Ci/km², 15,000 between 40 to 80 Ci/km², 1,000 above 80 Ci/km²), was estimated to be about: 54,000 man-Sv.

3. COST AND EFFECTIVENESS OF COUNTERMEASURES

In the absence of adequate data, the model only considered protective measures in two broad categories: relocation of the population, and improvement of living conditions. Of the many measures taken to improve living conditions, only a few have a significant effect on the doses received; the provision of clean food is perhaps the most important in this respect. Relocation was assumed to be totally effective, and the dose was considered to be zero as soon as the population has left the contaminated area. Two further aspects have been considered. First, for social and economic reasons, the relocation of a given settlement or a set of settlements, may necessitate the additional relocation of neighbouring settlements where these are economically dependent on those relocated. Secondly, there may be many people in each Republic who wish to be relocated, even when the level of contamination is below the criterion.

As far as costs are concerned, all costs used in the model were taken from the "State All-Union and Republican Programme" [1]. Two categories of costs have been distinguished: "one off" costs, and annual costs. Based on a detailed analysis of the resources allocation in the three Republics, the cost "per capita" of relocation and improvement of living conditions were estimated.

4. PROTECTION STRATEGIES

The current State All-Union and Republican Programme was based on the following criteria for the countermeasures:

- improvement of living conditions for the population living in

areas where the ground contamination was above 5 Ci/km²;

- relocation for the population living in areas where the ground contamination was above 40 Ci/km².

These two basic protective measures have been combined into strategies fitting with the generic conceptual framework presented in Figure 1. The value of 5 Ci/km² has been adopted in the model for level A. Expressed in terms of annual dose in 1990 or lifetime dose, this contamination level was corresponding to:

- . an average annual effective dose equivalent in 1990 = 2.2 mSv/y
- . an average lifetime effective dose equivalent (1990-2060) = 37 mSv

assuming no protective measures were taken. Altogether, 11 strategies have been evaluated with the model in which different values have been assumed for level B, the level above which it was assumed that relocation was implemented.

Figure 1: Basic scheme for the definition of "protective strategies"

5. COST-BENEFIT ANALYSIS

Strictly speaking, the evaluation of the various strategies was based on a differential cost-benefit analysis, here called cost-benefit analysis for simplification. To make judgements on the marginal costs per unit dose averted by the various strategies, it was necessary to introduce a reference value for the cost of the man-Sievert. The approach adopted in this study was to combine the use of a baseline monetary value of the man-sievert calculated according to the human capital method with a risk aversion factor, increasing with the level of contamination, to reflect the general attitude of the population living in the contaminated areas. The final conclusion concerning the level above which relocation was justified, was clearly conditional upon the attitude towards aversion. Based on the most conservative assumptions only population above 40 Ci/km² should have been relocated. Figure 2 presents the range of level of ground contamination (40 to 80 Ci/km²) for which the marginal cost of countermeasures and the marginal cost of the detriment are of the same order taking into account the sensitivity of the key parameters.

Figure 2: Cost-benefit analysis

6. CONCLUSION

This analysis was an attempt to provide a coherent framework for all the available data in 1990 concerning the cost and doses averted associated with various relocation strategies. Ideally the analysis should have been undertaken on a settlement by settlement basis, where proper account could have been taken of local variations in dosimetric and economic data. However, because of data limitations this was not possible. Using a baseline value of the man-Sievert, estimated on the basis of human capital considerations, the evaluation led to the conclusion that it was not justified to relocate anyone from the controlled zones. With some allowance for risk aversion, the results suggested that there were no strong arguments for the implementation of further measures other than those already envisaged, unless relocation costs would differ largely from the base case. Nevertheless, some other factors of a social or political nature could justify a more restrictive approach [4].

ACKNOWLEDGMENTS

We wish to express our sincere thanks to all the scientists and members of public ministries in the Republics of Byelorussia, Russia, and Ukraine, and at the All-Union level, for their help.

MODELING OF THE TRANSFER OF IODINE AND CESIUM VIA THE GRASS-COW-MILK PATHWAY AFTER THE CHERNOBYL ACCIDENT

Gerald Kirchner

University of Bremen, Dept. of Physics, Postfach 330440, D-2800 Bremen 33, FRG

ABSTRACT

More than 60 data sets of time dependent activities of iodine and cesium in grass and milk measured after the Chernobyl accident are evaluated using the concepts of linear compartmental theory. The transfer kinetics can be described by models including two (^{131}I) or three (^{137}Cs) compartments. Calculated weathering half lives and equilibrium transfer coefficients into milk are in the range of values reported in reviews of experimental data based on observations of atomic weapons fallout and on laboratory experiments.

INTRODUCTION

After the Chernobyl accident many measurements of time dependent activities of iodine and cesium isotopes in grass and milk samples were performed. Based on the analysis of 62 datasets¹⁻¹⁵, both the structure of compartmental models which adequately describe the kinetics of the transport of ^{131}I and ^{137}Cs via the grass-cow-milk pathway and numerical values of radioecological parameters are presented in this paper.

CALCULATIONAL METHODOLOGY

From datasets including nuclide concentrations in the milk of single animals both the structures of *minimal* compartmental models which adequately describe the measured transfer kinetics and numerical values of the associated transfer rates were calculated using the concepts of linear compartmental theory¹⁶. Additionally, equilibrium transfer coefficients grass \rightarrow milk were calculated. As averaged milk samples do not represent the transfer kinetics of the individual animals¹⁶, for these data sets only equilibrium transfer coefficients could be determined.

RESULTS AND DISCUSSION

Results of the analyses are given in Tab. 1, structures of the minimal compartmental models are shown in Fig. 1. For both nuclides feeding experiments established the existence of a long-term storage compartment¹⁷ which in a part of the datasets of Tab. 1 is not observed. Explanations could be (a) experiments of too short duration, (b) difficulties to resolve processes with numerically small transfer rates from data scattering (especially in the case of experiments with constant nuclide intake), (c) problems to fit experimental data to sums of more than three exponentials¹⁸.

Mean values of weathering half-lives - 5.9 ± 0.7 d (^{131}I) and 9.5 ± 0.9 d (^{137}Cs) - are in good agreement with data given in a previous review¹⁹.

The range of equilibrium transfer coefficients given in Tab. 1 agrees well with nuclear weapons fallout data²⁰, but their mean values of $(3.8 \pm 0.5) \cdot 10^{-3}$ d/ ℓ (^{131}I) and of $(3.4 \pm 0.3) \cdot 10^{-3}$ d/ ℓ (^{137}Cs) are lower.

CHERNOBYL: A CONTRIBUTION TO OUR LEARNING PROCESS

O. Ilari and C. Viktorsson

Organisation for Economic Co-operation and Development
Paris, France

The Chernobyl accident and its widespread impact have prompted a process of critical review and revision of approaches to the management of accidents that has fully involved the international community. The OECD/NEA has participated to this effort by analysing the lessons learned from the accident and contributing guidance for a fresh approach to the protection of the public in the event of a nuclear accident.

INTRODUCTION

One of the main driving forces to achieve progress in our society is learning from experience. This is true in improving radiation protection as it is in any other human undertaking. Although this is unfortunate, we must accept that accidents and malfunctions are one of the most powerful sources of experience and, in this respect, the Chernobyl accident, in 1986, has triggered, and still continues to stimulate, one of the most wide-ranging learning processes ever experienced in radiation protection, in areas such as accident consequence assessment and management, emergency preparedness, radioecology and the like. In effect, before Chernobyl the attitude of national authorities and radiation protection operators was one of relative self-confidence with respect to the validity and effectiveness of international guidance and of national preparedness for the protection of the public in the event of nuclear accidents.

The reality of a major accident as the Chernobyl one did, however, show that the degree of preparedness to manage the consequences of an accident of that size was not satisfactory. In fact, although the radiological impact in countries other than the Soviet Union was not large, the progressive spread of contamination at large distances caused considerable concern in Member countries. The reactions of national authorities were varied, ranging from a simple intensification of the normal environmental monitoring programmes up to compulsory restrictions on the marketing and consumption of food and other measures directly affecting the public. This apparent disharmony of protective actions and intervention levels caused concern and confusion among the public, perplexities among the experts and difficulties to national authorities, including loss of public credibility. All this resulted in a widespread perception that several lessons should be learned from this negative experience and a consensus that efforts should be directed towards a better international harmonization of the scientific bases and co-ordination of criteria and measures for the protection of the public in case of emergency.

These conclusions have triggered a vast effort of improvement of emergency planning arrangements in almost all Member countries, but also a renewed attempt by several international organisations to apply the Chernobyl lesson to the rationalisation of principles and criteria and the enhancement of harmonisation and co-ordination of their practical application to the management of nuclear accidents.

THE ROLE OF THE NEA

The NEA, through its Committee on Radiation Protection and Public Health (CRPPH), has played an active role in this process assisting Member countries to identify the main lessons to be learned from the accident and promoting a number of co-operative actions to transform these lessons into improved accident management concepts and procedures.

The CRPPH felt that a first step for establishing where the Agency's effort should be applied was to make an independent assessment of the radiological impact of the Chernobyl accident and a critical review of the consequent emergency responses adopted by the different countries. The Agency, therefore, prepared a first report, published in 1987 (1), which analysed in some detail the radiological impact in all the OECD countries and the protection measures adopted by those countries. This analysis, of course, had a preliminary character in view of the provisional data available at the time, but it still remains today the only assessment established on the basis of information provided by the Member countries and officially endorsed by the national authorities concerned. The NEA also carried out, at that time, a detailed survey of the organisational and technical aspects of the emergency preparedness existing in the Member countries at the time of the Chernobyl accident, as well as of the changes introduced or planned as a consequence of that accident (2). These analyses allowed to identify the principal concerns of the authorities and the public opinion in the different countries.

The first conclusion that could be drawn from these analyses was of a conceptual nature. It was realised that the impact of a major nuclear accident would inevitably have an international dimension and it would require, therefore, a closer harmonization of the intervention criteria beyond the mere harmony of the general principles, which was already existing, as well as an extension of the space and time horizons on which to base the emergency plans, by adding to it elements of greater flexibility and a capability to manage contaminations affecting large territories, and with consequences extending over long time spans. Another important conclusion of the CRPPH analyses was the need to improve the technical systems used for the assessment of the radiological impact of an accident, such as monitoring methods and network systems for rapid alarm and real time assessments, calculation models and analysis methods. Finally, the failures of the systems of communication and information have been one of the major objects of blame during and after the Chernobyl accident. This lesson was not missed and it resulted in a considerable attention being focused on the need to improve the quality and the effectiveness of the communication of information in case of emergency among competent authorities and towards the public.

A significant part of the problems identified by the CRPPH were clearly the responsibility of the national authorities. However, the Committee was able to identify a few areas where the Agency could provide a contribution compatible with its vocation and its limited resources.

The intervention criteria

The first priority was attributed to the question of criteria and levels for intervention. The existing international recommendations, although their general principles were valid, had demonstrated their limitations during the practical management of the Chernobyl accident

consequences at large distances and in the long term. Thus, starting from a critical analysis of the existing recommendations, a group of experts of the Agency examined all the aspects of the intervention issue and developed a number of novel ideas on the determination of criteria and levels for intervention and their practical implementation (3, 4). In particular, the NEA group proposed a reasonably detailed approach for the application of the principles of justification and optimisation of interventions in the definition of the intervention levels and introduced the concepts of "upper boundary" and "lower boundary" of individual dose in the process of optimisation.

A particularly interesting concept is that of upper boundary, defined as the total individual dose, resulting from the whole of exposure pathways, beyond which the possibility of deterministic effects and the probability of stochastic effects are considered unacceptable. Beyond the upper boundary the intervention would thus become mandatory irrespective of the indications provided by the results of the justification and optimisation procedures. The validity of this idea was confirmed by a widespread demand for a criterion of this kind which had been expressed on several occasions in the international debate. The concept of lower boundary, a very small individual dose below which protective actions are unlikely to be justified even if the costs of the intervention are also very small, was also considered very useful and necessary by many experts. However, this concept does not appear to have been well received in the recommendations of other international organisations. Another original contribution introduced by the NEA was the consideration, which was absent in the previous international guidance, of the impact of certain special exposure pathways affecting specific groups, such as workers not involved in emergency operations, and the definition of specific protection criteria for these groups.

The technical issues

In the field of the technical aspects of emergency planning, the NEA has chosen to limit itself to the study of a few issues which had not attracted the attention of other international organisations. First of all, an analysis was made of the possible differences in the radiological consequences of an accident if this were to happen in different seasonal and climatic conditions and how these factors could affect the application of emergency plans (5,6).

The Chernobyl experience was also the indirect source of another initiative recently taken by the NEA in the field of emergency exercises, which, surprisingly, had never enjoyed before a particular attention at the international level. A work programme is currently under way for an exchange of information and experience on national practices, the study of criteria and technical methods for the execution of emergency exercises and, as a final step, the organisation of international exercises under the NEA's aegis. Multinational or international emergency exercises are, in fact, seen as being of particular value to test the compatibility and co-ordination of neighboring countries' approaches to emergency planning by the simulation of scenarios which extend beyond national borders and to contribute to better mutual understanding and, possibly, closer harmonization of the basic approaches to emergency response on a truly international basis.

The communication with the public

Last but not least, it was understood with the Chernobyl accident that the communication between countries and with the public is a fundamental component of a correct management of a nuclear accident, especially if it has an international impact. The information of the public is not the main vocation of the NEA, which is primarily a technical agency. However, it was decided to bring some contribution to those who are responsible for the information of the public and several initiatives were taken by the Agency in this field.

One interesting idea that began to be aired in 1987 was that of creating an international system for the classification of incidents and accidents according to their degree of severity, and impact to safety, to be used to facilitate the information of the public. At the end of 1987, a group of experts of the NEA had already set up a series of criteria for the development of what would have been called since the international severity scale for nuclear accidents and incidents. Subsequently, in 1989, the NEA and the IAEA decided to join their forces in this international undertaking and launched jointly, in 1990, the International Nuclear Event Scale (INES), which was adopted by a large number of member countries for a trial period before its final establishment on a permanent basis. A success of this endeavour would mean a significant step towards a better coherence and clarity in the communication with the public.

CONCLUSION

In conclusion, the Chernobyl accident has revealed a number of weaknesses in the protection system such as it was conceived before the accident, but it has also indicated new perspectives for improvement. In this context, in which the international co-operation has played a major role, the NEA has tried to draw a maximum of lessons which could be useful to its Member countries and to provide, within the limits of its modest resources, an active contribution to the international co-operation and the improvement of radiation protection.

ABSTRACT

In 1990, the IAEA conducted a whole body counting programme in the Soviet Union as part of its project on The Radiological Consequences in the USSR from the Chernobyl Accident: Assessment of Health and Environmental Effects and Evaluation of Protective Measures. Approximately 9,000 people from 9 towns in three republics were counted to corroborate measurements of internal ¹³⁷Cs contamination in the effected population made by the Soviet specialists following the accident. A mobile whole body counting facility, equipped with 4 chair counters was loaned to the Agency by the SCPRI, France for use in the measurement programme.

INTRODUCTION

As part of the IAEA international assessment programme carried out in 1990-91, a project was implemented by the IAEA to provide independent measurements of the internal doses currently received by individuals in 9 selected settlements in the USSR [1]. During the period 5 July to 7 September 1990 a whole body counting campaign was conducted in the BSSR, RSFSR and UkrSSR, using a mobile whole body counting van provided by the SCPRI, France. Nearly 10,000 total measurements were made including reference measurements of a calibration phantom, as well as of van staff, for quality control. The results for 9,058 people are reported here.

COUNTING PROCEDURE

The mobile van is equipped with four chair counters. Each counter has a 7.62 × 7.62 cm cylindrical NaI crystal housed in a collimated lead shield. The person is positioned for counting so that the shield is centered on the chest, over the region of the lungs, and in contact with the body. The counting period was 5 minutes. The background rates for the counters were determined by inserting a conical plastic plug into the collimator.

During counting, the person being measured provided some self shielding, thus reducing the counter background. Unfortunately, the degree of self shielding was variable, depending on the mass of the person. This is a particularly a problem in evaluating results for small children. Since the counting procedure as established by SCPRI was intended to be used for adults, it did not make provision for corrections based on wide variations in body mass.

The data were processed with a multichannel analyzer and a portable computer using software developed at SCPRI. The SCPRI data-unfolding process is intended to accommodate up to three radionuclides. However, the counting statistics were often poor, so only results for ^{137}Cs are presented in this report. From information provided by whole body counting specialists in Kiev and Minsk, based on their counting results, the ratio of ^{137}Cs to ^{134}Cs was approximately 6.5. Results of this ratio for an environmental sample, dried green peas grown in the Chernobyl region and assayed in December 1990, ranged from 7.9 to 8.8. This would be equivalent to 7.2 in August 1990, the mid-point of the whole body counting project.

The limit of detection (LOD) as defined by the data-processing software of the mobile van is three times the background count standard deviation. Because of the high variability in background from one town to another, the LOD is variable. In addition, the efficiency depends significantly on the size of the person being counted. Therefore, a single value cannot be quoted. However, a typical LOD for an adult is about 0.74 kBq (0.02 μCi), while for a small child the value drops to about 0.19 kBq (0.005 μCi).

COUNTER CALIBRATION

Since the mobile van was designed for operational emergency response applications, the calibration is based on a 70-kg reference man, 170 cm tall. The design of the counters in the counting van is such that only activity in the torso is detected. For adults this means that the mass of tissue seen by the counter is roughly constant. Following a review of the counting procedure, it was concluded that the calibration was reasonably accurate in the weight range 50 to 90 kg. However, for individuals outside that range the results could be significantly in error. For a child weighing 20 kg with a height of 100 cm, for example, the original calibration would overestimate the caesium burden by a factor of 2.6. Therefore, it was recommended that a modified correction factor based only on weight be used:

$$CF = \frac{70}{\text{Weight (kg)}} \quad (1)$$

During the measurement programme, a plastic cylindrical phantom containing ^{137}Cs was used to check the counter performance on a daily basis. In addition, a few members of the van staff had measurable levels of ^{137}Cs . They were also counted at regular intervals.

At the end of the counting programme, the van returned to Seibersdorf. At that time, the calibration of each counter was checked with a standard bottle phantom obtained from the Battelle Pacific Northwest Laboratory in the USA. The phantom contained 11.2 kBq ^{137}Cs in a solid polyurethane tissue substitute.

RESULTS

Summary statistics and internal dosimetry results for the nine settlements in the BSSR, RSFSR and UkrSSR are presented in Table 1. Since the measurements were made at only one time, it is impossible to determine time dependent changes in the internal body levels. Therefore, a constant intake was assumed. A conversion factor for specific body burden to dose rate of 2.5 $\mu\text{Sv/a}$ per Bq/kg was used to calculate annual dose.

The results for a given population can be expected to have a log normal distribution. The distribution of specific body burdens for the settlement of Novozybkov, the largest population counted is shown in Figure 1, with an estimate of the best fit for a log normal distribution. The quality of fit varies from village to village. In some cases, non-statistical factors influence the results. For example, the assignment of the value of the detection limit to those measurements at or below that limit obviously biases the low activity results upwards.

This effect can be seen more clearly in the cumulative normal probability plots of the log of the specific body burden. The overlying straight line represents the distribution that would be expected for a population having a log normal distribution without additional influences. These plots also demonstrate deviation from the expected distribution at higher values of the specific body burden. The reason for this deviation has not been definitely identified. A possible explanation is that it is the result of a small subset of the population that does not observe the dietary restrictions imposed by local authorities, or that dietary habits (such as eating large quantities of forest mushrooms) predispose members of the population to higher body burdens.

Fontenay-aux-Roses

ON THE WORLDWIDE FALLOUT FROM THE CHERNOBYL ACCIDENT

ABSTRACT

Numerous measurement's results of cesium 137 deposition from the Chernobyl accident were gathered and they were compared with a modelling which is simplified and adapted to the long distances. The figure shows a good agreement between measurements and model. It shows also that the radiological impact of the accident, lesser beyond 2000 km than that of all nuclear weapons tests, or lesser than that of one year of natural radioactivity, diminish strongly with the distance from the place of the accident. Some very small cesium 134 detections in the south hemisphere can be easily related to the Chernobyl accident.

INTRODUCTION

Grâce à des simplifications convenables, il est possible de montrer clairement que la distribution mondiale des retombées radioactives observées de l'accident de Tchernobyl est en accord satisfaisant avec une modélisation classique, et que l'essentiel des conséquences radiologiques en est connu et à l'abri de toute contestation.

LES PARAMETRES DE LA MODÉLISATION

Même simplifiée et mondiale toute modélisation des retombées d'une pollution telle que celle due à cet accident dépend de quelques paramètres déterminants qui concernent l'émission, l'éloignement, la diffusion, les dépôts secs et précipités et la remise en suspension. Emission mise à part ces paramètres participent à la déconcentration des nuages de polluants, les plus efficaces étant ceux des dépôts, qui appauvrissent les nuages, surtout après le premier millier de kilomètres.

UNE MODÉLISATION SIMPLIFIÉE

Pour simplifier la modélisation on a remplacé les émissions réelles par une émission unique ponctuelle instantanée et les trajectoires réelles, d'ailleurs mal connues, par une trajectoire unique de plus courte distance ou de plus court délai pour chaque point d'observation. Ces hypothèses sont toutes majorantes pour les concentrations maximales. Le traitement de la diffusion par la turbulence de l'atmosphère est classique et comporte notamment une épaisseur de mélange constante de 1000 mètres. Le dépôt sur les surfaces et la remise en suspension sont traités par les coefficients

habituels dont les valeurs sont tirées de la bibliographie. Au delà de 2000 km, la correction d'appauvrissement des nuages par le dépôt, dite "à la source", conduit à des appauvrissements exagérés et doit être amendée en conséquence.

LES RÉSULTATS EXPRIMÉS EN DÉPÔT DE CÉSIUM 137

De très nombreux résultats d'observation et de mesure, provenant de presque toutes les parties du monde, ont pu être rassemblés /1/, /2/, /3/, /4/, /5/, /6/, /7/. Ils sont exprimés en dépôt de césium 137 récent, associé à l'isotope 134, c'est-à-dire provenant avec certitude de l'accident de Tchernobyl. Le césium 137 est en effet, avec sa longue période, un très bon indicateur des transferts à grande distance, et son dépôt une composante essentielle des doses délivrées. Tous ces résultats sont reportés, en Bq/m^{-2} , en fonction de la plus courte distance en kilomètres, ou de la durée de transfert en jours, sur la figure où la modélisation est représentée par trois courbes. La courbe supérieure n'est qu'une indication de l'absence de réalisme d'un calcul sans correction d'appauvrissement du nuage. La courbe inférieure implique une correction d'appauvrissement unique, trop sévère aux grandes distances. La courbe intermédiaire est un ajustement empirique qui implique un appauvrissement moins sévère à partir de 1000 km. Cette troisième courbe sépare le domaine en deux parties telles que toutes les observations doivent se trouver dans la partie inférieure et aucune dans la partie supérieure. Cette modélisation est en effet systématiquement majorante. De plus elle n'est valable que sur une trajectoire et enfin une précipitation intervenant sur une trajectoire ne peut entraîner qu'une majoration supplémentaire maximale d'un facteur de l'ordre de 10.

On voit que l'alignement des observations est satisfaisant et que l'importance de la retombée décroît fortement en fonction de l'éloignement, en raison même de la rétention qu'elle provoque. On voit aussi sur la figure que la retombée totale en césium 137 des essais nucléaires aériens, de l'ordre de 5000 Bq/m^2 et quasi homogène sur l'ensemble de la planète, correspond à celle de l'accident de Tchernobyl à une distance d'environ 2000 km du lieu de l'accident /8/. On sait (UNSCEAR) que l'impact radiologique de l'ensemble des essais nucléaires aériens est de l'ordre de celui d'une année moyenne de radioactivité naturelle.

Plus on s'éloigne du lieu de l'accident plus les hétérogénéités de la retombée ont tendance à s'estomper en raison des dimensions atteintes par les nuages et des recoupements de trajectoires. Mais en même temps on tend vers une faible contamination générale de la planète qui se stabilise momentanément, selon un équilibre du dépôt et de la remise en suspension, autour de valeurs limites inférieures de l'ordre de $1 \mu\text{Bq/m}^3$ dans l'air, et de $0,1 \text{ Bq/m}^2$ en surface, soit pour un coefficient de remise en suspension de l'ordre de 10^{-5} m^{-1} . Ces valeurs limites, qui sont aussi des limites de détection, même pour des laboratoires spécialement équipés, sont de l'ordre de grandeur actuel des résidus de la retombée

des essais nucléaires aériens. Leur appartenance à l'accident de Tchernobyl ne peut être établie qu'en passant par l'isotope 134. Il semble que quelques stations françaises de Polynésie et de l'océan indien aient fourni des prélèvements permettant d'obtenir de telles détections /7/, /9/. Cette circonstance confirmerait l'absence d'effet de barrière de l'équateur sur la diffusion de fines particules transportées par l'atmosphère, même dans les basses couches.

CONCLUSIONS

- 1 - L'accident de Tchernobyl n'apporte pas d'information révolutionnaire de nature à modifier significativement les errements en vigueur en matière de modélisation de la dispersion de polluants atmosphériques.
- 2 - Si l'accident de Tchernobyl est certes un événement tragique pour les populations proches de la Centrale, et si on a pu dire que cet accident était une catastrophe mondiale (média), on ne peut sûrement pas dire qu'il s'agisse d'une catastrophe radiologique mondiale. Son impact radiologique diminue en effet fortement en fonction de l'éloignement, et au delà de 2000 km il est inférieur à celui des essais aériens ainsi qu'à une année moyenne de radioactivité naturelle.
- 3 - Compte tenu des lois connues de la dispersion à l'échelle mondiale, il ne serait pas nécessaire de faire intervenir d'autres sources que celles de Tchernobyl pour expliquer correctement d'éventuelles très rares et très faibles détections de césium 134 dans l'hémisphère Sud.

ABSTRACT

A procedure for estimates of the abundance and size distribution of nuclear fuel particles in the Chernobyl fallout is described, which allows calculations of the inhalation dose due to nonvolatile radionuclides contained therein. These are represented by the gamma-emitter Ce-144. An example is given for the Chernobyl nuclear power plant area based on the autoradiographic analysis of a soil sample and gamma-spectrometric and electron microscopic analysis of isolated fuel particles. At larger distances from Chernobyl the relative importance of nonvolatile radionuclides decreases with distance; it is highest in regions contaminated by the explosion plume as obtained from the Ce 144 to Cs-137 isotopic ratio in the fallout.

INTRODUCTION

The emission and dispersion of micrometer sized nuclear fuel particles due to the explosion of the reactor core is a unique feature of the Chernobyl fallout /1/. Different types of particles have been detected /2-9/. The majority consists of a UO₂ matrix depleted in volatile radionuclides like Cs-137, but retaining refractory radionuclides like Cs-144, Sr-90 or transuranium isotopes, which thus can easily be identified via the long-lived gamma-emitter Ce-144. A typical Ce-144 activity of a 4 µm particle was about 10 Bq at May 1st, 1986. A small fraction is formed from metallic segregations of ruthenium and molybdenum in the fuel; they were characterized by Ru-106 and their activities per particle of equal size were about 1000 times larger. The inhalation of those particles during the passage of radioactive clouds in the initial phase of the accident contribute to the inhalation dose, which depends on the number and size of those particles and which demands for microdosimetric calculations /10/. In this contribution an approach is outlined, which allows a rough estimate of these quantities from the determination of the number and size distribution of fuel particles deposited on the ground assuming Stokesian sinking of these particles in air. It is restricted so far to the more abundant UO₂-type particles.

Fig. 1: Autoradiographic exposure of a soil sample taken at the cooling pond of Chernobyl nuclear power plant in September 1990 and exposed in June 1991 (Kodak "Direct Exposure"). The dark spots indicate nuclear fuel particles.

NUMBER AND SIZE DISTRIBUTION OF FUEL PARTICLES IN THE FALLOUT

This analysis is based on a soil sample taken in September 1990 at the western shore of the cooling pond of Chernobyl nuclear power plant (about 4 km distance from unit 4). Via autoradiography a number of fuel particles could be identified in this sample (fig. 1). A few of them could be isolated and analyzed by means of gamma spectrometry and electron microscopy. The predominant Ce-144 line in the respective gamma spectra and the characteristic U X-rays in the corresponding electron probe X-ray analysis proved their UO₂-type character [11]. The size of these particles was estimated from electron microscopical images (fig. 2). Thus a size - activity relation could be established and the activity per particle could be related to the spot size in the autoradiographic exposures, which eventually allows the classification of autoradiographic spots with respect to the corresponding particle activities and sizes (fig. 3). From the autoradiography of fig. 1 ground inventories of at least 10000 particles/m² with diameters < 5 μm and 5000 particles/m² with larger diameters were estimated. A finer classification needs additional autoradiographic exposures and a better understanding of the activity - spot-size relation of the autoradiographic exposures. On the other hand, assuming only particles with 2 μm and 10 μm diameter, respectively, the measured total Ce inventory of the soil sample is reproduced from these figures within a factor 4, which gives the proper order of magnitude.

ESTIMATE OF PARTICLE INHALATION

The following procedure allows estimates of the number and size distributions of inhaled particles: From the particle diameter d obtained from autoradiography the corresponding sinking velocity in air is calculated using Stoke's law, i.e. $v_{\text{dep}} = \frac{d^2 g \rho}{18 \eta}$, η

$1,8 \cdot 10^{-5}$ kg/m² viscosity of air, $\rho = 11$ g/cm³ density of UO₂ particles, and from the inventory n of particles of this size on ground the corresponding time-integrated

10 μm

Fig. 2: Scanning electron microscope image of a large-size fuel particle isolated from water plants in Kiev reservoir in 1990 (from ref. 11).

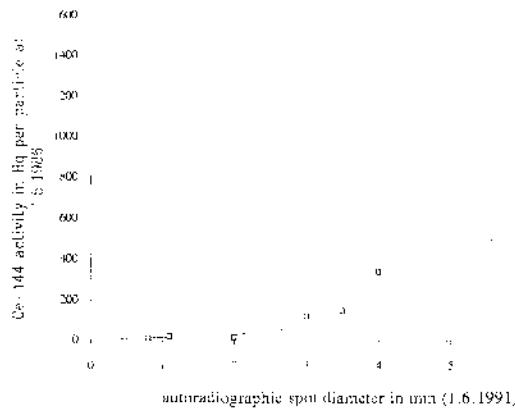

Fig. 3: Relation between Ce-144 activity, corrected for nuclear decay since May 1st, 1986, and corresponding spot diameter of autoradiographic exposures (Kodak "Direct exposure") of fuel particles (fig. 1) produced in June 1991.

particle concentration C in air was obtained from $C = n/v_{dep}$. Multiplying this value with the mean human inhalation rate of $0,7 \text{ m}^3/\text{h}$ results in the number of particles of this size inhaled by a person resting at the site of deposition during the passage of the cloud. Of course any influences of nonuniform particle distributions, turbulent motions and wind drifts are neglected in this oversimplified approach. As an example, the particle distribution at the sampling site shall be represented by $10000 \text{ particles}/\text{m}^3$ with a uniform diameter of $2 \mu\text{m}$, and $5000 \text{ particles}/\text{m}^3$ $10 \mu\text{m}$ in diameter. Then we arrive at deposition velocities of $1,2$ and $30 \text{ mm}/\text{s}$ and numbers of inhaled particles per person of 1600 and 32 , respectively. The total inhaled activities of both groups of particles, on the other hand, are roughly equal, but taking into account the higher retention probability of smaller sized particles in the lung it is presumed that the small-size fraction will cause the more important contribution to the lung dose.

EXTRAPOLATION TO LARGER DISTANCES FROM CHERNOBYL

Beyond, say, 200 km distance the direct determination of particles in soil samples will hardly be possible today due to radioactive decay and decreasing particle diameter with distance. From the rather detailed Cs-137 contamination maps, however, the number distributions of particles can be reconstructed, if reasonable assumptions for the size spectra of particles as a function of distance are made and if the local Ce-144/Cs-137 isotopic ratio in the fallout is known. Fig. 4 shows local Ce-144/Cs-137 isotopic ratios determined so far, which vary with distance and in particular with contamination time: Whereas in the regions contaminated by the first plume produced by the explosion this ratio is particularly high and even exceeds the original core value in the evacuation zone due to volatilization of Cs-137 and preferential deposition of fuel particles (e.g. position 2, from which the soil sample described above is taken), it is rather small e.g. in central Europe contaminated by a plume emerging from the accident site only more than one day after the explosion. Correspondingly both particle sizes and particle numbers are rather small in central Europe, e.g. about $40 \text{ particles}/\text{m}^3$ with particle sizes above $2 \mu\text{m}$ were detected in Konstanz in Southern Germany [5].

Fig. 4: Isotopic ratio of Ce 144 to Cs 137, normalized to the respective ratio in the reactor core prior to the explosion and corrected for nuclear decay since April 26th, 1986, for soil samples from different sites in Europe. Samples from areas contaminated by the same plume are characterized with the same symbols. Sample no. 2 was used for the investigations reported above.

CONCLUSION

Inhalation of nuclear fuel particles from the Chernobyl fallout containing nonvolatile radionuclides is only a minor contribution to inhalation dose outside USSR. Near the accident site, however, this contribution may become important and a microdosimetric approach seems to be appropriate for dose estimates. A procedure for the reconstruction of the number and size distributions of inhaled particles from measurements of deposition densities of these particles and their sizes using autoradiographic, gamma spectrometric and electron microscopic techniques is described. Considerable efforts with respect to representative determinations of the ground inventories of these particles and to a reconstruction of their transport in air are necessary, however, for reliable dose calculations.

The help of the Integrated Radioecological Expedition of USSR Academy of Sciences and of H.-J. Schodlock in sampling and support from German Research Foundation for travelling are gratefully acknowledged.

U.S. DEPARTMENT OF ENERGY CHERNOBYL DATABASES

R.A. Kennedy, J.A. Mahaffey, S.K. Smith, and F. Carr, Jr.

Pacific Northwest Laboratory
Richland, WA, USA

ABSTRACT

The Chernobyl Database project is developing and maintaining an information system to provide researchers with data and resource materials relating to the Chernobyl nuclear accident of April, 1986. The system is the official United States repository for Chernobyl data. The system includes a collection of Chernobyl-related documents, a database of bibliographic references, and a collection of radiological measurements records. In addition, products have been developed to make the resources more accessible and easy to use. These products include a personal-computer-based bibliographic search system (*ChernoLit*¹), two printed bibliographies, and a personal-computer-based radiological measurements database system (*ChernoDat*).

BACKGROUND

Initial studies of the Chernobyl accident were conducted under emergency conditions with primary attention directed toward characterizing the immediate potential hazard to the human population in various parts of the world. Since the emergency passed, efforts have been redirected toward long-term research to investigate health and environmental consequences of the accident. Use of data collected during and after the emergency presents an opportunity to evaluate historical risk, transport, and deposition models previously based on laboratory experiments, theoretical calculations, and simulated accidents, with limited real measurement data. Thus, Pacific Northwest Laboratory (PNL) was designated by the U.S. Department of Energy (DOE) as the official U.S. repository for information related to the Chernobyl accident and was chartered to generate products that facilitate research. These products include the printed bibliographies as well as the *ChernoLit* and *ChernoDat* software packages.

Developing the Chernobyl information system has been challenging for at least four reasons. First, no formal agreements exist to provide data from the accident to our information system. Organizations must be identified, contacted, and asked to share their data. Second, there is no standardized approach to measurement recording; information is reported with varying levels of detail and summarization. Often,

¹ *ChernoLit* is a trademark of Battelle Memorial Institute, Columbus, OH, USA.

measurement data and reports from the same agency have varying content and format. Third, supporting information was not (and possibly could not) be collected during the emergency-response period. These items include precise measurement locations, data quality information, background levels, and equipment used for collection and analysis. Fourth, specific uses and users of the Chernobyl information system were not identified, and requests for information vary tremendously.

CHERNOLIT

The Chernobyl Bibliographic Search System (*ChernoLit*) provides bibliographic data in a usable format for research studies relating to the Chernobyl accident. *ChernoLit* is a portable and easy-to-use product that includes search capabilities on bibliographic data. The user may specify names, words, and phrases of interest. These search criteria may be logically compounded. The user may also specify which database fields are to be searched. The user may interactively view the references, including the abstracts, or may generate a report. Reports may be directed to the screen, to the default printer, or accumulated in a folder that is written to a disk file when the user exits *ChernoLit*.

ChernoLit runs on an IBM² PS/2, AT, or fully-IBM-compatible computer configured with either a 5-1/4 inch or 3-1/2 inch high density floppy disk drive. A minimum of 8 megabytes of free disk space is necessary to execute the software. An operating system of DOS 3.3 or higher is required. For best performance, use of a mouse is recommended. If printed reports are desired, a printer must be available to the computer.

ChernoLit has been implemented as a FoxPro³ 2.0 run-time application consisting of pull-down menus, shortcut keys, text buttons, and dialog boxes as well as the bibliographic database. This stand-alone system is provided in compressed format on floppy disks. An automatic install procedure loads the application onto the user's computer. A version that executes on the Macintosh⁴ computer will be available in the future.

Over 4400 references concerning the accident, complete with abstracts, are included in *ChernoLit*. The data contained in

² IBM, PS/2, and AT are trademarks of International Business Machines Corporation, Boca Raton, FL, USA.

³ FoxPro is a trademark of Fox Software, Inc., Perrysburg, OH, USA.

⁴ Macintosh is a registered trademark of Apple Computers, Inc., Cupertino, CA, USA.

the database was obtained from three electronic literature searches and from requested donations from individuals and organizations. These literature searches, conducted in 1989 and 1991, interrogated the ENERGY SCIENCE AND TECHNOLOGY database (formerly DOE ENERGY) of the DIALOG⁵ Information Retrieval Service. ENERGY SCIENCE AND TECHNOLOGY, provided by the U.S. DOE, Washington, D.C., is a multi-disciplinary database containing references to the world's scientific and technical literature on energy. All unclassified information processed at the Technical Information Center of the U.S. DOE is included in the database.

In addition, information on many documents has been manually added to *ChernoLit*. Most of this information was obtained in response to requests for data sent to people and/or organizations throughout the world.

CHERNODAT

The Chernobyl Radiological Measurements Information System (*ChernoDat*) is a software package which will provide access to radiological measurements collected in response to PNL requests subsequent to the Chernobyl accident. Data in *ChernoDat* are organized into a central database, containing data in a standardized record format, with multiple satellite databases containing the data in their original record formats. *ChernoDat* will allow the user to browse, query, and export the radiological data from both the central and satellite databases. The browsing feature allows the user to toggle between data in the original record and a standardized record. The query feature allows the user to obtain a data subset and then export the subset to an ASCII file for analysis.

ChernoDat will run on an IBM PS/2, AT, or fully-IBM-compatible computer configured with a VGA monitor, 3-1/2 inch high density floppy disk drive, and a hard drive with 7 megabytes of free disk space. An operating system of DOS 3.3 or higher is required. Performance will increase as the amount of available RAM is increased up to a limit of 16 megabytes.

ChernoDat is implemented as a Paradox⁶ Runtime 3.5 application consisting of pop-up menus, on-line help, and query-by-example filtering. The application requires Paradox Runtime files which will be included with *ChernoDat* on the 3-1/2 inch high density diskettes. An automatic installation program is used to install the compressed format files.

⁵ DIALOG is a registered trademark of Dialog Information Services, Inc., Palo Alto, CA, USA.

⁶ Paradox is a registered trademark of Borland International, Scotts Valley, CA, USA.

At present, the central database consists of over 48,000 records which have been standardized from five satellite databases. The data records in the satellite databases has been donated by the following agencies: State of Washington Department of Social and Health Services (Pickett 1986); Ministry of Agriculture, Fisheries and Food, Welsh Office (1988); Safety Analysis Unit, National Institute of Radiological Sciences - Japan (1988); Chernobyl Protective Measures Assessment Team, United States Nuclear Regulatory Commission (1986); and Stone & Webster Engineering Corporation (1986).

CONCLUSIONS

Two software packages have been prepared by PNL under the Chernobyl Database project for the U.S. DOE. PNL will continue to provide updated products that will assist researchers who are conducting studies related to the Chernobyl accident.

**THE EUROPEAN DATA BASE EUROGRID:
METHODOLOGICAL PROBLEMS AND RECENT DEVELOPMENTS**

ABSTRACT

The aim of the EUROGRID data base is to provide the necessary data to estimate the radiological impact and the economic consequences in case of a large nuclear accident. The data taken into account are populations, land use, agricultural productions, livestock and employment for different sectors of the economy. These data are compiled on a 10 000 km² grid basis. To allow such evaluations at short distances of the release source some parameters (populations) are also available on a 100 km² basis. Further parameters are actually considered to estimate the pollution transfer by surface water and the doses received by inhalation or external irradiation.

1. DESCRIPTION SUCCINCTE DE EUROGRID

L'accident nucléaire de Tchernobyl a mis en évidence la prépondérance de l'ingestion dans les doses reçues à grande distance de l'émission. Pour évaluer ou prévoir l'impact individuel et collectif de l'ingestion de produits alimentaires contaminés, il est nécessaire de disposer d'une base de données relative aux populations et aux productions agricoles. C'est dans cette optique que la base EUROGRID a été développée à l'échelle de la Communauté Economique Européenne.

Figure 1: EUROGRID
Grille Européenne

mailles qui couvrent les douze pays de la Communauté Economique Européenne (cf. Figure 1)/1/.

Conjointement à ce projet, le développement de logiciels destinés aux évaluations des conséquences économiques d'un accident de type radiologique (ou chimique) a conduit à enrichir EUROGRID de paramètres participant à l'estimation des coûts (effectifs salariés par exemple).

Les paramètres inclus dans la base de données sont: les populations résidentes, l'utilisation des sols, les productions agricoles, le nombre d'emplois par secteur d'activité économique et la quantité de lait collectée. Ils sont évalués pour chacune des mailles de 10 000 km²,

L'évaluation des conséquences d'un accident à partir d'un réseau maillé suppose que la concentration des polluants (dans l'air ou au sol) est homogène à l'intérieur d'une maille. Dans le cas de mailles de 10 000 km², cette hypothèse n'est acceptable qu'à grande distance de l'émission. Pour évaluer les conséquences à courte distance, un maillage de 100 km² a été défini et une base de données sur ce maillage est en cours de documentation.

2. LES DIFFICULTÉS MÉTHODOLOGIQUES

Les problèmes méthodologiques sont de deux ordres :

1 - L'acquisition des données

En ce qui concerne **les populations**, la précision des données existantes dans tous les pays au moyen des recensements autorise une confiance suffisante, même dans la grille à mailles fines. Les données sont en effet disponibles au niveau des communes dont on connaît les coordonnées géographiques. Cependant, il faut être conscient que ces recensements ne fournissent qu'une valeur approximative de la population présente dans une maille à un moment donné (périodes estivales, zones industrielles, ..).

L'acquisition des données concernant **les surfaces et les productions agricoles** est plus délicate: l'idée initiale, qui consistait à exploiter des images provenant de satellites, a été rapidement abandonnée, essentiellement à cause de son coût prohibitif. L'utilisation des statistiques locales se heurte à une difficulté majeure: plus le niveau d'acquisition des données est fin, plus on se heurte au secret statistique. Une solution de compromis a été retenue; elle consiste à utiliser les données au niveau régional telles que collectées et publiées par EUROSTAT /2/, et à ventiler les données dans les mailles en fonction de la portion de surface des régions dans chaque maille. L'homogénéité de ces données n'est qu'apparente, car il existe de grandes disparités entre les équipements et l'organisation des services statistiques des pays de la Communauté; ces différences apparaissent clairement dans les publications EUROSTAT au niveau du recueil varie de la région au pays tout entier.

En ce qui concerne **l'emploi**, le degré d'élaboration des données est très différent d'un pays à l'autre; la nécessité de disposer d'une classification commune à tous les pays nous a conduit ici encore à utiliser les données EUROSTAT.

Enfin, les seules données disponibles au niveau des **produits laitiers** concernent la collecte du lait, connue au niveau des laiteries. Chaque laiterie peut couvrir des zones de collecte importantes et dispersées géographiquement.

Une difficulté essentielle dans la réalisation de la base de données est la nécessité d'une actualisation régulière et la prise en compte des bouleversements géopolitiques récents (réunification de l'Allemagne).

2 - La réalisation de logiciels d'exploitation

L'utilisation de cette base de données a nécessité le développement de produits logiciels permettant l'interrogation de la base et la visualisation des données. Deux produits, accessibles sur micro-ordinateur, ont été récemment réalisés. Le premier (QUERY), exploite la base de données sur grandes mailles (10 000 km²); il permet de formuler une requête c'est à dire de délimiter une zone de la Communauté répondant à certains critères (cf. Figure 2); de visualiser la zone correspondant au critère de sélection, puis d'interroger les mailles de la zone sur la valeur de paramètres sélectionnés par l'utilisateur (cf. Figure 3). Le second logiciel, entièrement graphique (EUROVISU) permet en outre la consultation des données sur le système de mailles fines (100 km²).

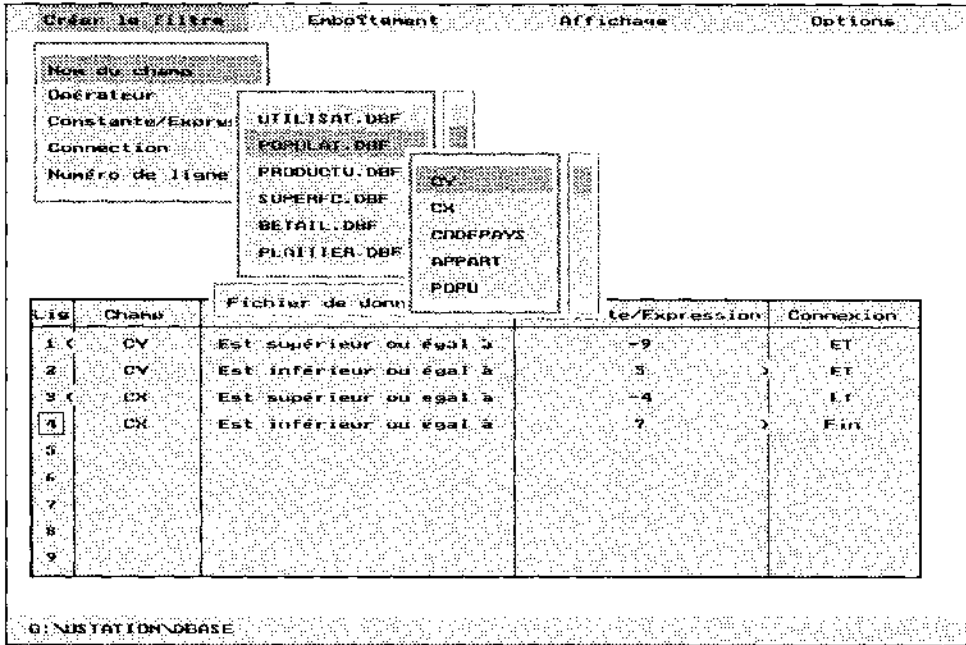

Figure 2 : Construction d'une requête

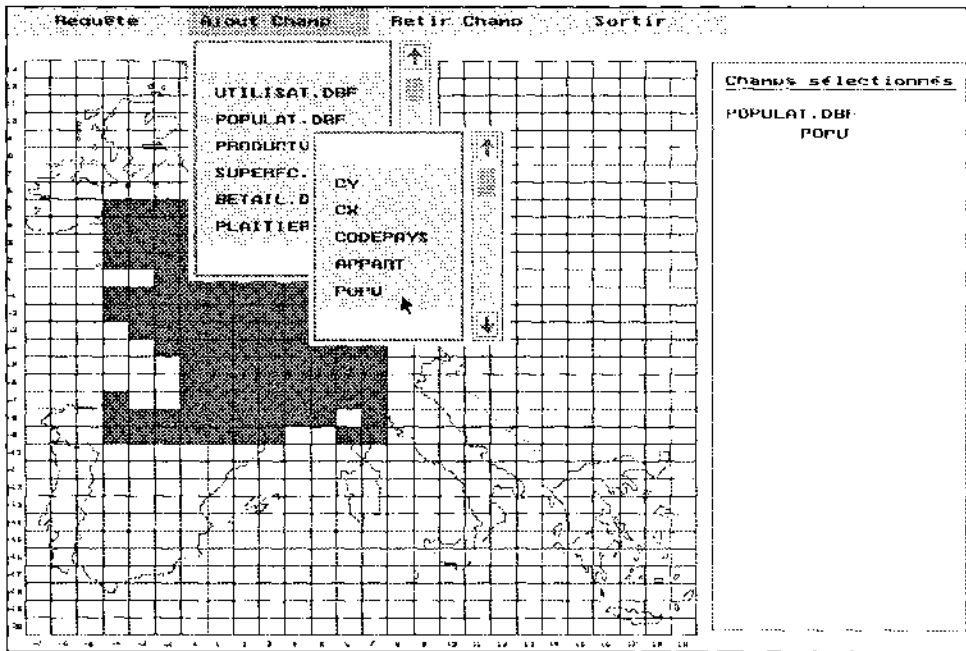

Figure 3 : Visualisation et interrogation de la base

3. LES DÉVELOPPEMENTS DE EUROGRID

En plus de l'**extension géographique** (l'introduction de l'Allemagne unifiée est prévue, celle des pays de l'Est est envisagée), on cherche actuellement à enrichir la base de données par des informations permettant une évaluation des **transferts par l'eau** (emplacement des stations de pompage, quantités prélevées, zones de distribution et d'utilisation (irrigation, usage industriel ou domestique)). Une étude de faisabilité est en cours. De plus, l'introduction des données relatives aux **caractéristiques de l'habitat et du mode de vie** permettra l'estimation des expositions par inhalation et par irradiation externe. Enfin, pour tenir compte du fait que zones de production et de consommation ne sont pas identiques, on souhaite introduire des **coefficients d'échanges entre mailles**, sur la base de statistiques douanières ou de flux interrégionaux.

MONITORING MAN-MADE RADIATION USING A 256 CHANNEL
PORTABLE GAMMA-RAY SPECTROMETER

ABSTRACT

Measurements in Finland with a portable NaI(Tl) gamma-ray spectrometer showed that the natural gamma-ray spectra from potassium, uranium and thorium could be separated from the gamma-ray spectra of ¹³⁴Cs and ¹³⁷Cs due to fallout from Chernobyl. A comparison of the portable spectrometer measurements with those from an ionization chamber showed that the dose rate due to ¹³⁴Cs and ¹³⁷Cs fallout and the individual dose rates from the three natural components could be determined with a portable spectrometer. Following calibration at one site of known contamination, the portable spectrometer could also be used to measure the deposition of ¹³⁴Cs and ¹³⁷Cs.

INTRODUCTION

Portable Na(Tl) gamma-ray spectrometers have been used by geologists and geophysicists for mineral exploration and geological mapping for many years. These spectrometers normally use a 7.6 x 7.6 cm detector and record 3 energy regions for monitoring gamma-ray emissions from potassium, uranium and thorium. Recently, portable spectrometers which record up to 256 channels of gamma-ray spectral data have become available. This paper describes how such a spectrometer (an Exploranium GR-256) can be used for environmental monitoring.

PRINCIPLE OF THE METHOD

Following a nuclear reactor accident, such as the Chernobyl event of 1986, many man-made radio-nuclides with a variety of gamma-ray energies and half-lives may contaminate the environment. Almost all these gamma-ray emitters have energies which are significantly below the 1460 keV gamma-ray peak of ⁴⁰K. By fitting the calculated potassium, uranium and thorium gamma-ray spectra to the high energy part of measured spectrum, the natural gamma-ray component can be determined. This component can then be removed from the measured spectrum, leaving behind the man-made component.

The procedure was first tested in Canada where the man-made component originated mainly from global atomic weapons fallout. Figure 1 shows a spectrum recorded outside the Geological Survey of Canada headquarters in Ottawa with a 256-channel portable spectrometer using a 7.6 cm x 7.6 cm NaI(Tl) detector. The natural gamma-ray component of the measured spectrum (also shown in the figure) was computed by fitting the calculated potassium, uranium and thorium spectra to the observed spectrum above an

energy of 1200 keV. The three natural gamma-ray spectra were determined from measurements on concrete calibration blocks, 1m x 1m x 30cm with known concentrations of the three radioactive elements. The fitted spectrum also includes the background contribution from cosmic radiation, radon decay products in the air and any radioactivity from the instrument itself. The background was measured in a small metal boat on the nearby Ottawa river.

The fallout spectrum shown as the difference spectrum in Figure 2 originates from an estimated 2.5 kBq/m² of ¹³⁷Cs and demonstrates the effectiveness of the spectral fitting method even in areas of low fallout.

Figure 1. A computer fit above 1200 keV of the potassium, uranium and thorium spectra to a spectrum measured in Canada.

Figure 2. The fallout spectrum obtained by subtracting the natural gamma-ray spectrum from the measured spectrum.

FIELD MEASUREMENTS

In the fall of 1990, a series of gamma-ray measurements were made in the Lammi - Padasjoki - Jämsä area in Finland where the ¹³⁷Cs contamination was as high as 200 kBq/m². Simultaneous measurements were performed with a calibrated Reuter-Stokes ionization chamber and the calibrated portable spectrometer at a measurement height of 80 cm above the ground. Additional measurements were made with the portable spectrometer at ground level to estimate variations in the radioactivity of the ground. At selected locations, soil samples were taken for laboratory determinations of ¹³⁴Cs and ¹³⁷Cs.

ANALYSIS OF RESULTS

Measurement of fallout

Figure 3 shows a measured spectrum and the fitted natural spectrum from a site where the ¹³⁷Cs deposition was approximately 120 kBq/m². The background spectrum, included in the fitted natural spectrum, was measured in a small boat on the Gulf of

Finland. The man-made difference spectrum (Figure 4) shows the 662 keV gamma-ray peak of ^{137}Cs as well as the gamma-ray peak at 795 keV due to ^{134}Cs which has a half-life of approximately 2 years. The gamma-ray windows used to measure ^{134}Cs and ^{137}Cs are shown in the difference spectrum. A correlation of the ^{137}Cs window count rates from the man-made spectrum with those from ^{134}Cs (Figure 5) shows that the $^{134}\text{Cs}/^{137}\text{Cs}$ ratio is the same for all sites measured. A similar correlation coefficient of 0.998 was also found from the laboratory analyses of the soil samples.

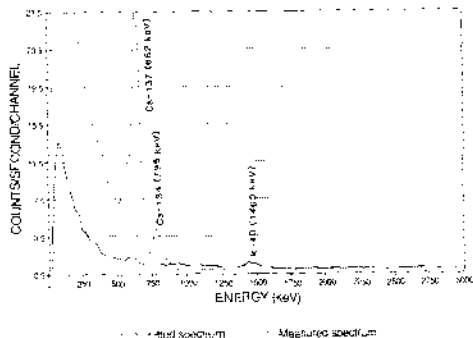

Figure 3. A computer fit above 1200 keV of the potassium, uranium and thorium spectra to a spectrum measured in Finland.

Figure 4. The fallout spectrum obtained by subtracting the natural gamma-ray spectrum from the measured spectrum.

Figure 5. Correlation of the ^{134}Cs and ^{137}Cs window count rates from fallout.

Figure 6. Correlation of the ^{137}Cs window from fallout with ^{137}Cs deposition.

The laboratory measurements of ^{137}Cs deposition were compared with the calculated count rates in the ^{137}Cs window from fallout (Figure 6). The scatter about the least squares line was attributed to localized variations in the deposition of ^{137}Cs

which were found by analyzing the ground-level gamma-ray measurements. The results show that following calibration at one site where the contamination is uniform, a NaI(Tl) gamma-ray spectrometer can be used to measure ^{134}Cs and ^{137}Cs .

Measurements of dose rate from fallout

In the spectral fitting procedure, the gamma-ray spectral shapes from unit concentrations of potassium, uranium and thorium are used to calculate the concentrations of the three radioactive elements in the ground. The individual air absorbed dose rates can then be calculated from these concentrations using the relationship:

1 percent potassium = $0.0131 \mu\text{Gh}^{-1}$
 1 part per million of uranium in equilibrium = $0.00543 \mu\text{Gh}^{-1}$
 1 part per million of thorium in equilibrium = $0.00269 \mu\text{Gh}^{-1}$

The ionization chamber measurements include radiation from fallout and natural gamma radiation as well as a background component from cosmic radiation and radon decay products in the air. This background was also measured on the Gulf of Finland. The radiation dose from fallout can therefore be determined from the ionization measurements by subtraction of the background plus the calculated natural radiation dose.

Figure 7. Correlation of the ^{137}Cs window count rate from fallout with the dose rate due to fallout.

The fallout component of the radiation dose, deduced from the ionization chamber measurements is compared with the portable spectrometer ^{137}Cs window count rates from fallout in Figure 7. The good correlation ($R = 0.95$) shows that a NaI(Tl) spectrometer can be used to measure the radiation dose from fallout, following calibration at one site with an ionization chamber. At the same time, the calculated ground concentrations of potassium, uranium and thorium can be used to estimate the radiation dose from each natural radioactive element.

RADIATION EXPOSURE DUE TO INCORPORATION OF RADIONUCLIDES
IN TWO SELECTED PLACES OF THE RSFSR FIVE YEARS AFTER THE
CHERNOBYL ACCIDENT

P. Hill, R. Hille
Forschungszentrum Jülich GmbH

ABSTRACT

First results of a large scale survey on the body content of radionuclides of Russian people during summer 1991 are presented. Data obtained for two villages of Klincy county (district of Briansk) are compared to those obtained in Klincy. An average body burden of 2 kBq, 3.7 kBq and 22 kBq Cs-137/134 has been found in Klincy town, Pestschanka and Weprin respectively corresponding to whole body doses of 0.08 mSv/a, 0.14 mSv/a and 0.88 mSv/a in 1991 resulting from incorporation of Cs-activities mainly through ingestion. The interdependence of environmental and body burden is discussed.

INTRODUCTION

During summer 1991 the environmental burden (water, soil, nutrition) and the body content of γ -emitting radionuclides of more than 150.000 persons in the RSFSR have been examined by a German expedition in close collaboration with the RSFSR's Goskom Chernobyl. The project was financed by the Federal Minister of Environment and carried out by the Research Centre Jülich (KFA). An area of approximately 10 000 km² extending from close-to-Moscow Tula up to Slynka at the Byelorussian border and such including regions of low and high contamination levels in the districts of Briansk, Kaluga, Orel and Tula has been covered in the survey. Up to 7 mobile environmental and whole-body counting laboratories have been operational with a total number of 7 γ - spectrometers and 20 whole-body- counters. About 150 german specialists have participated in the task group.

Each person examined received an official certificate giving the activity of the Cs 137/134 mixture in the body and a judgement on the radiation risk involved. Observed activity levels were generally much less and in no case higher than the annual limit of intake acceptable for professional radiation

workers. Only for less than 1 % of the people examined the results suggest the necessity of a further surveillance by health physicists and physicians similar to the regular medical examination professional radiation workers undergo.

The results obtained in two villages of Klincy county bearing a higher than average environmental burden and /or activity content of nutrition are presented and compared to those obtained in Klincy town.

KLINCY COUNTY

Klincy county is situated in the western part of Russia close to the Byelorussian border approximately 100 km east of Gomel and 160 km west of Brjansk. The town of Klincy (80.000 inhabitants) being the second largest city of Brjansk district is as well an administrative as an industrial center of this else rural region. The countryside is hilly and there are little woods. Each of the twenty sowchoses provides a place of living for an average 1200 inhabitants and consists of 2 - 3 villages. Weprin showing the highest dose rates of environmental radiation in the county is located in its western part. Pestschanka is situated in a less contaminated area north of Klincy.

EXPERIMENTAL PROCEDURE

Two small lorries each equipped with two QMB-1 incorporation monitors have been used to examine the village's population. Each monitor contained in a chair configuration two plastic-scintillation detectors calibrated for a Cs 137/134 mixture corresponding to the well known mixture of post-Chernobyl Cs-activities. The detectors have been shielded by 1 cm of lead. The data evaluation procedure included a correction of contributions from natural K-40 radiation. It could be shown that those are the only γ -emitting radionuclides of some importance. Additional corrections include self-absorption of β -rays in the body and shielding of background radiation by the examined persons. The mean detectable activity has been estimated to be 1 kBq.

Two Herfurth incorporation monitors have been used to examine a control group in Clincy town. Each of them contained one large plasticscintillator detector in a bed configuration calibrated to the Cs 137/134 mixture observed. The lead

shielding was 5 cm thick. Absorption of sky-shine and cosmic radiation by the body had been estimated with water phantoms and was accounted for in the data evaluation procedure. The mean detectable activity is less than 0.5 kBq.

In all cases the activity has been assumed to be distributed in the whole body. Depositions in the lung or in the G.I.-tract would be over estimated.

RESULTS AND DISCUSSION

A total of 172 people were measured in the village of Pestschanka and 199 out of Weprin's 300's population could be examined. The percentage of young people has been 17.6 % in Weprin and 37.2 % in Pestschanka. For the control group an arbitrary fortnights examinations have been selected out of the measurements done with Herfurth incorporation monitors in Klincy town. The group consisted of 4170 persons including 375 young people.

Activities determined in Klincy ranged from 0 to 49 kBq the average value being 2 kBq. In Pestschanka generally slightly higher activities have been found. An average activity of 3.7 kBq has been calculated. In the village of Weprin the activity distribution is considerably shifted to higher values the average activity being 22 kBq. The maximum activity observed has been 115 kBq.

Average specific activities have been calculated to be 28 Bq/kg in Klincy, 67 Bq/kg in Pestschanka and 330 Bq/kg in Weprin. It should be noted that in Jülich (FRG) this value has been 0.3 Bq/kg in 1990.

Assuming continual intake and using dosefactors of ref. 1 valid for adults to determine the dosefactor of the Cs 137/134 mixture average doses of 0.08 mSv/a for Klincy, 0.14 mSv/a for Pestschanka and 0.88 mSv/a for Weprin can be evaluated.

Using a method proposed by Sauermann (ref.2) to estimate the lifetime doses by comparison with a Berchtesgaden(FRG) control group average values of 3.6 mSv, 6.7 mSv and 40 mSv result in the case of men for Klincy, Pestschanka and Weprin respectively.

Average body burdens found are given in Table 1 together with results of an investigation on the environmental burden (ref. 3). Table 1 shows a strong correlation of body burdens and activity content of nutrition. It suggests body burdens to be due to ingestion. It is known that in rural areas the nutrition of people is mainly self-produced. Therefore the strong correlation between environmental and body burden is typical for small villages. In urban areas the global nutrition support is more important. Therefore the average incorporation is in Klincy town by a factor of nearly 2 lower than that of Pestschanka although the soil activity is much higher. Furthermore this indicates that the body burden does not result mainly from inhalation of dust even not if the summer was hot and dry like that of the year 1991.

	average body burden		dose	soil	milk + dairy	berries +
	total	specific	rate		products	mushrooms
	kBq	Bq/kg	$\mu\text{Sv/h}$	kBq/ m^2	Bq/l resp. Bq/kg	Bq/kg
Klincy	2.0	28	0.26	190	< 64	< 230
Pestschanka	3.7	67	0.17	71	120	250
Weprin	22	330	0.92	1000	810	2600

Table 1: Average values of incorporated and environmental (ref.3) Cs 137/134 activities. All numbers are rounded to two significant digits.

CALIBRATION OF PERSONAL DOSEMETERS IN TERMS
OF THE ICRU OPERATIONAL QUANTITIES

Joseph C. McDonald

ABSTRACT

The International Commission on Radiological Units and Measurements (ICRU) has defined several new operational quantities for radiation protection purposes. The quantities to be used for personal monitoring are defined at depths in the human body. Because these quantities are impossible to measure directly, the ICRU has recommended that personal dosimeters should be calibrated under simplified conditions on an appropriate phantom, such as the ICRU sphere. The U.S. personal dosimetry accreditation programs make use of a 30 x 30 x 15 cm polymethylmethacrylate (PMMA) phantom, therefore it is necessary to relate the response of dosimeters calibrated on this phantom to the ICRU operational quantities. Calculations of the conversion factors to compute dosimeter response in terms of the operational quantities have been performed using the code MCNP. These calculations have also been compared to experimental measurements using thermoluminescent (TLD) detectors.

INTRODUCTION

The ICRU has defined four operational quantities that are recommended for radiation protection (ICRU, 1985). The ambient and directional dose equivalents are to be used for the environmental, or area, monitoring of strongly and weakly penetrating radiations, respectively. These quantities are specified at depths in the ICRU sphere (ICRU, 1980). The quantities for personal monitoring are the individual dose equivalents, penetrating and superficial. These quantities are also defined for strongly and weakly penetrating radiation, respectively. The individual dose equivalent quantities are specified at depths in the human body, so it is impossible to measure them directly. In practice, a personal dosimeter is constructed so that the detecting element is covered by an appropriate amount of tissue-equivalent material, and this dosimeter is then calibrated on a simplified tissue-equivalent phantom. However, most dosimeters in use in the U.S. are sensitive to backscattered radiation from the body and from calibration phantoms. When calibrations are performed with dosimeters mounted on a PMMA slab phantom, corrections must be applied to account for differences in backscatter between the PMMA phantom and the ICRU sphere.

In the U.S., there are two programs for the accreditation of personal dosimeters. They are the Department of Energy Laboratory Accreditation Program (DOELAP) and the National Voluntary

Laboratory Accreditation Program (NVLAP). These programs require the use of a rectangular PMMA phantom (DOE, 1986, ANSI, 1983). Therefore, conversion factors are needed to relate the response of dosimeters irradiated on a PMMA phantom to the operational quantities. Calculations of this type have been performed for photon and neutron irradiations (Hertel and McDonald, 1990, 1991).

CALCULATIONS AND MEASUREMENTS

The determination of values for conversion factors can be accomplished either by calculation or measurement, or both. The most desirable situation is to use both methods and compare the two. It has been the approach at the Pacific Northwest Laboratory to use the Monte Carlo computer code MCNP (ORNL, 1983) and to perform confirmatory measurements in a geometry that closely approximates the conditions used in the irradiations for the accreditation programs.

The first case considered in the calculations was for photon irradiations. The dose equivalent at a depth of 1 g/cm^2 in the ICRU sphere was calculated along with the dose equivalent at a depth of 1 g/cm^2 in a PMMA dosimeter placed on the face of a $30 \times 30 \times 15 \text{ cm}$ PMMA phantom. This approximates the recommendation given by the ICRU for a dosimeter to be covered with an appropriate amount of tissue equivalent material and calibrated on a suitable phantom (ICRU, 1988). The front face of the phantom was placed at a distance of 100 cm from point sources of radiation that were used to simulate the actual irradiation conditions. Similar calculations were performed with the ICRU sphere as a phantom.

Backscatter factors were measured with thermoluminescent dosimeters ^7LiF (TLD-700) chips placed either on the surface of a PMMA slab phantom or on a thin water filled plastic sphere that was 30-cm in diameter. Corresponding measurements at the same reference distance were made with the TLD mounted free-in-air (Large, et al., 1990). Results of the measurements and calculations are shown in Table 1. For dosimeters sensitive to backscatter, these results could be used to correct the air kerma to directional dose equivalent, $H'(10)$, conversion factors. These data also compare favorably to the recent calculations of Bartlett, et al. (1991).

The calculations for neutron irradiations used the larger $40 \times 40 \times 15 \text{ cm}$ PMMA phantom required by the accreditation programs (DOE, 1986, ANSI, 1983). The front face of this phantom was placed at 50 cm from the radiation sources. A PMMA dosimeter was again mounted on both the surface of this phantom and on the ICRU sphere. The dose equivalents at a depth of 1 g/cm^2 in the ICRU sphere and at the same depth in the dosimeter were calculated. The results of these calculations are shown in Table 2. The present results are within the expected uncertainties of previously reported calculations of conversion factors between fluence and $H'(10)$. Confirmatory measurements are planned for the neutron irradiations using TLD-albedo dosimeters and CR-39 plastic track-etch dosimeters.

CONCLUSIONS

The process of relating the response of dosimeters, calibrated in terms of metrological quantities, to the operational or limiting quantities can be accomplished by the use of appropriate conversion factors. It is also possible to calibrate dosimeters on the rectangular solid PMMA phantoms required by the U.S. accreditation programs, and to relate the response of such dosimeters to the ICRU operational quantities. The conversion factors given in this report were calculated by the Monte Carlo code MCNP and compared to measurements taken with TLD's. The agreement obtained between these two methods was within the expected uncertainties for them. Future work will include the verification of the neutron conversion factors by experimental measurement.

Evaluation of Methods of Calculating the Internal Dose
from Radionuclides Deposited in the Human Body

Karl Z. Morgan
113 Danbury Drive
Oak Ridge, TN 37830

Since the Chalk River Tripartite Conference in Chalk River, Canada in September 1949, there has been very little change in the method of calculation of dose to the critical body organ. In this paper some of the early developments in health physics are reviewed and a new perspective is provided by obtaining the dose, d , in tissue spheres of radius equal to the range of alpha particles. A dust particle with the average alpha contamination is at the center of each sphere. Then some of the spheres are compacted (crushed) to fill up a form (mold) equal in shape to that of the critical body organ. The ratio of the number of spheres comprising the total radioactivity to the number of spheres fitting into the form is the overlap, p , and the total dose to the critical body organ is equal to $d \times p$.

Health physics originated about the time the first pile (reactor) began operating at the University of Chicago on December 2, 1942. The first health physicists (E.O. Wollan, H.M. Parker, C.C. Gamertsfelder, J.C. Hart and K.Z. Morgan) transferred from Chicago to Clinton Laboratories, now Oak Ridge National Laboratories, ORNL, in September 1943. Wollan left health physics at this time and in the fall of 1944 Parker, Gamertsfelder and Hart moved to Richland, Wash. where they established the health physics program at the Hanford plutonium producing facility. This left me as director of the ORNL Health Physics Division.

One of the major health physics problems in the early period was that of setting the maximum permissible body burden, Q , and maximum permissible concentration, MPC, of radionuclides in air, water and food. H.M. Parker at Hanford, J.H. Hamilton at Berkeley, W.H. Langham at Los Alamos, J.E. Rose and L.D. Marinelli at Argonne National Laboratory, G. Failla at Columbia University, A.J. Cipriani at Chalk River, J.S. Mitchell and G.J. Neary in London and I at ORNL each came up with different values of Q and MPC. The differences were due to different methods of calculation and the use of different input parameters.

One of the problems in setting radiation protection standards during the war was the tight security which limited exchange of information and sometimes was enforced at a ridiculous level. For example, our Health Physics Division was forced to change the name of the instrument we developed and called Pluto because it suggested Plutonium. We had named it Pluto after the cartoonist's snooping dog named Pluto so we changed the name to Snoopy. In 1945 I prepared a paper for publication suggesting how to make calculations on internal dose, setting for example $\lambda = \lambda_r + \lambda_b$ where λ_r and λ_b are the radioactive and biological elimination coefficients, respectively, and using the relation $dQ/dt = P - \lambda Q$ and giving mathematical procedures for dealing with parent-daughter radionuclide relationships and values of Q and MPC for 13 radionuclides. But, alas, the paper was held up for years and not released by security until finally it was published in 1947.¹ So far as I am able to determine this was the first paper published showing how these calculations should be made.

During this early period it occurred to me that if I knew the stable element distribution in the body organs and their concentration in food, water, urine and feces, I could determine quite easily how radioisotopes of these same elements are taken up, retained and eliminated. I went to the library expecting to copy down these values for common elements such as Sr, Cs, Co, Fe, Zn, P, K, I, U, Th, etc in one afternoon but after searching for a week, I was convinced such data had not been published. Then I arranged a contract with Isabel Tipton of the University of Tennessee to work with us in conducting an X-ray and neutron activation analysis of elements in tissue of human body organs. Mary J. Cook from our Health Physics Division visited pathology laboratories all over the US collecting samples of human body organs for these analyses and many samples were sent to us from overseas. This study resulted in the publication of concentration values for 33 elements in 37 human body organs as published in ICRP-2 (1959).² These data were extremely valuable in obtaining Q and MPC values.

One of the problems in the calculation of Q and MPC in this early period was that each person making these calculations used his own values of organ mass, element composition of body organs, rate of intake of air, water and food, the urine and fecal elimination rates, body water, etc. Mary Jane Cook of our Division and H. Lisco of Argonne National Laboratory independently collected these data and I presented them at the Chalk River Conference (1949). This led to the establishment of the Standard Man, many of whose features were published in the ICRP-2 report in 1959. After the Chalk River Conference most internal dose calculations referred to the Standard Man so it became much easier to compare calculations of Q and MPC. Years later under the chairmanship of W.S. Snyder, ICRP-23³ was published giving much more detailed information (480 pages) regarding Standard Man and his name was changed to Reference Man.

There were 25 attendees at the Chalk River Conference, 5 from the UK, 9 from Canada and 11 from the US. This conference served as a mile post and principal beginning of international cooperation and standardization in the fields of both internal dose and of external exposure. Here we did much more than christen Standard Man and set values of MPC for 18 radionuclides. This was a new beginning for health physics at the international level. Prior to this time I had had frequent meetings with H.M. Parker, W.H. Langham, L.L. Marinelli etc. from the US and occasional meetings with world leaders including I.H. Gray, W.V. Mayneord, R.M. Sievert, etc. This meeting at Chalk River was the spark that led to the reorganization of the International X-ray and Radium Protection Committee which, organized in 1928, had ceased to function during the war years after 1937. The 1950 meeting of ICRP in Harwell, England marked what some consider the beginning of ICRP. Here we set the stage for the formation of the Health Physics Society at Columbus, Ohio in 1955.

In 1953 NCRP-52⁴ was published giving Q and MPC values for 45 radionuclides and in 1955 ICRP published values of Q and MPC for 93 radionuclides in the British Journal of Radiology.⁵ ICRP-2 and NCRP-69⁶ were both published in 1959 and the texts of the two were almost identical--perhaps not surprising because I was chairman of the Internal Dose Committees of both NCRP and ICRP during the 20 year period following 1950. ICRP-2 and NCRP-69 each gave Q and MPC values for 236 radionuclides. W.S. Snyder and Mary Rose Ford did most of the tedious calculations in grinding out these values.

Before I retired from active membership in ICRP in 1971, our internal dose committee was criticized for using the same occupational dose limit of 5 rem/y for total body, gonads and active (red) bone marrow. Obviously, whole body dose should be lower than dose to individual organs. Snyder and I argued that the solution was simple--just lower the whole body limit to 2.5 rem/y. Unfortunately, ICRP in ICRP-26⁷ (1977) removed this discrepancy in the wrong direction and it was not until 1990⁸ that ICRP reduced the level to 2 rem/y. The dose limit was kept at 5 rem/y for total body but raised for all other body organs in subsequent publications of ICRP-30⁹ (1979-88). MPC values should have been reduced, not raised. ICRP's use of the target organ that receives dose from radionuclides in organs outside the critical organ as well as that from radionuclides within the critical organ was a welcome improvement in ICRP-30 that could be implemented only in later years when computers could lend a hand. I am pleased with the lower values of MPC in ICRP-61 published in 1991 but most of the values are still too high.

Over the past 15 years I have assisted some 150 persons injured by exposure to ionizing radiation in their efforts to obtain compensation for their injury. In 1989 I was involved with E.P. Radford in the Martin case in which a family sold their home at a loss because it was contaminated with plutonium resulting from substandard waste disposal practices at the Windscale, England nuclear facility. In the course of calculation of the dose to the critical epithelial lung tissue by the usual gross dose method, it occurred to me why be stuck with this same old gross dose method I developed 45 years ago. By the familiar gross dose method I had calculated the annual dose to 1 g of the epithelial tissue as

$$\text{Total Dose} = \frac{5.05 \times 10^{-3} Q(\text{Bq}) E(\text{MeV/dis}) RBE(\text{Sv/Gr})}{5.05 \times 10^{-3} \times 0.0275 \times 5.3 \times 20} = 0.0147 \text{ Sv/y}$$

A considerable amount of data had been assembled by us as shown in Table 1.

Table 1

1.5 μm	- mean diameter of dust particle
4 μm	- mean diameter of tissue cell
1 g/cc	- density of tissue
2 g/cc	- density of dust particle
1 g	- mass of epithelial tissue
10.6 Bq/cc	- specific activity of dust
5.3 MeV/dis of Pu alphas	
0.00449 cm	- range of α particles
6.62×10^{-9} Bq/cc	in Merlin home
2.3×10^7 cc/day	- adult male breathing rate
T_b	= 100 days, $\lambda = 2.53 \text{ y}^{-1}$
f_a	= 0.0025
12 hr/day in home	

Radford also had obtained 0.0147 Sv/y. I developed what I called a differential method. In this pursuit relations were found as follows:

$$\begin{aligned} \text{mass of respirable particle} &= \frac{4}{3} \pi r^3 \rho = \frac{4}{3} \pi (1.5/2 \times 10^{-4})^3 \times 2 \\ &= 3.53 \times 10^{-12} \text{ g} \\ \text{activity of particle} &= 3.53 \times 10^{-12} (\text{g}) \times 10.6 (\text{Bq/g}) \\ &= 3.746 \times 10^{-11} (\text{Bq/particle}) \end{aligned}$$

mass of tissue within range of q' g on dust particle (called an Alpha Range Ball, ARB) = $\frac{4}{3} \pi (4.49 \times 10^{-3})^3 \times 1 = 3.79 \times 10^{-7} \text{g}$
 dose to each ARB = $d = 3.746 \times 10^{-11} \text{Bq/ARB} \times 3.154 \times 10^7 (\text{S/y}) \times 5.3 (\text{MeV/dis})$
 $\times 1.602 \times 10^{-6} (\text{erg/MeV}) \times 1/10^4 (\text{gGr/erg}) \times 20 (\text{Sv/Gr}) \times 1/3.79 \times 10^{-7} (\text{ARB/g})$
 $= 5.294 \times 10^{-5} \text{Sv/y}$

$Q(\text{Bq}) = P/\lambda (1 - e^{-\lambda t}) = P/\lambda$ at equilibrium

$Q(\text{Bq}) = 4.2 \times 10^{-9} (\text{cc/y}) \times 6.62 \times 10^{-9} (\text{Bq/cc}) \times 0.0025/2.53 (\text{y}^{-1}) = 0.0275 \text{Bq}$ in critical tissue

$n = 0.0275 (\text{Bq}) / 3.746 \times 10^{-11} (\text{Bq/part.}) = 7.33 \times 10^8 = \text{no. of ARB's to be squeezed (crushed) into a tissue form (mold)}$

$1(\text{g}) / 3.79 \times 10^{-7} (\text{g}) \text{ in ARB} = 2.64 \times 10^6 = \text{no. of ARB's that can be crushed into a critical tissue form (mold) without overlap (i.e. with multiple occupancy of space in the tissue form)}$

$p = 7.33 \times 10^8 / 2.64 \times 10^6 = 278 \text{ overlap}$

Total dose = $d \times p = 5.29 \times 10^{-5} \text{Sv/y}$ without overlap $\times 278 \text{ overlap} = 0.0147 \text{Sv/y}$. This differential dose calculation of course gives the same result as the commonly used gross dose method. It is not given here or recommended as a substitute but rather as a new perspective. I hope it will be of help to the handful of us who are trying to help those injured by exposure to ionizing radiation as well as a help to the large numbers of health physicists who rally to defend the company or the government on the defense.

When W.T. Ham was president of the Health Physics Society, he asked me to explore ways of making our society more international. I wrote to over 1,000 persons in 35 different countries and received an overwhelming support for a truly international radiation protection association. IRPA's first meeting in Rome, September 7, 1966, was the bringing to fruition of the goal many of us had longed for since health physics began. As IRPA's first president, I was proud of our new organization and now I can be proud again if our members rally to the aid of persons injured by excessive exposure to ionizing radiation as a major responsibility.

PARAMETRES RESPIRATOIRES POUR LA PROTECTION RADIOLOGIQUE

M. Roy,

La dosimétrie des radionucléides inhalés a besoin de valeurs de dimensions des voies aériennes et de volumes d'air respirés chaque jour par les personnes exposées aux gaz et aux aérosols. A l'aide de données récentes fournies par des enquêtes socio-économiques et par la physiologie respiratoire des valeurs standards ont été rassemblées pour des individus-types de la population : travailleur adulte, personne au foyer, enfants de 3 mois, 1, 5, 10 et 15 ans. Ces paramètres peuvent être adaptés à différents groupes de la population mondiale.

RESPIRATORY PARAMETERS FOR RADIOLOGICAL PROTECTION

Dosimetry of inhaled radionuclides requires informations upon airway dimensions and air volumes breathed every day by people under exposure to gases and aerosols. Using recent data of economic surveys, and of respiratory physiology, modern standards have been tabulated for specific categories of a population: adult worker men and women, housewives, children 3 months and 1, 5, 10 and 15 years old. These parameters can be adapted to various population groups in the world.

INTRODUCTION

Dans ses publications 23 et 50 (1,2), la Commission Internationale de Protection Radiologique (CIPR) recommandait pour l'individu standard caucasien, adulte homme et femme, enfant nouveau-né et âgé de 10 ans, des dimensions et des paramètres ventilatoires repris ensuite par les rapports 1982 et 1988 de l'UNSCEAR. Lors de l'élaboration de son nouveau modèle de dosimétrie des voies respiratoires, la CIPR a souhaité actualiser ces données, les préciser pour les adultes et les enfants aux âges définis dans sa publication 56 (3 mois, 1,5,10 et 15 ans) (3) et pour les populations ne se satisfaisant pas des standards caucasiens.

DIMENSIONS DES VOIES AERIENNES

Les volumes et surfaces respiratoires sont liés à la taille corporelle dont la croissance, plus ou moins rapide, se termine à l'âge adulte par des valeurs variables selon les régions du monde. Ces relations n'ont pas partout la même forme. Un exemple en est donné par les régressions de la capacité résiduelle fonctionnelle (CRF) (4), (utilisée en

dosimétrie comme indice du volume alvéolaire) en fonction des tailles chez l'homme adulte. On retrouve aussi de telles différences chez enfant. Dans la plupart des pays, les valeurs biométriques et fonctionnelles ont été établies par les spécialistes et sont prêtes pour la modélisation pulmonaire.

PARAMETRES VENTILATOIRES

Les volumes courants, fréquences respiratoires et débits de ventilation sont probablement un peu différents selon les régions car les besoins individuels en oxygène dépendent du volume corporel. Malheureusement les observations détaillées, aux différents âges, au repos et à l'exercice, n'existent que chez les Caucasiens. Dans les autres populations, les comparaisons que l'on peut faire sur les rares données montrent que les volumes courants et les fréquences varient souvent en sens inverse et que le débit ventilatoire reste assez constant dans notre espèce (5,6). Il est donc raisonnable d'adopter, au moins provisoirement, les mêmes standards pour l'ensemble des populations.

EMPLOIS DU TEMPS

La plupart des enquêtes dans ce domaine ont été publiées dans les pays occidentaux (7). Plus récemment, des études économiques très complètes ont permis d'établir, pour la population française, les occupations journalières des adultes, travailleurs ou personnes au foyer, et des enfants de divers âges (8, 9). Le lieu où se situent ces activités a aussi été défini. Ces données sont surtout valables pour les pays industrialisés qui jouissent d'un climat tempéré. Dans les autres régions du monde, il est possible que l'emploi du temps général (travail, loisirs, sommeil) soit assez voisin mais que les activités journalières se déroulent dans un environnement particulier (extérieur, montagne, habitats spécifiques, etc...) et que des études locales soient nécessaires pour les préciser.

VENTILATIONS JOURNALIERES

En attendant de pouvoir disposer de données complètes sur les diverses populations, et pour obtenir au moins pour un groupe d'individus, un ensemble cohérent de valeurs, aux emplois du temps précédents ont été associés, pour les activités décrites, les paramètres ventilatoires des Caucasiens, très proches de ceux des autres groupes de population. Pour l'homme adulte on a donc défini quatre niveaux standards d'exercice : sommeil, repos assis, exercice léger et exercice violent (10, 11). Les valeurs correspondantes, pour la femme et les enfants aux différents âges, ont été fournies par des données fonctionnelles (12, 14). Finalement on a obtenu les volumes d'air journaliers respirés par les adultes et par les enfants.

CONCLUSION

La précision de la dosimétrie des radionucléides inhalés peut être améliorée par l'introduction de paramètres respiratoires spécifiques de chaque groupe d'individus, selon leur âge, leur sexe et leur emploi du temps. Pour les différentes populations on connaît assez bien les dimensions pulmonaires et on admet que les paramètres ventilatoires varient peu, mais pour l'emploi du temps et les ventilations journalières, les standards occidentaux sont utilisés par défaut. La connaissance des valeurs réelles propres à chaque contrée constituerait ici un progrès sensible.

PERSONNEL NEUTRON DOSIMETRY IN BRAZIL: 7 YEARS EXPERIENCE

C.L.P. Maurício and E.S. Fonseca

Instituto de Radioproteção e Dosimetria
Comissão Nacional de Energia Nuclear
22780 - Rio de Janeiro - RJ - Brazil

ABSTRACT

The Brazilian neutron personnel monitoring service has been in operation since 1983, and nowadays monitors about 200 workers monthly. It uses an albedo type dosimeter with ^6LiF and ^7LiF TLDs. About 4% of dosimeters evaluated presented some neutron dose (> 0.20 mSv). The majority of these doses, some of which were quite high (12 mSv maximum), were received by people that work with Am-Be sources for oil prospection and research including calibrations). The obtained results in routine, intercomparisons (accuracy within -30% to $+43\%$) and calibrations show that the Brazilian albedo dosimeter system is appropriate for the national neutron fields.

INTRODUCTION

Since November 1983, the Instituto de Radioproteção e Dosimetria (IRD) has operated routinely the Brazilian neutron personnel monitoring service. Nowadays it monitors monthly about 200 workers in the areas of research and power reactors, accelerators, well logging, moisture gauges and Am-Be sources used for calibration and research activities.

Over these years the albedo neutron system has been improved. The evaluation has been computerized, allowing a better quality control, including some error messages¹. Several field calibrations have been made and the single sphere technique² was adopted since 1989³. Besides, for quality guarantee, IRD albedo system has participated since 1985 in international intercomparisons and is periodically recalibrated with certified Am-Be sources.

BRAZILIAN NEUTRON DOSIMETRY SYSTEM

The IRD albedo capsule consists of a semi-spherical polyethylene part covered by boron and aluminium with a place for one pair of commercial $^6\text{LiF:Mg,Ti}$ (TLD 600) and $^7\text{LiF:Mg,Ti}$ (TLF 700) $3 \times 3 \times 0,9$ mm³ chips from Harshaw Chemical Company⁴. The TL dosimeters are evaluated in a Telecyne TLD reader 7300C connected to a clone IBM PC/XT microcomputer¹. This connection, home made in 1989, allows a computerised TLD glow curve analysis, necessary for better quality control in albedo neutron dosimetry.

For dose equivalent assessment, ^{60}Co calibration factors are used for TLD 600 and TLD 700. The neutron dose equivalent is calculated by multiplying the normalized readout difference (TLD 600 - TLD 700) to a field calibration factor (CF)⁵. This factor is necessary due to the high energy dependence of the albedo dosimeter. Each monitored person uses a belt with two albedo capsules attached symmetrically to reduce the dosimeter - body distance effect and to correct the angular dependence⁶.

As the IRD albedo capsule has only one component (albedo TLD pair), it is impossible to identify any neutron field change, making necessary a precious evaluation of the calibration factor, which may vary from 0,04 to 2,2 mSv/mSv ^{60}Co for the Brazilian occupational neutron fields (table 1).

RESULTS

Table 1 shows a summary of the measured doses in the different work places. The majority of monitored people work in oil propection, where a higher dose incidence percentage is found (7%). The second highest dose incidence (6%) is found in research and calibration using Am-Be sources, with the highest dose measured up to now (12,00 mSv).

Table 1 - Dose equivalent levels and calibration factors for the Brazilian work places.

Work place	CF (mSv/mSv ^{60}Co)	H ₂ ≥ 0.2 mSv* (%)	Number of employees	H _{max} (mSv)
well logging	2.2	7	84	2.40
moisture gauge	2.2	2	36	2.30
power reactor	0.04	0.5	30	0.30
research				
AmBe sources	2.2	6	23	12.00
reactor	0.04	0	2	
cyclotron(control room)	0.23	1	11	0.70
TOTAL		4	186	

* 0.20 mSv = register level

Since 1985, the IRD has taken part in all the Personnel Dosimetry Intercomparison Studies (PDIS) promoted by the Dosimetry Application Research (DOSAR) facility staff of the Oak Ridge National Laboratory (ORNL), USA. The results obtained, excluding non perpendicular irradiation incidence (due to a negligible angular dependence) are shown in table 2.

As it is mentioned above, the IRD albedo system needs a previous calibration factor evaluation for each neutron field. Because of this, when the albedo is irradiated for the first time in a different neutron field, it is impossible to make a correct dose evaluation, even with informations of near neutron energy. This explains the high discrepancies obtained in PDIS 11 (first irradiation with the HP RR), in PDIS 12 (first irradiation with Pu-Be source) and in PDIS 16 (first irradiation in a 14 MeV neutron beam). For the $^{252}\text{Cf}(\text{D}_2\text{O})$ field, good agreement was obtained since the first irradiation in PDIS, because the IRD albedo dosimeter was already calibrated for this field.

Table 2 - Performance of Brazilian albedo neutron dosimeters at Personnel Dosimetry Intercomparison Studies (PDIS/ORNL).

Neutron field	$H_{\text{IRD}}/H_{\text{reference}}$ (neutrons)					
	PDIS11	PDIS12	PDIS13	PDIS14	PDIS15	PDIS16
HP RR	1.90	0.85				
HP RR (13 cm steel)	1.51	0.76				
HP RR (12 cm lucite)	0.98	1.02				
HP RR (20 cm concrete)	1.46					
HP RR (lucite + ^{137}Cs)		0.93*				
HP RR (steel + lucite + concrete)		0.97*				
$^{238}\text{PuBe}$		0.58*	1.15	1.43	1.05	0.74
$^{252}\text{Cf}(\text{D}_2\text{O})$			0.94** 0.87	0.72** 0.84	1.40	0.78
$^{252}\text{Cf}(\text{D}_2\text{O})$ without Cd				0.91		
^{252}Cf (polyethylene) + ^{137}Cs				0.70		
$^{252}\text{Cf}(\text{D}_2\text{O})$ + ^{137}Cs					1.41	1.03
^{252}Cf + $^{252}\text{Cf}(\text{D}_2\text{O})$ accelerator (14 MeV)					2.80*	0.33

* Radiation fields unknown to participants prior to evaluation.

** Two different irradiation, for low (< 1 mSv) and high dose (> 1 mSv).

Except for one mixed unknown spectra of PDIS 15 (^{252}Cf - $^{252}\text{Cf}(\text{D}_2\text{O})$), the other results of IRD albedo system are accurate to within - 30% to + 43% of the reference values. In PDIS 14, even for a new field (^{252}Cf (polyethylene)), an acceptable agreement in dose evaluation was achieved. As the albedo was already calibrated with ^{252}Cf sources with different other shields, in this case, it was possible to estimate the calibration factor⁵.

The measured standard deviations of the dosimeters irradiated in each field (normally three) in the PDIS vary from 0 to 17% for neutron equivalent doses in the range of 0,31 to 6,00 mSv. In 70% of the dose evaluation a standard deviation smaller than 10% has been achieved.

CONCLUSION

The results show that the brazilian albedo dosimeter system presents a good performance and is appropriate for all the national neutron fields already tested. The routine results show the importance of individual neutron monitoring and the need of a critical analysis of the neutron work routines, with the aim of checking the possibility of dose reduction, mainly in the areas with doses higher than the recommended levels.

Brazil has no tradition in neutron individual monitoring as it has in photon monitoring. Therefore many brazilian workers occupationally exposed to neutrons still don't wear any kind of neutron dosimeter. It is necessary to know all these work places and evaluate each neutron spectra and local albedo calibration factor. And, finally, to include neutron dosimetry in the Brazilian radiation protection norms and standards.

MODELS FOR THE ASSESSMENT OF INTERNAL DOSE AND IMPLICATIONS FOR THEIR PRACTICAL APPLICATION

J A B Gibson, R K Bull and R C Carpenter

AEA Environment and Energy, B364, Harwell Laboratory
Oxon, OX11 0RA, UK

ABSTRACT

Current problems in internal dosimetry arise from limitations in both the practical techniques available and the biokinetic models which are used to convert monitoring data into estimates of intake and dose. In this paper we discuss these problems and their possible resolution via new developments in measurement techniques and modelling. Intercomparison exercises can be used to help standardise internal dosimetry methods and computer systems can provide databases of dosimetric information and expert assistance in the assessment process. These developments should aid the Europe-wide acceptance of dose records. The implications for internal dosimetry of ICRP 60 are discussed.

MEASUREMENTS

(i) Air sampling. Personal air samplers (PAS) and static air samplers (SAS) provide sensitive measurements of airborne contamination. However gradients in aerosol concentrations can result in differences in aerosol collection by nose/mouth and sampler of a factor ~2-3, though these differences are reduced for long sampling periods (1). Also, an annual limit of intake (ALI) for, say, ^{239}Pu , corresponds to only a few tens of micron-sized particles per m^3 , leading to severe statistical fluctuations in sampling. Whilst a PAS probably gives a good indication of long-term averaged exposure to 'background' levels of airborne contamination, operational experience (2) shows that PAS data are poorly correlated with bioassay results for a discrete intake.

(ii) In-vivo monitoring. In-vivo counting can measure a few becquerels of activity of gamma-emitting nuclides in the whole body or specific locations. Amongst actinides, useful data on lung contents of ^{241}Am can be obtained but ^{239}Pu is not readily detectable at useful levels of activity. The initial ^{239}Pu intake may be inferred from ^{241}Am measurements only if the $^{239}\text{Pu}/^{241}\text{Am}$ ratio is well known.

(iii) Monitoring of urine and faeces. Faecal sampling offers relatively high sensitivity, particularly if carried out shortly after intake. Urine sampling gives much lower sensitivity for many nuclides, including actinides, but gives a measure of systemic uptake. At Harwell, urine analysis can yield a detection threshold of 0.2 mBq/24 h for ^{239}Pu . Despite this sensitivity, intakes of ~20% ALI of insoluble plutonium will remain undetected if they occur mid-way between quarterly urine samples. The new ALI for insoluble ^{239}Pu implied by ICRP 60, will worsen this problem.

At Harwell, routine annual faecal sampling has been introduced to improve our ability to detect actinide intakes. This step introduces its own problems as a faecal sample is

affected by small, very recent, intakes which can mask the longer-term clearance of larger intakes. Ideally, such samples should be given after about one week away from active work. Research is continuing into alternative analytical techniques to improve the detection thresholds for urine analysis. Inductively Coupled Plasma - Mass Spectrometry (ICP-MS) is currently being studied for the detection of very low levels of plutonium in urine. CR-39 plastic alpha track detectors are also being evaluated for long term counting of radiochemically separated actinides from urine.

MODELLING

Excretion may be calculated via either a compartmental model or an excretion function. At Harwell we use the former approach as this allows the retention of activity to be calculated for all conditions. The compartmental model is based on ICRP 30 (3) but, to obtain approximate agreement with actinide excretion functions, it contains dummy compartments holding a small fraction of the activity (4).

(i) The Task-Group lung model. An ICRP Task Group has recently proposed a new lung model (5) designed to allow calculation of doses to respiratory tissues simply and realistically. This model will not be adopted before 1993, but if it is, it will need to be incorporated into biokinetic modelling of radionuclide retention and excretion. It is important that the new model be compatible with available excretion data and to this end we have recently compared a well-documented Harwell actinide case with Task-Group Model predictions (6). The results of this study show (a) that a mechanical clearance component must be included so that faecal excretion decreases monotonically from 10 d to greater than 100 d post intake and (b) that an early phase of enhanced absorption to the transfer compartment should be included.

(ii) New systemic models. ICRP (7) have recently adopted a new model (8) for the bone-liver system in order to calculate age-dependent doses from actinide intakes. This model is more physiologically realistic than previous ICRP (3) treatments of bone and liver. It includes bone growth, remodelling and recycling of activity. General use of this model will lead to changes in doses per unit intake for actinides and hence in ALIs.

(iii) Intercomparisons. Two intercomparison exercises have recently been carried out, in which sets of bioassay and other data have been sent to participating laboratories for assessment. The first was restricted to plutonium intakes and involved only UK laboratories (9). The second covered a wider range of nuclides and involved laboratories throughout Europe (10). Whilst agreement between laboratories was generally good, differences arose from varying statistical treatment of data and the use of different metabolic models. A degree of standardisation of assessment methods will be important, after 1992, when free movement of workers between EEC countries becomes possible and dose records must be compatible.

THE EUROPEAN REGISTRY FOR INTERNAL DOSIMETRY

As a further step towards providing a common European framework for dose assessment, a European Registry for Internal Dosimetry (ERID) has been proposed (11). This will be split into three parts.

(i) ERIDA, a European Registry of Internal Dose Assessments, will use information supplied by European laboratories and obtained from the literature. It will consist of a database containing details of assessments which have features of general interest and will be available as a source of reference for dosimetrists. A prototype version has already been created. Each assessment file will typically contain excretion data, details of modelling and interpretation and references to published material.

(ii) ERAD, a European Registry for Autopsy Data using information obtained by individual laboratories in each European country is being considered following the establishment of a UK autopsy registry which is currently under detailed consideration.

(iii) ERMID, a European Registry of Mathematical Models. This will consist of an expert system written in a 4th generation language for use on an IBM-compatible microcomputer. The system will give access to a suite of models for analysis of excretion/retention data and calculation of doses. It will guide the user through a sequence of steps towards an optimum internal dose assessment, subject to rules governing the changes that can be made to models and model parameters. These rules will limit metabolic changes to those compatible with physiological data from studies of man and animals.

IMPLICATIONS OF ICRP 60

The new recommendations in ICRP 60 (12) will affect ALIs for several reasons:

- (i) Reduction in the annual dose limit from 50 mSv will reduce many ALIs by a factor of 2.5;
- (ii) Deterministic effects will no longer be used to set ALIs in almost all cases;
- (iii) Tissue weighting factors have changed, eg W_T for bone surfaces reduces from 0.03 to 0.01. This, with (ii) above, increases the ALI for class W ^{239}Pu from 200 to 300 Bq.
- (iv) Effective dose is now calculated by summing over all exposed organs and the 10% rule is now dropped.

One practical effect of these changes is that the ALI for class Y ^{239}Pu is reduced from 600 Bq to 300 Bq, further exacerbating difficulties in routine urine monitoring.

CONCLUSIONS

Internal dosimetry will undergo many changes in the next few years. Use of common databases and modelling techniques will result in increasing standardisation of dosimetry methods across Europe. However, changes in lung & metabolic models and dose limits could result in a series of fluctuations in ALIs.

ABSOLUTE CALIBRATION OF IN VIVO MEASUREMENT SYSTEMS USING MAGNETIC
RESONANCE IMAGING AND MONTE CARLO COMPUTATIONS

ABSTRACT

Lawrence Livermore National Laboratory (LLNL) is currently investigating a new method for obtaining absolute calibration factors for radiation measurement systems used to measure internally deposited radionuclides in vivo. This method uses magnetic resonance imaging (MRI) to determine the anatomical makeup of an individual. A new MRI technique is also employed that is capable of resolving the fat and water content of the human tissue. This anatomical and biochemical information is used to model a mathematical phantom. Monte Carlo methods are then used to simulate the transport of radiation throughout the phantom. By modeling the detection equipment of the in vivo measurement system into the code, calibration factors are generated that are specific to the individual. Furthermore, this method eliminates the need for surrogate human structures in the calibration process. A demonstration of the proposed method is being performed using a fat/water matrix.

INTRODUCTION

Current calibration methods for in vivo systems recognize the strong geometric dependence of the process. The validity of the actual counting results is directly related to the similarity of the distribution of radioactivity and absorbing medium used in the calibration procedure to that of the individual being measured. For this reason, surrogate human structures, or phantoms, are used to represent the human body during calibration. A phantom is loaded with a known quantity of radioactivity and then measured by the counting system in a manner representative of human subject measurements. By this means, appropriate calibration factors can be determined for the system.

Much emphasis has been placed upon the development of realistic phantoms. The number of organs included in more recent phantom models has increased, as has their detail with regard to size and shape. More attention has also been given to the use of tissue equivalent materials in constructing phantoms. Despite their increasing complexity, the fundamental problem remains that a phantom represents the "average" characteristics of the human body. Significant corrections must still be made to obtain calibration factors that are applicable to a given individual. Hence, a calibration method is needed that is more sensitive to variability between individuals with regard to anatomical and biochemical differences. A new calibration method being developed at LLNL achieves this objective through the use of MRI.¹

METHOD COMPONENTS

MRI techniques induce a strong, uniform magnetic field throughout the human body, reorienting the spin axis of atoms with magnetic properties. Radiofrequency pulses are then transmitted through the field, perturbing these aligned atoms. Subsequent energy dissipations by the excited nuclei are detected and used to identify the type of tissue being imaged. An anatomical layout of the individual is then determined based on the characteristic resonating patterns of different tissue types.

An advantage of MRI over conventional x-ray imaging techniques (e.g., computed tomography) is that it does not use ionizing radiation and is thus considered to be biologically safe. Additionally, MRI offers biochemical information not obtainable by other imaging modalities. A new MRI method developed at Stanford University improves upon the Dixon technique for obtaining fat and water images.² This method uses a magnetic resonance image that is a measure of the inhomogeneities in the induced magnetic field, B_0 . This information is used to correct the fat, water, and fat plus-water data to yield true fat/water images.

The usefulness of this detailed biological data to calibration procedures is realized by using Monte Carlo methods. The MRI data is used to define a radiation transport medium within a Monte Carlo code. Various tissues or organs of the body are selected as containing sources of radioactive material. Radiation detectors and their location relative to the radioactive material are then modeled into the code. The code then simulates the transport of radiation throughout the medium, repeatedly sampling its library of interaction properties for the MRI-determined biological data. Tallies are recorded for each radiation penetrating the detectors. The code thus simulates the calibration of the in vivo measurement system for the particular subject; i.e., performs an individual specific calibration.

The development of this method is being performed using the Monte Carlo code MCNP4.³ The input file format for this code lends itself well to this application, allowing for the definition of a cube representing each voxel of MRI information. The code is available on numerous operating environments, particularly the VAX and PC machines, and has been validated through years of countless users producing credible results. Quality assurance studies are planned by comparing results obtained using MCNP4 with those produced by other codes, namely MORSE and FGS4.⁴

DEMONSTRATION OF METHOD

The calibration method was demonstrated using a fat/water matrix. The sample was composed of a beef rib bone, sponge, and deionized water enclosed in a polypropylene container (see Fig. 1). A small plastic vial containing natural uranium (1.38 kBq ^{238}U) in solution was also present. The enhanced Dixon images were obtained using a General Electric 1.5-T SIGMA unit. Coronal plane images were made for a 3-mm slice, 24 cm field of view. Figure 2 displays the fat, water, and B_0 images generated.

The Monte Carlo code calculations proceed as follows. The integer data for each magnetic resonance image are reformatted into an acceptable input file for the MCNP4 code. Material specifications are made for each voxel based on a decision tree comparing the ratios of the integer values in the fat, water, and fat plus-water images. Detector systems must also be modeled into the code in an identical manner to the actual counting system used. Tallies record the energy spectrum of protons entering the detector's sensitive volume.

Calculation of calibration factors requires an additional Monte Carlo operation. A single point source, in this case the sample vial of natural uranium described above, is counted by the detector system in the absence of any additional attenuating medium. The layout is also modeled into MCNP4 and processed by the code. Resulting tallies, when divided by the activity of the source, measure the intrinsic efficiency of the detection system. This factor must be included in the final determination of calibration factors for the in vivo measurement system.

DISCUSSION

The method's demonstration has pointed to three areas that require further review. First, the MRI data for multiple slices may exceed the memory capacity of the computer running MCNP4. Each slice is composed of 256×256 , 2-byte integer data. The method requires three Dixon images per slice; i.e., fat, water, and fat-plus-water. Assuming a conservative 1-cm slice thickness, the memory requirements for the MRI data alone for the adult lung region could approach 18 mega bytes. Hence,

the computer's memory may be taxed by the MCNP4 input file considering the additional geometry and material specifications required. Towards this end, we are researching optimization of the computer hardware; i.e., extending computer memory. Another solution is the addition of adjacent voxels of similar tissue type. Convolution techniques such as 5-point and 9-point smoothing can be used to efficiently encode the input files. However, the reduced sensitivity from joining like voxels must also be investigated.

A second issue to be considered is the defining of organ boundaries within the MCNP4 code for assigning source distributions. A likely solution will be the use of an algorithm using the Laplacian technique for automatic edge detection. This also raises the third topic of concern, which is defining the source location within the tissue and organs of the individual. Uniform distribution within the lung tissue is the principal mode of calibration and will be the standard in developing this method. However, the input file to MCNP4 can easily be revised to accommodate whatever source distribution is desired.

This new method will be verified using a specially designed phantom. This phantom will be constructed of a plastic that can be imaged by MRI techniques. Various compartments within the phantom will be available for redistributing radioactive sources and absorbing media while providing a method for consistently reproducing measurement results. Additionally, a MRI data base of human volunteers, selected on the basis of varied body sizes and shapes, is being compiled. This data base will be used to assess the validity of a correlation between biometric data for an individual (e.g., height, weight, and chest-wall thickness) and the calibration method described here.

ACKNOWLEDGMENT

This research is being performed under appointment to the Nuclear Engineering and Health Physics Fellowship program administered by Oak Ridge Associated Universities for the U.S. Department of Energy.

This research is supported by the U.S. Department of Energy by the Lawrence Livermore National Laboratory under Contract No. W 7405 Eng 48 and by the U.S. Nuclear Regulatory Commission under Contract No. 60-91-348.

RECENT DEVELOPMENTS IN IN-SITU γ SPECTROMETRY

P. Jacob and R. Meckbach
GSF-Institut für Strahlenschutz, D-8042 Neuherberg, Germany

ABSTRACT

The objective of the present contribution is to improve standard in-situ γ spectrometry by two means: First, results of post-Chernobyl measurements of the attenuation of radiation from cesium, ruthenium, barium and iodine isotopes on lawns and meadows are presented, allowing to derive representative values of the attenuation of radiation for different time periods after deposition. Second, a method has been developed to derive the actual attenuation of the radiation from the measured spectrum by comparing the fluences of photons with different energies from single radionuclides. The application to 16 spectra demonstrates an obvious improvement of standard in-situ γ spectrometry.

INTRODUCTION

In-situ γ spectrometry has become a standard method for rapid determination of radionuclide activities in and on the ground. The accuracy of the results of standard in-situ γ spectrometry is limited by the fact that the method is based on an assumption of the gamma radiation attenuation by the soil. This attenuation is due to the surface roughness of the ground and to the depth distribution of the radionuclides in the soil.

In the first part of this contribution results of post-Chernobyl measurements of the radiation attenuation of different radionuclides are presented. These data may contribute to an assessment of appropriate attenuation parameters for standard in-situ spectrometry. In contrast to results from measurements of depth profiles, the presented data contain also the attenuation by the surface roughness.

The difference of the attenuation of the gamma radiation at different sites increases in general with the time after deposition⁴. Since in the standard method of in-situ γ spectrometry in general the same value of attenuation is assumed for all measurements over lawns in the same period of time, the uncertainty of the results also increases with time. Several groups are trying to improve this shortcoming and some results have already been published⁵⁻⁷. The presented methods use information contained in the measured spectrum to derive the attenuation of the unscattered radiation. They fall into two categories based on different effects:

(i) the ratio of the scattered radiation to the unscattered radiation increases with the attenuation of the radiation, and
(ii) the attenuation of the unscattered radiation depends on photon energy. Unfortunately, the results published up to now are either purely theoretical, have systematic deviations from soil samples, or are based on a very limited number of measurements, also burdened by some obscurities.

It is the aim of this contribution to explicitly demonstrate the possibility of improving in-situ γ spectrometry by a method of category (ii) as mentioned above. The method is applied to Cs-137, whose daughter nuclide Ba-137m emits photons with energies of 662 keV and of about 32 keV. The attenuation of photons with these two energies can be expected to be sufficiently different to allow an identification of the total attenuation. The method is applied to 16 spectra which have been recorded in the first half year after the reactor accident of Chernobyl and results are compared with activities per area which have been obtained by measurements of soil samples.

ATTENUATION OF UNSCATTERED RADIATION

The attenuation of the unscattered radiation over lawns and meadows was measured by the following method:

First, at each site 6 soil samples have been taken, each consisting of 5 soil cylinders, 15-20 cm deep and with a ground surface of 18 cm². The 5 cylinders have been taken from the edges and the center of a 10x10m square. Results for Cs-134 are given in Table 1. It may be assessed that 0.6-1.2 kBq·m⁻² of the Cs-134 activity were due to dry deposition and that the largest part was deposited during a wet deposition with a precipitation in the order of 5-15 mm (with the exception of the site Giglberg)⁹.

Site	Neuherb.	Neuhaus	Aurach	Giglberg	Grafin	Bad Reichenh.
activity per area (kBq·m ⁻²)	9.9±0.4	25.2±2.4	17.0±1.2	4.0±0.2	25.8±0.7	20.3±1.3

Table 1. Deposited Cs-134 activity as determined by soil sample including vegetation. The uncertainty bounds give the standard deviation of the mean value.

Second, in-situ γ spectrometry was performed at a height of 1 m above the center of the square, used for the soil sampling. The ratio of the measured unscattered photon fluences to the calculated unscattered photon fluence at a height of 1 m above a plane source with an activity as given in Table 1 on a smooth air-ground interface expresses the attenuation of the radiation due to surface roughness and migration into the soil. Results are presented in Table 2. Uncertainties of the results were derived from those given in Table 1 and from the uncertainty due to counting statistics as calculated by the analysis software (SPECTRAN F). The latter was multiplied by a factor of 1.2 to obtain the uncertainty of the measurement of unscattered photon fluences. The factor 1.2 was obtained in a series of test measurements for the range of some hundred keV to some MeV.

Measurement		Attenuation of unscattered radiation			
Site	Date	I-131 365 keV	Ru-103 498 keV	Cs-134 796 keV	Ba-140 1596 keV
Neuherberg B	04 June	0.52	0.47	0.57	0.62
Neuhaus	04 June	0.62	0.59	0.62	0.61
Neuherberg C	09 June	0.65	0.55	0.68	0.73
Aurach	10 June	0.75	0.62	0.64	0.70
Giglberg	10 June	(0.72)	0.56	0.67	(0.70)
Neuherberg B	03 July	-	0.52	0.60	-
Neuherberg C	03 July	-	0.56	0.65	-
Grafin	04 July	-	0.36	0.49	0.50

Bad Reichenhall	09 Oct	-	0.50	0.54	-
Neuherberg A	15 Oct	-	0.56	0.66	-

Table 2. Attenuation of unscattered radiation as derived from measurements of soil samples and in-situ γ spectrometry at several lawns and meadows in Southern Bavaria in the year 1986. The calculated uncertainty of the given values corresponds to a standard deviation less than 15 %, for values in parentheses less than 20 %.

The values in Table 2 are similar for all of the radionuclides given, only the radiation of Ru-103 is about 10 % more attenuated than the radiation of the other radionuclides. This result is in accordance with measurements of depth profiles [10,11].

With the exception of the site Neuhaus, which is a relative wet meadow in a (smooth) valley in the Alps, the attenuation depends clearly on the amount of precipitation during the deposition, which may be assessed from the deposited activities. In the case of Cs-134 the attenuation ranges from about 0.5 for Grafing und Bad Reichenhall to about 0.7 for Giglberg.

IN-SITU DETERMINATION OF ATTENUATION

The ratio of fluence rates of unscattered photons with different energies but emitted from the same radionuclide depends as shown in Table 3 for Cs-137 on the depth distribution. The ratio of the corresponding count rates of a typical portable detector system has a comparable sensitivity on the depth distribution parameter. This fact has been used to determine from measured photon spectra the depth distribution parameter and the activity per area⁸.

Relaxation mass per area ($g \cdot cm^{-2}$)	Ratio of fluence rates for 32 keV and 662 keV	Ratio of count rates for 32 keV and 662 keV
0.1	0.54	0.076
0.2	0.48	0.069
0.3	0.43	0.064
0.5	0.38	0.058
1.0	0.31	0.048
2.0	0.24	0.038
3.0	0.21	0.033
5.0	0.17	0.028
10	0.14	0.023

Table 3 Ratio of fluence rates at a height of 1 m above ground for 32 keV and 662 keV photons emitted by Ba-137m with an exponential distribution in soil. The third column gives the corresponding ratio for count rates as detected by a N-type high purity Germanium detector (Canberra) with a relative efficiency of 25 %.

Measurement		Cs-137 activity per area ($kBq \cdot m^{-2}$)		
Site	Date	Soil sampling	In-situ γ spectrometry	
			proposed method	standard ($1.5g \cdot cm^{-2}$)
Neuherberg B	08 Sep	18	15	19
Grafing	23 Sep	47	56	38
Neuhaus	30 Sep	39	47	47
Aurach	30 Sep	33	29	18
Bad Reichenhall	09 Oct	38	34	42
Neuherberg A	15 Oct	18	16	24
relative deviation from soil sampling			0.97±0.15	1.00±0.28

Table 4 Cs-137 activity per area ($kBq \cdot m^{-2}$) in the period September/October 1986 derived by soil sampling, by the method proposed and by the standard in-situ γ spectrometry using a depth distribution in the soil which has been optimized according to the results of the soil sampling.

The method has been applied to post-Chernobyl spectra⁸ and some results are shown in Table 4. The proposed method agrees well with the results of the soil sampling. Concerning standard in-situ γ spectrometry a value for the depth distribution parameter has to be assumed. Table 4 shows that the average deviations of the standard method from the results of the soil sampling are considerably higher than for the proposed method, even if a depth distribution parameter is assumed, which is optimized for the given situation so that the mean value of the deviation is zero.

ABSTRACT

This paper presents the outcome of a whole body counter intercalibration exercise carried out jointly by Brazil and Argentina under the frame of a cooperation agreement in the nuclear field. In order to estimate the corresponding calibration factors, a skull phantom contaminated with Am-241 belonging to the brazilian IRD and a mathematical model developed at the argentine CNEA, were used. The results obtained at both facilities showed an excellent correlation.

INTRODUCTION

An intercalibration exercise was performed between Brazil and Argentina whole body counter (WBC) facilities, under the Cooperation Agreement in the nuclear field between both countries. This exercise comprised the intercomparison of the performance of the detection systems for low energy photon emitters.

The long-term intakes of transuranic elements, like Am-241, may be evaluated by the determination of its skeletal burden. In order to estimate the committed dose, it is necessary to determine the Am-241 activity deposited in bone tissue.

The skull presents appropriate characteristics to perform those measurements since: (a) it is relatively easy to shield the head and adjacent detectors from radioactive emissions originating from other areas of the body; (b) there are no organs or soft tissues in close proximity to the skull that significantly concentrate bone-seeking nuclides; (c) it is one of the least anatomically variable structures among subjects of different height and weight; (d) it is possible to surround the head, almost entirely, with detectors, thereby improving the geometry for "in vivo" assay and minimizing the effects of possible head movement on the detection efficiency [Co76].

Both, a physical model and a mathematical model were used. The former was based upon a skull phantom while the latter consisted in the application of the Monte Carlo method to the photon transport in a MIRD-V phantom.

PHYSICAL MODEL

The skull phantom was constructed by covering a human skull, previously contaminated with Am-241, with a tissue equivalent material to a thickness obtained from available physiological tables.

MATHEMATICAL MODEL

It is based on the application of the Monte Carlo method to the photons transport in the antropomorphic and heterogeneous male phantom MIRD-V, which is a mathematical representation of the ICRP-23 reference man [Ic75, R185, R189].

The trunk is represented by an elliptical cylinder, 70 cm height and diameters of 20 cm and 40 cm. A truncated cone and an elliptical cylinder represent the lower extremities and the head, respectively. The skull is the volume between two nonconcentric ellipsoids with a volume of 846.8 cm³ and a mass of 1.258 g. Source characterization was done by generating a code based upon the random selection of the emission point in the whole volume of the skull.

DETECTION SYSTEM

The detection systems of both facilities consist of two phoswich detectors (Table I). Both systems make use of a pulse shape discrimination technique in order to reduce the background, though they apply it in a different way. The detectors are installed inside shielded rooms, specially designed for performing "in vivo" measurements of low activities of photon emitters. Table II shows some characteristics of the shielded rooms [R184, O185, O189].

Facility	Phoswich Detector			
	No.	diameter	thickness	window
IRD/CNEN	2	127 mm	NaI(Tl) 5 mm CsI 50.8 mm	Al 0.02 mm
GSRyN/CNEA	2	127 mm	NaI(Tl) 3 mm CsI 50.8 mm	Al 0.076 mm

TABLE I

Facility	Dimension [m]				Others characteristics
	high	large	width	thick	
IRD/CNEN	2.5	2.5	2.62	0.15	Steel lined with Pb, Cd, Cu
GSRyN/CNEA	2.3	2.3	1.8	0.15	Iron lined with Pb, Cd.

TABLE II

RESULTS

The skull phantom was measured in both facilities with the detector parallel to each side of the head. A similar configuration was used in the mathematical simulation.

Table III shows the calibration factors and minimum detectable activities (MDA) for both facilities for the 60 keV photopeak of Am-241 [Al63].

Facility	Energy Range [keV]	Calibration Factor [cpm/Bq]	MDA [Bq]
IRD/CNEN	45-65	1.37	1.6
GSRyN/CNEA	47-68	1.33	1.5

TABLE III

Table IV shows the calibration factor obtained for the physical and mathematical models and the relative difference between them.

Model	Calibration Factor [cpm/Bq]	Difference %
Physical	1.33	0.7
Mathematical	1.34	

TABLE IV

CONCLUSIONS

The calibration factors and the MDA calculated with both systems were in close agreement, in spite of the slight differences between them. In addition, the use of the mathemati-

cal model to evaluate the calibration factors is fully justified having into account the excellent correlation found between the simulation models used.

The application of the metabolic model for Am-241 proposed by the ICRP to evaluate activities in body organs [Ic78], shows that the inhalation of one ALI, results in a deposition of about 9 Bq in the whole skeleton, approximately 80 days after the contamination. As the skull represents 18% of the total mass of the skeleton, these systems are sensitive enough as to detect intakes of about 1 ALI.

Uruguay

ABSTRACT

To make certain of the appropriate development of thermoluminescent dosimetry as an essential technical support for the Servicio de Dosimetría Personal (SDP) of the DINATEN, the evaluation of some quality parameters is presented in the paper. Experimental values related to the accuracy and precision are compared with the metrological specifications of the ANSI N13151975. Experimental results are presented with regard to lower limit of detection, determination limit, linearity, homogeneity of the batch of dosimeters, replicability, thermal fading, and other influencing parameters. The conclusion of the evaluation satisfies the requirements of thermoluminescent dosimetry applied to a personal dosimetry system and offers a solid basis for the improvement of the SDP.

INTRODUCTION

The Dosimetry Group of the División Protección Radiológica y Seguridad Nuclear of the DINATEN offers a Personnel Dosimetry Service (SDP) to occupationally exposed to ionizing radiation workers. During the last years, film dosimetry was the main technical support. At the end of 1989, we decided to incorporate thermoluminescence technics (TLD) to the SDP routine. The first step of the implementation was an internal report (1) that summarizes the activities concerning the equipment requirements (2,3,4). Then, so as to make certain of the appropriate development of TLD technic, some quality criteria from analytical laboratory quality control (7) were applied. Their particular application to TL and to personnel dosimetry requirements were discussed. In the present paper, the evaluation of some quality parameters is introduced. Experimental results are compared with the metrological specifications of the ANSI N13.15-1985 (5).

MATERIALS AND MEASUREMENT CONDITIONS

The equipment used was the following: TL dosimeter cards G-1 with two TLD 100 chips (1/8"x1/8"x0.035"), a TL detector model 2000-C and a TL analyser model 2080 from HARSHAW Chem. Co.. A 137-Cs calibrated source TECH-OPS and

a NUCLEAR ENTERPRISE timer model 2546 were used for the dosimeter irradiations. The measurement conditions were(2): preheating temperature 120°C, reading temperature 265°C, photomultiplier tube voltage 684 V, acquisition time 20 s, reading time 15 s, heating time 15 s and preheating time 15 s.

EXPERIMENTAL MEASUREMENTS

The parameters evaluations were carried out under SDP(1) routine conditions. The experiences were performed with random samples of 10, from the SDP dosimeters batch, excepting where indicated.

Accuracy and precision

Table 1 shows acceptable limits of the average and standard deviation of the Performance Index(B and S respectively) specified by ANSI(5), and the calculated experimental results.

Tab. 1: Acceptable limits and experimental results for B and S for doses of 0.1 y 1 mGy.

	B(0.1 mGy)	B(1 mGy)	S
Category 1 (photons from 0.3 to 10 Mev)	≤0.47	≤0.15	≤0.20
Category 2 (photons below 0.3 Mev)	≤0.95	≤0.3	≤0.25
Experimental results	0.12	0.04	0.075

Lower limit of detection and quantification limit

Several criteria have been reported concerning the determination of the lower limit of detection(LLD) and the quantification limit(6,7). Table 2 shows the most usual ones and the experimental calculated results. In figure 1, those limits are presented with the experimental curve of relative standard deviation as a function of dose.

Batch homogeneity

The irradiation of the 250 dosimeter batch with 1 mGy showed a relative standard deviation of 6.5.

Replicability

The relative standard deviation of the responses of the irradiation of one single dosimeter with 0.5 mGy was 2.5.

Other influencing parameters

Several parameters affecting the TL response have been described (i.e. light, storing temperature, incidence angle, radiation energy). To study the effect of natural light on the TL response, dosimeters non irradiated and irradiated to 1 mGy were stored some at obscurity and some exposed to natural light. An increase of the average TL response equivalent to 0.2 µGy per hour of light exposure was observed.

DISCUSSION

Concerning accuracy and precision, LLD, LC, homogeneity, replicability and linearity (not presented in the paper), the experimental results are in agreement with the requirements of a personnel dosimetry system. Additional research seems to be necessary in order to study the thermal fading and the effect of other influencing parameters, particularly dosimeter energy response.

CONCLUSION

The present evaluation satisfies the requirements of TLD applied to a personnel dosimetry system, and offers a solid basis for the improvement of the SDP.

Ben Gurion University of the Negev, Beersheva, Israel

ABSTRACT

Previous studies have reported a significant residual signal in LiF:Cu,Mg,P (GR-200, Radiation Detector Works) which arises from a peak at 270°C with an intensity of 7-50% relative to the main dosimetry peak. We have found a method to prepare LiF:Cu,Mg,P in two forms; one with a TL sensitivity 30-40 times greater than TLD-100 but with a residual signal of only 2-3% following 240°C for 10 seconds readout, the other, even more optimized material, (SSD-NR), with a sensitivity 15-20 times that of TLD-100 but with the 270°C peak almost totally eliminated, leading to a residual signal of 0.25-0.5%.

INTRODUCTION

LiF:Cu,Mg,P is a thermoluminescent (TL) material of exceptional dosimetric characteristics (1). Its Co-60 gamma sensitivity is 15-40 times greater than that of TLD-100 (2,3) and enables ultra-low dose measurements in the microGy dose range far beyond the usual capability of TLD-100. LiF:Cu,Mg,P possesses other advantages. Due to the tendency of the dose response to enter early into saturation LiF:Cu,Mg,P is significantly more "tissue-equivalent" to low energy photons (<150 keV) than TLD-100. For the same microdosimetric reasons, the relative response to high ionization density particles is very low (4,5), and therefore, LiF:Cu,Mg,P can serve as an excellent discriminator against neutrons. Another important advantage is in clinical dosimetry: LiF:Cu,Mg,P shows none of the annoying supralinear properties of LiF:Mg,Ti. Finally, the greatly enhanced sensitivity should allow the fabrication of ultra-thin dosimeters of greatly improved performance in the measurement of superficial dose.

There has been one problematic area in the application of LiF:Cu,Mg,P. Annealing or readout above 245°C leads to an irreversible loss in sensitivity and changes in the glow curve structure (2). The maximum temperature of readout or annealing should therefore be no greater than 240°C (3) to ensure long-term stability and re-useability. In applications where repeated high temperature annealing is unacceptable (most areas of personnel and environmental dosimetry), this restriction leads to a total residual signal of 7-10% (3) and even as high as 30-40% (6) in currently available commercial material.

MATERIALS AND METHODS

Various parameters involving different aspects of the material preparation parameters were varied. These included: (i) The chemical form of the added impurities, (ii) concentration of the added impurities, (iii) parameters of the thermal regime, (iv) process atmosphere and (v) particle size distribution. In the "standard" preparation procedure (7) lithium fluoride powder of optical grade (Merck up 5686) was thoroughly mixed with the following activators: MgF_2 (BDH Magtran powder), CuF_2 (Koch-Light) or $CuCl$ (Atomergic Chemetals) and $NH_4H_2PO_4$ (Merck 1126). The mixture was then heated in a Pt crucible to $1000^\circ C$ under a controlled N_2/O_2 atmosphere in a total gas flow of 3-5 liters/minute. After 30 minutes in the molten stage, the material in the crucible was quenched to room temperature. The glow curve heating rate was $90^\circ C \text{ min}^{-1}$ to $400^\circ C$ in order to readout the entire high temperature TL. The relative areas of the glow peaks were estimated by computerized glow curve deconvolution (CGCD) or alternately by readout to $240^\circ C$ for 10 seconds followed by 5-10 successive readouts to estimate the total residual

EXPERIMENTAL RESULTS

For convenience, and to establish a basis and measure for comparison we have defined a relative figure of merit, RFOM, for "unannealed" $LiF:Cu,Mg,P$ dosimeters given by

$$RFOM = \frac{\text{Sensitivity of peaks (3+4) in } LiF:Cu,Mg,P \text{ relative to peaks (4+5) in TLD-100}}{\text{Ratio of peak 5 to peak (3+4) in } LiF:Cu,Mg,P} \quad (1)$$

Table 1. Effect of forms of phosphate

chemical species	conc. mg	sensitivity relative to TLD-100	ratio: peaks 5/(3+4)	other dopants	RFOM
1. $NH_4H_2PO_4$	3	25	0.45+-0.15	standard	55.5
2. Li_3PO_4	2.5,5	0.2	--	standard	-
3. LiH_2PO_4	5	8.7	0.53	standard	16.4
4. H_3PO_4	3	22.5	0.53	standard	42.5
5. H_3PO_4	3	22.6	0.27	$CuI-0.008M\%$	83.7
6. $H_3PO_4^*$	3	24.7	0.26	$CuI-0.008M\%$	95.0
7. $NH_4H_2PO_4$	3	23.5	0.35	$(NH_4)_2CO_3 + NH_4OH-1M\%$ ea.	67.0
8. $Li_4P_2O_7$	3	8.6	1.09	$CuI-0.008M\%$	7.9
9. $NH_4H_2PO_4$	1.5	10.5	0.76	$CuI-0.008M\%$	13.8
10. $(NH_4)_3PO_4$	3	6.6	0.76	standard	8.7

* Treated at $220^\circ C$ to form polymers

Table 1 shows the results of our investigations on the effect of the chemical form of the added phosphate. These were carried out during earlier studies when we had not yet arrived at the optimal conditions of other starting parameters for the minimization of the high temperature TL. The importance of

acidic hydrogen in the starting phosphate configuration is clearly indicated. On the basis of these RFOM values, and to lower the quantity of effluent gases, we decided to changeover to H_3PO_4 as a starting material. CuI also seemed at this stage to result in lower intensity of high temperature TL. The superiority of H_3PO_4 in reducing high temperature TL was later vindicated by further investigations at optimal conditions. CuI , $CuCl$, and CuF_2 , however, were found to be identical vis-a-vis the creation of high temperature TL. We also found that a small amount of O_2 in the melt atmosphere (0.5-1 M%) reduced the relative intensity of the high temperature TL by a factor two with no adverse affects on the main peak sensitivity. Figure 1 shows glow curves normalized to

Table 2
Residual Signal for
Consecutive Readouts

Readout	Relative intensity (%)		
	GR-200	SSD-UR	SSD-NR
1	100	100	100
2	2.50	2.04	0.38
3	1.40	0.86	0.13
4	0.80	0.40	0.13
5	0.60	0.25	0.04
6	0.40	0.15	-
7	0.35	0.07	-
8	0.27	-	-
9	0.21	-	-
10	0.16	-	-
total			
	6.7	3.8	0.70

Figure 1: Glow curves of various $LiF:Cu, Mg,P$ materials: (a) GR-200 (25:1, 7-10%); (b) SSD-NR (17:1, 0.7%); (c) SSD-UR (37.7:1, 3.7%) The figures in brackets show the sensitivity relative to TLD-100 and the total relative intensity of the undesirable high temperature structure labelled 5

identical peak 4-heights for two Ben Gurion University preparations and a typical batch of GR-200 for comparison purposes. Note that peak 5 at approximately 270°C can be entirely eliminated and that peak 4 is substantially narrower in the BGU-prepared materials. This suggests that peak 4 itself may be a composite of more than one peak. Reduction of the high temperature TL to negligible levels (<1%) (Fig. 1b) results in a loss in main peak sensitivity of a factor two, but the material is still 15-20 times more sensitive than TLD-100, and the resultant RFOM is 2400. The very high sensitivity material

(Fig. 1c) has a RFOM of 820 and the GR-200 material a RFOM of approximately 300 (Fig. 1a). Finally Table 2 shows the relative intensity of the residual signal following consecutive 240°C for 10 seconds readout in the three materials shown in Figure 1. The material in which peak 5 is eliminated (SSD-NR; Fig. 1b) is virtually free of residual signal.

SUMMARY AND CONCLUSIONS

We have developed a preparation procedure for LiF:Cu,Mg,P which results in a TL phosphor 35±4 times more sensitive than TLD-100. At this level of sensitivity the second-readout-residual is 2-3%. In further investigations we found that, we could produce a material with a sensitivity 17±2 times that of TLD-100, but with a second-readout residual of only 0.25%-0.5%, following 240°C for 10 seconds readout. This negligible residual is achieved via almost total elimination of the high temperature peak and renders the material useable in "unannealed" form. To sum up, astute manipulation of material preparation parameters has led to a LiF:Cu,Mg,P thermoluminescent material 15-20 times more sensitive than TLD-100 and useable in "unannealed" form due to elimination of the high temperature peak. This material, we believe, is the "long-sought-after" ideal "tissue-equivalent" gamma dosimeter which should bring significant advances to environmental and personnel dosimetry.

THE ACTIVITIES OF THE CANADIAN NATIONAL REFERENCE
CENTRE FOR IN-VIVO MONITORING

Gary H. Kramer

Environmental Radiation Hazards Division, Bureau of
Radiation and Medical Devices, 775 Brookfield Road,
Ottawa, Ontario, K1A 1C1

ABSTRACT

The Human Monitoring Laboratory (HML) has been designated as the Canadian National Calibration Reference Centre for In-Vivo Monitoring. The HML conducts nationwide inter-comparison programs for facilities engaged in whole body counting, thyroid counting and thorax counting. In order to conduct and maintain this program the HML also designs and builds phantoms.

INTRODUCTION

In 1983, the Atomic Energy Control Board (AECB) decided that a formal program of calibration for all forms of dosimetry was required. The AECB is responsible, under the authority of the Atomic Energy Control Act, for the health and safety of workers and the public from potential radiological hazards associated with the operation of nuclear facilities and the use of radioactive materials. The AECB, through its regulations, requires its licensees to determine the radiation dose received by workers and to control such doses below specified limits.

The AECB set up three working groups to determine the requirements for comprehensive calibration programs for external dosimetry, internal dosimetry and dosimetry of radioactive atmospheres. The working group for internal dosimetry recommended that the Bureau of Radiation and Medical Devices (BRMD) administer the calibration reference program for that aspect of dosimetry as a development of its existing informal calibration program.

In 1984, funding was obtained for this development and a reference centre was established at BRMD; part of the Reference Centres is the HML. The HML has now been designated as Canada's National Calibration Reference Centre for In-Vivo Monitoring. The HML is, therefore, a unique facility in North America as it provides an external calibration to a facility to either confirm that their in-house calibration is accurate or provides sufficient information so that the facility can confidently implement a new calibration data set. Currently this service is free of charge.

Since 1987 the HML has been improving and expanding the design of the phantoms used in the inter-comparison; recent advances have been heavily influenced by the recommendations of the Workshop on Standard Phantoms (1).

The use of the BRMD standard phantoms is two-fold. First, facilities can compare their results to other Canadian facilities and judge their performance based on the results. Second, and more importantly, the participation in the HML's Inter-comparison program allows the facility to demonstrate that their in-house calibrations are accurate and that the in-house quality assurance program is performing as expected. The use of an outside independent standard gives any quality assurance program more credibility than it would otherwise have if all quality control results were based on in-house data.

WHOLE-BODY COUNTING FACILITIES

The factors that can introduce uncertainties into the estimate of body activity can come from a variety of sources:

- Heterogeneous distribution of activity within the body that is subsequently evaluated using an efficiency derived from a homogeneous distribution. This uncertainty can often be mitigated if the whole body counter is a scanning type. The scanning type is relatively insensitive to distribution (2).
- Individual being monitored is a different physical size to the reference phantom that was used to calibrate the whole body counter.
- The phantom used to calibrate the whole body counter is not sufficiently anthropomorphic. This will introduce a systematic bias into all of the measurements.

Table 1 HML inventory of BOMAB Phantoms

The HML can provide an *In-Vivo* monitoring facility with a range of phantoms that can partially mitigate the problems outlined above. The present inventory of BOMAB phantoms held by the HML is shown in Table 1. The design, construction and detailed use of the phantoms is described elsewhere (3,4).

<u>Phantom</u>	<u>Size</u>	<u>Number</u>
PM Series	Ref. Male	7
PF Series	Ref. Female	2
P10 Series	Ref. 10 yr old	2
P4 Series	Ref. 4 yr old	2
PM5 Series	5% male	1
PM95 Series	95% male	1
PM _{sec}	Ref. Male	1

The BOMAB phantoms, which are accompanied by HML staff, are used as follows:

- Size dependency measurements
- Unknown radionuclide(s) identification. The unknown radionuclide(s) are not always homogeneously distributed so that the facility must both identify the radionuclide and its location in the phantom.

THORAX COUNTING FACILITIES

Thorax monitoring facilities are usually concerned with lung depositions; however, they can also be used to monitor other organs of the upper body such as the liver, abdominal contents or even the head.

The HML can assist Thorax monitoring facilities by use of the Lawrence Livermore National Laboratory Realistic Torso Phantom that has been recently (1) accepted as the closest approximation to a standard torso phantom until such times as a new model is constructed. The HML holds one LLNL phantom with a large variety of accessory to extend calibrations to different sized individuals.

The HML can also provide other radionuclides that can be inserted in the blank lung sets or other organs in the torso. For example, the HML has manufactured some ^{14}C inserts that can be loaded into the phantom to simulate a lung deposition of insoluble ^{14}C .

The different overlay sets can be combined with the phantom to simulate different chest wall thicknesses and also different chest wall compositions; however, in practise, it is not necessary to vary the chest wall composition if the photon energy exceeds 60 keV. The chest wall composition does not affect the attenuation for photon energies in excess of 60 keV and chest wall thickness is the only concern. The phantom is usually accompanied by HML staff.

THYROID MONITORING FACILITIES

The BRMD neck phantom has been re-designed to remove some of the shortcomings of the other two phantoms (6). This phantom is constructed from a material that is a good tissue substitute for ^{125}I ; the form is anthropomorphic (but no spinal column is included); the thyroid insert closely resembles the thyroid gland (although visually it does not look like a thyroid gland - see reference 5 for a better description); the depth of the thyroid insert can be varied; the size of the thyroid insert can easily be modified to simulate small or large thyroid glands.

The BRMD neck phantom is distributed to thyroid monitoring facilities on request. The phantom is sent with either simulated ^{125}I (^{129}I) or simulated ^{131}I ($^{133}\text{Ba} + ^{137}\text{Cs}$), a blank insert, an overlay plate for multiple depth measurements. The phantom is also sent with a document describing its usage (7) as HML staff do not usually accompany the phantom.

Typically the phantom will have two inserts for each radioiodine. One insert will have an activity in the tens of Becquerels and the other an order of magnitude higher. The users are not informed of these activities until after the inter-comparison is completed.

The phantoms may also be used as calibration standards. The HML sends the phantoms, on request, to facilities that would like to calibrate (or recalibrate) their monitoring equipment.

RADIOACTIVE LEVELS AND DOSES OF ^3H AND ^{14}C IN WHITE SPIRITS

DENG GUOLUN

Sichuan Institute of Radiohygiene Protection, Chengdu, China

White (and yeast) spirits is a general name for strong alcoholic beverages in China. The paper reports levels and doses of ^3H and ^{14}C in 65 spirits samples between 1986 and 1987. Experiments were made by measuring and analyzing each sample, using a low background liquid scintillation spectrometer.

Radioactive levels of 65 spirits samples are as follows:

Variant range of ^3H activity is $98.2 - 170.6\text{Bq}\cdot\text{dm}^{-3}$ and its average is $149.2 \pm 17.3\text{Bq}\cdot\text{dm}^{-3}$; Variant range of ^{14}C activity is $38.8-80.2\text{Bq}\cdot\text{dm}^{-3}$ and its average is $57.4 \pm 8.2\text{Bq}\cdot\text{dm}^{-3}$.

If the man drinks 200cm^3 of spirits daily, the annual dose equivalents will be $0.19\mu\text{Sv}$ of ^3H and $2.5\mu\text{Sv}$ of ^{14}C .

In ordinary strong alcoholic beverages that contain 57-60% alcohol, the mean ^3H and ^{14}C activities are $153.8\text{Bq}\cdot\text{dm}^{-3}$ and $60.3\text{Bq}\cdot\text{dm}^{-3}$, respectively, but in spirits of lower alcoholic content (38-40%), the mean ^3H activity is $114.6\text{Bq}\cdot\text{dm}^{-3}$, that is 25.5% less than ordinary spirits, and the mean ^{14}C activity is $46.1\text{Bq}\cdot\text{dm}^{-3}$, that is 23.5% less than ordinary spirits.

We compared the ^3H and ^{14}C contents of five kinds of staple grains from both Sichuan and Guangdong provinces. We learned that the level of ^3H activity in spirits is ten times higher than in grains and water, and the level of ^{14}C activity in spirits is equivalent to that in grains. White spirits has fully concentrated ^3H and ^{14}C from both grain and water, and activities increase with increasing alcoholic content. ^3H in spirits probably is averaged from both water and grain, and ^{14}C is averaged mostly from grain.

DOSIMETRY FOLLOWING INTERNAL CONTAMINATION:
COMPARISON OF SOME BIOASSAY MODELS

ABSTRACT

A Task Group of the ICRP is currently reviewing the model to be used for the respiratory tract. The choice of the model will not only change the dosimetry, but will also have consequences for the whole body burden as a function of time following an internal contamination. Therefore the data for the evaluation of the intake derived from the measurement of the body burdens must be recalculated, to be included in the new release of our compilation. Examples of the results of two models are given for the inhalation of ^{60}Co and compared to the current model and to measured data.

INTRODUCTION

An earlier compilation of data [1] provides predicted whole body retention functions for over 400 radionuclides, based on the models given in ICRP-30 [2]. Due to the development of a revised respiratory tract model by the ICRP, all inhalation data are now being recalculated. We also use this opportunity to include excretion functions in the new release of the report. The models we have used include the proposed ICRP-model [3] and the more simple version as given by Johnson and Milencoff [4]. The proposed ICRP-model involves 14 compartments, each with one or more subcompartments. All transfer rates are constant. The second model employs only three compartments, but the transfer rates are time dependent. Both models use mechanical transport of particles, independent of solubility. We compare the results of both models to the current version of the lung model.

MATHEMATICAL TREATMENT

The preliminary ICRP-model is incorporated in a PC-based programme, the Lung Dose Evaluation Programme, LUDEP [5].

We have used this code to calculate the whole body burden (fraction of intake as a function of time) for ^{60}Co . In the calculation default values are used for all parameters, i.e. a 1 μm AMAD aerosol is inhaled by a nose breathing lightly working adult male. The total deposition for this case is 45.6% of the intake: 28.5% in Extra-Thoracic, 5.6% in Bronchial and 11.5% in Alveolar/Interstitial.

The same default values are used for the three compartment model. However, here the deposition amounts to only 28%. This may be compared to the currently used value of 63%.

The three compartments (Extra-Thoracic, Slow-clearing and Fast-clearing Thoracic) are cleared mechanically to the GI-tract, described by three time dependent functions $G(t)$. The solubilisation is given by a function $B(t)$. After solving the set of coupled differential equations numerically (one for each compartment), all activities are added to obtain the whole body burden. The calculations are performed on a Tulip¹ personal computer. The programming language is Turbo Pascal² with its numerical toolbox. The whole body burden from the current ICRP-model is taken from our earlier compilation [1], based in ICRP-30.

¹ Tulip is a registered trade mark of Tulip Computers,
's Hertogenbosch, The Netherlands.

² Turbo Pascal is a registered trade mark of Borland International,
Inc., Scotts Valley, CA, USA.

RESULTS FOR ^{60}Co

As an example we have recalculated the body burden for inhalation of ^{60}Co , both for Class Y and W (called S and M in the new model). The results are given in Figures 1 and 2.

Figure 1 Calculated body burden after inhalation of ^{60}Co . + = example of actual measured data.

- Y = Class Y current ICRP-model
- S = Type S proposed ICRP-model
- 3 = Class Y 3-compartment-model

It is clear from this information that the main difference stems from the lower deposition values. In Figure 1 we have tentatively included the relative whole body burden measured for an actual inhalation case. There seems to be no real favorite among the models, but the new models predict the long term retention better in relation to the original deposition. This is probably the result of the inclusion of the fast mechanical clearing of the ET-compartment.

The more detailed nature of the proposed ICRP-model, however, makes a more precise calculation of the dose to different parts of the respiratory tract possible.

Figure 2 Calculated body burden for inhalation of ^{60}Co .

W = Class W current ICRP-model
M = Type M proposed ICRP-model
3 = Class W 3-compartment-model

The three compartment model predicts a faster clearance in both cases.

and East Anglian Regional Radiation Protection
Service, Addenbrooke's Hospital, Cambridge, U.K.

ABSTRACT

The results of a survey in which 1220 volunteers were monitored using the Addenbrooke's whole-body counter during the period April 1988 - March 1991 are presented. The decline in radiocaesium post Chernobyl was registered and special techniques of spectral analysis and data averaging were used to establish a maximum likely average radiocaesium body burden in the adult population. Other man-made radionuclides (eg. ^{99m}Tc , ^{131}I) were occasionally detected and the likely origins investigated. The presence of radon decay products in variable amounts influences the minimum detection level of other radionuclides and some consequences of this interference are discussed.

INTRODUCTION

One of the recommendations of the Black report (1) investigating the possible increased incidence of leukaemia near to a nuclear fuel reprocessing plant in the North West of England was that there should be more research using whole-body monitors into levels of radioactivity occurring in the general population. Cambridgeshire was selected as a suitable location to obtain baseline data on a large number of volunteers because it has a low level of environmental radioactivity.

In addition to ^{137}Cs and ^{134}Cs from Chernobyl, we were interested in measuring ^{99m}Tc and ^{131}I since, along with tritium (not detectable in a whole-body counter), they account for over 90% of all radioactive discharges in the locality (2).

THE POPULATION SAMPLE

1220 volunteers were each monitored for 1000 s in the whole-body counter. For statistical analysis of the local population, only persons who had lived in Cambridgeshire for more than three years and had not been knowingly exposed to radionuclides were included. This reduced the total number to 1032, 314 adult males, 521 adult females, 68 male children and 129 female children. Combining the children together into one group provides a total of about 200 which is probably larger than any single group of children monitored previously.

RESULTS AND DISCUSSION

1) Radiocaesium from Chernobyl

The average Cs: ^{40}K ratios each month for all adult males throughout the study are shown in Figure 1. During the period April 1988 - July 1989 this ratio was 2.34%. The ratio was 2.06%

for adult females but the lowest recorded ratio was for male children (1.47%); just significantly lower than that for female children (1.90%).

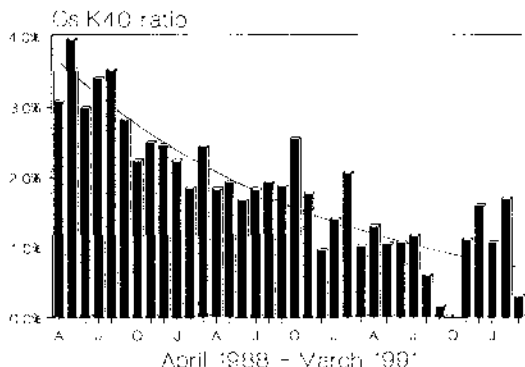

Figure 1. Monthly average contamination of adult male volunteers expressed as a ratio of radiocaesium to ^{40}K .

Although radiocaesium was readily detectable in all volunteers at the start of the study, by August 1989 results suggested that there was no definite evidence of caesium in some of the spectra and during the final twelve months from April 1990 there was no discernible trend in caesium levels (Fig. 1). Using a suitable model of exponential decay based on our own data, the average estimated effective dose per person to the population of Cambridgeshire from caesium radionuclides released from Chernobyl during the period April 1988 to March 1991 was 8.4×10^{-6} Sv for men, and 5.7×10^{-6} Sv for women.

For a single 1000 s measurement using the Addenbrooke's whole-body counter estimates of the minimum detectable amounts (MDA) of activity for ^{137}Cs and ^{134}Cs are 60 Bq and 30 Bq respectively. The major limitation is statistical, thus for large numbers of volunteers an averaging process may be used to obtain a more accurate figure for the population as a whole.

The spectra obtained since April 1990 have been summed for the four groups of volunteers. Unfortunately, analysis of the 662 keV peak from ^{137}Cs is confounded by a variable and unknown contribution from ^{214}Bi , a radon daughter, which emits 610 keV gamma rays. If we assume that all counts detected were due to caesium then the maximum remaining average level of caesium was 10 Bq for adult males and females. For the group of adult males the energy of the detected peak was half way between the peaks of ^{214}Bi and ^{137}Cs . This suggests that the average level of caesium activity remaining is probably about 5 Bq for adult males. For the group of female adults the peak detected was at 614 keV which suggests that most of the activity present was due to radon. For the male and female children, no peak could be detected in the summed spectrum during this phase of the study, so activity levels are even lower.

2) Other Man-made Radionuclides

In this category we have included manufactured articles containing radium. Fourteen volunteers had measurable activity either in or on their person and these are summarised in Table 1. On each occasion an explanation for the observed activity could be readily determined and the levels of activity were extremely small. Release of ^{99m}Tc and ^{131}I result from their widespread use in medicine for diagnosis and therapy respectively. It is notable that in 9 of the 14 cases where radioactivity was detectable, one of these two radionuclides was involved.

The benefit of adding spectra from different volunteers was again illustrated by looking for the 364 keV peak of ^{131}I in the summed spectra for 22 adult male volunteers who were all measured after the caesium activity from Chernobyl had become undetectable. The limit on detection is again set by radon decay products - the 350 keV peak from ^{214}Pb in this case. Radon decay products were known to be present in the summed spectrum because other peaks (eg. 610 keV from ^{214}Bi) were detected. Nevertheless, the minimum level of detectability for ^{131}I was reduced to 30 Bq from 60 Bq for a single 1000 s measurement.

Table 1. Man-made radionuclides detected in or on volunteers.

Nuclide	Number of cases	Estimated Activity (Bq)	Reason for Contamination
^{99m}Tc	6	<1000	subjects had been in Nuclear Medicine waiting room prior to monitoring.
^{22}Na	1	1000	accidental spillage during Nuclear Medicine test.
^{226}Ra	1	200	luminous watch after removal.
^{86}Rb	2	2000 600	used in studies at Medical Research Council laboratory on site.
^{232}Th	1	100	a physics teacher, Thorium was used at school. (could have been natural, poor statistics)
^{131}I	3	1000 200 100	all visitors to patients on radionuclide therapy ward.

When spectra for volunteers in all four groups were combined, the average activity in the energy window corresponding to ^{131}I was 10 Bq per person. However the energy of the peak suggests that most, if not all, of the peak was due to ^{214}Pb . We conclude that the only real evidence for ^{131}I activity in this sample of volunteers resulted from close contact with patients being treated with this radionuclide for therapeutic purposes.

3) Radon

The whole-body monitor has a very low radon level, so we were able to look for radon daughters in volunteers. Approximately 15 persons had unusually high levels of radon

daughters compared with the rest of Cambridgeshire volunteers. Rather more showed probable activity. There is no reasonably practical method of calibrating the whole-body counter for quantification of radon daughters (^{214}Pb and ^{214}Bi) but the activities seem to be in the range 200 - 1000 Bq. In some cases these can be traced to contact with a radon source such as an old luminous watch but other cases can only be explained by the presence of increased radon levels at home.

Measurement of radon contamination from the radon daughter gamma emission is difficult. Volunteers are measured fully clothed and radon daughters can be deposited onto dust from atmospheric radon thereby contaminating clothing and adding to the activity measured from internal radon. The biological half-life of inhaled radon is not known but is likely to be of the order of a few hours or less although the daughters are likely to remain in the body for longer. Hence, the ratio of radon daughters to radon is uncertain and the levels of radon daughters will depend on how recently the volunteer was exposed to radon.

CONCLUSION

Overall the project has achieved the primary objective, which was to establish a substantial database for a large group of volunteers from the same part of the U.K. The Chernobyl accident provided a fortuitous opportunity to validate the methodology on human volunteers rather than phantoms and the study continued for long enough to establish baseline data in the post-Chernobyl era. These data should prove valuable in helping to monitor the future effects on the population of the release of man-made radionuclides into the environment.

BIOLOGICALLY-EQUIVALENT DOSIMETRY FROM
NITROGEN-14 NUCLEAR QUADRUPOLE RESONANCE

D.E. Hintenlang, L.H. Iselin and K. Jamil

Department of Nuclear Engineering Sciences
University of Florida
Gainesville, FL 32611-2055 USA

ABSTRACT

A new method for measuring the damage to biological systems from ionizing radiation has been developed based upon the principles of ^{14}N Nuclear Quadrupole Resonance (NQR). NQR studies have been performed on several biologically-equivalent materials. Variations of NQR parameters are presented for materials exposed in gamma and neutron fields. The radiation induced structural changes are modeled and quantitatively correlated with photon and neutron fluxes and absorbed dose rates. Radiation induced changes in the NQR spectra provide a sensitive measure of potential biological damage.

INTRODUCTION

The NQR technique provides a sensitive probe of electron bonding configurations around the nitrogen sites for a number of organic, biologically-significant compounds. Detailed information on radiation effects is obtained by monitoring the interaction between the electric field gradient produced by the electron bonding configuration and the nuclear quadrupole moment of the probe nucleus. Studies have been performed on the simplest compounds of the urea family, urea and thiourea. By utilizing biological materials as dosimeter material, and monitoring the radiation induced changes, a representation of potential biological damage is obtained.

THEORY AND EXPERIMENT

The bonding configuration around ^{14}N nuclei produces an electric field gradient (EFG) at the nuclear site which causes splitting of the nuclear energy levels due to an interaction with the nuclear electric quadrupole moment (eQ). Observable transition frequencies between the energy levels are

$$\nu_+ = \frac{(3+\eta)e^2qQ}{4h} \quad \nu_- = \frac{(3-\eta)e^2qQ}{4h}$$

where η is the asymmetry parameter measuring deviation from axial symmetry, eq is the EFG component with maximum amplitude, and h is Planck's constant. These transitions are forced by the application of radiofrequency (RF) energy at the appropriate transition frequency. Single pulses of $14\mu\text{s}$ duration were used to excite the spin system at 77 K and the resulting free induction decays (FID's) were characterized to determine the radiation response of the material. All resonance frequencies for urea and thiourea were observed to occur at previously

reported frequencies between 2 and 3 MHz, using pulsed NQR techniques with a pulsed spectrometer commercially available.¹

RESULTS AND DISCUSSION

The initial radiation response of urea and thiourea has been characterized using gamma and neutron radiation fields. Gamma irradiations were performed with a ⁶⁰Co irradiator² providing a delivered dose rate of 0.122 Gy s⁻¹. The response of the NQR parameters of urea have been investigated with the urea in two physical forms. Dry polycrystalline urea does not exhibit any detectable change in its NQR

parameters for delivered doses of ⁶⁰Co radiation up to 2000 Gy. Hydrated polycrystalline urea exhibits pronounced changes in several NQR parameters when exposed to ⁶⁰Co radiation. The most pronounced effects are manifest as a decrease in the spin-spin relaxation time, T_2 , as the delivered dose increases, figure 1. These changes may be related to small changes in the chemical bonding configuration of the urea, and not large-scale structural rearrangement³. Urea studies demonstrate that the response of these materials may be greatly enhanced when water is incorporated into the polycrystalline matrix. A comparison of the response of the dry and hydrated urea samples demonstrates that radiolytic products created in the water subsequently attack urea molecules. This is the dominant mechanism for radiation effects, not direct interactions with urea molecules.

Thiourea has a molecular structure similar to that of urea, with the oxygen atom in urea being replaced by a sulfur atom to form thiourea. The NQR and radiation responses of these two materials would be expected to be quite similar. The incorporation of sulfur instead of oxygen, however, causes the two nitrogen sites in the molecule to become nonequivalent, and the sites experience different EFG's and resonate at slightly

Figure 1 Urea T_2 response to gamma irradiation

Figure 2 FID of thiourea

different frequencies. The thiourea FID is therefore complicated by the superposition of two FID's from independent nitrogen sites, and exhibits a more complex shape, figure 2. This requires that sophisticated data analysis methods be utilized. In this case a non-linear curve fitting program was developed and used to separate the T_2 's associated with each of the two components of the FID.

Studies analogous to those performed on urea were attempted on thiourea. Although dry polycrystalline samples were irradiated to much higher doses than the urea, no radiation induced changes were observed. Hydrated polycrystalline samples of thiourea cannot be studied because water reacts with the thiourea molecules and eliminates any NQR response. Dry polycrystalline thiourea was characterized for changes induced by exposure to neutron radiation. The samples were irradiated in the central beam port of the University of Florida Training Reactor with a fission neutron spectrum of flux $1.2 \times 10^{16} m^{-2} s^{-1}$.

Neutron irradiation resulted in a dramatic decrease in NQR signal intensity as illustrated in figure 3. A much greater fraction of ^{14}N nuclei are prevented from contributing to the NQR signal than would be expected from calculations of the number of thiourea molecules damaged by the delivered neutron fluences. This indicates that the NQR parameters are sensitive enough to be affected by radiation induced changes at least several molecules away.

Figure 3 Thiourea response to fission neutrons.

More complex molecules, such as guanidine sulfate, are expected to provide more sensitive probes of radiation induced changes using NQR techniques. Due to the superposition of several nitrogen sites, however, the quantization of contributions from each site requires more sophisticated data analysis methods. Traditionally, data analysis for magnetic resonance spectra has been done by discrete Fourier Transform (FT) of the time series data via the Cooley-Tukey Fast Fourier Transform algorithm.⁴ The FT power spectrum in frequency space is used to isolate the appropriate resonance frequencies and the FT absorption spectrum yields the spin relaxation times which are proportional to the inverse of the line widths. In pulsed NQR the loss of frequency-dependent phase information due to the spectrometry electronics results in a mixing of absorption and dispersion modes in the cosine portion of the FT. We have been unable to characterize the missing phase information and thus the individual line widths cannot be determined by this method.

The Marquardt method⁵ of non-linear least squares curvefitting was used to overcome this problem. The experimental FID is fit to a Lorentzian line in the time domain:

$$v(t) = \sum_{i=1}^N a_i \cos(\omega_i t + \phi_i) e^{-t/T_{2i}}$$

with $v(t)$ being the composite time domain signal, N the number of different ^{14}N sites, a_i the signal amplitude, ω_i the difference frequency between the applied RF and the resonance frequency, and ϕ_i the phase shift. A data reduction method recently applied to magnetic resonance spectra, HSVSD⁶, which converts the non-linear problem of exponentially damped sinusoids in the time domain into a linear problem in state space and solves by linear least squares, will be used in future work on more complex molecules.

CONCLUSIONS

This work represents the first observed detection of gamma and neutron radiation effects in bio-molecules using ^{14}N NQR. Neutron radiation is capable of producing direct effects in the compounds studied, while gamma radiation effects on the molecular structure occurred as a result of indirect interaction with radiolytic products formed in hydrated samples. While the system has yet to be optimized to maximize the response to ionizing radiations, more sophisticated data analysis methods are being developed to improve the detection limit of this dosimetry technique. Ultimately ^{14}N NQR is expected to provide a sensitive method for radiation dosimetry and the study of the response of fundamental biological systems to ionizing radiation.

IS TRACK-ETCH DOSIMETRY READY FOR NEUTRON PERSONAL
DOSIMETRY AT HIGH ENERGY ACCELERATORS?

N. Anthony Greenhouse
Bldg. 75, Rm.112
University of California
Lawrence Berkeley Laboratory

26 February 1991

Experiments in high energy particle physics began with Ernest O. Lawrence's cyclotrons at the University of California, Berkeley. The original and still current favorite personal monitor for neutrons is a Kodak photographic emulsion (Type A, or "NTA film"). Research at LBL and other accelerator laboratories suggests that electrochemically etched CR-39 plastic detectors have sufficient spectral response and sensitivity to replace NTA film as a personal neutron dosimeter. The primary advantages to CR-39 are its lack of photon response and minimal loss of latent track images.

We have compared responses of CR-39, NTA film, and bubble detectors in neutron fields where the spectra and dose equivalent rates were determined by Bonner spheres and NE-213 spectrometry techniques. Experiments at the Bevalac and the 88-Inch Cyclotron provided data which support the hypothesis about the appropriateness of CR-39. Other measurements also verified the "blind region" between ~ 6 and ~ 12 MeV. However, most of the dose equivalent is delivered by neutrons in excess of 10 MeV. Spectrometry at the Bevalac suggests that about 80% of Hn meets this limitation. It appears that (n,alpha) reactions and recoiling carbon and nitrogen nuclei cause the high energy response in CR-39.

INFORMING AND EDUCATING THE PUBLIC ON
RADIATION RISKS

F. LUYKX

Commission of the European Communities,
Luxembourg

ABSTRACT

Over the last decade, and especially since the Chernobyl accident, the need for informing and educating the public on radiation risks has been widely recognised by decision-makers around the world. In principle at least part of this task can be fulfilled by radiation protection professionals in that they know the subject and can, therefore, give correct and objective information and advice. However, since they generally lack experience of communicating with the public, suitable training programmes will be necessary. Such training should cover not just direct communication but should emphasize communication with information intermediaries, such as the media, the medical professions, the decision-makers and the educators. IRPA as a professional organisation should envisage taking up such training programmes in its future activities.

INTRODUCTION

The interest of competent authorities, politicians, nuclear utilities and radiation protection professionals in public information and education has strongly increased over the last decade in recognition of growing public concern for the environment in general and radiation protection aspects in particular. The problems of dispassionate communication with the public after the Chernobyl accident gave added impetus to this trend.

Whereas previous activity in this field was largely confined to the nuclear energy lobby, seeking to underline the advantages of nuclear power and to anti-nuclear organisations, promoting doomsday images of radiation risks, international, national and local authorities are now taking initiatives to improve communications, often with limited success. Initial efforts largely focussed on major nuclear accident risks, but there is now a burgeoning interest in the longterm consequences of low level exposure.

Public opinion surveys in Europe from 1988 to 1991 indicate widespread dissatisfaction with available information (1). The major criticisms are that such information is inadequate, unclear and unreliable but also refer to poor and slow distribution. The credibility of

the various information sources, is highest for (independent) scientists and medical practitioners, and lowest for government and government bodies; in addition to clarity, "good" information requires the authority of scientific knowledge coupled with independence from vested economic industrial and political influence.

INFORMATION INTERMEDIARIES

The normal public information channels are via intermediaries, the most important being:

- the media,
- the medical profession,
- the decision-makers, politicians and trade-union leaders.
- the educators,

Each of these tend to reach particular sectors of the general public and with different objectives.

The media play the most direct role in informing the public about risks from ionizing radiation. It is often said that, if the layman is not well informed, it is the fault of the media. They are criticized for being selective, tending to exaggerate controversy and uncertainty (2), introducing inaccuracies and omitting significant information.

It should, be borne in mind, however, that journalists operate under considerable constraints such as deadlines, editorial pressure, simplicity of presentation, currency of information and limited technical knowledge (3). The last point is particularly important; journalists cannot be expected to appreciate all aspects relevant to judging a situation. As Maclachlan has said (3), "The journalists' best allies in this regard are good common sense and trustworthy sources". Here, professionals in radiation protection can help by giving simple, correct but clear information on radiation risks.

The medical profession, including doctors, pharmacists and nurses, is for many a confidant for all problems related directly or indirectly to health. Training and education of this group on radiation risks, and especially on the possible radiological consequences of nuclear accidents, is, therefore, of extreme importance to public comprehension and averting mistaken, overhasty conclusions on health effects, as was the case on several occasions after the T.M.I. and Chernobyl accidents.

The decision-makers and politicians have the last word in deciding policies related to ionizing radiation but the trade-unions can considerably influence the formulation and execution of such policies.

After the Chernobyl accident we saw several instances of the scientific reality having little influence on political decisions taken to protect the public. One reason for this may be political opportunism but another, no less important, is ignorance. As in the case of the media, the decision-makers and trade-union leaders cannot have specialist knowledge of all fields; they need have trustworthy advisers.

However, the educators, especially teachers in primary and secondary schools, are probably in the longer term the most important group of intermediaries. They are in direct contact with the younger generation, many of whom will continue to draw on what they were taught long after they have left school and perhaps themselves become members of an intermediary group. However, since most teachers are strong defenders of environmental protection, which is appreciated by everybody, they are often anti-nuclear and, due at least partly to gaps in their own knowledge, may consider radioactivity as one of the biggest dangers.

As a result pupils are misinformed from the outset and it will be extremely difficult to change their attitude in later life. Education of the educators must be a first priority.

Within the European Community a programme has been started recently to have environmental studies included in all primary and secondary school curricula by the year 2000 at the latest and listed as a formal examination option as soon as possible after that date (4). Teacher training programmes are being initiated and pilot radiation protection training manuals for teachers in primary and secondary education have already been produced (5).

RADIATION PROTECTION PROFESSIONALS AND PUBLIC INFORMATION

The general public's attitude towards radiation risks depends more on the credibility of the speaker than on the information given. Since practically all opinion surveys show an appreciable public faith in scientists because they know the subject and therefore can give correct and objective information (provided they are seen as independent), radiation protection professionals should consider assistance in informing and educating the public as part of their vocation.

Unfortunately a reproach, often encountered and too often well founded, is that the experts use language unintelligible to the layman. In a talk at a NEA workshop in 1987 (6) Dr. Wilkie, presenting the journalist's view, said about professionals: "... if a journalist telephones them, then they are nervous, hesitant to talk; they answer the questions precisely with myriad qualifications (which never realistically have a hope of getting printed)".

Thus, what the radiation protection professionals really need is training in public communication techniques since most have no experience in this field. Since most health physicists will rarely have direct contact with the public at large the first task will be training on how to inform and educate the intermediary groups. Moreover, since the objectives and backgrounds of these groups differ, it is clear that each has to be treated separately, although the final aim will be the same, i.e. to allow the development within the public of a well informed and realistic attitude towards radiation which should be recognized as no more than a feature of everyday life. More initiative is needed in this field.

CONCLUSIONS

All those having social and political responsibilities are convinced of the necessity of informing and educating the public on radiation risks. This task can, at least partly, be fulfilled by the radiation protection professionals, particularly in support of identifiable intermediary groups. But, since communicating with the public is an art in itself, it should not be undertaken without prior training. IRPA, as a professional organisation, should envisage initiating such training programmes in its future activities.

Media and Political Implications
on Radiation Policy in the United States

Lynne A. Fairbent
Scientific Advisor to
Assistant Secretary for Environment, Safety and Health
U.S. Department of Energy

It was becoming more and more difficult to set regulations based solely on scientific facts in the United States. Recently, the influence of the media and political processes has resulted in efforts to establish prescriptive legislation without regard to science. One such example is the issue of "below regulatory concern" (BRC). In the U.S., BRC is used to define a level of radioactivity that need to be regulated simply because the material is radioactive. The regulatory and technical issues of BRC are not at issue although there is debate within the U.S. scientific community on a single numerical value to be applied in all circumstances. However, the public and political issues related to BRC are perhaps the most difficult ones to address.

This paper reviews the difficulty in conveying to the non-scientific community the rationale for "de-regulating" radioactive material through a review of the BRC process.

MEDICAL X-RAY EXPOSURES IN THE UK

G A M Webb and B F Wall

National Radiological Protection Board,
Chilton, Didcot, Oxon, OX11 0RQ, UK.

ABSTRACT

Recent studies in the UK show that substantial savings could be made in the collective radiation dose to the population from medical x-rays without detriment to patient care. One significant area of potential dose reduction is to reduce the very wide ranges in the doses delivered to different patients for nominally the same diagnostic procedure. National protocols for measuring patient doses and comparing them with guideline reference doses for common x-ray examinations are described. They will help to identify those operating at the top end of these ranges and encourage them to reduce their doses towards the norm.

POTENTIAL FOR PATIENT DOSE REDUCTION

According to figures published by UNSCEAR (1), the UK carries out only about one half of the number of medical x-ray examinations per head of population than the average figure for all other developed countries for which recent data are available. In spite of this, a document published last year by the Royal College of Radiologists and the National Radiological Protection Board (2) on the extent of unjustified and non-optimised x-ray examinations in the UK, indicates that a reduction of nearly one half in the collective dose to the population from medical x-rays might be possible without detriment to patient care.

Clinically unjustified x-ray examinations have been addressed by the Royal College of Radiologists in a booklet providing guidelines for doctors on referral criteria (3). It identifies the uninformed or uncritical use of x-ray examinations in screening tests or as part of routine practice as the greatest source of unnecessary referrals. Indeed, representatives of the College felt that it would not be unreasonable to suggest that at least 20% of x-ray examinations carried out in the UK are clinically unhelpful in the sense that the probability of obtaining information useful for patient management is extremely low (2).

Once medical exposures have been correctly justified, the optimisation of patient protection, i.e. ensuring that radiation exposures are kept as low as reasonably achievable (ALARA) consistent with obtaining the desired diagnostic result, provides another fruitful area for beneficial dose reduction. Exposures can be kept ALARA by critical examination of both examination procedures and imaging equipment. To assess the potential for such dose reduction both locally and nationally requires measurement of the doses typically delivered by each x-ray facility and their national variation. Suitable measurements and control procedures are being encouraged in the UK by the development and publication of a nationally agreed protocol.

NATIONAL PROTOCOL FOR MONITORING PATIENT DOSE

A National Protocol for Patient Dose Measurements in Diagnostic Radiology (4) has been developed by representatives of NRPB, the Institute of Physical Sciences in Medicine

(IPSM) and the College of Radiographers and will soon be published. The most important features are described below.

1 Quantities to be measured

The recommended dose quantities have been selected to meet the following objectives:-

- (a) To be capable of unambiguous definition so that everyone can clearly understand exactly what is to be measured.
- (b) To be capable of simple direct measurement with readily available dosimeters of sufficient precision and accuracy. Valid comparisons can then be made with previous measurements at the same facility, with measurements in other facilities and with national norms.
- (c) To provide a measurement of the typical dose received by adult patients examined in a particular facility from either:-
 - (i) a particular type of radiograph
 - or (ii) a particular type of complete examination.

To meet these objectives the following two dose quantities are recommended:-

- (i) **Entrance Surface Dose** (including backscattered radiation) for individual radiographs.
- (ii) **Dose-Area Product** for complete examinations.

Other dose quantities exist which may be more closely related to the radiation risk to the patient, eg. organ doses, effective dose or the total energy imparted to the patient. They cannot however be measured directly and have to be inferred. Methods for deriving such quantities from the directly measurable quantities recommended in this protocol have been developed by NRPB and are being extended. These will increase the utility of the two recommended directly-measurable quantities which still, however, remain more practicable for periodic checks and comparisons of patient dose.

2 Choice of dosimeters

Thermoluminescent dosimeters are preferred to ionisation chambers for entrance surface dose measurements because they are small, unobtrusive and, if stuck directly to the skin, fully measure backscattered radiation. Ionisation chamber measurements in free air (without a patient or phantom) are not ruled out in suitable circumstances, but such measurements must be corrected using appropriate backscatter factors.

Specially designed large-area, transparent ionisation chambers are available for attaching to the diaphragm housing of x-ray sets to measure dose-area product, and are the recommended dosimeter for this purpose. They do not interfere with the examination and will integrate the dose both over the area of the x-ray beam and over complete examinations involving radiography and fluoroscopy.

It is expected that both types of measurements will usually be carried out by radiographers with the active assistance of medical physicists particularly in providing suitably

calibrated dosimeters. The protocol describes how both TLD systems and Dose-Area Product Meters should be calibrated and specifies desirable levels of accuracy.

3 Sample selection

Advice is given on how to select an appropriate measurement sample so that valid comparisons can be made between facilities and with national norms. The objective of the measurements is to obtain an indication of the typical dose that is being delivered to an average adult patient by the procedures and equipment used in a particular facility for the types of radiograph or examination under study. To meet this objective measurements should preferably be made on a representative sample of at least 10 adult patients rather than on phantoms or in free air.

It is recommended that dose measurements should concentrate on those types of radiograph and examination that make a significant contribution to the collective dose from medical x-ray examinations. These are indicated in Table 1 where reference dose values are also given. Measurements on other types of radiograph or examination which would provide useful information on the performance of a particular x-ray facility are not to be excluded, but for the majority of standard radiographic or fluoroscopic facilities, patient dose monitoring should be initially concentrated in the above areas. Computed Tomography and mammography are deliberately not covered by the protocol.

4 National collation of dose data and Reference Dose Levels

Important features of the Protocol are that it provides guideline reference doses based on earlier national surveys and it recommends a system for the continual national collation of patient doses. Users of the Protocol are encouraged to send their results to NRPB so that trends in patient dose can be analysed and reference doses based on national norms can be revised if necessary. At present, reference doses are based on the 3rd quartile values of the mean doses delivered by x-ray departments in a national patient dose survey conducted by NRPB in the mid 1980s.

Table 1. Reference dose values

Entrance Surface Dose per radiograph		(mGy)	Dose-Area Product per examination	(Gy.cm²)
Lumbar spine	AP	10	Lumbar spine	15
	Lat	30	Barium enema	60
	LSJ	40	Barium meal	20
Abdomen	AP	10	Intravenous	
Pelvis	AP	10	urography	40
Chest	PA	0.3	Abdomen	8
	Lat	1.5	Pelvis	5
Skull	AP	5.0		
	PA	5.0		
	Lat	3.0		

Since 75% of radiology departments can operate satisfactorily with mean doses below the third quartile values, it is recommended that those departments that are found to exceed this level should conduct thorough and immediate investigations into the reasons for their excessively high doses. The investigations either should lead to revisions in techniques or equipment to bring the doses into line with the majority or, exceptionally, should lead to a thorough justification of the need for high doses in that particular clinical circumstance. We believe that the reference levels correspond to the ICRP 60 (5) concept of a "dose constraint" for medical exposures.

The achievement of mean doses below the reference (3rd quartile) level should not be construed as an indication of satisfactory or optimum performance per se. It may well be possible to reduce doses further without loss to the diagnostic value of the examination and such reductions should always be pursued in line with the ALARA principle. However, particular attention should be paid to checking image quality if mean doses fall significantly below the 1st quartile values. Simple methods for checking image quality are outlined in the protocol.

CONCLUSIONS

Adherence to the procedures recommended in this protocol will ensure that radiologists and radiographers are kept aware of how the doses that they currently deliver to their patients compare with national norms so that they can bring them into line with modern accepted practice. The national collation of patient dose data will enable the impact of patient protection measures and trends in medical exposures in the UK to be assessed and the guideline reference doses to be revised if necessary.

EXPOSITIONS AUX PATIENTS POUR QUELQUES EXAMENS RADIOGRAPHIQUES AU QUEBEC

R. Carrier, P. Charland

Département de physique biomédicale
Hôpital Notre-Dame de Montréal
1560 rue Sherbrooke Est, Montréal, Canada, H2L 4M1

ENTRANCE EXPOSURE FOR SEVERAL RADIOGRAPHIC EXAMINATIONS IN QUEBEC

More than one hundred radiographic rooms have been visited and measured. The technical parameters used by X-ray technologists have also been collected. These numbers have been put in a worksheet and results obtained for entrance exposure for the eight most frequent X-ray examinations. Large variations are observed and the results are comparable to other foreign evaluations. A correlation analysis with multiparameters have failed. The variation could not be explained by a general trend on the kV selections or processing speed or thickness of filtration.

INTRODUCTION

Des inspections de radioprotection doivent être faites dans toutes les salles de radiographie au moins à chaque deux ans, selon la réglementation du Québec. Dans le cadre de ces vérifications, nous avons mesuré pour chaque salle de radiographie visitée, les valeurs d'exposition aux différents kV, la précision de ces kV et la couche de demi-atténuation à 80 kV. Nous avons également relevé le type d'écrans intensificateurs utilisés et nous avons procédé à une mesure sensitométrique des conditions de développement des films. D'autres parts, nous avons demandé à la technicienne de la salle, de nous communiquer les différentes techniques utilisées pour 8 examens standards reconnus comme étant les plus fréquents, soit: crâne latéral, poumon PA et poumon latéral, colonne lombaire AP, colonne dorsale AP, colonne dorsale latérale, bassin AP, colonne cervicale AP. Les kV, temps de pose et courant, ainsi que la distance foyer-film nous ont ainsi été fournis.

C'est la compilation de ces informations et des calculs à partir de ces données et des valeurs mesurées qui nous ont permis d'obtenir les résultats que nous vous livrons dans cette présentation.

MATERIEL ET METHODES

Nous avons exprimé en introduction la nature des données recueillies. Ajoutons à cela que tous les examens considérés réfèrent à un patient masculin

de taille moyenne (72 kg). Toutes les mesures ont été faites avec un électromètre Keithley et une chambre d'ionisation Keithley 15cc. Les relevés de la précision des kV ont été faits avec un kVp mètre Victoreen. Les analyses sensitométriques ont été faites à partir de l'exposition d'un film par un sensitomètre Victoreen jugé constant pendant les 3 ans de l'étude. La lecture des densités a été faite avec un densitomètre Macbeth.

Les valeurs d'exposition à la surface du patient ont été calculées à partir des paramètres communiqués et des valeurs mesurées. Le calcul a été fait à l'aide du chiffrier Lotus 123. L'interpolation dans la table des kV a été faite selon une courbe d'ajustement du 4e degré. Nous avons, bien sûr, tenu compte de la distance foyer-film pour les différentes techniques et l'exposition à la surface a été corrigée par la loi de l'inverse du carré de la distance, tenant compte de l'épaisseur de l'organe, et de la distance patient-film. Les résultats du chiffrier sont très comparables aux résultats obtenus avec le logiciel JCAHDOSE distribué par Douglas J. Simpkin (1990).

Nous avons constaté à l'observation des données que pour le même examen radiographique, il y avait de grandes différences dans le choix des techniques radiographiques et à titre d'exemple en figure 1, on constate que pour un crâne latéral les choix de kV peuvent être aussi écartés que 30 kV. Nous avons également constaté de très grandes variations dans la sensibilité des films jumelés aux conditions de développement, ce que nous montre la figure 2. La banque de données inclut des salles travaillant avec des films sensibles au vert et d'autres films sensibles au bleu. De façon à rendre les choses comparables, nous avons divisés l'étude en deux catégories de films. La figure 3 montre la distribution des salles selon l'épaisseur de la couche de demi-atténuation à 80 kV. Certaines salles ont une filtration relativement faible et d'autres une très forte filtration ce qui a certainement une influence sur les expositions obtenues dans ces salles respectives.

Figure 1 Répartition des kV utilisés pour réaliser une radiographie du crâne en latéral

Figure 2 Répartition des sensibilités pour les 87 salles utilisant du films sensibles à la lumière verte.

RESULTATS

Les figures 4 à 11 présentent les histogrammes des résultats d'exposition à la surface des patients pour les 8 techniques considérées. Dans chaque cas, on observe un écart-type très significatif et ainsi de très grandes variations. La moyenne apparaît acceptable et suit les valeurs de l'étude américaine NEXT. Il apparaît que quelques cas significativement élevés nécessitent une correction importante ou aurait fait l'objet d'une erreur dans la transmission des données qui nous ont été communiquées.

Une analyse de corrélation multiple a été essayé et aucun paramètres n'a pu être placé dans une expression de régression avec un coefficient statistiquement significatif selon le test de Student.

CONCLUSION

Compte tenu des variations importantes qui ont été relevées, il nous apparaît que, malgré les réglementations nombreuses qui touchent les équipements, il y aurait place à un mécanisme orienteur au niveau de la standardisation et de l'optimisation des techniques et des appareillages.

ESTIMATION OF EMBRYONIC DOSES IN RADIOLOGICAL EXAMINATION ON UPPER GI-TRACT IN JAPAN

K. Ohta, M. Kai and K. Kusama

Department of Radiological Health, Faculty of Medicine,
The University of Tokyo, Tokyo, Japan

ABSTRACT

Embryonic doses on X-ray health screening of upper GI-tract of about 100 subjects in five health screening facilities were investigated from viewpoints of optimization of protection in medicine. The embryonic doses were derived from the skin doses of each subject measured with TLDs and the examination procedures of upper GI-tract, i.e. duration times of fluoroscopy, numbers of fluorographies or radiographies, voltage and current during examination. The results are as follows: (1)Embryonic doses and skin doses on the maximum point in each subject ranged from 0.3 to 5.5 mGy and from 8.9 and 210 mGy, respectively, (2)Duration time of fluoroscopies and numbers of fluorographies or radiographies ranged from 0.6 to 7.6 min. and from 7 to 40 exposures, respectively.

INTRODUCTION

Per caput dose of medical exposure in Japan is 1.6 mSv; this is about 5 times higher than that of other advanced countries, i.e. United Kingdom[K1]. Immediate reduction of medical exposure is necessary. The X-ray examinations on upper GI-tract which contribute large effective dose to the population are very popular in Japan. The frequency of these examinations per 1000 population is 175(total number is about 19 million)[B1]. About 44% of these examinations are applied to females and about 10% of the female subjects are under years 30 of age[H1]. From viewpoints of radiation protection of embryo/fetus, exposure from these examinations should be reduced.

Because dose limitation is not applied to medical exposure, reduction of exposure should be performed by justification of practice and optimization of protection. X-ray examinations on upper GI-tract could be regarded as a typical diagnostic procedure. So dose constraint in optimization should be considered too[1].

In our previous studies it was made clear that doses of X-ray examinations on upper GI-tract were widely different among subjects. In order to estimate the distribution of embryo/fetus doses among subjects and facilities, we investigated the examination procedures of upper GI-tract and the skin doses in more than 100 subjects in five X-ray health screening facilities.

METHODS AND MATERIALS

The types of X-ray equipment investigated in this report in each health screening facility are shown in Table 1. The uterus doses of each subject were estimated by the following information;

- (1)Skin doses of each subject
- (2)Relationship between surface doses and uterus doses estimated by phantom experiments
- (3)Examination procedures of each subject.

The skin doses of each subject were measured by the following methods;

- (1)TLDs : Mg₂SiO₄:Tb(Kasei Optonix) and CaSO₄:Tm(Panasonic)
- (2)Reader: Victoreen model 2800M
- (3)Calibration: ionizing chamber(Capintec 192X with model PM-05 probe); 90 and 100 kVp X-ray in free air
- (4)Measuring points: front and back surface at 10 cm below xiphisternum, front and back surface at the position of uterus.

Total error of skin doses by the present methods was about 20%.

RESULTS

The investigated procedures of examinations are shown in Table 1. There were remarkable differences of duration time of fluoroscopies and numbers of exposures in gastro-duodenum examinations among facilities. Distribution of duration time of fluoroscopies is shown in Fig. 1. Duration time of fluoroscopies ranged from 0.6 to 7.6 min.

The points of the maximum skin doses were located at 10 cm below xiphisternum in the side of incident X-ray. The skin doses on the maximum point in each subject ranged from 8.9 and 210 mGy and distribution in each facility is shown in Table 1 and Fig. 2. Distribution of embryonic doses is shown in Table 1 and Fig. 3. The embryonic doses ranged from 0.3 mGy to 5.5 mGy.

DISCUSSION

It was made clear that embryonic doses and skin doses of each subject and facility distributed widely. These differences should be considered in estimation of the per caput dose from medical exposure in Japan. It seems that the different purpose of the X-ray health screening of upper GI-tract gave rise to the wide difference in the number of exposures and duration time of fluoroscopies. X-ray health screening of upper GI-tract is applied to healthy subjects as the first screening. So the purpose and the procedures of these should be reconsidered from viewpoints of justification and optimization.

The widely differing embryonic doses and skin doses on the maximum point indicate the necessity of application of dose constraint to X-ray health screening of upper GI-tract. The value of dose constraint must be considered on the basis of our present results.

POTENTIAL EXPOSURES IN RADIATION MEDICINE

César F. Arias

Comisión Nacional de Energía Atómica - Argentina

ABSTRACT

Accidental exposures have progressively caused greater concern along last years and the concept of potential exposures has been deeply explored in the new ICRP recommendations. Severe accidents have been produced by radiation sources employed in medicine. The particular way in which these sources are used enhances the probability of undesirable exposures of workers, members of the public and patients. Nevertheless safety of medical sources have frequently not deserved the same degree of attention as other radiation sources. The tools of probabilistic safety assesment can be applied to evaluate and improve the safety of these sources.

THE CONCEPT AND SIGNIFICANCE OF POTENTIAL EXPOSURES

Any practice with radiation sources implies the irradiation of persons in conditions that can be regarded as normal, what means that radiation doses will be received by people according to predictable patterns, and in any case below certain limits. This objective can be achieved through an appropriate design of equipment and facilities and imposing restrictions to people's behavior.

Nevertheless since devices and people may fail the possibility of accidents can never be ignored. When an accident occurs radiation doses becomes distributed in an unexpected way. The exposures that results from events which are not certain but that can not be disregarded are called potential exposures.

Normal exposures usually contributes more than accidental exposure to collective doses through different places and along the time. However accidental exposures may cause a concentration of effects in place and time that are not justifiable and are not accepted by public opinion.

In the new recommendations of the International Commission of Radiation Protection (1), potential exposures deserves the same consideration as planned exposures what implies a significant evolution from the previous recommendations (2).

Concern about a potential exposure refers to its posible severity and to the probability of occurrence. The severity of an accident depends on the distribution of doses it produces and the number of exposed individuals.

The probability of accidental events with radiation sources depends directly or indirectly on human factors. Sources where safety relies strongly on human behavior have greater probabilities for potential exposures; that is the case of movable sources and unsealed sources, for instance. Since radiation emissions of radioactive sources can not be controlled any radioisotopic source which is not longer used and has not been adequately disposed has a high potentiality for accidents.

POTENTIAL EXPOSURES RELATED TO MEDICAL RADIATION SOURCES

Medical sources are by far the most numerous and spread radiation sources any community has. According to UNSCEAR (3) in the world exist: 18.000 Radiation Therapy machines (4.300.000 procedures per year); 23.500 Nuclear Medicine machines (23.500.000 procedures per year); 440.000 X Rays machines (1.380 millones procedures per year).

These sources are located at buildings usually frequented by many people totally ignorant about radiation risks and radiation protection (members of public).

Some sources are fixed and have large activities. (teletherapy sources). Some others have lower activities and are movable (brachytherapy sources, nuclear medicine sources). The first ones can cause infrequent and severe accidents. The second ones can cause more frequent and less severe accidents.

Radiation safety of medical sources depends on the behavior of many people: phisicians, technicians, nurses, physicists, maintenance workers, and sometimes responsibilities for the sources control are not well defined. In some countries radiation risks and protection have been poorly known by personnel involved in medical application of radiation for a long time. Consequently, safety routines may have been very weak in thoses countries. Additionally, in some countries regulatory procedures related to medical sources are less stringent than for other sources. Such circumstances contributes significantly to raise the potentiality for accidents, in particular when radioactive sources are not longer in use.

Radiation accidents may cause the abnormal exposure of workers and members of the public. Medical sources are used within facilities normally open to general public. Potentiality for public implications is then significant for these sources. However the number of exposed people involved may be much higher if the accident extends outside the facility.

Patient potential risks must also be considered (particularly in radiation therapy). Accidental situation may occur when a patient receives wrong doses, (greater or smaller than expected); or wrongly localized; or when a righth dose is received by a wrong patient. Doses greater than prescribed involves over exposure risks while lower doses may be cause of treatment failure.

REVIEW OF SOME SIGNIFICANT ACCIDENTS PRODUCED BY MEDICAL RADIATION SOURCES

According to C. Lushbaugh (9) 101 fatalities attributable to radiological accidents have occurred between 1944 and 1989; 28 of them have been caused by medical sources. Non fatal accidents or incidents have involved many people; in U.S. during 1988; 470 patients were subjected to medical missadministrations; 438 in diagnostic procedures and 32 in radiation treatments. (2)

Medical radiation sources have caused overexposures to workers and members of the public as consequence of accidents. Patients have been subjected to missadministration of doses.

I) SOME SIGNIFICANT ACCIDENTS THAT HAVE PRODUCED DOSE MISSADMINISTRATIDN TO PATIENTS

- 1) 1986 - U.S. Texas - Linear accelerator unit (4)
Consequences: Two patients died after receiving doses of 200 Gy
Main cause: Wrong interaction between operator and computer.
- 2) 1988 - U.S. California - Tc^{99m} source employed in nuclear medicine (5)
Consequences: a patient received a dose 1000 times greater than prescribed.
Main cause: Failure in following protocol for radiopharmaceutical injections.
- 3) 1987 - 1988 U.S. Maryland - Co⁶⁰ therapy unit (5)
Consequences: 33 patients received doses exceding up to 75% prescribed values.
Main cause: Computer programme was not upgraded after source was changed.
- 4) 1990 - Spain - Zaragoza - Linear Accelerator unit (6)
Consequences: 27 patients were overexposed 14 died
Main cause: Wrong functioning of energy selector after maintenance procedure.

II) SOME SIGNIFICANT ACCIDENTS THAT HAVE PRODUCED OVEREXPOSURE IN WORKERS AND MEMBERS OF THE PUBLIC

- 1) 1965 - U.S. X Ray fluoroscopic equipment (7)
Consequences: Two workers suffer burns in hands
Main cause: Interlock failure during maintenance operations.
- 2) 1984 - México - Ciudad Juarez - Co⁶⁰ Therapy unit (8)
Consequences: 5 persons receives doses between 3 and 7 Gy - 80 persons received doses greated than 0,25 Gy; 814 building had to be demolished.
Main cause: A therapy equipment was disassembled without removing the source and 6000 cobalt pellets were dispersed into building materials.

3) 1987 - Brazil - Goiania - Cs137 Therapy unit (8)

Consequences: 4 persons (members of the public) died - 14 persons received doses greater than 1 Gy - 54 persons received doses greater than 0.25 Gy - 42 residences were contaminated and 4 had to be demolished.

Main cause: A no longer used source was abandoned without any safety measure.

PREVENTION OF ACCIDENTS WITH MEDICAL SOURCES

Accidents are part of the unpredictable future. But unpredictability refers to the time at what the event may occur, not to the characteristics of the event itself. Any possible accidental event can be described as a potential event before it may occur and the possible sequences of causes that lead to it can be identified. By assigning probability figures to equipment failures and to human failures the probabilities for undesirable accident can be calculated (Probabilistic safety assesment). By increasing redundancy in the safety systems, assuring their independency and minimizing the influence of human failures the probably of accidents can be reduced below acceptable limits.

By adopting these and other complementary means uncertainty about the future can not be completely avoided but prevention of accidents can be achieved on statistical basis.

This is the philosophy proposed by the ICRP for potential exposures and their application can be fully adopted for the safe employment of radiation sources in medicine.

DIRECT MAGNIFICATION RADIOGRAPHY AND PATIENT EXPOSURE

J. Schütz, H.-L.Kronholz and G. Reuther*

Klinik und Poliklinik für Strahlentherapie
*Institut für Klinische Radiologie
Westfälische Wilhelms-Universität Münster
Münster, Germany

ABSTRACT

Direct magnification radiography (size of focal spot of X-ray tube 0,010 mm) visualizes details below the threshold of standard radiography. In combination with high speed film/screen systems up to a fourfold magnification the exposure of a normal radiogram is not exceeded. In this respect Digital Luminescence Radiography (DLR) with its high speed and imageprocessing capability is ideally suited.

INTRODUCTION

Radiographic objects contain innumerable details varying in size and contrast. Direct magnification radiography visualizes details below the threshold of standard radiography [1,2,3,4,5,6]. A microfocal tube, however, is a prerequisite for direct magnification. At University of Münster a microfocal tube with a size of focal spot of 0,01 mm is in clinical use, a second one with a size of the focal spot of 0,001 mm is used experimentally.

As magnification ratio is inversely related to the spatial resolution of the film/screen, best resolution is achieved when the geometrical blurring of the microfocus and the film/screen system are equal [7]. This is called the optimum magnification ratio [8,9]. A magnification exceeding the optimum ratio leads to overmagnification with further gain in resolution [10]. A small degree of overmagnification will be tolerated despite some blurring as larger objects are perceived more easily.

CONCLUSIONS

Up to a fourfold magnification the patient exposure of a normal radiogram will not be exceeded due to the air gap between patient and film that renders anti-scatter grids unnecessary and due to the necessity for high speed film/screen systems. Filter materials are crucial to patient exposure as well. Investigations with different filter materials proved K-edge filters of no value except for mammography [11,12]. Al-filters should be the

material of choice for any other application.

As low spatial resolution of film/screen systems may be compensated to a large extent by direct magnification the application of digital luminescence radiography seems to be ideally suited. The full range of contrast enhancement and image processing capabilities becomes available at the unrivaled spatial resolution of radiographic imaging. This may be of special interest in direct magnification mammography as well.

For clinical use the following combinations of size of the focal spot and film/screen are specially suited:

type of image	focus size (μm)	magnification	filter (μm)	exposure (cGy)	time (s)	screen/film system speed (S)	resolution (mm)
mammogr. 30 kV	25	2	76 Mo	0,30	9,5	0,002 cGy S = 50	< 0,09
tissue 40 kV	25	2	1500 Al	0,10	2,2	0,001 cGy S = 100	< 0,09
fluoroscop 100 kV	100	5	50 Cu	0,45	0,2	0,0005 cGy S = 200	< 0,120

Object 5 cm, focus-film distance 60 cm (mammography)
others 90 cm.

**DOSES AND DETRIMENT TO PATIENTS
FROM VASCULAR AND INTERVENTIONAL RADIOLOGY**

F. Diaz-Romero and J. Hernandez-Armas

Hospital Universitario de Canarias,
Tenerife, Canary Islands, Spain.

ABSTRACT

A survey was conducted on 1389 patients to establish the representative values of doses for different types of vascular and interventional X-ray examinations in Tenerife (Spain). Two large-area transmission ionization chambers were used for the measurements and a Monte Carlo computer program for calculations. Tabulated results of characteristic quantities for each type of procedure are presented. The collective effective equivalent dose is 9 man-Sv. The detriment, following ICRP-26, was 0.077, and 0.092 when all stochastic effects were taken into account.

INTRODUCTION

Vascular-Interventional Radiology (VIR) is a merging of classical vascular diagnostic radiology and new interventional radiology, developed from the Seldinger technique and applied in the field of therapy in addition to that of diagnosis. In VIR procedures two X-ray beams (radiography and fluoroscopy) are normally used to study patients' different anatomical areas. These procedures routinely involve several films, each of which would be difficult to classify in standard views. In fluoroscopic screening the radiologist may spend several minutes manipulating the position or the size of the X-ray beam over the region of interest. Although the doses to patients in VIR procedures are highest between X-ray examinations, the radiological impact on the population is small because of the low frequency involved with these types of procedures. The dosimetric data for some procedures carried out in France are presented in a paper published by Maccia et al. (1).

In the present paper the results for 8 different vascular and interventional radiology examinations and procedures are given. The patients were inhabitants of the province of Tenerife (Canary Islands), which has a population of approximately 700,000.

EXPERIMENTAL MEASUREMENTS

1830 VIR procedures of 1389 patients were studied. To obtain dosimetric data, two large-area transmission ionization chambers (Diamentor, PTW) were used. With this equipment the dose-area product for 435 procedures was obtained using the cameras for each X-ray tube (radiography and fluoroscopy). The sample is representative of the total number of studies. In all procedures technical and medical parameters were registered. To determine the dose-area product for each procedure, we found the corresponding figure per unit of mAs, irradiated area and number of radiographs or fluoroscopy screening times. When the dose-area

product was known, the entrance skin dose (ESD) and energy imparted (EI) to each patient were calculated. The value of EI can be used as a measure of radiological effect on patients. Our results are shown in Table 1.

We used the ESD values to calculate the organ doses, with the aid of a PC computer program, based on the Monte Carlo method, supplied by the Center for Devices and Radiological Health, Rockville, Maryland. This program did not give us the doses for breast, bone and "remainder". We assume the hypothesis of a constant relationship between doses to near anatomical organs when they are explored by X-ray with similar projections (irradiated area, technical parameters, etc.). The values of individual organ doses presented by Jones and Wall (2) were used to obtain those relationships. Hence our results, which are shown in Table 2.

Our values for organ doses and equivalent effective doses are, generally, lower than those presented by Maccia et al., although it is difficult to draw a comparison since we are unfamiliar with some of the technical aspects of their examinations.

The calculation of detriment poses some difficulties because the ICRP-26 (3) definition contains a certain degree of ambiguity. In fact, we obtained the detriment (fatal and severe hereditary effects) using the risk factors proposed in the above publication although modified by the factors of probability of expression as a function of age at exposure proposed by Wall (4). The relationship between energy imparted and detriment as presented by this author has been used by us to derive another value for detriment. To obtain the detriment corresponding to all stochastic effects we have used the above risk factors and the mortality rates as severity factors. The values were 0.077 (for the two first methods) and 0.092 for the last one. The values were corrected where clinical terminal patients were not considered. Account was also taken of this consideration in calculating the value of the collective effective equivalent dose (CEED). The correction can be established at 15% lower than the uncorrected values.

CONCLUSIONS

- 1.- EED (mSv) and EI (mJ) for VIR procedures are related by the expression: $E=0.025 EI^{0.59}$.
- 2.- CEED due to 1830 VIR procedures in Tenerife was 9 man-Sv. The dose rate per 100,000 inhabitants of Tenerife in 1990 was estimated to be 0.7 man-Sv.
- 3.- The relationship between detriment for stochastic effects (Dse) and EI(mJ) can be formulated by: $Dse=4375 EI^{0.897}$.

A COMPARISON OF THE EFFECTIVE DOSE EQUIVALENT, H_E , WITH THE WEIGHTED DOSE, W_D , FOR THE SIX-YEAR-OLD PEDIATRIC PATIENT EXPOSED TO CT EXAMINATIONS. J.C. Blechinger, J.R. Prince, Pediatric Radiological Research Laboratory, Department of Radiological Sciences, University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma 73190.

The effective dose equivalent, H_E , introduced by the ICRP to describe radiation risks to radiation workers, has since been applied to members of the general public. Although some data are available on H_E 's from medical exposure to CT, no data are available for pediatric exposures. We present estimates of H_E from a GE 9800 CT scanner for the 6-year-old pediatric patient and compare these data to the weighted dose, W_D , proposed by Beninson and Sowby [1].

The computed tomography dose index (CTDI) was measured and compared to the literature [2]. CTDI data were then used to estimate organ doses from data in [2]. Ponderation factors from [1] were used to calculate W_D for both male and female patients.

The measured CTDI was 1.2 cGy/100 mAs at 120 kVp. Results of H_E and W_D calculations are summarized in Table 1.

Table 1. Estimates of H_E and W_D for the 6-year-old pediatric patient for various CT examinations in Sv/Gy.

Examination	# of Slices	H_E	W_D (Males)	W_D (Females)

República Argentina

ABSTRACT

The preliminary results of a program undertaken to estimate the doses to patients associated with dental radiology practices in Argentine, are presented.

Information collected from the search demonstrated that the Dieck and coronal techniques are the most commonly used practices, while all the examinations are performed by using a circular collimator. For both practices, the dosimetric studies were carried out on a Rando Alderson phantom. All dose measurements were made using thermoluminescent detectors LiF and CaF₂. In addition, a mathematical model was developed by applying the Monte Carlo method to a MIRD-V phantom. Circular and rectangular collimators were used.

Absorbed dose distribution on head and neck, as well as surface dose distribution, were estimated. The comparison of the performance of both collimators shows that the use of the rectangular one allows for a dose reduction of 80%. Besides, a good correlation between the physical and mathematical models applied was found.

INTRODUCTION

The preliminary results of a program undertaken to estimate the doses to patients associated with dental radiology practices in Argentina are presented. This program includes the following steps:

- a) a statewide survey was carried out on unidentified professionals involved in dental radiology in order to obtain information on the radiology techniques applied, irradiation conditions, number of examinations, etc.;
- b) dosimetric assessments concerning dental radiology practices;
- c) analysis of the working sites;
- d) recommendations on optimization of radiology practices.

Over a total of 1200 dentist resident at La Plata city, there were 300 of them surveyed. The survey showed the following results:

- The techniques most frequently used are: Dieck (41.8%); four film interproximal (coronal) (24.1%); occlusal (16.5%); Fitzgerald (10.7%); extraoral (7%). In all cases, circular collimation was used.
- Film type : 3 x 4 cm² (35.2%)
- Operation voltage: 80 kVp (32.3%), 65 kVp (29.8%)
- Operation current: 10 mA (87.7%)
- Exposure time : from 0.1 s to 1 s (76.5%)

-Image analysis : visual (100%)

Up today, dosimetric data was attained regarding both Dieck and coronal techniques. For the former, the assessed practice consisted in 14 consecutive exposures of the upper maxilar and the mandible, while for the latter, 4 exposures of premolar and molar teeth were performed.

DOSIMETRIC ASSESSMENT

The dosimetric assessment was carried out by using a physical model based upon an equivalent tissue phantom RANDO (Alderson) and LiF and CaF₂ thermoluminiscent detectors. By distributing them in the inner parts and on the surface of the head, the neck and the trunk, absorbed doses in organs and tissues were evaluated.

Two types of collimators were used, a circular one (CC) and a rectangular one (RC). The performance of the latter was assessed.

The irradiations were made by using an OSO X-ray unit, with an operation voltage and a current of 60 kVp and 10 mA, respectively. Both collimators, 7 cm diameter window CC, and 3 x 4 cm² window RC, were used with a 15 cm focus-skin distance.

Tables 1 and 2 show the corresponding results. Mean absorbed doses exceeding $5 \cdot 10^{-2}$ mGy are presented. Figures 1 and 2 show the distribution of the mean superficial doses in the head and in the neck.

An overall error of 20% may be assigned to the expressed results. The main contributions to this error may be described as follows: a) Use of a mean mass attenuation coefficient, not fully representative of the energy distribution inside the phantom; b) Errors in the assigned mass fraction of an organ in the phantom slabs.

As an alternative, a mathematical model based upon the application of the Monte Carlo method to the photon transport in the MIRD-V phantom was used [1]. In order to improve the dosimetric evaluation in the head and the neck, the MIRD-V phantom was modified by including an upper maxilar, a mandible and parotid, sublingual and submaxilar glands. The X-ray spectra at the output of each collimator was simulated, as well as the shadow of the incident beam on the phantom surface.

The results corresponding to Dieck's technique are shown in Table 3. Only absorbed doses with a variation coefficient less than 5% are presented.

CONCLUSIONS

The evaluation of the information recalled from the professionals showed that the working conditions are satisfactory enough as to allow the obtention of the necessary image quality for a proper diagnosis.

Dosimetric data demonstrate that the use of a RC implies a reduction of the absorbed dose in the lens of two orders of magnitude, and, as a mean, a five fold dose reduction for the other organs. This significant dose reduction may be explained by the lessening of the exposure area, without diminishing the diagnosis quality. Absorbed doses in trunk organs are not significant.

Results obtained with the two models do not differ more than 15%, for those organs described in a similar way in both phantoms, while the difference increases to 30% for sublingual and submaxilar glands, which are not easily localized in the RANDO phantom. The above mentioned results justifies the use of the mathematical model in future dosimetric assessments.

ASSESSMENT OF PATIENT SKIN DOSES IN DIAGNOSTIC RADIOLOGY

J.P. Wade, K.E. Goldstone and P.P. Dendy

East Anglian Regional Radiation Protection Service
and Medical Physics Department
Addenbrooke's Hospital
Cambridge, England

ABSTRACT

In the light of recent UK legislation and the increased awareness of patient doses by the general public, there was a need for more extensive direct measurement of the doses received by patients. A program was introduced in Autumn 1990, in the East Anglian Health Region to monitor the skin entrance doses for a range of common radiographic procedures. The results already obtained have raised questions about the suitability of some of the equipment and techniques used. For very low doses the relationship between dose and image quality is also being investigated.

INTRODUCTION

In the last few years there has been much interest in reducing the doses received by patients during routine diagnostic x-ray investigations. In the U.K. this has been backed up in legislation by the Ionising Radiation (Protection of Persons Undergoing Medical Examination or Treatment) Regulations 1988 which require a person physically directing an exposure to ensure the dose is as low as reasonably practicable while achieving the required diagnostic result. Furthermore, x-ray departments are required to formulate a strategy for dose reduction.

The National Radiological Protection Board (NRPB) with the Royal College of Radiologists (RCR) published a report on "Patient Dose Reduction in Diagnostic Radiology" (1) where it is recommended that each x-ray department should make measurements on skin entrance doses and these should be compared with national norms and, in time, their own previous results. As very few x-ray departments have the facilities for doing this, the East Anglian Regional Radiation Protection Service undertook the task of providing this service for all the x-ray departments in the East Anglian Health Region, in both the public and private sectors.

PROGRAM ORGANISATION

Because of the geographical spread of the x-ray departments involved in this program, a postal system had to be used. Batches of sachets containing thermoluminescent dosimeters (TLD) were sent out to each participating x-ray department with an instruction sheet, record sheet and padded return envelope. The TLD's used are lithium fluoride extruded chips which were read out in a Toledo reader; the batch was calibrated for diagnostic energies and all doses are quoted for diagnostic energies. On the record sheet details of the exposure factors (kVp, mA and time), focus-film distance and whether an automatic exposure control device had been used were recorded, and space was provided to attach the exposed TLD sachets. The instruction sheet included advice on the selection of patients for dose measurements; patients were to be of average size and no children under 16 years of age were to be included. The TLD sachet (which contains two chips) was stuck on to the patient at the centre of the entrance field during the radiographic view being measured. Where a repeat radiograph was required, the TLD sachet was to be left on the patient for the repeat and this would reflect the dose actually received by the patient. The TLD's and record sheet were returned to the Radiation Protection Service for processing and the x-ray department was informed of the results.

Thirty six x-ray departments, eight of which are in private hospitals or clinics, have participated in one or more parts of the study. Each participating department was issued with an identifying code which was used in all correspondence and in particular when results were sent out and comparisons between departments were made. A selection of simple radiographic views have been chosen, covering a range of anatomy and exposure factors. The views selected were AP Abdomen, PA Chest, Lateral Lumbar Spine and Lateral Skull. The average entrance dose for each department was then compared to guideline doses recommended by the NRPB (2) for the radiographic view being studied. Any department with average doses above the guideline dose was contacted with a view to reducing their doses by looking at the techniques and equipment used.

DOSE RESULTS

For the AP Abdomen view the individual entrance doses ranged from 0.97 to 41.6 mGy with an average of 7.9 ± 6.5 mGy and the departmental average doses varied from 3.7 mGy up to 19.4 mGy. Every department with an average dose over 10 mGy (the guideline dose for AP Abdomen) was contacted with a view to assessing how dose reductions might be made and several

departments have already made changes which have resulted in dose reductions up to 65% with very little reduction of image quality. Examples of changes have included the change of film/screen combination or the change in kVp where the response of the film/screen combination is energy dependent.

From early results on PA Chest skin entrance doses it rapidly became apparent that two very different radiographic techniques were being employed. The first technique uses 60-75 kVp and a chest stand without a grid; this is good for imaging the soft tissue in the lungs. For this technique the average skin entrance dose measured was 0.16 mGy with a range of 0.01 mGy (the minimum dose measurable) to 0.88 mGy. The second technique utilises 120 - 130 kVp and a high factor grid in the chest bucky. The average skin dose for this technique was 0.25 mGy with a range 0.01 to 1.57 mGy. The departmental average skin doses varied from 0.04 mGy up to 0.48 mGy. The NRPB guideline dose for PA chest is 0.3 mGy. In our survey all the departments with average doses greater than this were using the high kVp technique. These results and their implications are being discussed elsewhere (British Institute of Radiology Annual Conference, Birmingham England, May 1992).

For lateral lumbar spine radiographs the individual entrance doses range from 3.2 mGy up to 103.8 mGy with an average of 19.3 mGy. The departmental average doses vary from 6.6mGy up to 45.3 mGy; the NRPB guideline dose is 30 mGy. The departments with higher than average doses were those which also showed higher than average doses for AP Abdomens but for various reasons have not yet made any dose-reducing changes to their equipment and/or techniques.

Skin entrance dose measurements have not yet been made on lateral skull radiographs.

PATIENT DOSE AND IMAGE QUALITY

It is well known that, because of the statistical nature of the interaction of x-ray photons with the image receptor, the detection of small objects which have low contrast difference with their surroundings is dose dependent. Therefore, in pursuing a policy of patient dose reduction it is important not to reach a point at which relevant clinical information is lost.

A number of theoretical analyses have been carried out to determine the minimum dose required to detect an object of given dimensions and contrast (3). To test these predictions we have designed a phantom consisting of small aluminium discs of different sizes, in the range 5-30 mm diameter and varying thickness up to 2 mm, that can be randomly arranged on a perspex plate and immersed in a tank of water. Contrast may

be adjusted by adding contrast medium to the water. A team of observers will be asked to examine films for "objects" and 50% detection limits will be established at different doses and compared with theory. Preliminary studies show that, for 70 kVp, a contrast $C (=0.4343\gamma(\mu_2-\mu_1)x)$ of about 0.21, a surface dose of approximately 0.13 mGy is required to perceive a 10 mm diameter aluminium disc.

CONCLUSION

Radiography staff have found the procedure for making direct measurements of the patient entrance dose easy and the results very informative. Comparison of results between departments has readily indicated those departments consistently giving higher than recommended doses where priority should be given to reducing doses. Several departments have already reviewed their practices and made changes which have been assessed for their effectiveness in dose reduction by making repeat measurements after the change.

Perception studies have been initiated to determine whether there is a serious risk of loss of image detail for some of the lowest doses reported in the survey.

THE FREQUENCIES AND DOSES OF MEDICAL EXPOSURE IN CHINA*

Zhang Liangan, Zhang Jingyuan, Jia Delin, et al.

Institute of Radiation Medicine, CAMS, Tianjin, 300192

ABSTRACT

The frequencies and patient doses of medical exposure were investigated in China. The sampling surveys of the work covered 15000 hospitals in 24 provinces. In the work, we compile data of 11 million cases. The data were analyzed by computer, and the frequencies, averages of skin and organ dose per examination, and population doses per capita (He, LSD, GSD, SSD) were found.

METHODS

Epidemiological stratified sampling was employed in this research. According to the results of sampling, the frequency of medical exposure was surveyed in more than 15000 hospitals in 24 provinces. Sampling measurements of patient skin dose covered 2000 hospitals in 14 provinces.

Thermoluminescent dosimetry (TLD) was adopted for patient dose monitoring. During monitoring, a TLD detector was attached to each patient to monitor patient skin dose (d). Organ dose (D_T) of each patient was determined by the following equation :

$$D_T = C_T d \quad [1]$$

where C_T is the conversion coefficient of d into D_T. C_T was determined in simulation experiments using an anthropomorphic phantom.

In clinical nuclear medicine, the organ dose of a patient receiving radiopharmaceuticals can be estimated by MIRI method⁽²⁾.

The effective dose equivalent (He), genetically significant annual dose(GSD), annual mean bone marrow dose per capita (CML), leukemia significant annual dose(LSD), and malignancy significant annual dose(SSD) were also calculated in this work.

RESULTS

The frequency of diagnostic X-ray was 145.1 examinations per 1000 population, much higher than that of nuclear medicine or radiation therapy. High annual frequency of diagnostic radiation were noted in chest, abdomen, G.I., and extremities examination, with the annual frequency of chest examination being the highest. The frequency of chest fluoroscopy (the predominant form of chest examination) was about 88.9 cases per 1000 population; 7.5 times that

* This work is a contract project of International Atomic Energy Agency No.4964/R1/RB

of chest radiography (Table 1) .

Table 1. Annual frequencies of medical exposure in China (cases per 1000 population)

Type	Frequency	Type	Frequency
Diagnostic X-ray	146.1 (Total)	Nuclear medicine	0.62 (Total)
Chest		Thyroid scintigraphy	0.086
Fluoroscopy	84.3	Thyroid uptake	0.281
Mass fluoroscopy	26.6	Liver scintigraphy	0.087
Radiography	11.9	Kidney scintigraphy	0.162
Abdomen	12.7	Others	0.066
Alimentary canal	6.0	Radiotherapy	0.09 (Total)
Spine	4.0	Esophageal cancer	0.018
Pelvis	1.3	Pharyngeal cancer	0.023
Extremities	11.6	Breast cancer	0.012
Dental radiography	2.1	Others	0.037
Others	6.8		

The annual frequency of age group 20 to 29 was the highest, but mass examination comprised an important part of the annual frequency for this age group. When mass examination was deducted, the annual frequency peak occurred in age group 30-44, and the differences among various age groups were obvious, with males being exposed more frequently than females in every age group.

The annual frequency of utilization of various nuclides in nuclear medicine were surveyed. The relative frequency for ^{131}I was the highest (about 88%), while that for $^{99\text{m}}\text{Tc}$ was the lowest (less than 1%).

In this work, patient skin dose means the dose to that part of a patient's body surface where a TLD dosimeter was worn. The patient skin dose per G.I. examination was the highest about 61.6 mGy/exam. The doses of lumbar spine examination and cholecystography were higher than that of chest examination(32.6 and 26.8 mGy/exam). As for chest examination, the patient skin dose for fluoroscopy was 10.4 mGy/exam, 10 times that of radiography(Table 2)

Table 2. patient dose per examination in various diagnostic X-ray procedure (mGy/exam)

Organ	Chest		G. I.	Lumbar spine	Abdomen	Pelvis
	Flu.	Rud.				
Skin dose	10.4	1.07	61.6	32.6	8.40	11.0
Testicles	<0.01	<0.01	0.26	0.10	0.02	0.87
Ovary	<0.01	<0.01	1.06	6.86	0.17	5.23
Red marrow	0.27	0.04	6.06	1.82	1.63	1.04
Colon	0.10		8.06		0.02	
Lungs	0.61	0.19	9.29	1.88	0.01	
Stomach	0.19		7.79		0.01	
Effec. dose	0.29	0.07	7.36	2.87	0.13	1.63

The differences in patient skin dose from X-ray machines of various capacities were analyzed. Here, the patient skin dose

from X-ray units of small capacity (<50 mA) were the highest, about 2 times that of big capacity machines(>100 mA).

Organ doses of patients receiving diagnostic X-ray examinations were estimated by reference to the results of patient skin dose measurements and simulation tests. The average organ doses per examination for X-ray procedures are given in Table 2. The gonad dose in lumbar spine examination was the highest, but the doses to other organs were also remarkably high in G.I. examination.

The average administration quantities per examination or treatment are listed in Table 3. Although the same procedure may be used, the annual effective doses per examination may differ greatly when different radiopharmaceuticals are used. For example, in thyroid scintigraphy, the annual effective dose per examination is 93.8 mGy with ^{131}I , and this is 300 times that with $^{99\text{m}}\text{Tc}$.

Table 3. Patient dose in nuclear medicine procedures

Type	Nuclide	Administered quantity (MBq/exam)	Effective dose (mGy/exam)
Brain scintigraphy	$^{99\text{m}}\text{Tc}$	137.7	1.8
Thyroid scintigraphy	^{131}I	5.9	93.8
	$^{99\text{m}}\text{Tc}$	23.2	0.3
Liver scintigraphy	^{198}Au	21.7	21.7
	$^{99\text{m}}\text{Tc}$	96.6	1.2
Thyrotoxicosis	^{131}I	162.2	2596.0
Polycythemia vera	^{32}P	8.7	14.8

The annual dose equivalent per capita were analyzed in the work. The major sources of the organ dose equivalent per capita came from G.I. examination and chest fluoroscopy.

Using the values in Table 2, CMD, GSD, LSD and SSD were estimated (Table 4). Here, age and sex distributions were taken from national statistics data⁽²⁾. The total CMD, He, SSD, LSD and GSD for medical X-ray diagnostic were 73.7, 88.1, 65.7, 69.0 and 9.81 $\mu\text{Sv/a}$ respectively.

Table 4. population dose equivalents per capita for diagnostic radiology ($\mu\text{Sv/a}$)

Type	He	CMD	LSD	GSD	SSD
Chest					
Fluoroscopy	22.4	20.8	20.4	0.46	19.7
Radiography	0.83	0.65	0.62	0.04	0.66
Alimentary canal	45.7	36.6	34.0	1.22	30.1
Cholecystography	0.63	0.48	0.48	0.04	0.63
Lumbar spine	10.7	7.32	8.83	3.90	6.96
Pelvis	2.05	2.05	2.05	3.15	2.05
Abdomen	1.96	1.49	1.49	0.14	1.96
Others	3.83	4.41	3.23	0.88	3.66
Total	88.1	73.7	69.0	9.81	65.7

DISCUSSION

For comparison, the main characteristics of medical exposure in countries with various levels of health care are listed in Table 5. In general, the health care level of a country was determined according to the serving population per physician. So China's health care was below 2. Some features of medical exposure in China, such as annual frequency of diagnostic examination and population per X-ray machine, are at level 2, some features are at level 3 or 4, but the equivalent dose per capita from nuclear medicine are at level 1. This situation was caused by high patient dose in nuclear medicine in China.

Table 5. Main characteristics of medical exposure in countries with various levels of health care*

Item	Level of health care				China
	1	2	3	4	
Popoles per physician	<1000	1000-2999	3000-9999	>9999	1106
Annual frequencies (cases/1000population)					
Diagnostic radiology	760	160	60	30	145.1
Nuclear medicine	18	1.2	0.4	0.2	0.82

Estimation of Organ Biodistribution of Activities in Human from External Measurement with TLD

T. Nakamura, M. Matsumoto, H. Watabe, M. Itoh and J. Hatazawa

Cyclotron and Radioisotope Center, Tohoku University
Aoba, Aramaki, Aoba-ku, Sendai 980, Japan

ABSTRACT

Biodistribution due to intravenous administration of F-18-fluorodeoxyglucose (FDG) in positron emission tomography (PET) studies was estimated from external measurement with thermo-luminescence dosimeters (TLDs) attached on the body surfaces of normal volunteers. The cumulated activities in nine source organs, brain, heart, lung, liver, kidney, pancreas, spleen, bladder and remainder of the body, were estimated by the unfolding method from the body surface dose measured with the TLDs. Cumulated activities thus obtained well agreed with those obtained with the direct measurements by PET. The TLD method will greatly contribute to internal dosimetry of patients because of its easy-handling.

INTRODUCTION

Internal dosimetry resulting from nuclear medicine is important in comparing the benefit of a procedure with its potential risk. The estimation of internal dose due to intake of radioisotopes has been established by the MIRD method. In the MIRD method, the doses absorbed in target organs are estimated from cumulated activities in source organs. The information on cumulated activities has been obtained for some specific organs necessary for nuclear medicine directly by PET, but is very scarce for other source organs in human. Organ biodistribution of cumulated activities usually has been measured in animals and extended to human, despite of the metabolic difference.

Here in this study, we developed a new method to estimate the biodistribution of radioactivities, which are injected into patient in nuclear medicine procedures from external exposure measurement with TLDs. In this method, a number of TLDs are attached on patient's body surface close to source organs to obtain the information on body surface doses. The organ biodistribution of radioactivities can be obtained from the surface doses by the inverse transform method coupled with the radiation transmission factor calculated with an aid of a mathematical phantom.

This new method has great advantages that cumulated activities in several organs can be obtained easily with a single procedure, and the measurements of

body surface doses are simultaneously done with the PET study, since TLDs are too small to interrupt other medical measurements. The measurements of body surface doses were done in clinical PET studies with F-18-FDG performed at the Cyclotron and Radioisotope Center (CYRIC) of Tohoku University.

MATERIALS AND METHODS

In our TLD method, the absorbed dose on a body surface is given by

$$\begin{aligned}
 C_i &= R_{i,1} X_1 + R_{i,2} X_2 + \dots \\
 &= \sum_j R_{i,j} X_j,
 \end{aligned}
 \tag{1}$$

where C_i is the absorbed dose at i -th TLD position, X_j the integrated activity of j -th source organ during the TLD attachment on the body surface and R_{ij} the absorbed dose at i -th TLD position per unit cumulated activity of j -th source organ. This equation can be expressed as a matrix equation,

$$C = R \cdot X
 \tag{2}$$

The C -vector capere obtained from the TLD measurements and the R -matrix can be calculated by using the MIRD mathematical phantom, so that one can obtain the X -vector by performing the inverse transform of the above matrix equation.

A pair of TLDs of $CaSO_4(Tm)$ were attached at nine points on a body surface just above brain, thyroid, heart, left and right lungs, liver, left kidney, spleen and bladder which were regularly selected in the PET sutdy. Figure 1 shows the TLD positions in the framework of MIRD phantom, together with their Cartesian coordinates and nearby source organs. Eight organs were selected as source organs, i.e., brain, heart, lungs, liver, kidneys, pancreas, spleen and bladder which are already known as organs which accumulate F-18-FDG by Mejia et al. (1) The remainder part of the body was treated as a single source organ in which radioactivity was uniformly distributed. Then in total, nine regions were considered as the source organs in this study. Nine values of TLD doses, C_i , determine nine values of organ activities, X_j , by unfolding Eq. (1).

Calculations of the R component, R_{ij} , are done by the VADMAP code (2) based on the point kernel method with the MIRD mathematical phantom composed of water. The lung is assumed to be composed of water whose density is 0.3. From the measured body-surface doses at nine points, C_i , and the calculated response of body-surface dose at each position per unit

cumulated activities. R_{ij} , cumulated activities in nine source organs can be unfolded by the slightly modified SAND-II code (3) based on the successive iterative method. This unfolding is practiced under the constraint condition that the sum of cumulated activity in each source organ must be equal to the total accumulation of administered activity as follows,

$$\begin{aligned} X_{\text{total}} &= X_1 + X_2 + X_3 + \dots \\ &= \int_0^t A_0 \exp(-\lambda t) dt, \end{aligned} \quad (3)$$

where A_0 is the injected activity, λ the decay constant of F-18 and t the measuring time period.

RESULTS AND DISCUSSION

The TLD measurements of body-surface dose were done for 7 normal volunteers. Five volunteers were measured for 1 hour after administration of F-18-FDG and two patients were measured for 2 hours after that. The measured data of C_i were converted to the cumulated activities in source organs by the modified SAND-II unfolding code. As the TLD measurements could be done only during the course of clinical PET procedure, the estimation of the cumulated activities was also possible only for that period. The contribution of residual cumulated activities after the TLD measurement can be estimated, assuming that a biological clearance is negligible and only physical decay dominates.

Figure 2 shows the correlation of the present results of cumulated activities given by the TLD method and those by the direct PET measurements. (1) Generally speaking, good correlation can be seen between our TLD method and the PET reference values except for kidney and brain. The discrepancy on the brain activity may be due to inhomogeneous distribution of activity in the brain, and that on the kidney activity may come from a large difference of physique between the MIRDO phantom and each individual, since the distance from the seventh TLD position to the kidney was largest among all as seen in Fig. 1.

It can be concluded that the new method to estimate the organ biodistribution in human from the surface dose measured with TLDs gives sufficiently good results considering experimental errors. This TLD method has great advantages that cumulated activities in numbers of human organs can be estimated very easily at once, and that the TLD measurements can be done simultaneously with medical study without interrupting it.

ABSTRACT

The dose to some selected organs has been estimated from intake of radionuclides taking into consideration the organ weights in Indian Man and Child of various age groups using dose coefficients as given by ICRP-56. The effective dose computed as per new tissue weighting factors given by ICRP-60 increased by 40-75% from the old values from the ingestion of ^{131}I and ^{144}Ce . However, only marginal change was found in the case of ^{137}Cs . In Indian Population, there was a further increase upto 20%.

INTRODUCTION

ICRP-56 (1990) has computed age-dependent dose coefficients (also called dose equivalents) for various organs and tissues to members of the public from intake of most radiologically significant radionuclides that might be released to the environment due to various human activities. These dose coefficients have been estimated for ICRP Reference Man, Child and Infant. However, Indian population differs significantly from their ICRP counterpart as regards anatomical and physiological characteristics as shown by Venkatraman et al (1963) and Jain et al (1991, 1992). In the present study, efforts are made to estimate dose to some selected organs for different ages taking into account dose transformation factors as estimated by the method suggested by Yamaguchi (1978). Further the revised effective dose was computed using revised tissue weighting factors as recommended by ICRP-60 (1991) from intake of some radionuclides and compared the same with the corresponding estimated values for Indian Population.

METHODOLOGY

The weight of five organs, namely, brain, kidney, liver, lungs and spleen was obtained from extended study of 2000 postmortem records in Indian population (Jain et al, 1992) of various age groups. These organ weights being

different from ICRP counterpart and hence the dose coefficients will be different in these subjects than their ICRP counterpart. The dose coefficients in Indian population of various age groups namely 1yr, 5yr, 10yr, 15yr and adult was computed by computing the dose transformation factors (DTF) for different organs using the method suggested by Yamaguchi (1978). These transformation factors are multiplied by the corresponding organ dose coefficients to give the revised dose estimates to the organs. In the present study, only three radionuclides ^{131}I , ^{137}Cs and ^{144}Ce were considered. The transformation factors for various organs were worked out for the principal gamma energy emitted by these radionuclides. The effective dose, E was also computed for ingestion of these radionuclides utilising the new tissue weighting factors as given by ICRP-60. Thymus is taken as surrogate to oesophagus and colon is considered to be the same as ULI (Phipps et al, 1981). However, the dose coefficients for all the remainder organs were not available in ICRP-56 and it is considered that the dose to these organs is the same as the average dose to 8 remainder organs for which information is available. Further the effective dose was also computed for Indians of different age groups utilising the transformation factors as calculated for selected organs above. For the other organs, if the weight of the organ is less than 20 g, DTF is taken as 1 and for the others, DTF has been computed considering the organ masses to be proportional to the body weight.

RESULTS & DISCUSSION

Table 1 gives the mean DTF for various organs in the Indian population for the photon energy 133-662 keV, the variation being negligible for different gamma energies considered.

Table 1. Mean dose transformation factors

Age	Brain	Kidney	Liver	Lung	Spleen	Others <20 g
1 yr	1.01	1.05	0.88	0.82	0.82	1.09
5 yr	1.12	1.12	0.96	0.82	0.83	1.12
10 yr	1.08	1.14	1.00	0.93	0.90	1.17
15 yr	1.09	1.16	1.12	0.89	0.98	1.20
Adult	1.06	1.25	1.21	1.01	1.09	1.16

Table 2 gives the effective dose (E_1) as given by ICRP-56, the revised value of ICRP-56 (E_2) and the revised estimated value of E_2 for Indian population (E_3) from the ingestion of ^{131}I , ^{137}Cs and ^{144}Ce . The revised effective dose, E_2 to ICRP Reference population was found to be increased by 64-75 % for ^{131}I and did not differ in Indian population as more than 99 % contribution to effective

dose comes from dose to thyroid, whose weight did not differ in Indians. In case of ^{137}Cs , E_2 was found to differ marginally from old values due to near uniform distribution of the radionuclide in the body. In Indian population, E_3 values were marginally higher than for ICRP counterpart due to increased organ doses proportional to change in DTF's. However, in case of ^{144}Ce , E_2 were found higher by 39-46 % than old values and increased further in Indian population for the reasons alike ^{137}Cs .

Table 2. Effective dose from ingested radionuclides

Effective dose(Sv/Bq)	Age at intake				
	1 yr	5 yr	10 yr	15 yr	Adult
^{131}I

E_1	4.3E-8	2.1E-8	1.3E-8	7.2E-9	5.8E-9
E_2	6.2E-8	3.0E-8	1.9E-8	1.0E-8	8.4E-9
E_3	6.8E-8	3.4E-8	2.2E-8	1.2E-8	9.7E-9

CONCLUSION

The revised effective dose to the population from the ingestion of ^{131}I and ^{144}Ce was found to be increased by 40-75 % for various age groups. However, a marginal change was noted for ^{137}Cs . In Indian population, there was a further increase (upto 20 %) from the revised values.

ABSTRACT

Effective dose has been calculated for three technetium-99m labelled agents used for CBF studies using W_T values recommended by ICRP-1977 and ICRP-1991. The estimated values of effective doses are lower than the earlier one by 10 %. For an average Indian, administration of the same activity results in 8-12 % higher effective dose. It is suggested that amount of activity to be administered to a patient may be normalised to his/her weight.

INTRODUCTION

In India, the levels of activity used in the department of nuclear medicine for diagnostic purposes, have risen dramatically, mostly due to availability of a large variety of radiopharmaceuticals. A necessity has been felt in the department to carry out dosimetric investigations of some of the new radio-tracer agents that are used/are likely to be used for regional cerebral blood flow studies. These investigations are carried out using positron emission tomography (PET) that can provide quantitative images of tracer distribution with high spatial resolution and are able to employ radiotracers that participate in distinct and well defined biochemical/physiological processes. Despite of the recent developments in instrumentation and oxygen-15 dispensing unit, due to high cost, PET investigations may take considerable time to get established at least in developing countries. SPECT and employing technetium-99m labelled compounds that are more economical and are more widely available, is considered to be a system of choice for most of such studies in the country. Radiation dosimetry of such 'diagnostic probes' has become necessary due to: (i) the recommendations of International Commission on Radiological Protection (ICRP-1991) that have brought about significant changes in the methodology of effective dose (that indicates the radiation risk to which the patient is exposed as a result of a particular radiodiagnostic investigation) computation particularly in assigning new set of values to tissue weighting factors (that represent the relative radiation sensitivity of an organ or tissue) and (ii) the prospect that administration of the same amount of radio-tracer agent to a Reference Man (ICRP-1975) and to an average Indian patient may give rise to different effective doses (due to the difference in anatomical characteristics of the latter).

MATERIALS AND METHODS

Intensive efforts are being devoted to design new radio-tracers that will cross the intact blood brain barrier and are capable of measuring regional cerebral blood flow. At present, three such radiopharmaceuticals that have significant potentiality are: technetium-99m hexamethylpropylene amine oxime ($^{99m}\text{Tc-d,1-HMPAO}$), technetium-99m ethylcysteinate dimer ($^{99m}\text{Tc-L,L-ECD}$) and $^{99m}\text{Tc-MRP 20}$ or one of its derivatives, marketed by Amersham, DuPont and Medgenix respectively. These compounds are retained by brain to the similar extent and diffusion rather than metabolism is considered to be the rate limiting step. Table 1 gives the effective dose data of these agents considering the values of tissue weighting factor, 'W_T', as recommended by ICRP-1991. For comparison, the effective doses have also been computed taking into consideration 'W_T' values recommended earlier (ICRP, 1977).

Table 1. Effective dose (mSv) due to the administration of 740 MBq of the technetium labelled agents for rCBF studies considering 'W_T' values recommended by ICRP (1977) and ICRP (1991)

Radiopharmaceutical	Effective Dose	
	using 'W _T ' of ICRP-1977	using 'W _T ' of ICRP-1991
$^{99m}\text{Tc-d,1-HMPAO}$ (Neirinekx et al 1989)	6.02	5.48
$^{99m}\text{Tc-L,L-ECD}$ (Holman et al 1989)	3.64	2.83
$^{99m}\text{Tc-MRP 20}$ ** (Bossuyt et al 1990)	4.12	4.16

**In case of $^{99m}\text{Tc-MRP 20}$, the biodistribution data is still incomplete and as such the effective dose values are very approximate only.

For calculating the effective dose, a procedure that is slightly different from that of Smith (1990) has been adopted and has been outlined in another paper (Gupta and Nagaratnam).

The effective dose calculations have been carried out keeping in mind the anatomical, chemical and physiological characteristics of Reference Man (ICRP-1975). It has been reported that an average Indian differs significantly from the Reference Man (Venkataraman et al, 1966). Data on weight and

size of the body as well as that of the specific organ masses have also been compiled from postmortem records of 2000 cases (Jain et al, in press). Employing this data and computing Dose Transformation Factors (Yamaguchi, 1978) for Indian physiques, effective dose estimation due to the administration of same quantity of radiopharmaceutical has been carried out for an Indian adult and shown in Table 2.

Table 2. Effective dose (mSv/740 MBq) due to technetium-99m labelled agent to a Reference Man and to an average Indian adult using recent 'W_T' values

Radiopharmaceutical	Effective Dose	
	Reference Man	Average Indian Man
^{99m} Tc-d,l-HMPAO	5.48	6.02
^{99m} Tc-L,L-ECD	2.83	3.30
^{99m} Tc-MRP 20	4.16	4.86

RESULTS & DISCUSSION

All the three technetium-99m labelled agents are poorly retained by brain. The clearance from blood and excretion into urine are faster for ^{99m}Tc-ECD. Consequently, dosimetrically the compound is more favourable especially with respect to liver, kidney and intestine. This faster clearance from blood results also in brain images with enhanced contrast. The effective dose to a patient is lower for ^{99m}Tc-ECD. The recent change in 'W_T' values lowers down the estimated effective doses by about 10 % due to all the three compounds. In Indian subjects, administration of similar activities causes 9-12 % higher effective dose mostly due to the difference in their organ weights. Therefore, perhaps, a more rational approach in deciding the amount of radiopharmaceutical that is to be administered may be, to take cognizance of the patient weight.

ABSTRACT

ICRP (1991) has recommended new values to tissue weighting factor W_T . The effect of changes in ' W_T ' values on effective dose 'E' for two technetium-99m based agents used for myocardial perfusion studies, have been investigated. Due to different biological behavior, the effective dose due to one compound is higher by 12% than the other for the same administered activity. Using the new values of W_T , the effective doses are found to be lower for technetium based agents in comparison to $^{201}\text{TlCl}$.

INTRODUCTION

The concept of effective dose equivalent 'H_E' (now effective dose E) introduced by the International Commission on Radiological Protection (ICRP-1977) for radiation workers, has been successfully applied for patients undergoing radiodiagnostic investigations. In nuclear medicine, the concept is utilised to indicate approximate risk to which the patient is exposed as a result of the investigation and comparing this risk with the possible diagnostic benefits. The effective dose is represented by $E = \sum W_T H_T$ where H_T is the mean absorbed dose in the organ or tissue 'T' (for the emission of most of the nuclides used in diagnostic nuclear medicine mean absorbed dose and equivalent dose are similar) and W_T is the tissue weighting factor representing the relative radiation sensitivity of organ or tissue 'T'. Using the general equation of Coffey and Watson (1979) for biodistribution of the radionuclides in the body and methodology of absorbed dose estimation by Snyder et al (1975), absorbed dose and subsequently using the tissue weighting factors recommended by ICRP(1977), effective dose due to a large number of radiopharmaceutical preparations were compiled (ICRP-1987).

New biological information related to the detriment associated with radiation exposure, is now available. That has necessitated the revision of ICRP recommendations made earlier. The new ICRP recommendations (1991) have brought about significant changes in the methodology of computation of effective dose, particularly regarding the numerical values of ' W_T ' assigned to different tissues or organs. These developments have made it necessary to examine the effect of recent ICRP recommendations on the computation of effective dose due to some new radiopharmaceuticals and comparing the same with conventionally used radionuclide preparations. The

discussion is restricted to pharmaceuticals used for myocardial perfusion studies.

MATERIALS AND METHODS

Nuclear cardiology has helped to predict and to assess the effect of revascularisation procedures, to avoid needless angiography and to improve the diagnosis of coronary artery diseases. Recently two technetium based radiopharmaceuticals have become available for myocardial perfusion studies - Technetium-99m [MIBI]₆ where MIBI is 2-methoxy isobutyl isonitrile and Tc 99m - Teboroxime marketed by Du Pont Pharma and Squibb Diagnostics respectively. These preparations have very different pharmacokinetics in the body probably because of their charges and different oxidation states of technetium. Table 1 gives the effective dose received due to the administration of 1110 MBq of the radiopharmaceuticals and assuming 2 hour urinary bladder voiding intervals, considering tissue weighting factors recommended by ICRP (1977) and ICRP (1991).

Table 1. Effective Dose (mSv) due to administration of 1110 MBq of technetium-99m MIBI and Teboroxime considering W_T values recommended by ICRP (1971) and ICRP (1991)

Radiopharmaceutical	Effective dose	
	W_T of ICRP-1977	W_T of ICRP-1991
Technetium-99m MIBI	13.95	10.17
Technetium-99m Teboroxime	14.21	11.76

Based on data of Stabin (1990) and McSherry (1991)

In absence of complete data on mean absorbed doses to all organs or tissues of interest, the following procedure for approximation has been adopted:

- (i) Mean absorbed dose to LLI wall has been used to approximate the dose to colon (Phipps et al 1991).
- (ii) Whenever the mean absorbed dose to an organ or tissue and the explicit value of W_T assigned to it are available, the contribution of the organ or tissue to the effective dose to the body has been computed as per standard procedures recommended by ICRP-1977 and ICRP-1991.
- (iii) In other cases after carrying out the procedure (ii), the remaining residual value of W_T is equally divided between the remaining organs or tissues of group 1 and group 2 as specified by ICRP (1987). In carrying out these calculations, the provisions of ICRP (1991) recommendations have been kept in mind. This is a

slightly modified approach of that suggested by Smith (1990).

Calculating in the similar fashion, the effective dose due to $^{201}\text{TlCl}$ has also been computed and compared with these technetium based agents in Table 2.

Table 2. Comparison of effective dose due to three radiopharmaceuticals used currently for cardiac perfusion studies

Radiopharmaceuticals	Effective Dose (as per recent W_T values)
MIBI	6.78 mSv/740 MBq
Teboroxime	7.80 mSv/740 MBq
$^{201}\text{TlCl}$	8.70 mSv/111 MBq

Discussion and Conclusion

MIBI is cleared more rapidly from the blood and liver than Teboroxime. Therefore the radiation dose of the BATO complex is higher to the liver but lower to the intestine and kidney and its effective dose is also higher than MIBI by about 12%. However, the effective dose of both the technetium labelled agents is favourable compared with that of $^{201}\text{TlCl}$.

DISCHARGE LEVEL OF PATIENTS RECEIVED THERAPEUTIC AMOUNT OF RADIO-ACTIVE IODINE 131

S. Koga, K Koshida, *T. Orito, *A. Takeuchi and *S. Suzuki
Department of Radiology, Fujita Health University School of Medicine

*Department of Radiological Technology, Fujita Health University School of Health Sciences, Toyoake, Japan.

INTRODUCTION

Iodine 131 utilized for treatment of thyroïdal disease is the only Radionuclide (RN) presently used for therapy in Japan. The patient administered therapeutic amount of I-131 must be accommodated in a RN ward. However, there are only small number of data which can be used in investigating the criteria for permitting the patient to leave the RN ward. In 1976, ICRP suggested in Publication 25 the maximum allowable activities at discharge of patients following treatment with RN. 15mCi of I-131 were thought the level not likely to arise unacceptable hazards in the patient's home if the patient did not come into close contact with young children. This paper describes levels for discharge from hospital of patients treated with I-131. The level was determined by comparing the possible exposure dose to those individuals whom the patient are in daily contact with the annual dose limit for the public.

MATERIAL and METHOD

We evaluated external radiation dose of each family of the patient based on the data on spatial dose distribution around the three radioactive patients, and data on the distance between the patient and individuals, length of the time spent at each distance, and each individual's age which were recorded and analyzed on 53 subjects from 14 ordinary Japanese families.

Spatial dose distribution curves based on the measurement of clinical cases were studied around the patients treated with I-131 for thyroid carcinoma and they were administered 3.7, 3.26 and 3.33GBq of I-131, respectively. The measurement of the spatial dose distribution was performed using an ionization survey meter at the point every 30cm in the flat surface 80cm over the floor surface. Linear scan ningo were also carried out using Medical Universal Human

Counter in order to know the distribution of RN with in the patient's body.

14 housewives living in Toyoake City were taken as the models of the patients with hyperthyroidism, because the considerable proportion to the patient with hyperthyroidism was female of those ages. The investigation was carried out by means of the interviews and questionnaires which were performed by public health nurses of the Department of Public Hygiene Nursery Services, Fujita Health University Hospital. They visited each home of the subjects more than three times and taught how to enter in the questionnaires. After the withdrawal of those questionnaires position and time in the proximity of the subjects and their family members were analysed.

RESULT and DISCUSSION

1) Spatial dose distribution curve around the patient had been reported by Orito, one of the authors.

2) Distance between the subjects and their family members and time spent at those distances

Table 1 (a), (b)1, and (b)2 show the distances between the subjects and their family members and time spent at those distances. more than 180cm were treated as infinities. Husband of those subject were all workers at outside of their home, so that their chance being close in position with their wives was limited to the period from the night to the morning. While for the children, the shorter the distance and the longer the time spending with their mothers. Levels for discharge to home of patients who received therapeutic dose of I-131 based on external radiation dose.

Fig.1 shows the residual radioactivity as a function of the distance from the patient in the bed room. The activity gives her husband dose equivalent of 1mSv. Curve (a), (b) and (c) are residual radioactivity assuming that with effective half lives of 3.9, 5.9 and 7.2days respectively.

Fig 2 shows the residual radioactivity as a function of the age of the patient's child. The activity gives her child dose equivalent of 1mSv, Curve (a), (b) and (c) are the residual radioactivity assuming that with effective half lives of 3.9, 5.9 and 7.2 days respectively.

The allowable activity at discharge should be decided to ensure the

patient family not to exceed the dose limit recommended from ICRP to the member of the public.

If it is permissible to use a subsidiary dose limit of 1mSv in a year, calculated discharge levels from hospital to home are as

Table 1 Distance between the subjects and their family members and time spent at those distances

follows. Maximum residual activity should be less than 0.1 GBq, if

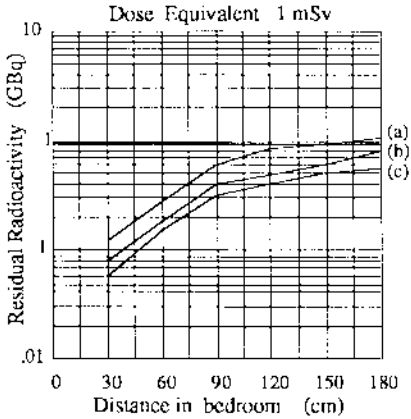

Fig 1 The residual radioactivity as a function of the distance from the patient in the bedroom.

Fig 2 The residual radioactivity as a function of the age of patient's child.

the distance from the patient in bed room is 50cm or more and there is no children younger than one year in the home. No restriction is necessary for the patient with residual activity of 0.05 GBq or less.

CONCLUSION

This paper describes levels for discharge from hospital of patients treated with I-131. The level was determined by comparing the possible exposure dose to those individuals whom the patients are in daily contact with the annual dose limit for the public. The external radiation dose was calculated by using the data on the distance between the patient and individuals, length of the time spent at each distance, and each individual's age. The following levels were obtained.

For the patient to be discharged from the hospital, the maximum residual radioactivity should be less than 0.1GBq if the distance from the patient in bedroom is 50cm or more and the age of her children are all over one year. No restriction is needed for the patient with residual activity of 0.05GBq.

(mode, cinétique, niveau éventuellement en fonction de la saison ou du stade végétatif) des principaux contaminants (iode, césium, strontium, ...) dans le produit lui-même et dans ses principaux dérivés. Ces fiches doivent également proposer aux producteurs des mesures préventives et aux industriels chargés de la transformation des consignes d'exploitation. Un tout premier ensemble de fiches techniques a été rassemblé par la Fédération Nationale des Syndicats d'Exploitants Agricoles (FNSEA) et par l'IPSN.

Les études générales de radioécologie ont fourni de nombreuses valeurs de coefficients de transfert ; le programme RESSAC a permis d'obtenir des données sur les facteurs d'interception des végétaux lors d'un dépôt et poursuit l'étude des facteurs de transfert avec un terme-source représentatif d'un accident sur réacteur et des lysimètres contenant des blocs de sol prélevés autour de sites nucléaires en exploitation.

Une première utilisation des bases de données et des fiches techniques est l'établissement, par les experts, de cartes situant les points où prioritairement des prélèvements d'échantillons seraient à faire.

3 - MOYENS ET ORGANISATION EN CAS DE CRISE

Au début de la phase post-accidentelle, en un premier temps sur la base des prévisions de retombées puis avec les résultats des toutes premières mesures, il faut bâtir un plan de caractérisation de la contamination dont les résultats doivent permettre de définir une stratégie d'action. Ceci se fait dans le cadre d'une organisation de crise qui regroupe auprès du Préfet les représentants des principaux services publics.

3.1 - Plan de caractérisation de la contamination

Pour bâtir ce plan, les bases de données et les fiches techniques précédemment décrites sont nécessaires mais non suffisantes. Il faut une grande implication des experts de l'agriculture, tant au niveau national que local, auprès du Préfet. En effet ce sont ces experts qui connaissent le milieu, l'état réel des productions et leur importance socio-économique compte tenu de la saison et de la région concernées. Ils seront à même de définir, par produit, les meilleurs emplacements pour effectuer les prélèvements et également, ce qui est très important, de faciliter le contact avec la population rurale.

3.2 - Recueil, validation, synthèse et exploitation des résultats de mesure

Les prélèvements et mesures, réalisés avec des protocoles pré-établis par des équipes appartenant à des services différents ont besoin d'être validés et synthétisés. Ici encore, le rôle des experts de la filière agro-alimentaire est fondamental ; ils doivent s'assurer de la suffisance et de la cohérence des résultats puis de la pertinence de la présentation. Cette présentation doit se faire, autant que possible, sous forme cartographique, transmissible, via les réseaux de télécommunication, vers les différentes cellules de crise (niveau local et national). C'est à partir de cette synthèse que les experts (du programme RESSAC pour l'IPSN, de la filière agro-alimentaire pour la cellule du Préfet) proposeront une stratégie d'action avec un choix de contre-mesures adaptées. Des systèmes experts commencent à être opérationnels et pourraient servir de base de départ aux réflexions des experts présents lors de la crise.

4 - INFORMATION, FORMATION ET EXERCICES

Les experts potentiels du Préfet en cas de crise (services agricoles, vétérinaires, des eaux, ...) sont en général peu impliqués normalement dans les problèmes de contamination radioactive. Il est donc nécessaire d'informer, de sensibiliser puis de former et d'entraîner ces experts de façon régulière.

Le milieu agricole lui-même doit également être informé si l'on veut qu'il réagisse correctement à ce qui peut arriver. C'est dans ce but que l'IPSN a réalisé avec la FNSEA un document de caractère pédagogique qui explique comment réagir en cas d'accident.

Les exercices de simulation permettent aux représentants des pouvoirs publics et aux experts de s'entraîner. Depuis 1987, trois exercices nationaux portant sur la phase post-accidentelle ont été réalisés. La simulation, pour être efficace, exige une longue préparation qui est d'ailleurs souvent l'occasion de vérifier les données disponibles et de sensibiliser les experts, surtout au niveau local, qui sont amenés à participer. Pour pouvoir simuler les résultats de mesure dans l'environnement, l'IPSN a mis au point le logiciel GEREM, déjà utilisé sur des micro-ordinateurs portables lors de précédents exercices. Ce logiciel pourrait, entre les exercices nationaux qui ne peuvent pas être très fréquents, servir à entraîner les acteurs de la crise en fournissant, à la demande, des "résultats" de mesure qu'il faudrait interpréter et synthétiser.

5 - CONCLUSION

L'accident de Tchernobyl a sensibilisé les pouvoirs publics et l'opinion aux conséquences d'une contamination radioactive de l'environnement. En France, le programme RESSAC fournit un ensemble de données sur les transferts de contamination et les modes de réhabilitation des sols. Parallèlement les pouvoirs publics poursuivent la mise au point du Plan d'action Post-Accidentel (PPA) et organisent des exercices nationaux de simulation de la phase post-accidentelle d'un accident sur réacteur.

Il apparaît clairement que le rôle des experts de l'IPSN et de la filière agro-alimentaire est essentiel si l'on veut d'une part se préparer efficacement (documents, bases de données, organisation générale) aux situations de crise et d'autre part gérer au mieux une éventuelle crise, c'est à dire prendre les décisions les plus appropriées et savoir les justifier et les expliquer à la population et à ses divers représentants. Pour que ces experts soient pleinement efficaces dans le domaine nucléaire, il faut les informer, les sensibiliser et les faire participer, avec tous les autres acteurs, à des exercices de simulation de plus en plus réalistes.

**EFFORTS ENTREPRIS PAR ELECTRICITE DE FRANCE (EDF)
POUR REDUIRE LES REJETS LIQUIDES
HORS TRITIUM DES CENTRALES REP**

P. HARTMANN

Service de la Production Thermique
Paris - La Défense

**ELECTRICITE DE FRANCE EFFORTS TO REDUCE RELEASED
RADIOACTIVITY (EXCLUDING TRITIUM) OF LIQUID WASTE IN PWR
NUCLEAR POWER PLANTS**

EDF operates a pool of nuclear power plants which now consists of 52 PWR units. The released radioactivity (excluding tritium) of liquid waste has been decreasing by a factor of about 10 for the last 10 years. This good result is due to :

- the modifications implemented to avoid the mixing of wastes of different origins and the improvement of certain treatment systems,
- the setting up of a management strategy including administrative targets and the necessity of reducing liquid waste arising at source.

These actions have also allowed to minimize the amount of solid waste and therefore their cost.

INTRODUCTION

Depuis 1977, EDF a mis en service et exploite un parc de production d'électricité qui comprend actuellement 52 réacteurs à eau sous pression REP.

Comme beaucoup d'activités industrielles, l'exploitation des centrales nucléaires engendre la production d'effluents et de déchets. Les effluents radioactifs liquides et gazeux des centrales nucléaires, qu'ils proviennent du réacteur ou des circuits des auxiliaires, sont collectés, traités et analysés avant d'être rejetés dans l'environnement suivant des modalités strictes définies par la réglementation française.

EFFORTS ENTREPRIS PAR EDF DEPUIS 10 ANS

Depuis 1980, EDF a engagé des actions visant à réduire les rejets des effluents radioactifs des centrales nucléaires à un niveau aussi faible que raisonnablement possible (principe ALARA).

Ces actions ont principalement porté sur :

- l'amélioration des circuits de collecte et de traitement des effluents liquides (tri des effluents par nature afin d'éviter les mélanges, et donc faciliter les traitements ultérieurs et la comptabilisation des volumes produits ; installation de moyens de traitement supplémentaires),
- la mise en place d'une organisation permettant une gestion rigoureuse des effluents et des déchets solides liés au traitement (motivation du personnel pour limiter la production d'effluents à la source lors des opérations de maintenance, création de comités de gestion chargés de fixer des objectifs et d'analyser tout dysfonctionnement, désignation d'un responsable par site pour la coordination des actions).

Ces mesures, introduites depuis 10 ans, ont permis de réduire de façon significative les volumes d'effluents produits et, par conséquent, les rejets de radioactivité hors tritium d'un facteur 10 en 10 ans (Fig. 1 et 2). Ces bons résultats se sont également accompagnés d'une diminution du volume des déchets solides liés au traitement (Fig. 3) et donc, des coûts correspondants.

Les rejets de radioactivité hors tritium des centrales françaises se situent actuellement aux environs de 25 GBq/tr x an soit 5 % de la limite fixée par la réglementation française ; l'impact sanitaire sur le public de cette limite étant lui-même 200 fois inférieur aux Normes de Base de la Communauté Européenne.

Ces rejets conduisent à des équivalents de dose de l'ordre de 10^{-8} Sv pour l'individu du public le plus exposé, ce qui est faible, voire négligeable comparé à la radioactivité naturelle ($2 \cdot 10^{-3}$ Sv en France en moyenne).

CONCLUSION

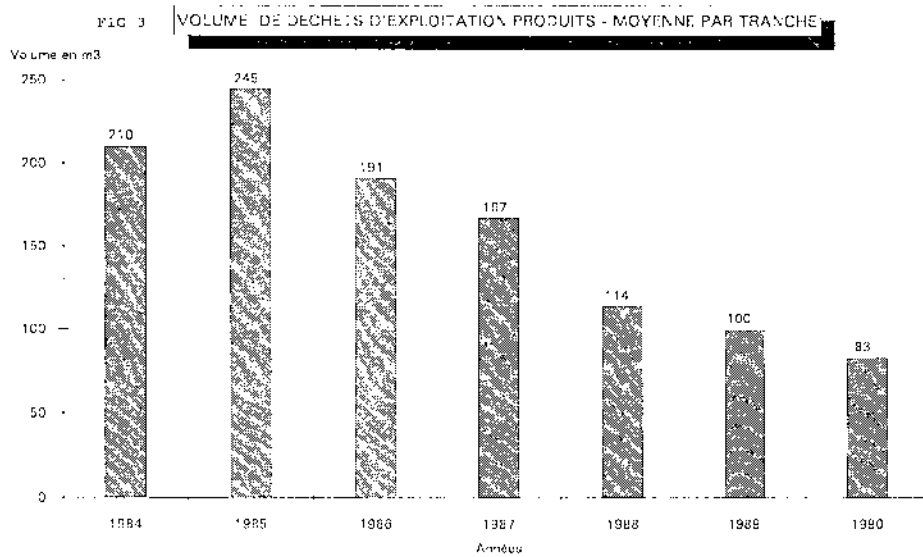

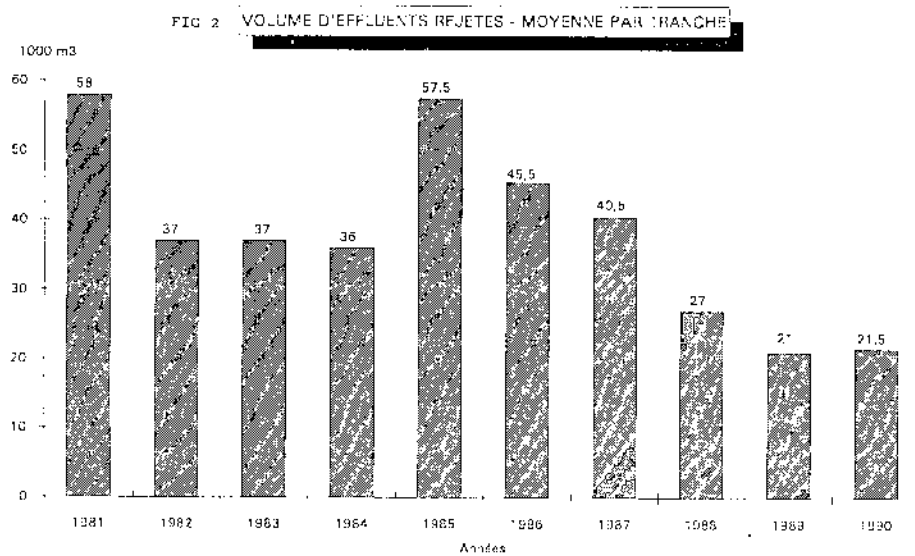

Bien que toute nouvelle action visant à réduire les rejets de radioactivité dans l'environnement serait sans incidence notable sur la santé des populations, les efforts entrepris par EDF depuis 10 ans seront poursuivis dans un souci de bonne gestion et de réduction des coûts liés aux traitements des effluents et des déchets solides.

DISPERSION OF RADIONUCLIDES AND RADIATION EXPOSURE AFTER
LEACHING BY GROUNDWATER OF A SOLIDIFIED
CORE-CONCRETE MELT¹

A. Bayer*, W. Tromm, I. Al-Omari

Kernforschungszentrum Karlsruhe,
7500 Karlsruhe 1, Germany

ABSTRACT

After a core meltdown accident it cannot be completely ruled out that the melt will reach, and partly penetrate, the concrete foundation. The amounts of some radionuclides leached out by the passing groundwater are estimated. The transport of dissolved radionuclides in groundwater is simulated by an analytical dispersion model; the underlying parameters are the hydrogeological characteristics of the Upper Rhine Valley. Simple models are used to estimate the ensuing radiation exposures for various exposure pathways. A number of technical and administrative measures are indicated which allow the radionuclide concentration in the groundwater and the radiation exposure to be reduced considerably.

PENETRATION INTO THE REACTOR FOUNDATION OF THE CORE CONCRETE MELT

Findings of the "German Risk Study, Phase B" indicate that a core meltdown accident could well cause the melt to penetrate into the reactor foundation and pass through it down to the bottom side of the foundation within five days. Even if the passing groundwater were to prevent complete melt-through, there would still be a direct contact of the groundwater with the resolidified melt surface through fissures, cracks, etc., which could cause the fission products to be leached.

For the purpose of this study, the distribution of fission products and activation products within the melt is assumed to be roughly homogeneous. Of the volatile fission products, 10% of the original inventory is assumed to remain in the melt, while it is 100% of the others. From the point of view of radiation protection, three radionuclides have been found to be important in investigations of the resultant radiation exposures: Sr-90, Tc-99, and Cs-137.

LEACHING OF THE RESOLIDIFIED MELT, RADIONUCLIDE TRANSPORT

The resolidified melt is assumed to establish a contact surface vis-a-vis the groundwater with a diameter of 16 m. Because of the gaps and fissures in the concrete it may be assumed, by a way of approximation, that the actual contact surface area will be roughly a factor of 10 larger than the postulated one.

¹Since 1988 with the Bundesamt für Strahlenschutz, München-Neuherberg

As the resolidified melt is probably less resistant to leaching than the glass specially developed for final storage, for which a leaching rate of 10^{-4} g/(cm² x d), was determined, this number is increased by a factor of 100; this means that the estimate is based on a leaching rate of 10^{-2} g (cm² x d). In the light of the leaching experiments meanwhile performed at the Karlsruhe Nuclear Research Center with slag arising from the BETA experimental facility, this number may be considered to be conservative.

The distribution in the groundwater of radionuclides as a function of time and space was determined by an analytical solution of the transport equation:

The Philippsburg Nuclear Power Station, which is located on the Upper Rhine River, was selected as the reference site. The relatively homogeneous structure of the aquifer of that site allows the transport equation listed above to be solved analytically for the radionuclide concentration to be determined in this way. Some important hydrogeological data of the Upper Rhine Valley are listed in Table 1.

Table 1: Hydrogeological data of the Central Upper Rhine Valley

Thickness of aquifer:	M = 50 m
Porosity:	n = 0,2
Migration velocity:	v _a = 3,3 m/d
Dispersion coefficients:	D _x = 33 m ² /d D _y , D _z = 1,65 m ² /d
Bulk density:	ρ _B = 2,12 g/cm ³

EXPOSURE PATHWAYS TAKEN INTO ACCOUNT

Six exposure pathways were taken into account in the detailed study /2/.

The results obtained for two exposure pathways are described below:

- The incorporation of drinking water from groundwater (800 l/a). The drinking water consists of contaminated groundwater from the environment of the reactor, the basic assumption being that no decontamination processes are employed.
- The incorporation of drinking water from river water (800 l/a). The drinking water is taken from the river, again under the assumption of no decontamination processes being used.

RESULTS

Figure 1a shows the concentration in the groundwater and in the river water 500 m away from the reactor between 100 days and 100,000 days. The groundwater was assumed to be discharged into the river water 500 m from the reactor, and the discharge rate of the river was assumed to be 1000 m³/s.

The radiation exposures were determined on the basis of the concentrations found in the groundwater and in the river water. Figure 1b shows the effective equivalent dose for an adult. The following results were determined for groundwater:

Tc-99 is transported rapidly with the groundwater; it contributes to the radiation exposure practically throughout the entire leaching period. However, the radionuclide concentration and the effective equivalent dose of Tc-99 attain only relatively low levels of 10^6 Bq/m³ and approx. 10^{-3} Sv/a, compared to the other two nuclides. This is a consequence, above all, of the small inventory of Tc-99.

The highest radionuclide concentration of approx. 10^{10} Bq/m³ is reached by Sr-90 after some 5000 days. The effective equivalent dose for an adult is above 10^2 Sv/a. After a prolonged period of about 10,000 days, Cs-137 reaches a maximum of about 10^8 Bq/m³. The effective equivalent dose for this radionuclide is approx. 1 Sv/a.

The groundwater is highly diluted when entering the river water. Consequently, concentrations will be lower, as will be the radiation exposures, by an approximated factor of 10^3 .

COUNTERMEASURES

To limit radiation exposures by administrative measures, water extraction wells can be closed down, and the river water can be decontaminated in preparation of its use as drinking water.

Some technical measures, which may be taken to limit the spreading of radioactivity, are these:

- Installing impermeable walls around the plant.
- .. Pumping off the groundwater in order to dry the reactor foundation.
- Installing extraction pumps to prevent the groundwater from leaving the site.
- .. Making special use of soil freeze techniques.

In the light of those possibilities, it is meaningful to keep a set of decision-making methods ready in case a flexible intervention were required in a real accident situation.

PROBABILISTIC RISK ASSESSMENT OF PLUTONIUM AIR TRANSPORT

SUMMARY

A probabilistic risk assessment has been carried out in France for the air transport of plutonium oxide as a contribution to the continuous review of the IAEA Regulations. Based on accident data from IACO, the accident probability for a 6 000 km journey is $3.7 \cdot 10^{-6}$. The package failure rate for present packages resisting impacts at 80 or 90 ms^{-1} lies between 2 and $3 \cdot 10^{-7}$. This figure does not improve significantly with the use of reinforced packagings (meeting the 130ms^{-1} impact test). This work among others from US and UK led the IAEA to envisage more stringent requirements for air transport of radioactive materials packages and to propose a 85 ms^{-1} impact test.

RESUME

Dans le contexte de la révision périodique de la réglementation, l'AIEA a décidé d'examiner l'opportunité d'une réglementation spécifique pour le transport aérien. La France a contribué aux travaux préparatoires en réalisant une évaluation probabiliste du risque sur le transport aérien du plutonium. Sur la base des données internationales d'accident, la probabilité d'accident pour un trajet de 6 000 km est de $3,7 \cdot 10^{-6}$. L'emploi de colis résistant à des impacts de l'ordre de 80 à 90 ms^{-1} conduit à une probabilité d'ouverture de 2 à $3 \cdot 10^{-7}$ par trajet. Au delà de ces valeurs, l'amélioration des colis (résistant par exemple à des impacts de 130 ms^{-1}) n'améliore pas sensiblement ce résultat. Cette étude, parmi d'autres, a conduit l'AIEA à envisager des critères plus stricts pour le transport aérien de matières radioactives et à proposer un test d'impact à 85 ms^{-1} .

INTRODUCTION

Pour toute matière radioactive, la réglementation AIEA actuelle est satisfaite par l'utilisation de colis B qui doivent subir des tests de résistance à l'impact (chute de 9 m sur surface rigide soit une vitesse d'impact de 13,4 ms^{-1}) et à l'incendie (feu de 30 minutes à 800°C). Ces tests sont insuffisants pour représenter le type d'environnement accidentel propre au transport aérien. Une première évaluation probabiliste du risque a été faite aux Etats Unis en 1977 [1]. Plus récemment, dans un travail pour les Communautés [2], Brown et al se sont posé le problème des critères d'essai pour les colis destinés au transport aérien. L'étude présente [3][4] vise à la fois l'estimation du niveau de risque correspondant à la conception du colis aujourd'hui utilisé en France pour le transport de l'oxyde de plutonium issu du retraitement, et l'examen de la pertinence d'un renforcement de l'emballage destiné au transport aérien. Les résultats des différentes étapes de l'étude sont

brièvement présentés ci-dessous.

ACCIDENTOLOGIE AERIENNE

Le but de cette étape est de définir, de façon probabiliste, l'environnement accidentel - c'est à dire les contraintes susceptibles de s'appliquer à un colis de transport de plutonium. En principe cette partie de l'étude n'est pas spécifique d'un colis, toutefois l'analyse faite concerne essentiellement le cas de colis de l'ordre de quelques tonnes. Sur la base des accidents aériens tels qu'ils sont recensés par l'Organisation Internationale de l'Aviation Civile (OACI), l'arbre des événements d'un accident a pu être quantifié (figure 1).

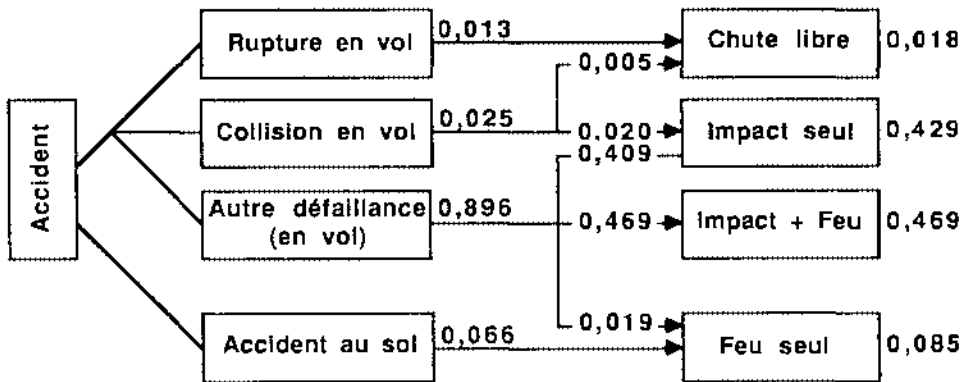

Figure 1: Arbre des événements de l'accident aérien.

Les taux d'accidents utilisés sont tirés de [2]. Ils sont définis pour chaque phase de vol (décollage, montée, en route, approche, atterrissage) et varient en fonction de la longueur du trajet. Pour des trajets de 1000 ou 6000 km, les valeurs sont respectivement de $1,2$ et $3,7 \cdot 10^{-6}$ accident par vol (sans escale). La grande fréquence des feux est à noter, ainsi que leur gravité : Température et durée sont supérieures à celles des tests de l'ATEA pour les colis de transport (800°C , 30mn). Toutefois à cause de la grande dispersion des épaves et du bon comportement du colis, l'analyse a été centrée sur l'impact, dont la gravité a été exprimée en fonction de la vitesse réelle observée et de l'angle d'impact au sol. La rigidité du sol est traduite par un coefficient de réduction de la vitesse réelle.

ACCIDENTOLOGIE ROUTIERE

Les études classiques ont fait l'objet de développements spécifiques pour estimer quantitativement les scénarios très rares (par exemple coincement entre deux camions en choc frontal) susceptibles de produire des contraintes très sévères [3].

LA REPONSE DU COLIS ET LES TAUX D'OUVERTURE

Le comportement du colis est lié au seuil de résistance aux contraintes exprimé ici comme une vitesse d'impact (vitesse équivalente à un impact sur surface rigide). Pour les colis utilisés aujourd'hui (FS 47) le seuil serait de l'ordre de 80 ms^{-1} (cf campagne d'essais COGEMA). Le tableau I présente les probabilités d'ouverture pour trois trajets.

Tableau I: Probabilité d'ouverture des colis de transport selon leur résistance pour un trajet type

	Vol de 6 000 km ($3,7 \cdot 10^{-6} \text{acc}$)	Vol de 1 000 km ($1,2 \cdot 10^{-6} \text{acc}$)	Route : 1 000 km ($2,5 \cdot 10^{-4} \text{acc}$)
Colis résistant à un impact à:			
80 ms^{-1}	$0,33 \cdot 10^{-6}$	$0,95 \cdot 10^{-7}$	$6,5 \cdot 10^{-7}$
90 ms^{-1}	$0,20 \cdot 10^{-6}$	$0,66 \cdot 10^{-7}$	$3,3 \cdot 10^{-7}$
130 ms^{-1}	$0,13 \cdot 10^{-6}$	$0,42 \cdot 10^{-7}$	$0,16 \cdot 10^{-7}$

LES CONSEQUENCES D'UN RELACHEMENT

Le calcul des conséquences nécessite la connaissance de la composition isotopique du mélange, de sa granulométrie et de la quantité relâchée. Pour le mélange étudié, la composition dérive du retraitement du combustible PWR irradié à 33000 MWjt^{-1} et refroidi 3 ans. Sa granulométrie correspond à un diamètre aérodynamique médian de 10 microns. Les essais destructifs réalisés par la Sandia ont montré que même un colis détruit ne relâchait pas tout son contenu. Le taux de relâchement a été fixé ici à 5% du contenu. Le facteur de dose calculé pour une granulométrie de 1 micron (estimation conservatrice) est de $1,8 \cdot 10^6 \text{ Sv}$ par gramme inhalé. Dans les conditions atmosphériques stables avec un vent de 1 ms^{-1} , un individu pourrait recevoir une dose de 1 Sv à 434 m pour un relâchement de 10 g. Sous l'hypothèse d'une densité démographique de 100 hab.km^{-2} (moyenne de la France), la dose collective est de l'ordre de $1,5 \text{ hSv}$ par gramme de mélange rejeté à l'atmosphère.

ESTIMATION DU RISQUE

En reprenant les hypothèses précédentes (granulométrie, composition du mélange, 100 hab.km^{-2} , 5% de rejet) on peut associer aux événements précédents (tableau I) l'espérance mathématique de la dose collective. Ce calcul a été effectué pour une cargaison de 150 kg, ce qui correspond à 10 colis et sensiblement au retraitement du combustible associé à l'exploitation d'un Gwe pendant un an (cf tableau II). Il faut noter la relative faiblesse du risque mesuré par l'espérance de la dose collective (associée toutefois à des événements de probabilité faible : 10^{-7} par trajet). Le transport aérien présente un risque, par kilomètre parcouru, plutôt moindre que celui dû au transport routier, à cause de la plus faible occurrence des accidents. Remarquons que le transport aérien, par rapport à la route, est d'autant plus recommandé que le colis est moins résistant. En fait la sécurité repose là sur le vecteur de transport.

Tableau II: Espérance mathématique des doses pour un trajet type [hSv]

	Vol de 6 000 km	Vol de 1 000 km	Route : 1 000 km
Colis résistant à un impact à:			
80 ms ⁻¹	3,7 10 ⁻³	1,1 10 ⁻³	7,3 10 ⁻³
90 ms ⁻¹	2,2 10 ⁻³	0,74 10 ⁻³	3,7 10 ⁻³
130 ms ⁻¹	1,5 10 ⁻³	0,47 10 ⁻³	1,8 10 ⁻⁴

CONCLUSIONS

L'examen de la fréquence des accidents de gravité extrême et les résultats précédents montrent qu'il paraît peu intéressant d'envisager des colis résistant au delà de 90 ms⁻¹. En effet, une faible réduction des doses collectives nécessite un accroissement très grand de la résistance des colis. Cette amélioration des performances atteint assez vite la limite des possibilités techniques, et s'effectue dans un domaine où la croissance des coûts est extrêmement forte.

L'AIEA n'a pas jugé inquiétante la situation présente (cf résultats ci-dessus), mais elle a observé que ce niveau de sûreté reposait sur le fait que les concepteurs ont mis au point des emballages considérablement plus solides que ne l'exige la réglementation présente. En conséquence l'Agence a jugé nécessaire de consolider cet état de fait par une prescription réglementaire adaptée. La valeur de 85 ms⁻¹ a été finalement proposée [6] comme vitesse du test d'impact pour le transport aérien de matières radioactives.

CONTAMINATION MEASUREMENTS ON PERSONS
AFTER A NUCLEAR ACCIDENT

R. Maushart

Laboratorium Prof.Dr.Berthold GmbH & Co.
Wildbad, Germany

ABSTRACT

The purpose of contamination measurements after accidents is threefold: to detect and localize contaminations; to determine the level of contamination as a base for medical decisions; and to check the scope and efficiency of the decontamination measures.

Persons involved in accidents should never measure their contamination themselves. The radiation protection personnel, whether it belongs to the medical team or to the disaster control squads, must be familiar with the measuring instruments and experienced in handling these instruments. A high priority has to be placed on training and constant practice.

The monitors used must meet the special requirements of an emergency situation. This includes resistance against environmental factors - temperature, humidity, vibrations - as well as the simplicity of handling the instrument, and the clear presentation of the results.

CONTAMINATION MEASUREMENTS AND MEDICAL CARE OF PERSONS ADDITIONALLY CONTAMINATED

Several international and national guidelines exist for treating persons exposed to radiation or contaminated after a nuclear accident (1, 2, 3). However, they focus almost exclusively on the medical care, without discussing the necessity, let alone the practical performance, of procedures related to a contamination measurement.

It seems justified, therefore, to clarify the role and purpose of contamination measurements in the medical treatment of contaminated persons. In the course of the decontamination process, four steps can be emphasized for the measuring technique: detecting - preventing - ensuring - documenting.

First, the level and extensions of person contaminations have to be determined. Particularly, if a large number of persons have been contaminated, these measurements serve as a basis for determining where the high level of contamination requires that immediate steps be taken, and where a treatment is less urgent (the treatment itself is beyond the scope of this paper).

A second purpose of the measurements is to prevent immediate harmful effects of the contamination. For the affected person this is a too high skin dose, on the one hand, and the incorporation of the activity through possible wounds.

With regard to the staff one has to make sure that contamination cannot be passed on or neglected. This is equally true for staff, environment and instruments.

Third, contamination measurements should ensure that the provisions taken have been effective. During person decontamination the success has to be checked by measurement until the desired values have been reached. Moreover, the measurement has to rule out any chance that contaminations are missed.

Finally, the results of the measurement are used for documentation purposes. This documentation is required not only for a later analysis and evaluation of the accident and its consequences; it also serves for clarification of possible legal claims of the affected persons.

Regardless of the great importance of contamination measurements in the course of decontamination procedures, one has to say clearly that the medical treatment always has priority in an emergency. In some situations no measuring instruments may even be available at all, but a decontamination has to be performed nevertheless.

However, a professional medical treatment of contaminated persons can only be ensured in conjunction with a professional contamination measuring technique.

TYPE AND NUMBER OF INSTRUMENTS REQUIRED

The most important instrument for measuring contaminated persons is a portable contamination monitor with large-area detector (at least 100 cm² area). How many of these instruments are required is dependent upon the planned person throughput of a decontamination facility.

Two aspects should be considered. On the one hand, it is advisable to keep separate instruments for the "hot" entrance area and the "cold" exit area - and to label them accordingly! - in order to avoid crossover contamination between early and late decontamination areas. On the other hand, spare instruments should be available in the event of heavy contamination or when one instrument is defective.

It is also advisable to provide wall holding devices for the portable instruments. There, the monitors can be "parked" when they are not being used; they may also serve as semi-stationary hand monitors for the staff.

Larger facilities should provide one or several stationary hand-foot-monitors at the entrance and exit, which should be equipped with result printers. At least the instruments positioned at the entrance should be provided with a contamination protection (foil). Patients may enter the monitors positioned at the entrance only under the supervision of the staff performing the measurement. The staff enters the patient's ID prior to the measurement which will then be documented together with the result of the measurement.

The contamination monitors should indicate the result as area-related activity in the unit Bq/cm² (discussion and reason for this requirement in (). A proper calibration is required. The bases for this are national and international standards (4,5). Calibrations are essentially type test which are performed by the manufacturer.

Regardless of the calibration, a regular function check of the monitors is required. This is simply a good laboratory praxis. Suitable test sources are usually supplied by the instrument manufacturers.

REQUIREMENTS FOR CONTAMINATION MONITORS

When checking persons involved in an accident for contamination, who may even be injured, this is usually done under difficult conditions. The difficulties are, on the one hand, of a psychological nature, such as stress, insecurity, improvisation and high time pressure; on the other hand, there are the concerns of the environment in which these measurements have to be carried out. Due to the fact that for decontamination a person has to wash, shower and change clothing all the time, it may be wet, warm, crowded, and noisy. Moreover, the visibility may be quite bad due to vapour or insufficient light. Therefore, contamination measuring instruments have to meet special requirements to make sure that reliable results will be obtained.

These requirements concern the mechanical as well as the electronic construction of the measuring instruments. The key words "robust" and "moisture resistant" characterize the mechanical, and "intelligent" the electronic features. There is, however, an additional requirement concerning the simple and reliable handling of the monitor. It is characterized by the terms "simple and clear".

Of particular importance is the quick response of the monitor. Especially when detecting contaminations it is necessary that the result indication adjust as quickly as possible to the changes of the current measured value, without becoming blurred by random statistical variations. Modern micro-processors can be taught to behave accordingly via software. Furthermore, for the clear readability of the measured value it is quite useful to display only the statistically significant number of decimals.

In general, the requirement is to implement a high level of intelligence into the monitor electronics. This facilitates the user's own decisions and interpretations. It not only helps to avoid errors and mistakes, but enables the operator to focus his attention on the execution of the measurements, rather than on the instrument.

STAFF TRAINING AND PRACTICE

Even if the contamination monitors which are available after an accident meet all the requirements listed above: their professional use still requires well-trained and practised staff.

Persons accidentally contaminated should never measure themselves, not even if they have sufficient experiences in this field. The reason is not only a possible accident shock; it also has to be ensured that all persons involved will be measured according to the same routine and with the same care.

This indicates where training has to start. In addition to the actual handling of the measuring instrument, the execution and procedure of person contamination measurements, the interpretation of measured values and the documentation have to be taught and practised as well.

The importance of constant practice cannot be emphasized enough, although we cannot go into details. This can be combined with a regular function check of the instruments, which is required any way.

This principle is applicable, of course, for all emergency applications and is discussed in detail in (7).

ABSTRACT

The information necessary to introduce countermeasures in the environment in the early phase following an accidental radioactive release will be vague. A method to rapidly reduce gross uncertainties of the radiological picture will be incorporated as a part of a European emergency response system. Basically, it involves the tuning of the main parameters of a general dispersion model by continuous comparison of the model output with early radiological survey data in a feed-back loop.

INTRODUCTION

Following a major accidental release of radionuclides to the atmosphere appropriate countermeasures must be taken to mitigate the consequences to the population and the environment.

During the time lapse from the notification of an anomaly to the early phase following an accidental release only computer simulations based on real-time in-plant information and meteorological data will be available. A poor and uncertain knowledge of the main model parameters will possibly lead to erroneous and cost-ineffective decisions. On the other hand a global comprehensive view of the environmental contamination based only on measurements will emerge after an unacceptable long time delay. A possible way out of these difficulties is to organize an optimization scheme to acquire a confident knowledge of the actual and future radiological situation by comparison of model output, using a general dispersion model, and early radiological survey data in a feed-back loop. Once the gross uncertainties have been resolved model based extrapolations of the radiological situation will be possible.

OPTIMIZATION TECHNIQUES

The feasibility of feed-back will heavily rely on the availability of environmental survey data. Two optimization schemes were considered. The first one, as shown in fig. 1, is based on the comparison, using an acceptance criterion, of measured and calculated data. Basically the deviation between measurements and computation, as quantified by a comparison criterion, is minimalized. The fulfilment of an

acceptance criterion has to guarantee a sufficient quality of the optimization. If according to this criterion a convergence of model results towards survey data cannot be achieved, the optimization cycle has to be performed on a reduced measurement data set rejecting outlying data.

The main drawback of this method, if applied blindly, is the generation of solutions which fit well mathematically but without relation to the physical reality (ref. 1). For example, if extrapolating the calculations to other places, using the optimized set of input-parameters, most certainly the accordance between measured values and the corresponding computed value of the physical quantity under consideration will be very bad if an adequate sampling scheme is not followed in the determination of these input parameters. For this reason this optimization scheme is transformed to a regression of measured data, assuming the validity of a general dispersion model as shown on fig. 2.

In simple terrains the main sources of uncertainties are : wind direction, source term, effective height, dispersion parameters and wind speed.

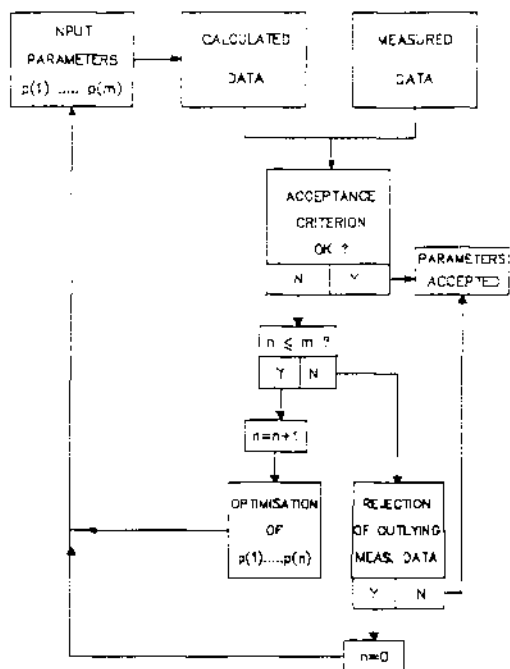

Fig. 1 : General scheme of the optimisation system (first approach)

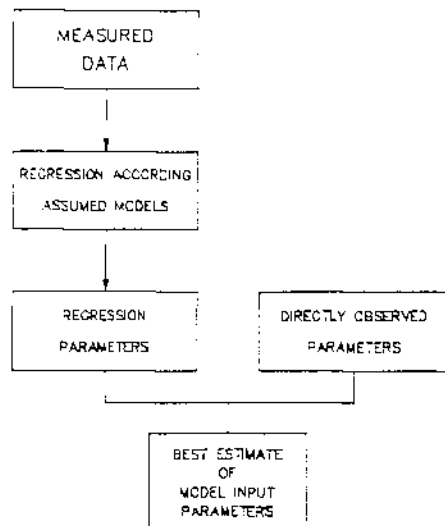

Fig. 2 : General scheme of the optimisation system (second approach)

An environmental sampling strategy must be worked out carefully. The most reliable survey methodology promises to be a sampling on several rings lying at different distances from the source around the ground level projection of the plume axis, cutting off too low values of measurements to avoid a "noise" (ref. 2).

ALTERNATIVE METHOD : FUZZY LOGIC

An increasing number of practical optimization systems use the so-called fuzzy logic instead of numerical optimization techniques. Fuzzy logic is appropriate to translate a qualitative judgement into a degree of membership to a given group. A logic has been developed to derive a degree of "possibility" or "necessity" to conclusions, based on the combination of several fuzzy information (ref. 3).

Each environmental observation O can in this way be appreciated and qualified as e.g. in very good agreement, good agreement, poor agreement, very poor agreement with the predictions P , using an agreement membership function. An application of the fuzzy logic might allow to define boundaries to the possible values of the model input data or parameters.

This approach has been combined with an analysis of spatial distribution of P/O ratios. A variation of a key-parameter of the prediction model will introduce a specific spatial distribution of the P/O ratios. In a normal situation with a good fit between predictions and observations the P/O ratios are distributed symmetrically around 1, without any correlation between the P/O ratio and the geographical position. An artificial decrease of the source term, e.g. will decrease all the P/O ratios. A shift in wind direction will decrease the P/O values under the real wind direction and increase the ratios under the assumed wind direction. Analogous graphical transformations of the P/O distributions can be associated with variations of other parameters. After an analysis of typical P/O distributions an expert system will be developed to propose variations to the input parameters, transforming the P/O ratio distribution to an acceptable distribution centered around 1, without a spatial correlation.

PRACTICAL IMPLEMENTATION

In the framework of radiation protection research programmes of the Commission of the European Communities (DGXI and DGXII) an European emergency decision support system covering all time phases and distance ranges after a nuclear accident is under development. The main emphasis has been put on the early stage, where quick and reliable predictions are required in real-time taking due account of on-line monitoring data and environmental measurements (ref. 4).

Independently of the actual realization of the optimization technique the necessary interface to accept environmental measurements, such as γ -dose rates, activity air concentrations and soil contamination, to compare them with model predictions have been foreseen in a separate system module.

CONCLUSION

A design has been developed for inclusion of early environmental data into an optimization procedure in case of a nuclear accident, to improve confidence in model prediction. An analysis of tracer experiments has shown the opportunity as well as the drawback of applying several methods to feed-back monitoring data into a model. This will only be possible by application of a strict environmental sampling strategy. The most promising method candidate for implementation in the European decision aiding system is based on the analysis of the distribution of P/O ratios following the variation of certain key parameters.

ACKNOWLEDGEMENTS

DEVELOPMENT OF ON-BOARD VEHICLE MEASUREMENTS FOR EMERGENCY SITUATIONS

ABSTRACT

In case of accident in a nuclear power plant, measurements must be carried out very quickly around the site, in order to control and limit the consequences for the population. Measurements which have the priority are the gamma dose rate, the total beta activity, the gamma activity due to I 131 (charcoal filter) and due to Cs 134/137 (paper filter). To fulfill the requirement, EDF has developed and selected necessary equipments, putting the emphasis on the reliability and on the ease of use. A computer controlled system dedicated to dose rate measurement and gamma spectroscopy is described, as well as an autonomous programmable, air and water sampling device.

1. INTRODUCTION

En cas d'incident ou d'accident survenant sur une installation nucléaire, il est prévu de mettre en oeuvre une organisation de crise pour maîtriser la situation, limiter et surveiller la dispersion des produits radioactifs dans l'environnement, dans le but final de minimiser les conséquences sanitaires pour les populations.

Cette organisation consiste à mettre en place :

- des actions internes : le Plan d'Urgence Interne (P.U.I.), c'est-à-dire la mobilisation immédiate des équipes pour protéger le personnel et limiter les effets de l'accident ;
- des actions externes liées à l'environnement du site : le Plan Particulier d'Intervention (P.P.I.).

C'est le Préfet de la région concernée qui met en oeuvre le P.P.I. et qui décide et coordonne les actions des Pouvoirs Publics, visant à la protection des populations et de l'environnement au voisinage du site.

Pour prendre ses décisions, le Préfet s'appuie principalement sur les conseils de la Direction de la Sécurité des Installations Nucléaires (D.S.I.N.) du Ministère de l'Industrie et du Service Central de Protection contre les Rayonnements Ionisants (S.C.P.R.I.), organisme dépendant du Ministère de la Santé.

De plus, il dispose de nombreux moyens d'intervention :

- Centre de Secours des sapeurs pompiers ;
- Cellules Mobiles d'Intervention Radiologiques (CMIR) ;
- moyens de contrôle de la radioactivité par le Commissariat à l'Energie Atomique (C.E.A.) ;

Dès les premières heures, l'exploitant transmet des informations au Préfet sur :

- les rejets en cours, le cas échéant ;
- l'évaluation prévisionnelle des rejets potentiels, compte tenu de la nature de l'accident et des conditions météorologiques ;
- les résultats des mesures pratiquées sur le site et à l'extérieur du site.

Pour ce dernier point, la réglementation fixe l'obligation de disposer d'au moins deux véhicules laboratoire tout terrain pour réaliser les mesures dans l'environnement.

Compte tenu de l'importance du parc nucléaire et de la défiance du public vis-à-vis des informations contradictoires sur les niveaux de radioactivité dus à l'accident de Tchernobyl, EDF a décidé de réexaminer les choix faits lors du démarrage du programme électronucléaire en 1978.

En 1990, un Groupe de Travail, constitué d'exploitants, a eu en charge :

- d'établir le besoin en mesures radioactives
- de définir des choix technologiques et méthodologiques communs à l'ensemble des sites EDF
- de faire valider les appareils et procédures de mesure
- de créer des séances de formation à l'usage des futures opérateurs

La livraison des premiers véhicules est prévue fin 1991.

2. DEFINITION DU BESOIN

En situation accidentelle, les mesures prioritaires sont les mesures de débit de dose, en des points situés sous le vent.

Ces premières mesures sont ensuite complétées par des mesures sur les filtres, frottis et cartouches à charbon actif, à savoir :

- . activité bêta totale sur filtres et frottis,
- . activité spécifique des radio-éléments les plus contraignants pour l'environnement (spectrométrie gamma simplifiée : mesure globale halogènes par la mesure I 131 et mesure globale des aérosols par la mesure Cs 134 + Cs 137).

Enfin, il pourra être effectué des prélèvements de végétaux, lait et sol.

3. CHOIX DU MATERIEL

Le matériel de mesures sur le terrain doit être fiable, transportable et d'utilisation simple.

Les dispositifs de prélèvements et de mesures doivent être embarqués à bord des véhicules afin de les soustraire au rayonnement ambiant et de limiter leur contamination.

Pour s'affranchir d'une panne éventuelle d'un véhicule, ou de l'appareillage, les matériels embarqués doivent être identiques et interchangeables.

Les plages de mesure des appareils ont été déterminées à partir des calculs des conséquences des éventuels accidents, y compris les accidents graves.

Les types de matériels à embarquer sont les suivants :

- . matériel de transmission,
- . matériel de radioprotection et de contrôle individuel,
- . matériel de prélèvement,
- . matériel de mesures,

3.1. Matériel de transmission

Il est constitué d'un poste émetteur-récepteur permettant la liaison avec le site nucléaire.

3.2. Matériel de radioprotection et de contrôle individuel

Il est composé de :

- . gants et surbottes vinyl,
- . combinaisons légères jetables,
- . appareil respiratoire autonome,
- . films dosimètres,
- . stylo-dosimètres à lecture directe couvrant la gamme 0 à 10 Gy ou dosimètres électroniques.

3.3 Matériels de prélèvements

Pour disposer d'un matériel adapté aux conditions du terrain, EDF a fait développer un ensemble portable et autonome qui permet en plus des prélèvements d'air, d'effectuer des prélèvements de pluie : la "BAP 10" balise autonome de prélèvement (Société ARIES).

Ce système permet la réalisation de 4 prélèvements (quantification aérosols/halogènes) de 1 m³ d'air, et d'effectuer en parallèle la mesure en continu du débit de dose (avec enregistrement). Plusieurs modes de prélèvements peuvent être utilisés :

- . déclenchement immédiat,
- . déclenchement sur dépassement de seuil (prérégulé) ou consigne horaire.

Chaque véhicule est équipé de deux systèmes.

3.4 Matériel de mesures

MESURE DE DEBIT DE DOSE GAMMA AMBIANT

Pour répondre aux besoins, il a été décidé de disposer d'un appareil portable et autonome pour réaliser les mesures à l'extérieur et d'un appareil en fixe installé dans une fenêtre de la paroi interne du véhicule, couplé à un micro-ordinateur, capable d'effectuer des mesures, soit à l'arrêt, soit en mouvement.

Appareil portable et autonome : 1 par véhicule

Les spécifications sont les suivantes :

- . appareil robuste, léger et simple d'utilisation,
- . autonomie minimale de mesures de 48 heures,
- . étendue d'échelle de 10^{-8} à 0,5 Gy/h,
- . lecture directe en Gy/h,
- . mesure de rayonnement gamma pour des énergies comprises entre 50 Kev et 2 Mev.

Appareil en fixe dans le véhicule : 1 par véhicule

Les caractéristiques de la sonde de détection sont identiques à celles de l'appareil portable.

La complémentarité de cet appareil réside dans la possibilité de réaliser des mesures (continues ou ponctuelles) en roulant et grâce au couplage à un micro-ordinateur, de permettre des restitutions beaucoup plus performantes (historique et repérages géographiques).

MESURE DE L'ACTIVITE BETA TOTALE DES FILMS PAPIER

Chaque véhicule est équipé d'un dispositif de mesure de l'activité bêta totale.

L'activité à mesurer est comprise entre quelques Bq/m³ et 10 000 Bq/m³ (pour 1 m³ d'air prélevé et 10 minutes de comptage).

MESURE DE L'ACTIVITE SPECIFIQUE AEROSOLS/HALOGENES RETENUE SUR FILTRE ET CARTOUCHE A CHARBON ACTIF

Les mesures d'activité spécifique des éléments les plus déterminants - Iodes et Césiums- doivent pouvoir être effectuées en dehors du laboratoire d'environnement, afin de se prémunir d'une éventuelle contamination de celui-ci et surtout, de faciliter l'organisation des tâches.

L'analyse a conduit à rechercher un équipement à embarquer dans chaque véhicule, de spectrométrie gamma NaI, très simplifié qui soit capable, avec un minimum de manipulation (calibration automatique des spectres), de quantifier l'Iode 131, les Césiums 134 et 137 (mesures globales dans des fenêtres d'énergie prédéterminées), sans arrêter le véhicule et tout en conservant simultanément la mesure du débit de dose.

L'appareil SYME.10 développé par la Société ARIES a été retenu par EDF.

Le SYME.10 (SYStème de Mesures Embarqué) est un système, dont la partie centrale (microprocesseur) est commune avec la mesure du débit de dose et les balises de prélèvement.

MOBILE MONITORING UNIT FOR ASSESSING ENVIRONMENTAL RADIOACTIVE CONTAMINATION

A. Andrási, I. Fehér, I. Németh, J. Urbán and P. Zombori

Atomic Energy Research Institute of the Central Research Institute for Physics, Budapest P.O. Box 49, H-1525, Hungary

ABSTRACT

Mobile monitoring laboratory has been established for monitoring environmental radiation first of all in accidental conditions but which is also suitable for monitoring radiation in natural level. The applied equipments and devices ensure the measurement of dose and dose rate in wide range, nuclide specific activity concentration of ground deposition and in air /with special attention to iodine in aerosol and vaporous forms/ as well as in samples of soil, water, vegetation, food-stuffs, etc. The measured data are handled, evaluated and recorded by an on board computer which provides also rapid information for any further decision making or intervention.

INTRODUCTION

As a consequence of increased number of operating nuclear facilities, first of all nuclear power plants and the lessons drawn from the Chernobyl accident underlined the importance of establishing environmental monitoring systems for obtaining rapid information in accidental situation on the radiological conditions at the affected area and providing suitable data to the competent authorities for decision making. Mobile units suitable for monitoring radiological impact at any selected location in the field play an important role in emergency preparedness.

In Hungary the nuclear facilities at the Central Research Institute for Physics as well as the nuclear power plant at Paks necessitated the establishment of a mobile environmental monitoring unit as a part of the emergency preparedness programme. The main objective was to establish a mobile unit which is based on a reliable vehicle /preferably a cross-country car/ and is equipped with instruments and devices necessary for assessing environmental impact of a nuclear accident after initial information concerning the situation originating from the operators or from the early warning system becomes available. The requirement was also to provide measured data suitable for further decision making and intervention, if necessary. For better utilization the application field was intended to extend also for monitoring lower level of environmental radiation for instance from natural sources.

It has to be mentioned that the amount of financial support made available for this project was also a limiting factor in the selection of the vehicle and its instrumentation.

METHODS AND EQUIPMENTS

After careful survey of the offers of vehicles being potentially available considering prices, delivery conditions and other practical aspects a Volkswagen Transporter type four-wheel driven microbus was selected with enlarged inside dimensions. The car has been specially furnished for the given task facilitating the fixation and transportation of the necessary equipments and devices as well as to provide comfortable and practical conditions for different activities to be carried out in the vehicle.

The mobile laboratory has been prepared for the measurement of dose and dose rate in wide range, ground surface contamination, nuclide specific activity concentration in air /with special attention to iodine in aerosol, in elementary and organic vaporous form separately/ as well as in other samples like soil, water, vegetation, food-stuffs, etc. The following equipments are available for the measurements of the above quantities

- Dose, dose rate:
- High pressure ionization chamber
 - Portable dose rate meters/GM counters/
 - Portable TL reader with $\text{CaSO}_4/\text{Dy}/$ bulb dosimeters
 - Personal alarm monitors
 - HpGe gamma spectrometer for in situ nuclide specific dose rate measurement

- Ground contamination:
- Portable surface contamination monitor /GM-counter/
 - HpGe gamma spectrometer for in situ nuclide specific ground contamination monitoring

- Activity concentration in samples:
- Shielded HpGe gamma spectrometer for sample analysis
 - Shielded plastic beta-counter for samples of elementary and organic iodine from the air

The on board personal computer has multifunctional task namely it serves as a multichannel analyser for sample gamma spectrometry and as the central computer for spectrum evaluation as well as for data handling, recording, storing and searching. The computer also provides rapid information for the necessity of intervention. The scheme of the monitoring system can be seen in Fig. 1.

The mobile unit is equipped with a number of necessary devices like AC power generator, batteries, sampling devices and sample holders, tools for simple sample preparation, wireless communication system, etc.

The following equipments and methods applied in the mobile laboratory have been developed in our department

- Soil sampler,
- Aerosol and iodine sampler,
- PILLE portable TL reader with CaSO_4/Dy bulb dosimeters [1],
- G'PEAK WORKSHEET computer programme for gamma spectrum evaluation [2],
- Calculation method for determining activity distribution in the ground using only spectral information of in situ gamma spectra [3],
- Automatic evaluation of in situ gamma spectra,
- MOBSYS computer programme for unified handling, recording, storing and searching of all measured data.

The dose rate meters applied in the mobile unit enables to cover a measuring range from 10^{-9} to 5 Sv/h while in case of dose meters from 10^{-6} to 1 Sv

APPLICATIONS

The mobile laboratory plays an important role in the emergency preparedness programme in the country. There is no continuous inspection at present, however in case of emergency the mobile unit will be ready to start within a few hours and can act as an essential tool for surveying the radiation conditions in the intermediate phase of the accident.

The continuous preparedness of the equipments is ensured by their frequent use in the environmental laboratory after having been removed from the vehicle. The mobile unit is intended to be applied in normal situation also for different surveying programmes ensuring the proper use of equipments in field conditions and providing training for the staff.

The improvement of the methods applied and their regular control including participation in intercomparison exercises also in international level are regarded as a necessary and important part of the emergency preparedness. A meeting of several teams operating mobile units in the Central European region /Workshop on Mobile Laboratories for Monitoring Environmental Radiation, held in Faks, Hungary in the period 16-20 September 1991/ was organized to establish a cooperation between the participating institutions and to be a base of an international network to react in emergency.

FIELD MEASUREMENTS OF THE WASHOUT COEFFICIENT FOR GAZEUS IODINE LIKELY TO
BE RELEASED ON ACCIDENTAL CONDITIONS

Field experiments were performed in Brittany to assess the washout coefficient A for molecular iodine. During each run, a few grams of nonradioactive iodine were released from a 12 meters telescopic mast, and the rain was sampled at a short distance downwind along complete transversal sections of the plume. The amount of iodine in each sample was determined by ionic chromatography to calculate the washout coefficient. In most cases, the results obtained (a few 10^{-5} s^{-1}) are not so different as expected from the theoretical values assuming a complete solubility of iodine in rain water.

INTRODUCTION

Les modèles prévisionnels de dispersion à la suite d'un rejet accidentel hypothétique utilisent habituellement pour caractériser le lavage des polluants par la pluie un paramètre A appelé coefficient de lavage. Ce paramètre, qui a la dimension de l'inverse d'un temps, représente la fraction du polluant entraînée par la pluie par unité de temps. Dans le cas de l'iode moléculaire, les valeurs de ce coefficient ont été établies de manière théorique, sur la base d'une entière solubilité de la vapeur d'iode dans les gouttes d'eau de pluie, ces dernières étant supposées se comporter comme autant de "puits" jamais saturés. Cette hypothèse théorique du gaz infiniment soluble dans l'eau de pluie peut, *a priori*, paraître exagérément majorante. En effet, le lavage par la pluie des gaz contenus dans l'atmosphère dépend de nombreux facteurs liés à la réversibilité des échanges entre phases gazeuse et liquide, aux mécanismes de mélange à l'intérieur des gouttes et aux réactions chimiques susceptibles de s'y produire. Dans le cas de l'iode moléculaire, les modèles prévisionnels actuellement utilisés dans l'hypothèse d'un accident admettent que le coefficient de distribution entre phases liquide et gazeuse est très faible (c'est à dire que les phénomènes de désorption sont négligés), ce qui autorise l'emploi du coefficient de lavage, paramètre d'une manipulation commode, mais pas nécessairement approprié pour autant lorsqu'il s'agit d'un gaz. Les modèles théoriques existants qui prennent en compte la réversibilité de l'absorption du gaz par les gouttes (Dana 1972, Hales 1973 et Kumar 1985) sont, quant à eux, trop complexes pour être utilisables dans le cadre de la prévision des conséquences d'un accident.

Par ailleurs, les seules mesures expérimentales existantes sont anciennes (Engelmann 1966), rares, et très dispersées. Elles ont été obtenues soit à partir d'une émission d'iode stable réalisée sur un pylône de 13 mètres (3 résultats), soit à partir des traces d'iode radioactif rejetées par la

cheminée d'une installation. Dans le premier cas, les valeurs du coefficient de lavage obtenues étaient comprises entre quelques 10^{-7} et quelques 10^{-6} s^{-1} , c'est à dire 1 à 2 ordres de grandeur au dessous des valeurs théoriques basées sur une entière solubilité de l'iode et correspondant aux mêmes intensités de précipitation. Dans le second cas, les résultats étaient supérieurs d'un ou deux ordres de grandeur à ces mêmes valeurs théoriques, ce qui, selon l'auteur, pourrait être dû à une captation de la vapeur d'iode sur les gouttelettes formées par condensation de la vapeur d'eau au niveau du conduit de rejet.

De nouvelles expériences *in situ*, du même type que celles réalisées en 1966 par Engelmann, mais bénéficiant des nouvelles possibilités techniques, en particulier en matière de dosage de l'iode dans l'eau, ont été réalisées par notre Laboratoire en Bretagne en 1990 et 1991.

METHODES EXPERIMENTALES

En présence de différents types de précipitations, une quantité connue (Q) d'iode stable (quelques grammes) est injectée dans l'atmosphère par un dispositif d'émission produisant de l'iode moléculaire par sublimation de paillettes. L'eau de pluie est échantillonnée sous le vent de l'émission à l'aide de collecteurs de précipitations disposés en arc de cercle de manière à englober l'ensemble de la largeur du panache, et au vent de l'émission pour déterminer la concentration naturelle en iode de l'eau de pluie. A l'issue de l'essai, les volumes d'eau (v) collectés en chaque point sont mesurés et, après filtration des échantillons sur filtres Millipore de porosité $0,45 \mu\text{m}$, les concentrations (C) en iode sont déterminées par chromatographie d'ions associée à une détection électrochimique (système Dionex), ce qui autorise une sensibilité meilleure que un ppb. Le principe de cet appareil consiste à faire circuler un échantillon de 5 ml à travers une colonne de préconcentration et à balayer cette dernière par un éluant qui entraîne l'iode vers la colonne de chromatographie. On en déduit les quantités d'iode (q) précipitées en chaque point d'échantillonnage: $q = Cv$. Lors de chaque expérience, la vitesse du vent (u) au niveau du panache, l'intensité de la pluie, son pH et sa température sont mesurés, ainsi que le spectre dimensionnel des gouttes.

Pour toute section transversale complète du panache de longueur L on peut calculer le coefficient de lavage Λ par la relation:

$$\Lambda = Wm(x) L u / Q$$

W m(x) étant la quantité moyenne d'iode déposée par unité de surface sur la bande de sol de largeur dx située à la distance x de la source et englobant la largeur totale L du panache, quantité déterminée à partir des dépôts q déterminés en chaque point d'échantillonnage du transect et connaissant la surface d'interception des collecteurs.

DEROULEMENT DES ESSAIS ET RESULTATS

Onze mesures du coefficient de lavage ont été effectuées: 3 en Octobre 1990 et 8 en Juillet 1991, (les conditions expérimentales et résultats donnés en tableau 1). Les intensités de précipitation (0,9 à 4,8 mm/h) et les vitesses de vent (2,5 à 18,3 m/s) sont représentatives des conditions les plus fréquentes sous nos latitudes. Les concentrations de l'eau de pluie en iode dans l'axe du panache doivent suffisamment dépasser le bruit de fond de l'eau de pluie pour autoriser la mesure, sans toutefois risquer de perturber le mécanisme de captation par les gouttes. Les valeurs du coefficient de lavage obtenues sont en moyenne légèrement plus élevées lorsque la concentration de l'iode dans l'eau de pluie est très

faible . Ceci nous conduit à étudier des concentrations de quelques dixièmes de ppb (la durée des essais est d'une heure), ou d'une dizaine de ppb (la durée des essais est alors réduite à 2 minutes). Le coefficient de lavage est en moyenne de $5,6 \cdot 10^{-5} \text{ s}^{-1}$ dans le premier cas au lieu de $3,1 \cdot 10^{-5} \text{ s}^{-1}$ dans le second. Il est à noter que les concentrations moyennes indiquées dans le tableau 1 sont relatives non pas à l'eau de pluie ayant traversé le panache, mais aux échantillons tels qu'ils sont collectés, plus ou moins dilués en fonction des conditions expérimentales par de l'eau de pluie reçue avant et après le passage du panache. Aucune corrélation claire n'a pu être établie entre le coefficient de lavage de l'iode et l'intensité, le pH ou la température des précipitations.

Dans le cas d'intensités de précipitation élevées, les valeurs expérimentales présentées ici sont sensiblement plus faibles que les valeurs théoriques se fondant sur un lavage irréversible (Fig.1). Par contre, dans le cas d'intensités modérées, les résultats expérimentaux obtenus peuvent, compte tenu des incertitudes expérimentales, être considérés comme une validation du calcul prévisionnel actuellement employé dans l'hypothèse d'un rejet accidentel.

Des expériences complémentaires ont montré que lors d'essais de ce type, il convenait de s'assurer que le panache ne venait pas au contact des collecteurs de précipitation, la forte réactivité de l'iode moléculaire provoquant alors un dépôt sec très important venant masquer celui entraîné par la pluie.

CONCLUSION

Dans le cas d'intensités de précipitation inférieures à 3 mm/h (fréquent sous nos latitudes) , et lorsque la concentration d'iode dans l'eau de pluie demeure très proche de la concentration naturelle préexistante, ce qui est toujours le cas dans le panache d'un rejet radioactif, les résultats expérimentaux obtenus sont peu éloignés des valeurs du coefficient de lavage adoptées dans les modèles théoriques supposant une entière solubilité de l'iode dans l'eau de pluie. Ces dernières apparaissent par contre un peu trop élevées dans le cas d'intensités de précipitation importantes.

**GREEN BELT TO REDUCE CONSEQUENCES
OF REACTOR ACCIDENTS**

V.K. Gupta and Ramesh K. Kapoor
Atomic Energy Regulatory Board
Bombay-400 094

ABSTRACT

Airborne particulate activity has high deposition velocity on grass and crops. Green trees provide very high surface area per unit volume of space. A green belt, made up of optimally spaced and selected variety of evergreen trees, can, therefore, be utilized to reduce consequences of accidents in nuclear power plants, when release of radioactive materials is at ground level. Consequences of reactor accidents giving rise to ground level release in presence of a green belt in public domain are reduced by orders of magnitude. This may help reducing magnitude of emergency preparedness planning in public domain.

INTRODUCTION

Society and individuals are subjected to a variety of risks, both natural and technological. High probability-low consequence events do not attract as much public attention as low probability-high consequence events. Since it is difficult to modify probability of natural low frequency-high consequence events, society and individuals adopt various means of reducing consequences of these events such as construction of dams for reducing consequences of floods (1). Reduction of probability of high consequence events of man-made hazards such as in commercial aviation and nuclear power industry is achieved through engineering innovations. Nevertheless low probability-high consequence events in nuclear power industry have attracted special attention of individuals and society. A green belt around a nuclear power plant substantially reduces quantity of particulate radioactive material reaching public domain. Radiation exposure to population and early and continued mortalities for a hypothetical accident resulting in large, cold, ground level release of radionuclides for a light water reactor of 1000 MWe output shows fatality upto 13 km without green belt. This distance reduces to 2 km with a green belt.

ATTENUATION MODEL FOR GREEN BELT

Pollution attenuation factor, A_f of a green belt for ground level release is given by Kapoor and Gupta (2) :

$$A_f = \frac{F_D(X_1 + X_2)}{F_D(X_1) \{ \text{erf} \{ h_e / \sqrt{2} \sigma_z(X_1) \} e^{-\lambda X_1} + \text{erfc} \{ h_e / \sqrt{2} \sigma_z(X_1) \} F_D(X_2) \}} \quad \text{---(1)}$$

Schematic of a green belt of height h and width X_2 at a distance X_1 from nuclear power plant is shown in Fig. 1. Effective height h_e , and pollution attenuation coefficient λ are obtained from reference (2), $\sigma_z(X_1)$ is computed using relationship given by Hosker (3) and F_D is obtained from reference (4). V_d for particulate radionuclides is 0.01ms^{-1} and zero for noble gases. A_f are computed using Eq.(1) for 0.7, 1.0 and 1.5 Km wide

Fig.1 Schematic of a green belt around a nuclear power plant.

green belt of height 15 m consisting of pine trees planted at 50 m away from nuclear power plant(5).

DOSE EVALUATION FROM ATMOSPHERIC RELEASES

Released radionuclides, their inventory in reactor core and release fractions are taken as maximum of all release categories of light water reactor accidents (6). These are divided into volatiles and solids and noble gases due to their characteristic deposition velocities. Radioactive plume, emerging out of containment is dispersed by atmospheric turbulence and is carried away from site by wind. Given a reactor site and an accident starting time, which in turn specify atmospheric stability category and wind speed, concentrations of released radioactivity are calculated at the midpoint of chosen spatial interval and are assumed to be uniform within the interval. Buildings and structures of nuclear power plant would produce increased turbulence in near vicinity giving time integrated concentration \bar{X} as follows:

$$\bar{X} = \frac{Q}{(1.5 \sqrt{2\pi} \sigma_y \sigma_z + c.A) \bar{U}} \quad \text{----- (2)}$$

Q is source term, \bar{U} is mean wind speed and σ_y and σ_z are calculated using reference (3) for $z_0 = 0.01$ m. Vertical spread of plume is limited by the height of mixing layer L. c and A are assumed to be 0.5 and 2500 m² respectively. Plume gets depleted due to (i) radioactive decay of radionuclides and (ii) ground deposition. Plume depletion due to radioactive decay is considered only for decay of the parent nuclide and its depletion due to ground deposition is calculated using reference (4).

EXPOSURE PATHWAYS AND CALCULATION OF DOSES

Methodology of WASH-1400 (6) for assessment of doses to various body organs is used considering exposures through external exposure due to plume; internal exposure due to inhaled radionuclides and external exposure due to contaminated ground. Doses are calculated for all the 54 radionuclides individually and are added for each of the three pathways for bone marrow, GI tract, lung and thyroid using scheme of reference(6).

Green belt around nuclear power plant modifies concentration of released particulate radionuclides. Modified concentration \bar{X}_m for distances beyond green belt is obtained by dividing \bar{X} by A_f . Doses in presence of green belt around nuclear power plant are obtained using modified concentration \bar{X}_m for particulate radionuclides. Green belt does not modify

Fig.2 : Organ doses versus distance from nuclear power plant for stability category F (A-Without green belt,B- with green belt).

X for fission product noble gases as $V_d = 0$. Calculations are performed for all six stability categories. Results are presented for category F.

RESULTS AND DISCUSSION

Variation of doses without and with green belt of width 1.5 Km to bone marrow, lung, GI tract and thyroid with distance for stability category F is presented in figures 2 A and B respectively. The reduction factor of dose to bone marrow, obtained by comparing figures 2 A and B, is 40 at 2.0 km distance. This is less than A_f since only particulate radionuclides are attenuated by green belt. Radiation exposure to bone marrow is the dominant risk of mortality. Impact of green belt on early and continued mortalities due to bone marrow exposure is presented in figure 3, where variation of mortality probability with distance from nuclear power plant for atmospheric stability category F, without and with green belt of width 1.5 Km is presented. It is seen that mortality probability is one upto a distance of about 12 km without green belt and is about 0.5 at 2 Km and at 3 km it is almost zero with green belt around nuclear power plant.

CONCLUDING REMARKS

Benefits of developing a suitability designed green belt around nuclear power plants are:

THE RADIATION RISKS OF THE ACCIDENT SPECTRUM OF THE
GREEK RESEARCH REACTOR

J.G. Kollas

Inst. of Nuclear Technology and Radiation Protection
N.C.S.R. "Demokritos"
153 10 Aghia Paraskevi, Attiki, Greece

ABSTRACT

The Greek Research Reactor is a 5MW swimming pool type reactor located within the Athens area, a large population center of 3081000 inhabitants. The consequence analysis of the reactor focuses on the risks stemming from reactivity, coolant flow blockage, and loss of coolant accidents. Individual doses are estimated to a distance of 20km from the reactor site. Collective exposure and latent health effects for the inhabitants of the region are also calculated.

INTRODUCTION

The Greek Research Reactor (GRR) is an open pool type, light water moderated and cooled reactor with MTR type fuel elements, currently fueled with enriched uranium, that contains about 93% of U-235. GRR is located on the edge of the Athens larger area, about 10km from the city center, an area that concentrates more than three millions inhabitants.

The safety analysis⁽¹⁾ of GRR is based on the study of its response to postulated disturbances in process variables, and to postulated malfunctions, equipment failures, and operator errors. Four general groups of accidents are considered in the safety analysis report, namely loss of flow accidents, reactivity accidents, loss of coolant accidents, and minor accidents. The accident consequence estimations were performed using a PC version of CRAC.IPTA, a code that is based on the CRAC2 code⁽²⁾.

THE ACCIDENT SPECTRUM OF GRR

The first category of accidents considered in the safety analysis of GRR, includes accidents that cause a decrease of the removal rate of the heat produced in the reactor, such as primary pump failures, valve failures, partial flow blockage to fuel assemblies, loss of flow in the secondary cooling system, etc. Of all the accidents in this group the one with the potentially worst consequences is a coolant flow blockage accident (CFBA), that would cause a 50% failure of six fuel elements⁽³⁾. The assumptions concerning the releases into the environment from this accident are the following⁽³⁾: (a) 100% of the noble gases, 50% of iodines, and 1% of all other fission products of the melted fuel are released into the pool water, (b) 100% of the noble gases, and 10% of the remaining fission products in the pool water are released into the reactor building, (c) 100% of the noble gases, 10% of iodines, and 5% of the particulates in the reactor building are released into the environment

through the system of absolute and activated charcoal filters, (d) the release to the environment occurs through the reactor stack with an effective height of 50m, and lasts for ten hours. Such an accident has already occurred in similar reactors, and it is considered as the most serious realistic accident that could potentially affect GRR.

The second group of accidents includes accidents that involve a sudden increase in reactivity, such as maximum startup accidents, reactivity insertion accidents, excursions following the decay of a Xe-135 transient, loading accidents, control rod failures, etc. The most serious accident in this category is the maximum reactivity insertion accident (MRIA), that would cause the melting of less than 2% of the reactor core. The assumptions concerning the associated release of radioactive substances into the environment are similar to those of the CFBA.

The third group includes accidents that cause a loss of coolant, that might occur after such events as the rupture of the pool wall, the failure of an experimental beam tube or the thermal column, and most importantly the rupture of the primary cooling system. This last case involving the guillotine break of the largest pipe of the primary system defines the design basis accident (DBA) of GRR, a postulated loss of coolant accident that limits the potential risk to the public from any credible accident and for which the engineered safety features of the reactor are designed. The following assumptions apply to the DBA⁽⁴⁾: (a) 20% of the reactor core melts, (b) 100% of the noble gases, 50% of iodines, and 1% of all other fission products of the melted core are released into the environment, (c) the release into the environment occurs through leaks in the reactor building at ground level.

The fourth category includes accidents that have a minor impact, and do not lead to substantial releases that would affect adversely the general public. Such accidents are a fuel element cladding failure, the loss of ventilation in beam tubes and thermal column, the loss of primary electric power, etc. Since the consequences of such accidents are trivial they are not considered in the analyses performed.

RADIATION RISKS

The spectrum of accidents of GRR is delineated, as far as the consequences to the Athens population are concerned, by the three accidents CFBA, MRJA, and DBA, that are representative of the first three categories described previously. These consequences stem from both early exposure, i.e. direct irradiation by the passing cloud, exposure from inhaled radionuclides, and exposure to radioactive material deposited onto the ground, and chronic exposure, i.e. long-term groundshine from contaminated ground and inhalation of resuspended particles. Individual doses and cancer risks are estimated to a distance of 20km from the reactor site. Collective exposure and latent health effects for the inhabitants of the region are also calculated. The results are presented as dose curves for exposed individuals vs. distance from the reactor, or as complementary cumulative

Fig 1 Acute Bone Marrow Dose vs Distance from Reactor

Fig 3 Whole Body Collective Dose CCDF

Fig 4 Whole Body Latent Effects CCDF

Table 1. Summary of number of latent effects - Total exposure

Effect	Mean Values			Peak Values		
	DBA	CFBA	MRIA	DBA	CFBA	MRIA
Whole body	1.28	0.0461	0.0092	20.5	0.864	0.180
Thyroid	37.2	0.289	0.0568	672	5.85	1.21
Leukemia	0.27	0.0093	0.0019	4.33	0.177	0.037
Lung	0.45	0.0084	0.0017	7.59	0.158	0.033
Breast	0.30	0.0112	0.0022	4.80	0.209	0.044
Bone	0.12	0.0037	0.0007	1.90	0.071	0.015
GI tract	0.10	0.0038	0.0008	1.63	0.070	0.015
Other	0.31	0.0113	0.0023	4.88	0.213	0.044
<u>WB collective exposure (Sv)</u>	81.1	2.92	0.582	1300	54.7	11.4

distribution functions (CCDFs) for collective exposure and health effects. The consequences of these accidents for the 3081000 inhabitants of the larger Athens area are presented in Figs. 1-4. Furthermore Table 1 presents a summary of the latent health effects that result from the total exposure of the Athens population.

CONCLUSIONS

The results presented in the previous section indicate that the consequences of the CFBA and the MRIA are negligible in comparison to the consequences of the DBA, being on the average about two orders of magnitude smaller.

It is important to note in Table 1 the small magnitude of the health effects associated with the realistic CFBA and MRIA, which amounts on the average to a very small fraction of an event, while even their peak values do not constitute any significant impact.

ABSTRACT

Strontium 90 concentration in human breast milk - collected in Rome from May 1986 to December 1988 - was measured. The EPA recommended method was set up, with some modifications. Concentrations range from the lower limit of detection ($5-16 \text{ mBq}\cdot\text{kg}^{-1}$) to $58 \text{ mBq}\cdot\text{kg}^{-1}$. The committed effective dose from Sr-89 and Sr-90 to breast-fed infants, calculated utilising well-defined hypotheses, was in the order of $3 \mu\text{Sv}$.

INTRODUCTION

Research on radioactive caesium in human milk due to the Chernobyl fallout has been conducted in Italy since May 1986. Gamma spectroscopic measurements with high purity germanium detectors were made from May 1986 to December 1988 on pooled samples (from 5 to 10 nursing mothers in the first week after delivery)(1) and in 1989 on samples from individual women in a planned ad hoc study(2).

Caesium transfer factor from a mother's diet to her milk was assessed in both situations. The values agreed with the result obtained during the fallout period in the sixties - due to weapon tests - and with other values published after 1986 (see discussion in ref.2). Caesium 137 was studied in greater detail because in the post-Chernobyl environmental contamination of Western European countries it appeared at the time to be the most significant radionuclide(3).

On the other hand, strontium 90, the most significant radionuclide in the fallout period of the sixties, was fortunately quite low in the post-Chernobyl period: in Italy the Cs-137/Sr-90 ratio ranged from some hundreds to some tens. For this reason and because measurements are more complex and take more time, there is little environmental and human data available on strontium 90 after the Chernobyl accident. Therefore, in 1990 the authors decided to set up an experimental radiochemical procedure to measure strontium 90 concentration in the samples of human milk collected.

There were also other aims: i) to set up for the first time this experimental capacity in the Istituto Superiore di Sanità (National Institute of Health); ii) to gain experience in this experimental practice in order to promote it in environmental radioactivity laboratories set up in each Administrative District(4); iii) to evaluate the zero level of Sr-90 in human milk in case of possible future accidents.

EXPERIMENTAL METHOD

In order to separate Sr-90 in human milk samples the method recommended by the EPA(5) for milk was chosen. The method consists of fixing on a ionic exchange resin both strontium and barium present in human milk. Calcium in milk is first complexed with EDTA to avoid its taking the place of the two other chemical species on the resin. Both barium and strontium are removed by a concentrated solution of sodium chloride. The former is separated manually by taking advantage of its capacity to precipitate as a chromate. Strontium is recovered as a carbonate.

The method had to be adapted to 0.4-0.5 liter samples and in order to get good and reproducible yields, the following modifications to the original procedure were necessary.

i) The procedures require adjusting the milk pH value to 5.2, before fixing it on the ion exchange resin with ammonia. Samples studied always showed a lower acid content and therefore, the pH correction had to be made with acetic acid.

ii) The barium separation as chromate was repeated twice (instead of once) because in this way both a purer strontium carbonate and a higher yield of the Sr/Ba separation were obtained.

iii) The duration and velocity of centrifugation were increased: the former was doubled, the latter was changed from 2000 to 3000 r.p.m..

The improvements obtained by means of these modifications were tested with the atomic absorption spectrophotometry technique(6).

The Sr-90 measurements were taken with a gas flow α/β proportional counter with low background (<1 cpm), consisting of four detectors with ultra-thin windows ($260 \mu\text{g}/\text{cm}^2$), plus one guard detector, shielded by 10 cm of lead. The beta plateau is ≥ 200 volt with a slope $< 2.5\%$. The efficiency of the detectors was determined with Y-90 and Sr-90 filter sources, prepared with EPA methodology for standard sources, with the same geometry of the samples. The efficiency was found to be $> 45\%$ for Y-90 and $> 40\%$ for Sr-90. Both sources were monitored until Y-90 was either completely decayed or fully grown. On the Y-90 source this also permitted a check on the Sr/Y yield.

EXPERIMENTAL RESULTS

The filters obtained after the strontium separation in the samples were measured after having reached the Sr/Y equilibrium (that is after a minimum of 20 days). This allowed the filter to be counted over long periods (18-23 hours), thus reducing the high statistical error due to the very low activity of the samples.

The Sr-90 concentration in the pooled samples in the Rome area from May 1986 to December 1988 is shown in Figure 1. About 10 samples were found to be lower than or equal to the lower limit of detection(5) (in the range of $5-16 \text{ mBq}\cdot\text{kg}^{-1}$ depending on the experimental condition of each separation and count). The highest value was found in a 1986 sample equal to $58 \text{ mBq}\cdot\text{kg}^{-1}$. The concentrations are given as $\text{mBq}\cdot\text{kg}^{-1}$ because the determination of the sample weights could be made with a smaller error. However, the mean density of the samples resulted to be $1.02 \text{ kg}\cdot\text{l}^{-1}$.

It is not possible to know if the measured Sr-90 concentrations in human milk are due only to Chernobyl fallout, because no data was available on Sr-90 concentration in Italian human milk in the eighties before the accident. On the other hand, in the same years data was available on Sr-90 concentrations in cow's milk due to previous fallout.

The EPA radiochemical method also allows Sr-89 concentration to be determined by counting the filters a second time after 6-7 days. In this case, Sr-89 had already decayed due to the time that elapsed between sampling and counting.

Fig.1 Sr-90 concentration in pooled breast milk samples from Rome over the period from May 1986 to December 1988. The measured values are given with one standard deviation, the LLDs at 95% C.L.

The dose from Sr-90 to breast-fed infants was calculated assuming a four-month breast-feeding duration and a milk ingestion rate of $0.7 \text{ l}\cdot\text{d}^{-1}$. Dose conversion factors calculated by the NRPB(7) in the light of the new ICRP Recommendations were used. Even if Sr-90 concentration had been constant for the first four months after the accident at the highest level measured, the committed equivalent dose to bone surface in the infant would have been equal to $14 \mu\text{Sv}$ and the committed effective dose to about $1.3 \mu\text{Sv}$.

In order to estimate the effective dose from Sr-89, the Sr-89/Sr-90 ratio was assumed equal to 10 as it ranged approximately from 15 to 5 in Italy during May 1986(8). In the same hypotheses used for the calculation of the dose from Sr-90, the committed effective dose to breast-fed infants from Sr-89 was assessed in the order of $1.5 \mu\text{Sv}$ in the first four months after the Chernobyl accident.

These doses are negligible and the effective doses are even lower than that previously calculated for Cs-137 in the same samples (see ref.1). Such low doses to infants could also be related to the ban on the consumption of cows' milk and leafy vegetables for pregnant and nursing women and children under ten imposed in Italy in May 1986.

Finally, by using the values of Cs-137 concentrations previously measured in the same samples(1), the Cs-137/Sr-90 ratio in 1986 was calculated. The range obtained for this ratio is compared with those measured in cow's milk in some Italian Districts(8,9) in Table 1.

Table 1. Strontium 90 concentration and Cs-137/Sr-90 in human milk and in cow's milk in some Italian Districts (1986).

District	Sample	Sr-90 (Bq.l ⁻¹)	Cs-137/Sr-90

The Implication of ICRP Publication 60 for Nuclear Power Plants

R. Hock
Siemens AG, Offenbach, Germany

Abstract

The potential consequences of ICRP Publication 60 for the design and operation of nuclear power plants were investigated. Collective doses for plant personnel and maximum doses for members of the public are already so low particularly in plants of recent design that the increase in risk factors will not require additional protective measures according to the ALARA principle. The new limit for the individual occupational dose accumulated during 5 calendar years may require additional surveillance with respect to a few persons. The evaluation of the design of protection of the public against accidental exposures according to the new criteria needs further discussion.

ICRP Publication 60 contains a large number of basic changes in comparison to Publication 26. The most important change in principle is the requirement to include "probabilistic" exposures in the evaluation according to the three principles: justification, optimization and individual limits.

With respect to justification, this would require a new evaluation in which radiological hazards from planned operation and from potential accidents are both taken into account. By contrast, the optimization of protection against accidents and the not yet defined limits for the individual risk caused by potential accidents could be evaluated separately.

An upper bound for the occupational risk caused by accidental exposures can be estimated from operating experience. With respect to critical groups outside the plant (next neighbours) such data cannot be obtained from past experience. The existing methodologies used for probabilistic safety assessments have to be developed further to obtain such data. These can then specifically be used for the optimization of protective devices against accidents under the constraints of individual risk limits.

Whereas the extension of the radiation protection principles to include probabilistic exposures needs further methodological work the other changes contained in ICRP 60 brought can be applied immediately. The major ones of this category are the new risk factors and new individual limits with respect to normal plant operation.

If safety measures would be designed exactly to the optimum, increased risk factors would require additional measures according to the ALARA principle. Fortunately this is not the case. Older designs have been investigated many years ago and shown to be ALARA /1-4/. These analyses were based on much higher collective exposures than applicable today.

The trend of collective occupational exposure in nuclear power plants designed by SIEMENS is shown in Fig.1. Two conclusions can be drawn: Firstly, more recent designs feature much lower collective exposures and, secondly, at plants of older design - with generally higher collective exposures - exposures could be reduced by additional control and added protective devices. Any decrease in radiation exposure reduces the need for protection if the optimization criterion is applied. Therefore, a high degree of overprotection exists.

The influence of design improvements is shown even more clearly in Fig.2, where plants of the same size are compared on the basis of

their service lives.

It is evident that these improvements are much larger than the increase in risk factors from ICRP 26 to ICRP 60. We can conclude that despite the new risk factors we are still well on the safe side of the optimum. At this low level of exposure additional protective measures will have such a low return in terms of reduction of exposure that it is unlikely that even increased risk factors would balance out the cost.

The same is true with respect to collective exposures of the public. A measure for this exposure is the release of radioactive substances to the environment. As an example the radioactive liquid effluents (other than tritium) and the release of aerosols and gaseous iodine compounds are shown in Fig.3. The curves represent the overall tendency for the average of all plants built by SIEMENS. Individual plants sometimes deviate from that averaged long-term curves. In order to evaluate the safety margin with respect to the limits we calculated the hypothetical exposure of an individual assumed to stay permanently as a self-supplier at the most unfavourable location outside the plant boundary. A water flow rate which is typical for fairly small rivers at which some nuclear power stations are situated in Germany has been chosen for this evaluation. It turns out that the resulting exposure is below the new ICRP limits by several orders of magnitude. Additionally one has to keep in mind that the exposure of an average member of a critical group would be much lower than the exposure of the hypothetical person assumed for these calculations.

We have also evaluated the distribution of individual exposures of plant staff as a function of plant design and years of operation. An example of these evaluations is given in Fig.4 for a third generation BWR. Whereas the peak exposure has been one half of the limit for a single year in 1986 it decreased to only one fifth in 1990.

A more critical point is the new limit for five calendar years. Although this limit is not to be applied retrospectively a retrospective evaluation may show to what degree additional measures may be necessary in the future.

Figs.5 and 6 give examples of such evaluations: There is a limited number of people who may exceed the new limit in plants of older design, if no additional measures are taken. It is evident that the necessary reduction in peak individual dose is so low that it can be obtained by administrative means only. Job rotation will probably not even be necessary for the most exposed persons.

ASSESSMENT OF THE FEASIBILITY OF COUNTERMEASURES ASSOCIATED WITH THE RELEASE OF PLUTONIUM AFTER AN AIRCRAFT ACCIDENT.

SUMMARY

The air transport of radioactive materials has a very low accident risk (1000 times lower per kilometer than road) but potentially severe consequences. It is necessary to use reinforced packages. This communication examines the consequences of a severe accident to see what quantities released could be acceptably controlled. The example here is PuO₂ from reprocessed PWR fuel. Several criteria are taken into account (stochastic and non-stochastic effects, evacuation, decontamination). A value between 10 and 100 g of PuO₂ is the maximum limit for a "manageable" release. If a package has a capacity for greater quantities, more resistant packaging should be considered. The IAEA regulation is being modified ; the maximum considered quantity per package will be in the order of 20 g.

I INTRODUCTION

Le transport aérien des matières radioactives est l'objet d'un examen depuis cinq ans par l'Agence Internationale de l'Energie Atomique. La France a contribué à ce travail par la réalisation d'une étude [1] visant à savoir à partir de quelle quantité transportée un colis devrait répondre à des contraintes plus strictes que celles qui sont requises aujourd'hui. Le travail a consisté à passer en revue les divers types de conséquences d'un rejet et à juger à partir de quand la situation cessait d'être maîtrisable. Le produit étudié était le mélange d'oxyde de plutonium de retraitement.

II EVALUATION DES EFFETS SANITAIRES. L'IMPACT LIE A UN REJET ACCIDENTEL DE PuO₂

Partant d'un terme source lié à la défaillance mécanique ou thermique du colis, un modèle de diffusion atmosphérique a été utilisé pour évaluer l'impact sanitaire d'un rejet de PuO₂ suite à un accident d'avion. L'impact lié au passage de la bouffée initiale, et celui lié à la fraction déposée au sol ont été estimés séparément.

L'oxyde de plutonium considéré correspond au mélange isotopique issu du retraitement (combustible PWR irradié à 33 GWj/t, puis stocké 3 ans). Un pseudo "seuil de mortalité" doit être associé aux effets stochastiques dus à une incorporation de PuO₂ : 0,05 mg inhalé pour une poudre de 1 µm de diamètre ou 0,25 mg inhalé pour une poudre de 10 µm. L'équivalent de dose efficace engagé sur 50 ans est alors de 100 Sv; le dépassement de cette dose conduirait selon la CIPR [2] à une probabilité de décès par cancer radio-induit dépassant l'unité.

L'analyse des effets aigus lié à l'inhalation du plutonium a montré qu'ils ne se produisaient que pour des quantités inhalées supérieures au seuil précédemment indiqué, à savoir (pour une poudre de $1 \mu\text{m}$ de diamètre) :

1,8 mg inhalé : œdème pulmonaire en 1 mois

0,25 mg inhalé : fibrose entre 1 et 5 ans [3].

Ces quantités inhalées correspondent à des engagements de doses efficaces sur 50 ans de respectivement 3000 et 500 Sv.

Ces valeurs extrapolées de l'animal sont évidemment à considérer avec prudence. Pour fixer un ordre de grandeur, le seuil correspondant à l'apparition de fibroses a été retenu, ceci pour le passage de la bouffée atmosphérique. En supposant une densité de population autour de l'accident de 100 habitants par km^2 (valeur moyenne en France), on obtient alors les résultats indiqués sur le **tableau 1**. 1 kg de PuO_2 rejeté pourrait provoquer 5 fibroses pulmonaires.

Tableau 1 : Nombre de personnes susceptibles de présenter un effet aigu (fibrose pulmonaire) lors du passage de la bouffée initiale pour des conditions de diffusion normales et faibles (poudre de $1\mu\text{m}$).

Quantité rejetée (g)	Diffusion faible (vent= 1m/s)			Diffusion normale (vent= 1m/s)		
	Distance (m)	Surface (m^2)	Nombre de personnes	Distance (m)	Surface (m^2)	Nombre de personnes
10	25	210	ϵ	13	70	ϵ
50	73	1610	0,2	34	400	ϵ
100	115	3790	0,4	50	860	0,1
500	300	24400	2,4	130	4950	0,5
1000	430	50400	5	190	10500	1

Le délai de passage de la bouffée initiale est très bref. Ainsi, pour une vitesse de vent faible (1 m.s^{-1}) et un rejet de 100 g, les personnes exposées entre 50 et 500 mSv seraient touchées une demi-heure à une heure après l'accident, délai trop bref pour qu'une quelconque mesure puisse être prise, même le confinement.

Le risque d'inhalation lié à la bouffée initiale est le risque prépondérant, mais celui lié à la remise en suspension n'est pas négligeable pour un résident de la zone contaminée. Le risque d'ingestion lié à la contamination de la chaîne alimentaire reste faible au regard des deux précédents. Les hypothèses de calcul pour la contamination des aliments sont : une contamination du sol ($0,37 \cdot 10^6 \text{ Bq.m}^{-2}$), d'où proviendrait l'ensemble des aliments ingérés par une personne en une année.

La contamination du sol liée au dépôt a été estimée par le programme Batex [4]. Pour une vitesse de dépôt sec de 1 cm.s^{-1} et en l'absence de pluie, une quantité rejetée de 1 kg impliquerait une contamination du sol de $3,7 \cdot 10^6 \text{ Bq.m}^{-2}$ sur 8 km^2 ; de $0,37 \cdot 10^6 \text{ Bq.m}^{-2}$ sur 40 km^2 ; ... Le taux de remise en suspension retenu pour cette étude est celui estimé par le NRPB et repris par l'AIEA, soit 10^{-6} m^{-1} . Le **tableau 2** compare l'impact de chaque voie de transfert en prenant comme indicateur la surface à l'intérieur de laquelle les habitants auraient une dose d'au moins 50 mSv. Ainsi, pour une

densité de 100 hab.km⁻² et un rejet de 100 g, 700 personnes recevraient un engagement efficace de dose sur 50 ans supérieur à 50 mSv, dose uniquement liée au passage de la bouffée initiale. La remise en suspension seule n'impliquerait que 250 personnes à des doses supérieures à 50 mSv et la contamination par la chaîne alimentaire ne toucherait que 6 personnes à de telles doses.

Tableau 2 : Surfaces exposées à plus de 50 mSv pour chacune des voies de transfert, en fonction de la quantité rejetée.

Quantité rejetée (g)	Surface (km ²) exposée à une dose ≥ 50 mSv liée à :		
	bouffée initiale	chaîne alimentaire	remise en suspension
1	0,1	ε	ε
10	1	ε	0,3
100	7	0,06	2,5
1000	40	0,55	15

III LES MESURES DE PROTECTION

Le but des mesures de protection est de réduire les doses à la population. Certaines sont à court terme (évacuation, confinement, informations, ou conseils à la population). D'autres mesures à plus long terme visent la réhabilitation des sols (décapage, nettoyage, fixation des produits radioactifs, stockage,...). Pour la bouffée initiale, des mesures sont peu plausibles car il n'y a pas de délais d'alerte. Au vu des effets liés à la remise en suspension du PuO₂, des seuils de concentration ont été établis sur la base de la CIPR 40 [5] et du retour d'expérience d'accidents passés (comme celui de Palomarès). Les valeurs ci-dessous correspondent au centre de la fourchette recommandée par la CIPR (50 à 500 mSv pour l'évacuation). Le but de cette étude est en effet, non pas de définir une politique d'intervention, mais d'examiner l'ordre de grandeur des difficultés logistiques.

Pour la population :

- Evacuation au-delà de 7,4 10⁶ Bq.m⁻² (300mSv.an⁻¹)
- Confinement au-delà de 0,74 10⁶ Bq.m⁻² (30mSv.an⁻¹)
- Conseils à la population au-delà de 0,74 10⁴ Bq.m⁻²
- Rien en-deçà de 0,74 10⁴ Bq.m⁻² (0,3mSv.an⁻¹)

Pour l'environnement :

- Fixation et décapage au-delà de 0,74 10⁶ Bq.m⁻²
- Labour profond au-delà de 0,074 10⁶ Bq.m⁻²
- Rien en deçà de 0,074 10⁶ Bq.m⁻² (3mSv.an⁻¹)

L'application de ces mesures de protection entraîne des coûts, des doses aux intervenants, des quantités de déchets, ... Le **tableau 3** indique en fonction de la quantité rejetée, les surfaces atteintes et le volume des déchets associés. 1 kg de PuO₂ rejeté impliquerait 1,5 10⁶ m³ de déchets. Pour information, la capacité du site de stockage de Soulaines (France) est de 10⁶ m³.

Tableau 3 : Impacts liés à la restauration des sols.

Quantité relâchée dans l'atmosphère	Surface à décaper (5 cm d'épaisseur à retirer) km ²	Surface à traiter (lavage, épandage de produit piégeant le Pu) km ²	Volume de déchets (associés au décapage) m ³
1 g	0,06	0,5	3 10 ³
10 g	0,5	4,5	2,5 10 ⁴
100 g	4,5	25	2,5 10 ⁵
1000 g	25	90	1,5 10 ⁶

IV CONCLUSION

Afin d'augmenter l'efficacité de la mise en place des mesures de protection, il serait utile d'effectuer un suivi particulier de l'avion en cours de vol pour augmenter la rapidité d'intervention en cas d'accident.

Le réalisme du recours à des mesures de protection dépend étroitement de la quantité rejetée. Les effets aigus pour un rejet 1000 g resteraient limités. Des dépassements de dose de 0,5 Sv pourraient s'observer à partir d'un rejet de 1 g; pour 100 g plusieurs dizaines de personnes pourraient être concernées. Des évacuations de population pourraient avoir lieu à partir d'un rejet de 100 g, elles concerneraient alors une surface de l'ordre du km² ce qui semble encore gérable. La réhabilitation des sols pourrait demander quelques jours à quelques semaines pour un rejet de 10 g. A partir de 100 g de rejet, malgré un impact sanitaire limité, le volume des déchets est difficilement acceptable.

Compte tenu de ces valeurs, les résultats de l'étude montrent qu'un rejet maximal de 10 à 100g de PuO₂ apparaît comme gérable en zone rurale et juste tolérable en zone urbaine dans la mesure où les capacités logistiques risqueraient d'être saturées. A ce jour, l'AIEA a établi un projet de réglementation [6], le seuil retenu pour les colis renforcés (colis "C") a été fixé en termes génériques à une valeur qui correspond à une vingtaine de grammes de ce mélange.

FREE RADICAL MEASUREMENT IN BIO-ORGANIC SUBSTANCES USING AN ELECTRON SPIN RESONANCE TECHNIQUE

C.L. Greenstock and A. Trivedi
Health Sciences and Services Division, AECL Research
Chalk River Laboratories, Chalk River, Ontario, Canada

ABSTRACT

Electron spin resonance (ESR) is a simple, rapid and reliable method to measure absorbed doses in tissue-equivalent bio-organic substances, particularly amino acids and sugars or biological samples such as teeth, nails, hair and bone, as well as items of clothing, jewellery, medication or confectionery. In this capacity ESR represents a useful adjunct to existing dosimeters in cases of retrospective monitoring of radiation accidents, inadvertent radioactive releases or contamination and other emergency or operational situations. Studies have been performed to establish the dose and dose-rate responses, energy dependence, minimum detectable dose limit, post-irradiation stability of the ESR signal, and the practical limits of sensitivity, reproducibility and quantitation.

INTRODUCTION

Free radicals formed by irradiation are trapped in solids, and their number is proportional to the absorbed dose. ESR signals from bone, teeth, nails and hair have been used in biological dosimetry to estimate the absorbed dose in the human body, but poor sensitivity, stability and reproducibility have limited their application (1). An alternative approach is to study the ESR signals in tissue-equivalent substances or man-made items generally found associated with or in close proximity to humans, which can act as surrogates in emergency dosimetry for estimating human exposure (2). We have studied the ESR spectrometry of irradiated sugars and compared their response with other bio-organic substances and biological samples.

EXPERIMENTAL METHODS

Various irradiated samples (200-300 mg) were placed in a quartz tube (4 mm ID) and exposed to microwaves (10 mW power) at an X-band frequency (9.6 GHz) inside a microwave cavity between the poles of an electromagnet (330 mT field), in a Varian E-109 spectrometer, and the ESR spectrum determined by scanning over a field range of 3.3 ± 0.01 mT.

The ESR machine was calibrated daily against strong pitch, and the ESR signals from irradiated samples were measured against an internal reference spectrum of Mn^{2+} ($7.7 \mu\text{mol L}^{-1}$ solution sealed in a 1 mm ID quartz microtube). Signal strengths were determined either as peak-to-peak heights or as areas under the second-derivative curve, and

by taking the average of at least three measurements per experiment, an estimated precision of $\pm 10\%$ is obtained.

RESULTS AND DISCUSSION

Most forms of radiation dosimetry have limitations (3,4) for retrospective estimates of accidental (acute) or occupational (chronic) exposure. Biological and biochemical indicators (5) show some individual variability and fluctuations in the lack of a reliable base-line reference point prior to irradiation; most changes are short-term with indeterminate time-dependent responses. Cytogenetic methods are quite sensitive but require specially trained and highly skilled operators to perform the complex analyses (5).

The remaining methods are biophysical and include ESR dosimetry (1), lyo- and thermo-luminescence(6), spectrophotometry, densitometry and radiography (Table 1). Excluding LiF crystals and sensitive X-ray film, which would not normally be present at the scene of an accident prior to irradiation, emergency dosimetry must often rely on commonly available materials or readily obtainable biological samples, and ESR dosimetry is the only technique that can be used with such a wide range of materials (1,5).

Table 1: Biophysical Dosimetry

Sample	Method*	Dose Range Gy
Amino acids	ESR	1-10 ⁵
Sugars	ESR	1-10 ⁵
Amino acids	Lyoluminescence	10-10 ⁶
Sugars	Lyoluminescence	10-10 ⁶
LiF	Thermoluminescence	10 ⁻⁵ -10 ⁵
Plexiglass	Spectrophotometry	10 ³ -10 ⁶

* Precision $\pm 5\%$.

Biological samples suffer from irreproducibility, and consequently we have concentrated on universally available tissue-equivalent granulated table sugar (sucrose) as a suitable material (2). The ESR signals obtained following irradiation are simple, stable and reproducible, with a lower limit of detection of ~ 0.5 Gy, a linear dose response up to very high doses ($\geq 10^4$ Gy), independent of dose-rate and photon energy. This, combined with the universal application of ESR dosimetry to foodstuffs, human samples and bio-organic substances (Table 2), the ease of collecting and handling samples, their post-irradiation signal persistence and stability (Table 3), and the straight forward and rapid non-erasive measurement capability, make ESR a useful biophysical dosimeter for a variety of radiation applications including radiation processing,

polymerization and vulcanization of rubber, waste treatment, food irradiation, sterilization of medical supplies as well as for emergency dosimetry.

Table 2: ESR Signals from Irradiated Biological and Bio-organic Samples*

Category	Sample	Signal Intensity.g ⁻¹	Relative Sensitivity
Grains and spices	Flour-bleached	0.07	0.0
	Rye	3.70	0.05
	Wheat	4.35	0.05
	Popcorn	8.14	0.09
	Cinnamon	3.75	0.05
	Pepper-black	8.73	0.10
	Rice-long grain	6.69	0.07
Biological samples	Teeth-crushed	22.65	0.25
	Human finger nails	50.09	0.59
	Human Hair } black } grey	53.00 42.78	0.59 0.48
Bio-organic samples	Sugar-granulated	77.27	0.86
	RTV+ bound	89.89	1.00*
	Placebo	150.12	1.73
	Alanine-paraffin pellet	157.65	1.75

*10 Gy absorbed dose.

+Signal normalized to Dow Corning RTV Silicone pellets containing sucrose.

CONCLUSIONS

ESR spectrometry can be used as a biophysical dosimeter to measure absorbed doses ≥ 0.5 Gy in bio-organic substances (alanine, glucose) and biological samples (hair, nails). The ESR signals are directly proportional to absorbed dose, independent of dose-rate and photon energy (50-1250 kV), and stable for long periods after irradiation.

Table 3: ESR Dosimetry Using Biological and Biochemical Indicators.

Indicator System	Target Organs	Bioassay Site	Dose Range Gy	Time Period of Applicability After Exposure
Hair	whole-body partial body	hair	1 - 4	days/weeks
Nail	partial body	nail	1 - 4	days
Tooth	whole-body oral cavity	tooth enamel	0.5 - 5	years
Bone	whole-body	bone	0.5 - 5	years
Sugar Crystal	-	-	≥ 0.1	months
Organic Molecule (alanine)	-	-	≥ 0.1	months

TISSUE EQUIVALENT PROPORTIONAL COUNTERS
IN HEALTH PHYSICS

ABSTRACT

The ICRP new standards put electronic dosimeters forward, especially in the case of neutrons. Proportional counters are an attractive solution : they are able to separate n doses and gamma doses and to give dose equivalents. The microscopic simulation of their gas gain makes it possible to achieve a global understanding of their mechanism. The main objective is to design an individual dosimeter. In this prospect, it is interesting to use a multicellular cathode in front of an anodic wire set, the expected sensitivity being 15 times higher as that of an ortho-cylindrical counter of a similar size. A monocellular prototype is in a preliminary step of development.

INTRODUCTION

Longtemps, la dosimétrie individuelle s'est satisfaite de dosimètres passifs. La situation était telle que les grands organismes de recherche diminuaient progressivement leurs travaux dans ce domaine, considéré comme au point. Le rapport ICRP n° 60 a bouleversé les données : le passage à 0,1 sievert pour cinq ans constitue une réduction des limites pour les travailleurs permanents (catégorie A) d'un facteur de 2,5 ; parallèlement, le facteur de qualité des neutrons est multiplié par un facteur 2 environ. Pour les neutrons, les limites actuelles de détection devront être réduites d'un facteur cinq et plus [1] : les dosimètres passifs sont d'une sensibilité insuffisante.

PROGRESSION DE LA DOSIMETRIE "ACTIVE"

Il faut se tourner vers les détecteurs électroniques. Ils sont employés depuis longtemps dans la surveillance de zone, mais la miniaturisation de l'électronique associée leur ouvre la voie de la dosimétrie individuelle. Deux systèmes sont en concurrence : les dosimètres électroniques à diode (par ex. la "DOSICARTE") et les compteurs proportionnels à milieu équivalent au tissu. Les domaines

d'emploi sont différents : la dosicarte excellerait pour les photons ; par contre, il sera difficile de discriminer la part des neutrons dans un bruit de fond gamma important. Par ailleurs la sensibilité aux neutrons est insuffisante.

INTERET DES COMPTEURS PROPORTIONNELS MICRODOSIMETRIQUES

a) Ils donnent le spectre différentiel de l'énergie linéaire $y(dy)$ en fonction de y (figure 1) : en fixant un seuil, on sépare ainsi les composantes neutrons et photons.
 b) On déduit d'un tel spectre le facteur de qualité moyen, donc l'équivalent de dose. En effet : $D = \int d(y)dy$, $d(y)$ étant la dose venant des particules dont l'énergie linéaire est comprise entre y et $y + dy$; $H = \int d(y)q(y)dy$, $q(y)$ étant identique à la courbe $q(L\infty)$ en identifiant y à L (transfert linéique d'énergie).

Figure 1 : Structure du spectre microdosimétrique $y(dy)$ en fonction de $\log y$ dans un champ mixte ($n + \gamma$).

LE PASSE : LA DOSIMETRIE DE ZONE

Les premiers compteurs équivalents au tissu biologique ont été réalisés par H. H. ROSSI [2]. On s'efforce de simplifier les structures et de rendre les résultats aussi reproductibles que possible. Il y a des réalisations industrielles, mais il s'agit toujours de compteurs de volume assez important, non portables. Le détecteur CIRCE (Fontenay-aux-Roses) pour le spatial est intéressant, mais d'un prix trop élevé pour la radioprotection.

LE PRESENT : SIMULATION COMPLETE DU GAIN DU COMPTEUR

Pendant longtemps, on a calculé le gain par des formules analytiques supposant une situation d'équilibre [2].

L'intervention d'un groupe spécialisé dans les décharges dans les gaz a permis une simulation microscopique précise dans une situation de non équilibre [3]. On domine totalement le fonctionnement des remplissages gazeux à base de méthane et de propane, entre autres.

L'AVENIR : LA REALISATION D'UN DOSIMETRE INDIVIDUEL

On sait réaliser le remplissage gazeux optimal. Reste la structure du détecteur lui-même. Des essais ont été effectués par la Société Merlin-Gérin ; le compteur de la figure 2 est un prototype de volume important ; les difficultés de passer à un petit volume se sont avérées redhibitoires [4].

Figure 2 : Le compteur Merlin Gérin. Le volume sensible est un orthocylindre de 32,5 mm de diamètre. 1 : aluminium, 2 : plastique équivalent au tissu, 3 : isolant.

La réduction de sensibilité, accompagnant la réduction des dimensions conduit à envisager une géométrie plus complexe : il faut augmenter la surface d'échange entre les parois internes et le gaz ; on étudie un compteur multicellulaire dont la cathode est percée d'un grand nombre de canaux (figure 3) ; en face de chaque canal est tendu un fil anodique. Les canaux représentent une zone de dérive où le champ électrique (dirigé vers l'axe longitudinal du canal) est suffisant pour empêcher la recombinaison et guider les électrons vers l'anode, mais insuffisant pour provoquer une multiplication électronique. Les électrons qui émergent du canal sont accélérés dans le champ intense qui existe autour des fils anodiques.

On envisage de réaliser un compteur de $(12 \times 8 \times 3)$ cm³, ce qui est de l'ordre des dimensions d'une calculatrice de poche. Une cellule élémentaire (un canal, une anode) fonctionne actuellement et discrimine neutrons et photons. Par rapport à un compteur cylindrique de même volume, le gain de surface d'échange étant de quinze, le gain de sensibilité devrait être du même ordre de grandeur pour le compteur multicellulaire.

Figure 3 : Le compteur multicellulaire étudié par le S-DOS (Fontenay-aux-Roses).

CONCLUSION

Le problème du dosimètre individuel est difficile, même si la physique de son fonctionnement est bien connue. Deux points sont fondamentaux : 1) La réalisation d'un matériau équivalent au tissu de résistivité déterminée. 2) La pollution du gaz de remplissage (toute circulation de gaz était impossible) par une contamination venant des parois.

B. Weichlein, B. Masson - STATICE S.A, 25000 BESANCON (France)

NAUSICAA succède au système CIRCE. Il fonctionne avec un compteur proportionnel équivalent tissu suivant la technique microdosimétrique. En terme d'énergie linéique, il couvre une gamme de 0,3 à 1200 keV/ μ m dans le tissu et enregistre le spectre de TLE. Le débit de dose absorbée, entre 1 μ Gy/h et 20 mGy/h, ainsi que l'équivalent de dose associé sont mesurés en temps réel comme cela est nécessaire en radioprotection.

NAUSICAA est parfaitement adapté à la dosimétrie et à la radiobiologie spatiale où des événements de haut TLE, facteurs de qualité entre 10 et 20, peuvent être enregistrés.

**INSTRUMENT DESCRIPTION OF NAUSICAA USED FOR REAL TIME
MEASUREMENTS OF D, H AND L.E.T SPECTRUM IN COMPLEX FIELD**

The new instrument NAUSICAA is based on microdosimetric techniques using a low pressure tissue equivalent proportional counter. In terms of lineal energy, NAUSICAA device works in the 0.3 to 1200 keV/ μ m range in tissue and the LET spectrum is recorded. Absorbed dose rate, in the range of 1 μ Gy/h to 20 mGy/h, and dose equivalent rate are given in real time like it is necessary for radioprotection applications.

NAUSICAA is well adapted to space dosimetry and radiobiology where high LET events with quality factor in the range 10-20 are found.

INTRODUCTION

NAUSICAA est dérivé de l'appareil CIRCE. Ce dernier a été utilisé pour des mesures instantanées de dose absorbée et d'équivalent de dose, en décembre 1988, lors de la mission franco-soviétique à bord de la station orbitale MIR^(1,2).

La conception du nouvel instrument a été modifiée afin de tendre vers un système portatif utilisable au sol ou en vol. La fonction de l'appareil est d'obtenir des résultats rapides, lors de mesures dans un champ de rayonnement inconnu à faible débit de dose, tel qu'on souhaite le faire en radioprotection.

Pour répondre aux souhaits exprimés en radiobiologie, NAUSICAA fournit le spectre de transfert linéique d'énergie (TLE) associé à la mesure. Ceci permet, en particulier dans le cadre d'une application spatiale, de mettre en évidence la

présence de quelques particules (ions lourds) de TLE élevés, événements qui contribuent avec un poids important au facteur de qualité et à l'équivalent de dose.

DESCRIPTION DE NAUSICAA

Le capteur (Cf. Figure 1) est un compteur proportionnel cylindrique à champ axial dont les parois sont en équivalent tissu (E.T.). Le volume sensible (5 cm de diamètre x 5 cm de hauteur) est rempli de gaz E.T., à base de propane, sous faible pression (30 torr). On recueille ainsi l'énergie déposée par le rayonnement incident dans un site biologique d'une taille de $2 \mu\text{m}$ sous 1 cm de tissu.

Une mince enveloppe de 0,3 mm de Nickel constitue la paroi extérieure du capteur. Celle-ci assure la résistance mécanique et la parfaite étanchéité de la sonde.

Figure 1 - Représentation schématique en coupe de la sonde.

Une source émetteur-alpha (^{244}Cm), placée au niveau de l'embase du capteur, peut être mise en position mesure. Elle permet de vérifier la valeur du gain gazeux et de modifier si nécessaire la valeur de la THT appliquée afin de compenser toute variation de ce gain.

Cette méthode assure la longévité et le parfait fonctionnement du système sans être contraint d'effectuer un nouvel étalonnage du capteur. Il suffit de quelques minutes pour réaliser ce contrôle et celui-ci peut être programmé pour avoir lieu automatiquement à intervalle de temps régulier.

L'appareil de mesure est constitué d'un boîtier contenant l'électronique du système et d'une sonde reliée à ce boîtier par un câble souple comme le montre la Figure 2.

Le signal issu de la sonde est transmis au boîtier par un câble. Ce câble transporte aussi la basse tension nécessaire au préamplificateur situé dans la poignée de la sonde.

Le boîtier, alimenté par une source extérieure en 27 volts continu, consomme 3 watts et pèse moins de 3 kg pour un encombrement de 230 mm x 160 mm x 130 mm.

Les grandeurs dosimétriques caractérisant le champ de rayonnement sont inscrites sur un affichage digital. Lorsque

le temps de la mesure est écoulé, ces grandeurs, ainsi que le spectre des impulsions, sont enregistrés sur mémoire de masse (EPROM ou disquette). Un logiciel installé sur PC permet ensuite la lecture et la mise en forme des résultats.

Figure 2 - L'appareil NAUSICAA est constitué d'une sonde et d'un boîtier, contenant l'électronique du système, où sont affichés instantanément les résultats.

PERFORMANCES ET RESULTATS EXPERIMENTAUX

Le capteur fonctionne en régime proportionnel. A chaque événement, traité individuellement⁽³⁾, est associé le facteur de qualité suivant la définition de l'ICRP 21⁽⁴⁾.

On recueille ainsi la fréquence des événements jusqu'à un taux de 10 kHz et on mesure le débit de dose absorbée dans la gamme 1 $\mu\text{Gy/h}$ à 20 mGy/h . Avec le facteur de qualité associé, entre 1 et 20, l'équivalent de dose est immédiatement calculé.

Le rapport H/D indiqué par l'appareil correspond alors au facteur de qualité moyen du champ de rayonnement⁽³⁾.

Une campagne de mesures a été menée auprès d'une source de ^{252}Cf de faible activité⁽⁵⁾. Les grandeurs mesurées sont comparées dans le Tableau 1 aux valeurs enregistrées avec des détecteurs thermoluminescents ($^7\text{Li}_2$ $^{11}\text{B}_4\text{O}_7$), insensibles aux neutrons, et aux valeurs obtenues avec des détecteurs à bulles⁽⁶⁾, insensibles au rayonnement gamma.

Mesure neutron BULLES H_n [$\mu\text{Sv/h}$]	Mesure totale neutron-gamma CIRCE-NAUSICAA H_t [$\mu\text{Sv/h}$] D_t [$\mu\text{Gy/h}$]	Mesure gamma TLD D_g [$\mu\text{Gy/h}$]
69.5 \pm 6.0	66.5 \pm 2.1 11.2 \pm 0.2	3.5 \pm 0.2

Tableau 1- Débits de doses enregistrés auprès d'une source de ^{252}Cf par différents systèmes de mesures.

Les résultats rapportés ici représentent la valeur moyenne et l'écart-type pour 7 mesures de 2 heures à une distance de 1,66m de la source. On remarque évidemment la cohérence des

résultats, en dose absorbée comme en équivalent de dose, mais on peut constater aussi, par la valeur de l'écart-type rapportée, la bonne reproductibilité de la mesure.

Puisque chaque événement est individualisé lors de l'acquisition des données, il est alors simple de construire la distribution de TLE mesurée. Les hauteurs d'impulsion sont converties et classées sur 256 canaux en couvrant une gamme de 0,3 à 1200 keV/ μ . Cette grande dynamique dans les hauteurs d'impulsion traitées est assurée par un amplificateur logarithmique situé dans le manche de la sonde en sortie du préamplificateur linéaire.

Les ions lourds, tels qu'on les rencontre dans l'espace, conduisent à des dépôts d'énergie dans le tissu bien supérieurs à celui des neutrons. Lorsqu'un événement de ce type se produit, superposé à un champ donnant de faibles TLE, l'équivalent de dose et le facteur de qualité moyen subissent une nette augmentation. Seule l'analyse détaillée des événements permet de définir la contribution des ions lourds.

Une première approche dans cet esprit a été effectuée sur la station orbitale MIR avec CIRCE. Pour cette expérience, des mesures d'une durée de 30 secondes seulement permettaient de faire apparaître des facteurs de qualité élevés car faiblement pondérés par les événements de bas TLE⁽²⁾.

NAUSICAA apportera des renseignements plus précis sur ces événements en fournissant le spectre de TLE : même s'il est unique, un événement sera ainsi répertorié.

CONCLUSION

NAUSICAA permet d'effectuer, en temps réel, une dosimétrie de zone en champs complexes (neutron-gamma-particules chargées). Les données obtenues sont la dose absorbée, l'équivalent de dose et le spectre de T.L.E. dans la gamme 0,3 à 1200 keV/ μ m.

Le capteur, organe délicat du système, est aujourd'hui parfaitement adapté à une utilisation de routine: résistances aux chocs (normes spatiales) et durée de vie de bon fonctionnement.

L'ensemble forme un système très performant pour des mesures dans l'espace où siègent de fortes variations spatiales et temporelles, variations en débit et variations en nature de rayonnement.

MEASUREMENT OF HTO PERMEABILITY OF MATERIALS
FOR PROTECTIVE APPLIANCES

ABSTRACT

Tritiated water (HTO) vapor permeabilities were measured for plastic and rubber films used for protective appliances (suits, gloves, wrappings, etc.). The measurement data prove that polyethylene and butyl rubbers are materials suitable for HTO protective appliances with their lower permeability. The data also indicate that desiccating protective appliances before reuse is effective for restoring their original resistances to penetrating HTO vapor when they are repeatedly used.

INTRODUCTION

Characterization of protective appliances for HTO vapor penetrating through those appliances has been a major subject in an effort at reducing the dose due to HTO exposures. Because few data on the characteristics of Japanese appliances as barriers to penetrating HTO had been available, HTO vapor permeabilities were measured for various plastic and rubber films of materials currently used in Japanese radiation protection appliances.

EXPERIMENTAL MATERIALS

Data were obtained with film specimens of polyethylene, polyvinyl chloride and polyvinyl acetate. They are plastics used as the materials of protective suits or wrappings. Also characterized were the specimens of urethane, chlorosulfonic polyethylene (hypalon), chloroprene (neoprene), butyl rubber and natural rubber. They are rubbers used as the materials of protective gloves. These specimens were all made by several Japanese manufacturers. They had the thickness of about 0.1 or 0.2 mm and the HTO permeating surface area of 54 cm².

EXPERIMENTAL METHODS

The permeability parameters measured were permeation coefficients, diffusion constants and solubilities. Based on the diffusion theory [1], these parameters were obtained by measuring the flux of HTO vapor permeating through specimen films as a function of time.

The permeation coefficient, P, is calculated by Equation (1) at the steady-state permeation:

$$P = F_s L / \Delta p \quad (1)$$

where F_s is the steady-state flux of HTO vapor permeating through the film, l is the film thickness and Δp is the partial pressure difference of water vapor between both sides of the film.

By plotting $t^{1/2}F$ versus $l^2/4t$ of Equation (2) on semi-logarithmic graph paper, the diffusion constant, D , is obtained from the slope of the plots:

$$\ln(t^{1/2}F) - \ln \{ 2 C_1 (D/\pi)^{1/2} \} = l^2/4t \quad (2)$$

where t is the time elapsed after the start of the exposure of the film to HTO vapor, F is the flux of the water vapor permeating through the film and C_1 is the concentration of water in the film on the surface exposed to the vapor.

Then the solubility, S , is calculated using Equation (3) with C_1 obtained from the intercept of the plots mentioned above:

$$S = C_1 / p_1 \quad (3)$$

where p_1 is the partial pressure of the water vapor at the surface of the film exposed to the vapor.

In order to measure the flux of water vapor, F , as a function of time, an experimental apparatus was made consulting D. H. Dougty's study of the Sandia National Laboratories [2]. The apparatus consists of the following parts: a generator of HTO vapor; a sample film holder; ethylene glycol bubblers where penetrating HTO is adsorbed; and two closed loops inside which HTO vapor circulates. All the parts is built in a constant temperature box.

With this apparatus, the time-dependent flux of HTO (then F and F_s in the Equations) was obtained by measuring the amount of tritium adsorbed in the bubblers-traps at certain intervals of time by liquid scintillation counting. The partial pressures p_1 and p_2 in the Equations were determined by monitoring the temperature and the relative humidity inside the closed loops of the apparatus.

RESULTS AND DISCUSSION

Permeation Characteristics of Protective Appliance Materials

Table 1 shows a summary of the permeability measurements for the specimens of various materials. As to the plastic polymers, the permeation coefficient of polyvinyl acetate was slightly larger than that of polyvinyl chloride, while the value of polyethylene was about 1/10 of those of the other two materials. The highest diffusion constant was found in polyvinyl acetate, while polyethylene had the lowest value. The difference in the values of diffusion constant among these plastics was not so large as that in the values of permeation coefficient. The solubilities increased in the order polyethylene < polyvinyl chloride < polyvinyl acetate. The value of polyethylene was about 10% of that of the others.

The data therefore prove that polyethylene is the best material among tested plastics from the viewpoint of HTO permeability.

As to the rubber materials, the highest permeation coefficient was observed in urethane. Natural rubber had the second highest value followed by neoprene and hypalon. The permeation coefficient of butyl rubber was the lowest among our results and was about 1/300 of that of urethane. The lowest values of diffusion constant and solubility were measured in butyl rubber. The data thus prove that butyl rubber excels as a material for HTO handling gloves with its low HTO permeability.

Effects of Desiccation Treatment on Permeation Behavior

The specimen films had been measured for their original values of the permeability parameters, then the films were desiccated and measured again for any changes of the parameter values. The desiccation treatment was carried out by exposing the surfaces of the wet films to dry circulating air. The HTO once adsorbed in the specimen films could be removed by the desiccation treatment.

The parameter values and the vapor flux curve measured after the desiccation well agreed with the original ones as in Table 1 and Figure 1, respectively. It can therefore be concluded that the desiccation treatment is effective for restoring the ability of the materials as a barrier against HTO vapor. As shown in Figure 1, desiccating glove materials can recover the smaller flux region at the initial stage of permeation, where the exposure to permeating HTO would be relatively small. If a worker would desiccate his gloves after each daily HTO handling operation and reuse the dried gloves within the smaller flux region in any operation, his exposure to penetrating HTO could be less significant than that in cases where he would use the wet gloves for several days without desiccation.

CONCLUSIONS

From the experimental data, the followings can be derived:

- (1) polyethylene and butyl rubber are materials suitable for HTO protective appliances with their low permeabilities;
- (2) when a protective appliance is repeatedly used, desiccating it before reuse may be effective for restoring its original resistance to penetrating HTO vapor and for reducing degree of HTO exposure.

CONTRIBUTION OF COMPUTER SCIENCE IN CONTINUOUS RADIOACTIVITY
SURVEY IN PLANTS AND ENVIRONMENT OF CENTRE D'ETUDES DE SACLAY

Assignments of radiations survey board (local staff warning and overall follow up of plants) benefit by an important contribution of computer science in two fields :

- quality of measurements, principally measures of radioactive atmospheric aerosols pollution,
- increase of overall follow up by péripherals, especially by continuous recording measures.

The connection, by local network, of all survey boards can enable us further applications as decision making for incidental cases.

INTRODUCTION

Parmi les missions des unités de protection contre les rayonnements figure le contrôle permanent des:

- nuisances radioactives susceptibles de polluer l'environnement,
- risques radioactifs dans les installations.

Pour mener à bien ces missions elles disposent de systèmes de mesures en continu que sont:

- les Tableaux de Contrôle des Rayonnements (TCR) installés dans les installations (principalement les Installations Nucléaires de Base),
- le Tableau de Contrôle de l'Environnement (TCE) pour la surveillance de l'environnement du site.

Nous avons entrepris au centre de Saclay , depuis plus de 10 ans, un effort important de modernisation de ces tableaux de contrôle et à ce jour ce sont 10 "**systèmes informatisés de radioprotection**" qui fonctionnent en temps réel. Sur les 600 voies de radioprotection installées au centre d'études de Saclay, 530 sont traitées par un système informatisé.

En cas d'incident il est nécessaire de regrouper des informations provenant des différents systèmes de contrôle permanent (mesures dans l'installation en cause, mesures météorologiques, mesures dans l'environnement...). L'interconnexion des différents systèmes informatisés de contrôle de radioprotection en continu présente un intérêt majeur.

Tableaux de contrôle des rayonnements des installations

La mission d'un TCR d'installation est double :

- alerter localement les personnels du niveau de risque auquel ils sont soumis, cette mission est assurée par une signalisation, lumineuse et sonore, au poste de travail,
- permettre un suivi global de l'installation à partir du centralisateur en exploitant l'ensemble des mesures.

Les caractéristiques générales des TCR informatisés sont les suivantes :

Chaque voie de radioprotection est constituée :

- d'un capteur qui fournit un train d'impulsions de mesures et un état de fonctionnement,
- d'un coffret de signalisation qui reçoit une commande de signalisation et fournit un état de fonctionnement.

La gestion centralisée des mesures comprend :

- un synoptique d'alarmes,
- la visualisation permanente des états et des mesures,
- l'édition d'un journal de bord qui comporte : messages liés aux changements d'états et de plage et éditions cycliques de niveaux moyens et de cumuls,
- un traceur de courbes,
- un archivage des mesures sur plusieurs jours,
- un dialogue opérateur qui permet de modifier des paramètres de fonctionnement, d'éditer les mesures et cumuls et de tracer les courbes des mesures en temps réel ou en différé à partir de l'archivage.

Tableau de contrôle de l'environnement du centre de Saclay

Le TCE comprend des stations "environnement" (contrôle radiologique) réparties autour du site et une station météorologique située à l'intérieur du centre.

Chaque station comporte des capteurs appropriés et une unité de traitement, constituée autour d'un micro-processeur qui :

- assure l'acquisition des informations des capteurs,
- traite les informations capteurs pour élaborer une mesure exploitable,
- transmet au centralisateur les mesures et les états des capteurs.

Le rôle du centralisateur est de permettre un suivi aisé et permanent de l'ensemble des mesures des stations. Les mesures sont archivées et peuvent être facilement éditées sous forme de tableaux et de courbes.

La partie environnement utilise la balise à filtre séquentiel alpha et bêta composée de capteurs et d'une unité de traitement (BFSAB) développée spécialement à cet effet.

APPORT DE L'INFORMATIQUE SUR LA QUALITE DU TRAITEMENT DES MESURES

La mise au point d'algorithmes d'élaboration de mesures spécifiques à chaque type de capteurs [1] a permis d'obtenir une homogénéité des résultats de mesure. Toutes les mesures des TCR sont exprimées en LDO (Limite Dérivée Opérationnelle). Pour les mesures de contamination (aérosols et gaz) la LDO est égale à la limite dérivée de concentration dans l'air ($LDCA=LAI/2000h*1,2m^3h^{-1}$), elle dépend donc de la valeur d'un paramètre de radiotoxicité qui est introduit par les exploitants du TCR. Ce paramètre est choisi en faisant une hypothèse sur la contamination possible ; en général il est égal à la LAI la plus sévère probable pour le local surveillé. Dans le cas des mesures d'exposition externe la LDO est le débit de dose horaire moyen ($LAE/2000h$ soit $25 \mu Sv/h$).

L'intérêt de ces algorithmes se résume dans les quelques caractéristiques suivantes :

type de mesure (installation)	limite de détection	temps de réponse pour 1 LDO
Exposition externe	2.10^{-3} LDO	3 secondes
Gaz	0,2 LDO (C^{14})	3 minutes
Aérosols β	0,4 LDO ($Sr^{90}+Y^{90}$)	3 minutes
Aérosols α	0,5 LDO ($Pu^{238}+Pu^{239}$)	150 minutes

Dans le cas des mesures dans l'environnement où le bruit de fond, dû à la radioactivité naturelle, est variable et important par rapport à la sensibilité recherchée l'apport des traitements informatiques est fondamental, il peut se résumer dans le tableau ci-dessous :

type de mesure (environnement)	limite de détection	en présence d'un bruit de fond de
Exposit. externe	2 nGy/h	80 à 100 nGy/h
Gaz	50 mBq/m ³ (Kr^{85})	0,4 à 50 Bq/m ³ Rn^{222}
Aérosols β	0,2 mBq/m ³ ($Sr^{90}+Y^{90}$)	0,1 à 50 Bq/m ³ dér. Rn^{222}
Aérosols α	0,4 mBq/m ³ ($Pu^{238}+Pu^{239}$)	0,1 à 50 Bq/m ³ dér. Rn^{222}

Les principes généraux de tous les traitements ont été présentés au cours d'un séminaire AIEA [2].

APPORT DE L'INFORMATIQUE SUR L'EXPLOITATION DES MESURES

Sur ce plan l'apport de l'informatique se caractérise par:

- un suivi global de l'installation grandement amélioré grâce à la périphérie informatique et en particulier l'archivage des mesures qui permet à tout moment de ressortir les mesures des 10 à 20 derniers jours,
- un contrôle permanent du bon fonctionnement des différents composants du TCR : capteur, coffret de signalisation, unité de traitement et centralisateur,
- une très grande disponibilité des systèmes : à titre d'exemple 3 TCR organisés avec une architecture de traitement centralisé redondant ont accusé un taux d'indisponibilité de l'ordre de quelques 10^{-5} pour un temps de fonctionnement cumulé de plus de 200 000 heures.

Un autre aspect important est l'interconnexion des différents TCR et du TCE. Le RRRES (Réseau de Radioprotection et d'Environnement de Saclay) en place depuis plusieurs années permet de disposer en tout point de ce réseau des diverses mesures [3]. La connexion des TCR à ce réseau se poursuivra dans les années à venir.

CONCLUSION

L'obtention des mesures par des traitements élaborés améliore grandement la qualité de la radioprotection, nous continuons nos travaux dans ce domaine.

La fonction de centralisation bénéficie de tous les apports de l'informatique et son exploitation en est facilitée.

La réalisation d'un réseau constitue les bases qui permettront de réaliser, dans l'avenir, un système expert d'aide à la décision pour les situations accidentelles.

FAST AND SENSITIVE DETERMINATION OF SR-90 AND SR-89 ACTIVITY IN MILK BY ION-CHROMATOGRAPHY AND LIQUID SCINTILLATION

V. Figueiredo and A. Herrmann
Food Control Laboratory, Basel, Switzerland

1. ABSTRACT

A method for fast and exact determination of both strontium isotopes in milk and other foodstuffs, combining high performance ion chromatographic separation with by liquid scintillation counting, which enables the desired results to be obtained with very satisfactory precision and reproducibility within 24 hours, has been developed. The lowest detectable activity lies by 3 Bq/liter for Sr-90 and 1 Bq/liter for Sr-89 which is satisfactory for assessing a situation in a time of crisis.

2. INTRODUCTION

After the accident in Chernobyl, the old problem of Sr-90 and Sr-89 activity measurements became topical once more. Again it was evident that the public as well as the authorities expected quick and reliable information after the event from the responsible laboratories. Due to the wide bands of energy emitted by the beta-radiation, a chemical separation of the nuclides to be measured is unavoidable. The methods used at the moment [1,2,3] involve tedious separations and reliable results require waits of several to 20 days. The method described here, a combination of high performance ion chromatography and liquid scintillation, enables us to obtain the necessary strontium preparation purity and to determine the activities of both Sr-90 and Sr-89 correctly and exactly within a working-day.

3. EXPERIMENTAL

After the removal of the milk protein with trichloroacetic acid, the alkaline earth metal ions are precipitated as oxalates, converted to carbonates by ashing and the strontium as well as the barium ions precipitated as nitrate salts. An aliquot of the nitrate salt is put through a chromatographic system, the strontium peak-volume collected and the activity of both strontium isotopes measured by low-level liquid scintillation. The chemical manipulations require approximately 7 hours and the counting 3 hours.

3.1. ISOLATION OF STRONTIUM FROM MILK

The isolation of strontium is performed according to [4], using 1 liter of milk and adding 40 mg each of strontium and barium carrier. The procedure is interrupted at the level of the nitrate precipitation. The precipitate dissolved in 5 ml water (sample solution) is then used for the ion chromatography.

3.2. FINE CLEANUP OF STRONTIUM BY ION-CHROMATOGRAPHY

250 μ l of the sample solution are injected into the chromatographic system described below. After the detection by conductivity the strontium peak-volume is collected in a counting vial, mixed with PICO-AQUA cocktail and counted as soon as possible.

Column : DIONEX HPIC-CS3 and HPIC-CG3
Eluent : HCl 48 mM, diaminopropionic acid hydrochloride 16 mM
Flow-rate : 1 ml/min
Detection : Suppressed Conductivity

3.3. CHEMICAL YIELD

The chemical yield of the precipitation is also determined by ion chromatography after adequate dilution of the sample solution. The concentration of the sample solution and thereby the chemical yield are determined using an external standard.

3.4. MEASUREMENT OF SR-90/SR-89 ACTIVITIES BY LIQUID SCINTILLATION

The scintillation spectra are measured on a TRICARB 2250CA low level liquid scintillation analyzer from PACKARD. The activities of Sr-90 and Sr-89 of the collected fraction are determined by dual label DPM analysis with AEC (Automatic Efficiency Control) in the following optimized energy windows: 5-200 keV for Sr-90 and 200-1200 keV for Sr-89.

Preparation of the Quench Curves:

As commercially obtained Sr-90 is in equilibrium with its daughter Y-90, it is necessary to purify the Sr-90 standard solution by chemical separation [2] before preparing the quench sets.

Sample measurement:

The sample activity must be measured directly after the eluate is collected, but after a few minutes equilibration in the cooled sample collector. The samples are counted over a period of 180 minutes.

4. RESULTS AND DISCUSSION

At the present time adequate preparative columns are not available: the DIONEX HPIC-CS3 is an analytical column. However the quantities and volumes given here result in a good recovery rate of added strontium. Starting with one liter of milk, with the stated amounts of strontium and barium added, a chemical yield of $68 \% \pm 2 \%$ ($n = 10$) was obtained.

Under the given conditions of the ion-chromatographical purification the alkaline earth metal ions are separated, while the alkaline metal ions are eluted with the water peak. Trivalent ions such as lanthanides, yttrium and the transitional metals are held back by the column. If in the case of milk, the calcium is not removed with nitric acid separation,

a large excess of calcium will be present which prohibits a separation of the peaks. One single nitric acid separation completely eliminates any alkali ions that may possibly be present and reduces the calcium concentration by a factor of 1000.

Although the analytical chromatography column is clearly overloaded, the strontium-peak is well resolved from the barium-peak. The addition of barium carrier solution permits a well timed interruption of the collection of the strontium fraction.

With the possibility of dual label DPM counting, spectral separations of both radiations (max. energies: 0,546 keV for Sr-90, 1,492 keV for Sr-89), activity ratios of Sr-90/Sr-89 from 1:50 to 50:1 can be measured well. The two established quench curves in the chosen energy windows for Sr-90 and Sr-89 give a constant spill-up and spill-down. The efficiencies for both isotopes lie by 70 % for Sr-90 and 67 % for Sr-89.

Due to the ingrowth of Y-90, after a counting time of 180 minutes only an Y-90 activity of approximately 3 % of the Sr-89 activity will be present. The Beta-radiation from Y-90 appears mainly in the Sr-89 window and so can simulate Sr-89 activity.

5. QUALITY CONTROL OF THE METHOD

At the end of 1990 we received several food samples from Chernobyl, whose activity had been determined with gamma-spectrometry. In 5 samples, the Sr-90 activity was determined with the up to then applied method [2], which is based on the measurement of the chemically separated Y-90 using a gas-proportional counter. The direct determination of the Sr-90 activity of these samples was likewise carried out using the method described above, also only 250 ml of milk and 500 ml of water could be used (Table 1).

Table 1: comparison of the methods: Sr-90 in milk and water samples from Chernobyl (Bq/liter)

sample	method [2]	this method	difference
milk 1	5,6 ± 0,1	5,7 ± 0,6	+ 1,8 %
milk 2	8,4 ± 0,1	7,6 ± 0,8	- 9,5 %
milk 3	10,9 ± 0,2	13,8 ± 1,4	+26,6 %
milk 4	9,9 ± 0,2	10,0 ± 1,0	+ 1,0 %
pond water	46,9 ± 4,5	52,0 ± 2,6	+10,9 %

The difference in the results varies between 1 and 27 %, with a mean value around 10 %. In view of the given degree of pure statistical error (1 sigma), the differences are not significant except in milk sample 3. With the limited volume available, the results are very satisfactory.

A further comparison, on the basis of an interlaboratory test organized by the Berlin Ministry of Health (BGA) is shown in table 2.

Table 2: Interlaboratory test, BGA Berlin 1990 (Bq/liter)

nuclide	method [2]	this method	nomial value
Sr-90	4,3 ± 0,2	4,4 ± 0,4	4,2
Sr-89	-	7,0 ± 0,7	5,3

The sample (water) contained, apart from the two Sr-isotopes, also H-3, Co-60, Zn-65, Cs-134, Cs-137 and Ce-141. The strontium activities measured with both the tested methods agree very well with the expected value. The Sr-89 activity found by the method described here actually deviates by 30 % from the value given by the BGA, but with an activity of only 2,7 Bq/liter at the time of measurement (70 days after the reference date) it is not surprising.

6. CONCLUSIONS

The method described here has shown to be very reliable: the ion chromatography allows a maximum purity of the strontium fraction to be obtained, and the liquid scintillation permits a simultaneous determination of both strontium isotopes. The detection limit lies by 3 Bq/liter for Sr-90 and 1 Bq/liter for Sr-89. Even when this method, at the moment has only been tested by means of some samples from Chernobyl and spiked samples, it can be used for other foodstuffs with the appropriate preparation, without further ado, or in nuclear plant laboratories for their own control of waste water.

Thus it is possible to perform quick and reliable strontium analyses after an event and take the necessary precautionary measures or issue recommendations promptly.

STUDY OF MINI-COUNTERS FOR PERSONAL NEUTRON DOSIMETRY

The characteristics of three electronic detectors designed for personal neutron dosimetry are compared: a multicellular tissue equivalent proportionnel counter, a differential diode detector and a detector operating in a partial G.M. regime. The two detectors employed the same thin film of Boron-10 doped polyethylene as a neutron to proton converter.

INTRODUCTION

Il n'existe pas, à l'heure actuelle, de dosimètre électronique individuel commercialisé permettant d'évaluer, en temps réel, la dose due aux neutrons dans les champs mixtes. Les recherches entreprises dans le service sur ces capteurs dosimétriques concernent la conception et l'étude d'un détecteur électronique miniature susceptible d'équiper les futurs dosimètres individuels. Parmi les difficultés qui se présentent, les deux plus importantes sont l'obtention d'une sensibilité aux neutrons et d'une discrimination neutron/gamma suffisantes.

COMPTEUR PROPORTIONNEL

Le principal défaut des compteurs proportionnels, utilisés en microdosimétrie, est leur manque de sensibilité, consécutive à

la faible section efficace de collision élastique microscopique des neutrons avec les atomes d'hydrogènes constituant le matériau équivalent tissu. Pour compenser cet effet, il faut accroître la surface d'échange entre la cathode et le gaz détectant les particules secondaires chargées (1).

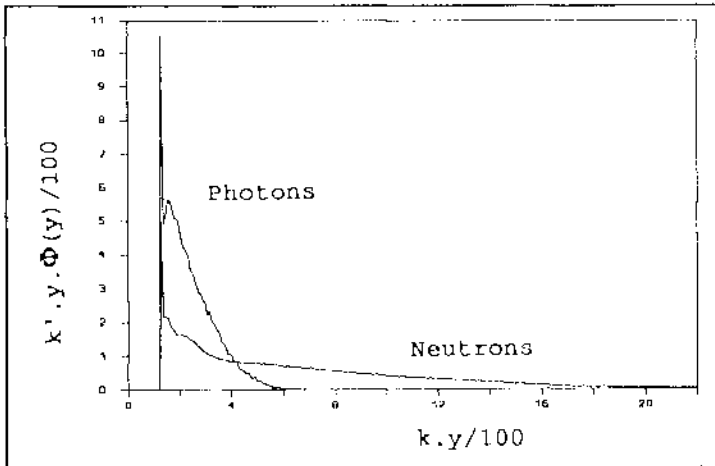

Figure 1: Distribution de la dose en fonction de l'énergie linéique.

Les comp-teurs proportionnels auront en général des dimensions importantes, diamètre supérieur à 5 cm (2), rendant ainsi impropre leur utilisation comme capteur dans un dosimètre individuel.

La surface d'échange, entre la paroi et le gaz du compteur développé dans le service, est accrue par le forage d'un ensemble de canaux borgnes orthogonaux à la surface interne (3). Selon le diamètre des canaux et l'épaisseur de la paroi, l'accroissement de surface peut atteindre un facteur 10 par rapport au compteur orthocylindrique de même volume (4). Le volume de détection n'est plus convexe et la simulation d'un site microscopique imparfaite. Ceci n'est pas rédhibitoire dans la mesure où une deuxième interaction du même neutron incident avec une nouvelle zone de la cathode est improbable. L'épaisseur entre les canaux est suffisante pour arrêter toutes les particules secondaires chargées à l'exception toutefois des électrons d'énergie supérieure au MeV.

Dans le cas du compteur multicellulaire (4), le calcul de la distribution de la longueur des cordes donne une distribution de Dirac dont la valeur la plus probable correspond sensiblement à la valeur moyenne. La figure 1 donne la réponse du compteur monocanal, normalisée à la même charge collectée pour les photons du cobalt-60 et les neutrons d'une source d'Am-Be. Ces spectres sont déformés par la présence de l'encainte métallique qui entoure, pour le moment, la maquette du compteur.

DOUBLE DIODES

De nombreux auteurs ont étudié la réponse aux neutrons des détecteurs solides de traces (DST) avec et sans convertisseur hydrogéné.

Figure 2: Réponse différentielle du système de détection, source Am-Be.

Barélaud et coll. (5) ont remplacé le DST par une diode. Celle-ci détecte les particules secondaires chargées créées dans le convertisseur, principalement les protons dus à la diffusion élastique des neutrons et les particules alpha dues à la réaction des neutrons de faible énergie avec le bore-10. Afin de séparer au mieux la réponse des photons de celle des neutrons, une deuxième diode, de caractéristique équivalente, mesure la composante photonique

ainsi que les interactions directes avec les neutrons. La différence de réponse des deux diodes est exclusivement liée à la réponse du convertisseur aux neutrons.

Le principal avantage de ce système est lié à la réponse du convertisseur; en effet Makovicka (6) a montré que, pour une épaisseur de polyéthylène d'environ 30 μm , le débit de fluence des protons émergeant du radiateur est sensiblement proportionnel (à $\pm 30\%$) au débit d'équivalent de dose neutronique entre 100 keV et 5 MeV. Une implantation adéquate en bore-10 permet d'étendre la gamme de mesure jusqu'à l'énergie des neutrons thermiques. Un second avantage est lié à la faible tension de polarisation des diodes particulièrement bien adaptée au détecteur individuel. Plusieurs inconvénients existent: le bruit de fond propre des diodes qui limite le seuil de détection à quelques dizaines de keV, l'épaisseur de la zone morte qui arrête les particules chargées de faible énergie ou très ionisantes, la forte sensibilité aux photons.

La figure 2 donne la réponse, pour les neutrons d'une source d'Américium-Beryllium, de la diode nue (a), de la diode sous convertisseur (b) ainsi que la réponse différentielle du système de détection.

COMPTEUR A REGIME GM PARTIEL

La sensibilité du système de détection est directement liée à la surface du détecteur, soit 1,5 cm^2 dans le cas des diodes. Afin d'accroître, sans coût excessif, la sensibilité du capteur, la diode est remplacée par un compteur fonctionnant en régime GM partiel dont la surface sensible peut atteindre plusieurs

Figure 3: Taux de comptage en fonction de la tension appliquée.

dizaines de centimètres carrés. Dans la maquette étudiée, la cathode est constituée d'une feuille métallique dont la surface intérieure est recouverte d'une fine couche de polyéthylène, ce dernier étant rendu macroscopiquement conducteur électrique. La cathode est constituée soit par un parallélogramme ou soit par un ensemble de tubes cylindriques.

celle du DINEUTRON pour un poids et un encombrement du détecteur plus faibles.

Les matériaux constituant la cathode et sa structure de maintien sont choisis de telle sorte que l'interaction avec les photons soit minimale; ceci permet de s'affranchir de l'utilisation d'un deuxième détecteur de compensation. Comme pour la diode, une implantation de la cathode en bore-10 permet de détecter les neutrons thermiques et épithermiques. La figure 3 donne, pour un même débit de dose, les réponses respectives du détecteur aux neutrons d'une source de californium et aux photons du cobalt-60 en fonction de la tension appliquée.

CONCLUSION

Si l'obtention d'un capteur dosimétrique individuel, à partir d'un compteur proportionnel pose encore de nombreux problèmes technologiques (gain gazeux, stabilité à long terme, etc.), il est par contre certain que la réalisation d'un compteur à régime GM partiel ou, plus encore, d'un ensemble différentiel à diodes ne pose aucun problème majeur. Il faut toutefois noter que le compteur proportionnel donne une information dosimétrique complète: dose, équivalent de dose et facteur de qualité moyen, alors que les détecteurs à convertisseur hydrogéné ne fournissent a priori que l'équivalent de dose.

DEVELOPEMENT OF AN AUTOMATIC IMAGE SCANNER FOR DOSIMETRY
ANALYSIS

Solid Nuclear track detector in dosimetry are necessary for numerous uses. We have developed image analysis for scanning and measuring nuclear tracks (alpha, proton and fission fragment) in various detectors. The track density makes it possible to calculate the activity concentration to which the detector has been exposed. Special computer programs enable us to count both low and high densities.

INTRODUCTION

L'analyse d'image a pour but d'extraire d'une image brute des informations concernant des structures particulières appelées "objet". Dans le cas du comptage de films dosimétriques, l'analyse automatique des traces nucléaires doit permettre d'accéder dans les meilleures conditions de temps et d'efficacité à la densité de trace et donc à l'exposition auxquelles ont été soumis les films.

LE SYSTEME D'ANALYSE D'IMAGE

Le système de base utilisé est commercialisé par la Société OLYMPUS sous le nom de CUE-2. Il comporte les éléments présentés sur la figure 1.

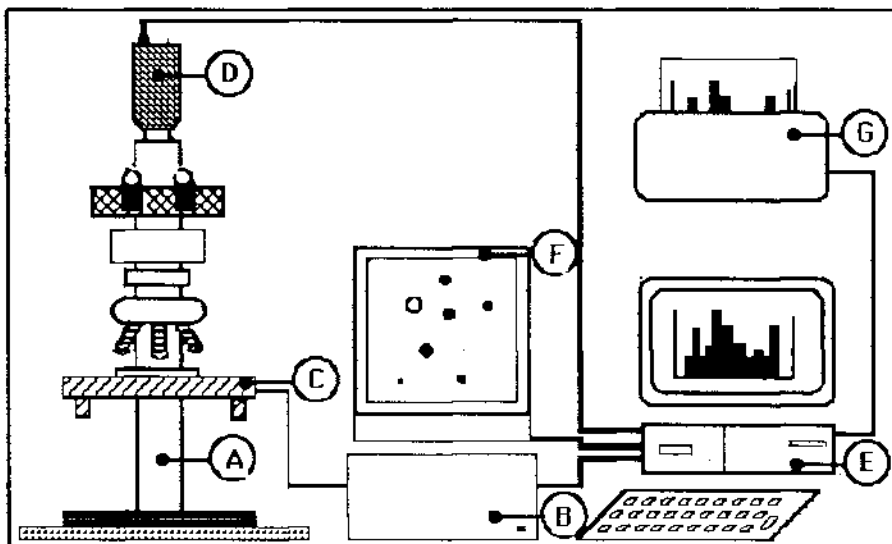

FIG 1: Le système d'analyse d'images

microscope optique (A), contrôleur de déplacement x, y et z (B), platine motorisée (C), caméra video CCD (D), micro-ordinateur (E), moniteur image(F) et imprimante laser (G)

DEROULEMENT D'UNE ANALYSE D'IMAGE

Le programme informatique réalise l'analyse d'image en quatre phases essentielles précisées dans le schéma suivant :

- acquisition de l'image : pour réaliser de telles observations, le traitement d'image est connecté a un microscope optique (BH2), pouvant travailler à la fois en lumière transmise ou en lumière réfléchie. Dans le but d'accroître son efficacité, le système est de plus équipé d'une platine microscope motorisée. Cette platine motorisée permet un déplacement suivant les trois axes x, y, z. Le déplacement suivant l'axe z permet le réglage de la netteté de l'image au moyen d'un système autofocus.

- mise en valeur et prétraitement : l'opérateur fixe un intervalle de niveaux de gris englobant au mieux les niveaux de gris des pixels constituant les objets. L'image est ensuite binarisée suivant les valeurs de niveaux de gris seuils imposés.

- analyse des objets de l'images : dans sa configuration de départ, le logiciel est capable de caractériser chaque objet analysé avec plus de trente paramètres géométriques (surface, périmètre, diamètre de férêt,...). dans le cadre des améliorations que nous avons développées l'ensemble des paramètres est fixable.

- sortie des résultats de l'analyse sous la forme d'histogrammes ou de courbes caractéristiques de chaque champ analysé ou de l'ensemble de la surface.

APPLICATIONS DU SYSTEME POUR LE COMPTAGE DE FILMS DOSIMETRIQUES

Ce type de détecteurs polymériques permet la caractérisation des interactions des rayonnements nucléaires suivant : alpha, neutron, proton et produits de fission.

Le but du développement d'une analyse de ces détecteurs par traitement d'image est principalement destiné à la détermination de densité des traces, c'est à dire à la mesure des événements nucléaires subits en surface. Dans certains cas, il est également nécessaire d'accéder à tous les paramètres de forme et à la cartographie des traces sur l'ensemble de la surface.

Pour ce faire, le système a été adapté à l'analyse automatique de détecteurs solides de traces nucléaires, deux catégories d'analyses ont requis une adaptation particulière :

- les films à faible densité de traces car ils nécessitent la prise en compte d'une surface importante du détecteur pour obtenir un résultat fiable.

Pour ce faire un programme informatique spécifique est utilisé pour piloter le déplacement de la platine en x et y afin de compter toute la surface de plus il y a également un contrôle des fluctuations de focalité avec correction en jouant sur l'axe z

- les films à forte densité de traces, car dans ce cas certaines traces se chevauchent, ce qui nécessite un traitement spécial pour les séparer.

L'étude de ce type de films à forte densité est réalisée en utilisant également un programme spécialement développé qui d'une part peut comparer les objets observés par rapport à une bibliothèque de traces se recouvrant ou peut retrouver par traitement mathématique la forme des traces initiales dans un recouvrement.

Les résultats obtenus par analyse d'image et leur comparaison avec ceux réalisés au moyen d'un comptage semi-automatique par un opérateur sont tout à fait adaptés à l'analyse de détecteurs à faible et à forte densité.

CONCLUSION

Les différents développements de l'analyse d'image présentés dans le cadre de ce travail montrent l'intérêt de cette technique pour l'analyse des traces nucléaires.

Les différents programmes informatiques nous permettent à la fois de qualifier et d'extraire des formes caractéristiques de traces d'une surface et de quantifier leurs répartitions sur le matériau.

Le temps d'analyse est très court, par exemple le traitement d'un détecteur de traces nucléaires qui demande une heure par cette technique en demande cinq fois plus en comptage optique par un opérateur.

De plus, l'automatisation de ce traitement permet de réaliser un nombre important d'analyses pour vérifier les résultats, ce qui par analyse optique directe n'est pas envisageable.

Après avoir développé des méthodes d'études efficaces, par observation microscopique, il s'avère que de nombreuses applications de ce traitement sont encore à venir.

BACKGROUND TRACKS IN CR-39 SSNTD SHEETS: THEIR CONTROL AND PREDICTION THROUGH AN INTERPLAY OF ETCHING PARAMETERS

ABSTRACT

High sensitivity of CR-39 film in turn leads to higher and variable background track-densities. A two-step etching process, each consisting of CE and ECE, is therefore suggested which permits not only partial freezing of the background but also allows to know its level. The procedure identifies bad pieces with scratches and determines the minimum detection limit (MDL) of each film individually. Activities as low as 0.2 mBq ($\approx 5 \times 10^{-15}$ curies) can thus be measured with low background films for exposure periods of 7-10 days (exposure is carried out after first processing).

INTRODUCTION

The discovery of low detection threshold CR-39 track detector by Cartwright et al in 1978 and subsequent appearance of its improved version, SR-86 (Fujii & Yokota, 1988) has tremendously extended the areas of application of technique of Solid State Nuclear Track Detection (SSNTD). One of the noteworthy areas of its applications is "measurement of low levels of activity in a variety of matrices. Our interest in this area has been constantly growing over the years. (Bhagwat et al, 1988). During the followup studies it became evident that the background in CR-39 pieces is largely variable. Further, though it should be preferably low, there should be a way of knowing it in advance. The possibility of controlling the background should also exist. This paper suggests a new approach to the problem highlighted above.

APPROACH TO THE PROBLEM

A two-step processing of CR-39 was visualised for the purpose. The first step was intended to i) reveal the background in the film ii) show the surface quality, i.e. with or without scratches and iii) select pieces for a particular measurement based on acceptable level of background. It was also realised that background tracks will increase further in number during second step of processing. It is the background appearing in the second step which will interfere with experimental measurement. If possible therefore, it should be quantified to enable assessment of contribution from the experimental exposure. The details of this investigation are explained in the following sections.

EXPERIMENTAL

Since the whole exercise is oriented towards measurement of low track densities, it was decided to incorporate both chemical etching (CE) and Electrochemical etching (ECE) in each step of processing so that large/entire area of film could be easily counted. The optimum etching times were selected as follows.

The conditions of processing during second step were those adopted for revelation of alpha tracks in CR-39, i.e. CE of 6h in 6N KOH at 60°C and ECE at room temperature (22° - 24°C) for 15h employing 6N KOH and applying an AC field of 6 Vp/μm of film thickness (= 500 μm) at 500 Hz.

The ECE conditions for the first processing were maintained the same as those in the second processing. The time of CE was however, varied to study its influence on revealed number of tracks. This data is shown by the lower curve in fig. 1. The time of CE was varied from zero hour to 18 h in steps of 2 h. The initial part of this curve is shown by dashed line. This was because a smooth curve was difficult to draw in this region due to large scatter in experimental points. The latter part of the curve, however, shows a smooth variation and is depicted by a continuous curve. This part of the curve also reveals that observed number of background tracks is low for chemical etching times corresponding to 12 to 14 h. The time of CE in the first processing was therefore fixed at 12 h for all subsequent measurements.

The upper curve in fig. 1 shows the effect of second processing (where CE and ECE conditions are already fixed) on the data revealed by the lower curve. It is seen that in the region of continuous curve, the final number of tracks continues to be low for the same region where the first curve has its minimum. This further substantiates the selection of 12 h of CE in the first processing.

RESULTS AND DISCUSSION

In order to study the relationship between number of tracks revealed in the first and second processing steps, a large number of films were subjected to two processing steps without any exposure in between. Fig. 2 shows this data. A quantitative relationship is found to exist between two sets of data, i.e. it is possible to predict the background generated during the second processing from the number of ECE spots observed after the first processing. The figure also shows 95% confidence level (CL) lines (= 1.96 σ), i.e. the standard deviation of the second step background is automatically known for any level of background.

Before obtaining the line of best fit, Dixon Criterion (Dixon, 1973) at 90% C.L. was applied to search for possible outliers. Two points (out of 39) were rejected on this basis. The line of best fit was then obtained by the method of weighted least squares. The equation for this line is

$$Y = 0.845 X \text{ -----} \quad (1)$$

The upper and lower bound lines at 95% C.L. are

$$Y = 1.514 X \text{ -----} \quad (2) \quad \& \quad Y = 0.176 X \text{ -----} \quad (3)$$

The coefficient of correlation (r) for the data was found to be 0.465. Student's t -distribution test was also applied ($t=3.512$) to the data [$t(0.99)_{37}=2.447$ from the tables] which proved that a significant relationship exists ($3.512 > 2.447$).

A salient point about the above study is that it permits i) rejection of pieces with scratches and ii) calculation of MDL separately for each film based on its background observed after the first processing. The MDLs corresponding to 2σ and 3σ limit as a function of ECE spots observed after the first processing are shown in fig. 3. Thus for 30 (or less) ECE spots after first processing, one can measure activities as low as 0.2 mBq (≈ 5 femtocuries) for exposure period of one week (see the 30 line).

APPLICATION OF THE TECHNIQUE

The above technique was used to evaluate the strength of standard alpha sources of low activity, prepared by evaporating a few lambda of standard stock solution on teflon planchets. Source area was 10 mm in diameter. The teflon planchets were thoroughly cleaned previously by employing standard chemical procedures and their background was measured by SSNTD technique only.

CR-39 films (after their first processing) were exposed to two such sources twice for 12 days each. The measured average source strength was (0.018 ± 0.0018) dpm ($= 0.3$ mBq) which is in reasonably good agreement with the quoted value of (0.024 ± 0.006) dpm ($= 0.4$ mBq).

CONCLUSION

The above results confirm the utility of the technique at the level mentioned. Further improvements in M.D.L. are possible by increasing the time of exposure. However, more significant contribution to M.D.L. may come from future improvements in the quality of CR-39 leading to lower backgrounds and reduced uncertainties.

Abstract

A neutron spectrometer based on Bonner spheres has been calibrated in monoenergetic neutron beams. The response matrix has been interpolated using a one dimensional transport calculation. The unfolding code SAND has been implemented on a personal computer leading to a compact measuring system. The validation of the response matrix and of the unfolding procedure was performed using measurements of known spectra. The system has been applied satisfactorily as a reference instrument in nuclear power plants and near medical accelerators.

1. Introduction

Dosimetric quantities related to neutron irradiation are strongly dependent on the energy spectrum of the radiation. Two common methods are used in order to obtain relevant dosimetric information. In the first one the neutron energy fluence is measured using a set of moderating polyethylene spheres (Bonner spheres); the dosimetric quantities (absorbed dose, dose equivalent, quality factor and radiation weighting factors) are obtained by convoluting the energy spectrum with conversion factors derived from Monte Carlo calculations. The second method is based on microdosimetric measurements using a tissue equivalent proportional counter (TEPC); in this case the LET spectrum allows the calculation of the dosimetric quantities.

The first approach was chosen because it provides through the fluence energy spectrum a better insight into the radiation protection conditions. A particular effort has been devoted to the determination of the characteristics and the performances of the system and to its integration in a compact measuring system.

2. Description

The spectrometric system used [1] comprises 11 moderating spheres made of polyethylene with diameters of : 2, 2.5, 3, 4.2, 5, 6, 8, 9, 10, 12 and 15 inches (") (from 5.08 to 38.1 cm). Spheres with diameters smaller than 6" can be covered by a cylindrical cadmium box, in order to absorb the thermal component of the incident neutron spectrum. The thermal neutron detector used is a miniaturized proportional counter filled with

helium-3. The preamplifier located close to the counter is linked through 20 m long cables to a standard spectroscopy instrumentation. An optimal discrimination level which insures a good rejection of noise and γ rays without affecting the neutron sensitivity too much, has been chosen.

The dead time of the electronics is 6 μ s and the gamma sensitivity of the ^3He counter is very low (0.01 imp. / μ Sv for the cobalt-60 γ field). The nominal value of the counter's sensitivity to thermal neutrons is 6.10^4 imp./ μ Sv which leads to a relative sensitivity (n/γ) of 6.10^6 . Even in the worst case where the bare counter is placed in a hard spectrum such as that of americium-berillium and where the sensitivity to neutrons is 1 imp./ μ Sv only, the relative sensitivity (n/γ) of the counter remains of the order of 100.

The results obtained are corrected for the system's dead time and normalised to the indication of the fluence monitor. They are unfolded by a version of the code SAND [2] operating on a PC. The 640 energy groups originally used by SAND have been compressed into 120, in order to reduce the processing time. The SAND program has been implemented in an environment which allows to visualize the unfolded spectrum after each iteration. The program stops when a reasonable stability of the result is reached. The unfolding code provides, in addition to the neutron spectrum and the total neutron fluence, different dosimetric quantities such as : \hat{D}_n and \hat{H}_n using conversion factors given in ICRP publication 21; $D_n^*(10)$, $H_n^*(10)$, $C_m = H_n^*(10)/D_n^*(10)$ and the effective dose equivalent, using conversion factors given in ICRP publication 51.

In a moderate field strength (≈ 100 μ Sv/h) the duration of a complete measurement, using all the spheres, is of the order of 30'; the deconvolution needs about 2' in order to get a precision on the dosimetric quantities better than 10%. The deconvolution can be monitored by visualizing the iteration steps of the spectrum on a screen.

3. Performances

The spectrometer has been calibrated with thermal neutrons at Cadarache (France), and with several monoenergetic neutron beams of energies : 8; 144; 250; 570 keV et 1,2; 2,5; 5,0; 14,8 MeV at the PTB, Braunschweig (Germany). The interpolation of the response curves between the calibration points is based on neutron transport calculations using the one dimensional code ANISN [3] and a recent condensed cross section library. The calculation has been matched to the measurement using a unique parameter, the intrinsic counter efficiency. The response functions of the spheres are presented in figure 1.

Figure 1. Response functions of the Bonner spheres

The validation of the deconvolution has been performed using the measurement in known neutron beams of americium-beryllium, californium and heavy water moderated californium sources [4]. The results obtained (examples are given in figure 2) confirm the good performances of the system, including the response matrix and the unfolding procedure.

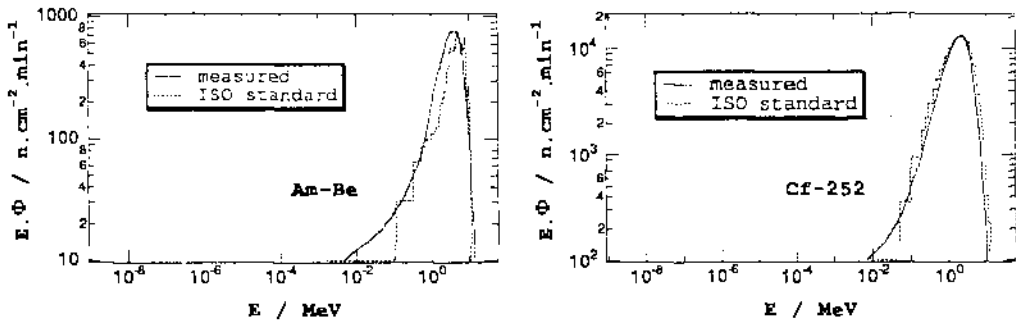

Figure 2. Comparison between the americium-beryllium and californium measured spectra and the ISO standard ones

4. Measurements of neutron fields

The system has been used in different neutron fields : nuclear power plants, medical accelerators, etc... It was not only possible to get the relevant dosimetric quantities, but also to calibrate operational instruments (rem-counters) in these fields [4]. On the other hand the knowledge of the spectrum gives a better insight into the radiation protection conditions.

In figure 3 the spectrum and the dosimetric quantities in two typical situations in a nuclear power plant are presented. The ratio of the response of the 9" sphere to that of the 3" sphere (9"/3") is given as a global indicator of the spectrum. The measurement near the entrance of the containment shows a moderated spectrum with a relatively low Q factor. The measurement performed near a transport flask presents a typical fission spectrum with hard components and a high Q factor.

Figure 3. Examples of neutron spectra inside the containment of a nuclear power plant (a), and near a transport flask (b)

5. Conclusions

The system presented is based on a firm background consisting of a detailed calibration and a careful validation of the unfolding. The instruments are incorporated in a compact system allowing on-site evaluation. It has been successfully applied in different neutron fields as a reference instrument.

ABSTRACT

CR-39 detectors were irradiated with fast neutrons and etched in several alkaline solutions. An automatic image analyzer was used to obtain the density and size distribution of etch pits. When etching conditions were kept at 30% KOH, 60°C and 8h, the sensitivity was found to be 3.1×10^{-4} , 4.2×10^{-4} and 2.0×10^{-4} for neutron energies of about 1MeV, several MeV and 14MeV, respectively. The size of etch pits increased with neutron energy. The etching time could be reduced to less than one tenth as a result of a rising from 60 °C to 90°C. After due consideration of background counts, a dose of 0.2mSv could be measured with this system.

INTRODUCTION

Many types of CR 39 detectors are used for personal neutron dosimetry. Chemical and electrochemical etching are performed to enlarge latent tracks caused by nuclear reactions to etch pits. There are several methods to count the etch-pits. A lot of conditions are proposed for the etching and the counting. The energy response of the detectors depends on the combination of these conditions intensely.^{1,2)} It is important to know the energy response under adapted etching and counting conditions for accurate dosimetry.

There is a demand for shorter etching time of CR-39 detectors. Several hours or more prolonged etching time is too long to adapt for practical measurement. Generally, high temperature promotes the etching, though it has a tendency to roughen the detector surface. It is set as a goal in this study to reduce the etching time to one hour or less without enhancement in surface roughness. In this study, sensitivity is measured for three energy regions of fast neutrons under our conventional and present etching conditions.

EXPERIMENTAL METHODS

The composition of the CR 39 plates used in the present study was 97% of allyl diglycol carbonate and 3% of diisopropyl peroxy

dicarbonate. The transparent plate with a thickness of 1.6mm was sandwiched with polyethylene sheets with a thickness of 0.1mm to form a detector. The detectors were irradiated with about 1MeV neutrons from a fast neutron source reactor, several MeV neutrons from an Am-Be source or 14MeV neutrons from a Cockcroft Walton type accelerator. Irradiated neutron fluences were estimated by an activation method.

After irradiation, the CR 39 plates were separated from the polyethylene sheets, and were etched in aqueous solutions of 30 wt% of KOH or NaOH at 60-90 °C for 0.4-20h. The solution was agitated by magnetic driven vanes during etching. After etching, the plates were immediately washed clean in flowing water and dried under clean ventilation. In order to determine the amount of bulk etching, plate thicknesses were measured before and after etching by micrometer callipers.

Etch pits and the state of the surfaces were observed using an optical microscope. The etch pits were counted with an automatic image analyzer having an optical microscope, TV camera and computer. The distributions of etch-pit diameters were measured with this analyzer. The number of etch-pits on an unirradiated and etched plate was subtracted from that of an irradiated and similarly etched plate.

Fig. 1 Growth of etch-pits on a CR-39 plate irradiated with fission neutrons. Etching conditions : 30% KOH, 60°C. Etching time : a 4h, b 8h, c 12h, d 16h.

EXPERIMENTAL RESULTS AND DISCUSSION

Figures 1(a-d) reveal the transition in shape and number of etch pits on a plate irradiated with about 1MeV neutrons. They represent the photographs of the same area of the plate at successive stages of etching, to show how individual etch-pits generate, grow and then disappear with progress of etching. It will be noted that in the course of etching, new etch pits are continually making their appearance. The etch-pits grow in size with etching time, become easily detectable and remain so during a certain period. Beyond the certain limits of etching time, however the etch pits begin to lose their shape, which makes it difficult to avoid counting loss.

The automatic image analyzer is able to adjust the lower limit of etch pit diameter and of contrast between etch-pit's black and surface's white. The lower limit of the diameter was set for 2 μm . That of the contrast was adjusted to be able to discriminate the etch pits from the surface roughness. The number of countable etch-pits increased rapidly with etching time in the first stage of etching. However, in the prolonged etching time, the increasing rate became slow because the appearance of the etch-pits had to compensate for the disappearance. From these observations, it was found that 8-12 hours were suitable for etching time when 30% solution of KOH or NaOH was used at 60°C.

With respect to 14MeV neutrons, Fig.2 shows an increase of etch-pit density and sensitivity with etching time. The ratio of the etch

Fig.2 Increase of etch pit density and sensitivity with etching time

pit density to the neutron fluence is termed sensitivity. In the case of about 1MeV and several MeV, similar relationships were obtained. When etching conditions were kept constant, the sensitivity was the highest for several MeV, middle for about 1MeV and the lowest for 14MeV. For example, when the condition was kept 30%KOH, 60°C and 8h, the sensitivities were found to be 3.1×10^{-4} , 4.2×10^{-4} and 2.0×10^{-4} for neutron energies of about 1MeV, several MeV and 14MeV, respectively. When etching conditions were kept constant, the average of etch-pit diameter increased with neutron energy.

From the experimental results, the following formulas (1) and (2) were obtained as relationships of bulk etching rate $V(\mu\text{m/h})$ and temperature $T(\text{K})$ of etching solution for KOH and NaOH.

$$V = 3.17 \times 10^{18} \exp(-1.13 \times 10^4 / T) \quad (1)$$

$$V = 3.11 \times 10^{18} \exp(-1.12 \times 10^4 / T) \quad (2)$$

Activation energies are calculated to be 0.89 and 0.88 eV for KOH and NaOH from the formulas (1) and (2). These values agree with the value derived before.³⁾ The bulk etching rate at 90 °C is twelve times as fast as that at 60°C. The increasing rates of the sensitivity and the etch pit diameter are approximately proportional to the bulk etching rate. The etching time could actually be reduced to less than one tenth as a result of a rising from 60°C to 90°C. This increase did not change the energy response and did not enhance in surface roughness. After due consideration of background counts, it was found that a dose of 0.2mSv can be measured with this detection system. At the present time, we adopt 30% KOH, 90 °C and 1h as ordinary etching conditions for fast neutron dosimetry.

**FIXED RADIATION PROTECTION CHANNELS ON EDF PWR
Gilles Champion EDF/SEPTEN F-69628 VILLEURBANNE
Jean-Marie Houin MERLIN GERIN PROVENCE BP No. 1 F-13560 SENAS**

INTRODUCTION

The power plant unit radiation protection system (designated KRT) groups together the fixed radiation protection channels designed for the radiation monitoring of a PWR in order to :

- check the condition of the various containment barriers,
- monitor the radioactive discharges into the environment,
- protect the personnel working on a PWR,
- assist the operator in an accident situation.

To fulfil all these functions with the minimum amount of different equipment items, it is merely necessary to combine about 80 different subassemblies (detectors, electronic signal shaping, ratemeters) to form the 50 channels which are installed on each EDF PWR. This modularity enables a channel to be easily tailored to the required function.

The methodology adopted by EDF and the manufacturer MERLIN GERIN PROVENCE to define the measurement subassemblies, select the sensor locations and qualify the equipment items complies with the IEC standards.

DESCRIPTION

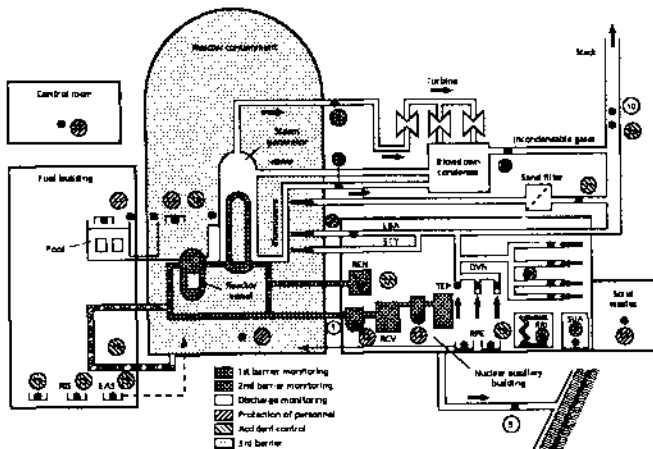

The location of the sensors is schematically shown in the drawing hereafter.

1. Barriers

The Process Stream Radiation Monitoring channel used for the first barrier is marked (1) in the diagram (IEC standard 768).

Checking of the second barrier requires the provision of more channels sensitive enough to detect as soon as possible the presence of noble gases in the air, indicating the loss of tightness of this barrier (locations 2 and 8). This also concerns the steam system for checking the condition of the steam generator (locations 3, 4 and 5), the intermediate cooling system (6) and the condensates of the heat exchangers (7) installed in the nuclear auxiliary building. The gas channels comply with IEC project standard 45A145.

900 MW REACTOR SCHEMATIC DIAGRAMM

2. Discharges

The liquid discharges (9) are monitored so as to prevent release into the environment due to a handling error (IEC standard 861). The gaseous discharges (10) are monitored at the stack by means of noble gas and aerosol channels (IEC standards 761-2 and 761-3).

3. Protection of Personnel

The aerosols and iodine in the air of the containment in the plant shutdown configuration are monitored (location 2). Area monitors are used for monitoring the irradiation (IEC standards 1031 and 532) :

- above the spent fuel pool (location 11),
- due to the head filters of the RCV (reactor control volumetry) and TEP (boron recycling) systems (locations 12 and 13),
- due to the solid wastes (location 14),
- in the control room (location 15).

4. Accident Condition

The containment air (16, IEC standard 951-3), primary coolant (17, IEC project standard 45A122), sump recirculation water (13) and the sumps (19) are monitored. The gases at the stack are also monitored in an accident condition (20, IEC standard 951-3).

EQUIPMENT AND RELEVANT QUALIFICATION

The measurement channel sensors are manufactured with the application of time-proved ionizing radiation measurement techniques and mainly concern :

- scintillation detectors (mainly sodium iodide) with coupled photomultiplier,
- proportional counters, Geiger-Müller or ionization chambers (simple and differential).

The experience gained from the operation of a great amount of identical equipment items has been taken into account to improve the equipment since the start of the French nuclear program.

The EDF radiation protection Technical Specifications (TS) is the reference document which has enabled coherence to be obtained between the manufactured and installed equipment.

The TS is in coherence with the IEC general recommendations concerning the qualification of electric equipment (IEC standard 780 : Qualification of Electrical Items, and IEC standard 980 : Recommended Practices for Seismic Qualification) and those relative to radiation protection channels (IEC standard 761-1 : Equipment for Continuously Monitoring Radioactivity in Gaseous Effluents, and IEC standard 951-1 : Radiation Monitoring Equipment for Accident and Post-Accident Conditions, and IEC project standard 45 BWC9 : Centralized System for Continuous Monitoring of Radiations).

The tests intended to check the conformity of the equipment items with the TS have been conducted for fifteen years by EDF in collaboration with the manufacturer. It is to be noted that all the subassemblies integrated in the fixed channels have been tested.

DEVELOPMENTS

The development of VAMCIS indicates the course followed by EDF and MERLIN GERIN PROVENCE for the design of channels providing better performance. This channel was constantly developed as from 1985 for both the continuous measurement of leaks in steam generators and the detection of a sudden rupture of a generator tube. This channel is installed at (5) in the diagram, in contact with the steam line and upstream of the relief valve.

Its rapid development and installation on all the steam generators (SG) of the EDF PWR was made necessary by the rapid degradation of the SG tubes, the absence of a continuous measurement without sampling, sufficiently reliable and accurate to indicate the leak rates.

If the sensor is still based on a scintillating system with sodium

iodide, the electronics has greatly advanced in order to :

- analyze the signal energy per 30 keV channel. This spectrometric measurement is accurate enough to identify the nitrogen 16 peaks,
- allow for the influence parameters (nuclear power, temperature) to suppress inadvertent drifts,
- make better use of the microprocessor capabilities for converting the raw count rates (pulses per second) into leak physical units (liters/hour).

The development of new fixed radiation protection channels to be installed on the future PWRs will be conducted according to these directions so as to possess information as regards the nature of the fission products in the primary coolant and the air of the containment. This will enable the harmonious integration of the increasingly strict requirements of the Safety Authorities as regards the control of nuclear accidents.

STEAM GENERATOR LEAK RATE MEASUREMENT CHANNEL - VAMCIS

CONCLUSION

The French system is installed in numerous power plants other than those of EDF, particularly the KOEBERG, ULJIN and DAYA BAY, VANDELLOS and SIZEWELL power plants. Many channels (VAMCIS, CHEG for instance) have been installed on Spanish, American and Belgian PWRs and in Slovenia.

These references provide the utmost guarantee for power plant operators as regards the availability of a dependable source for the procurement of spare parts throughout the operational life of a power plant. EDF also plays an important role by ensuring that the nuclear qualification of equipment items is maintained owing to the product surveillance system.

AN α -ACTIVITY IMAGING MONITOR SYSTEM FOR RAPIDLY DETECTING PU CONTAMINATION

ABSTRACT

A new type of α -activity imaging monitor system was constructed for rapidly obtaining the position profile of Pu contamination on filter paper. The system consists of a detector head, an image intensifier, a low-lag vidicon and an image processor. When the integrated image is taken with 10 min., PuO₂ particles more than 0.03 Bq and Pu(NO₃)₄ particles more than 0.13 Bq can be rapidly detected by spot separation processing.

INTRODUCTION

When an air monitor gives extraordinary α counts in Pu facilities, it is necessary to distinguish rapidly between Pu contamination and Rn daughters¹⁾. If the α counts are judged to be caused by Pu particles, the size distribution is an important in evaluating the inhalation exposures.

The authors constructed an α -activity imaging monitor system which was developed from the charged-particle imaging video monitor system²⁾. The present paper describes the methods for distinguishing between Pu particles and Rn daughters and estimating the size distribution of Pu particles.

IMAGING MONITOR SYSTEM

The schematic diagram of the imaging monitor system is shown in Fig. 1. The system consists of a detector head, an image intensifier, a low-lag vidicon and an image processor. The light image of α particles is integrated in the image processor. The system can display the distribution image of α particles becoming gradually clearer on a video display. The image memory consists of 512×512×16 bit words (512 k bytes). The integrated image and the processed image are stored on a floppy disk.

IMAGE PROCESSING FOR RAPID DETECTION OF PU CONTAMINATION

When the integrated image of a filter paper is taken immediately after sampling, both α spots of Pu particles and Rn daughters are observed on the image. Large Pu particles result in clearer α spots, while small Pu particles produce only a cluster of a few small α spots. Smoothing process is effective

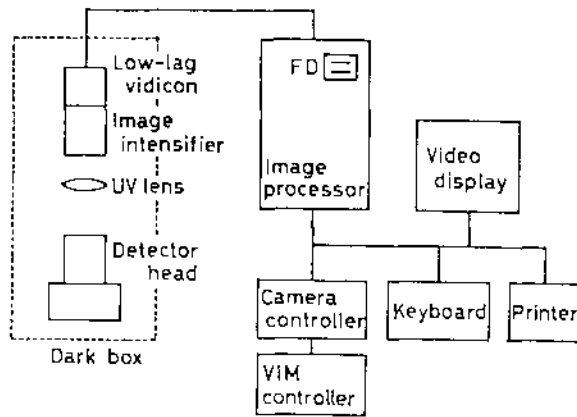

Fig. 1 Schematic diagram of the α -activity imaging monitor system.

Fig. 2 Distribution images of (a) PuO_2 and (b) $\text{Pu}(\text{NO}_3)_4$ particles. Superimposed images of Rn daughters images of 1,771 counts and the images of (c) PuO_2 and (d) $\text{Pu}(\text{NO}_3)_4$ particles.

for collecting the scattering α spots into one spots.

The integrated image shows nonuniformity. To evaluate the

image quantitatively, the uniformity correction process has been carried out by using a standardized α image.

The spots of Pu particles are separated from the small spots of Rn daughters by using threshold level (TL) and separate level (SL) determined as a function of Rn daughters concentration on the filter. The values of TL and SL were decided as the probabilities that the counts of one pixel and one spot have more than TL and SL are less than 0.05, respectively.

DISTINCTION BETWEEN PU PARTICLES AND RN DAUGHTERS

The applicability of the system for distinguishing Pu particles from Rn daughters was studied by using filters contaminated with PuO_2 particles, $\text{Pu}(\text{NO}_3)_4$ particles and Rn daughters. The whole activities of PuO_2 and $\text{Pu}(\text{NO}_3)_4$ particles are 2.37 Bq and 1.60 Bq. Figures 2 (a) and (b) show the images of PuO_2 and $\text{Pu}(\text{NO}_3)_4$ particles taken with 90 and 60 min. Figures 2 (c) and (d) shows the superimposed images of Rn daughters image of 1.771 counts and the images of PuO_2 and $\text{Pu}(\text{NO}_3)_4$ particles. The Rn daughters images of 5.475 and 10.857 counts were also superimposed on the images of PuO_2 and $\text{Pu}(\text{NO}_3)_4$ particles.

Figure 3 shows the detection limits of PuO_2 and $\text{Pu}(\text{NO}_3)_4$ particles when Rn daughters are present on the filter. The PuO_2 particle of 0.03 Bq ($1.41 \mu\text{m}$: activity equivalent spherical diameter) and $\text{Pu}(\text{NO}_3)_4$ particle of 0.13 Bq ($3.43 \mu\text{m}$) may be detected within 10 min, even if Rn daughters of 2 Bq are present on the filter. The activities of PuO_2 and $\text{Pu}(\text{NO}_3)_4$ particles of 0.03 Bq and 0.13 Bq in air per 1 m^3 are lower than DAC of ^{239}Pu particle ($0.2 \text{ Bq}\cdot\text{m}^{-3}$) in air.

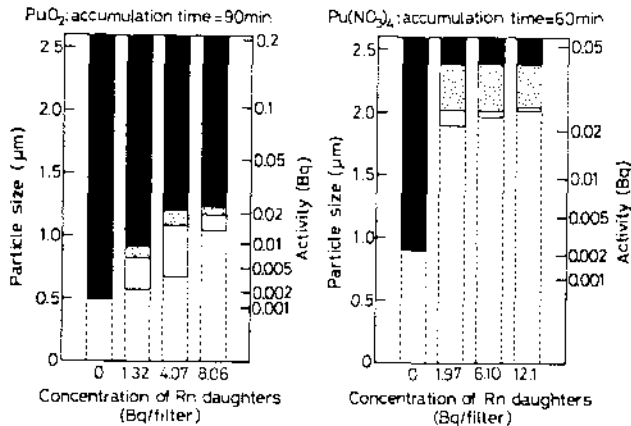

Fig. 3 Detection limits of PuO_2 particles and $\text{Pu}(\text{NO}_3)_4$ particles when Rn daughters are present on the filter.

ACTIVITY AND SIZE DISTRIBUTION OF PU PARTICLES

Radioactivity of PuO_2 particle is given by

$$D = 4.01 \cdot C \tag{1}$$

where D is PuO_2 activity (Bq) and C is the α count obtained on a uniformity-corrected image. The relation between the size and the activity of PuO_2 particle is given by

$$Y = (k \cdot D)^{1/3} \quad (2)$$

where Y is particle diameter (μm) and k is constant of 83.4 for PuO_2 particles and 319 for $\text{Pu}(\text{NO}_3)_4$ particles³⁾.

The spot count of each Pu particle in Figs. 2 (c) and (d) is converted into size by eqs. (1) and (2). The results shown in Figs. 4(a) and (b). The size of almost Pu particles is less than 4 μm .

Fig. 4 Size distribution of (a) PuO_2 and (b) $\text{Pu}(\text{NO}_3)_4$ particles.

CONCLUSIONS

The α -activity imaging monitor system has good spatial resolution. The integrated image can be evaluated quantitatively by the software programs. When the integrated image is taken with 10 min., PuO_2 and $\text{Pu}(\text{NO}_3)_4$ particles more than 0.03 Bq and 0.13Bq can be rapidly distinguished from En daughters by the spot separation processing. Moreover, the size distribution of Pu particles can also be determined from the integrated image.

INTELLIGENT DOSE RATE DETECTORS
FOR RADIATION MONITORING IN AUTOMATIC MEASURING NETWORKS

W.Rieck, H.Faatz, J.Frowein, B.Hoffmann, M.Iwatschenko-Borho, H.Schleicher

FAG Kugelfischer, Erzeugnisbereich Strahlenmeßtechnik, Erlangen, Germany

ABSTRACT

Several gamma and neutron doserate detectors have been recently developed which are specially designed for the application in networks: All the electronic components which are necessary for an automatic measurement mode are integrated inside the detector. This also includes a microprocessor and a serial interface. On request the probe transmits the complete measurement information. Up to 32 probes can be operated in one network.

A newly developed PC program (MRP = Monitoring Radiation Program) allows to handle, present, and store the data of up to 32 intelligent probes additionally to the data of other radiation monitors.

INTRODUCTION

Automatic ambient radiation measurements require the periodic acquisition and evaluation of signals. For this purpose in conventional systems the detector signals have to be amplified, computed and translated into a computer readable format. The new FHZ 601 A intelligent dose rate detectors perform all these steps of signal processing itself by its integrated microprocessor and analogue devices. The detector delivers completely calibrated digital data via a serial interface.

DETECTOR EXAMPLE

The FHZ 601 A intelligent probe combines the advantages of modern microprocessor electronics with the excellent properties of the FHZ 600 A proportional detector [1] which is successfully in use in several measurement networks and monitoring stations. The high sensitivity and the wide measuring range have as well been fully retained as the typical angular and energy response (see fig. 1). For the FHZ 600 A proportional

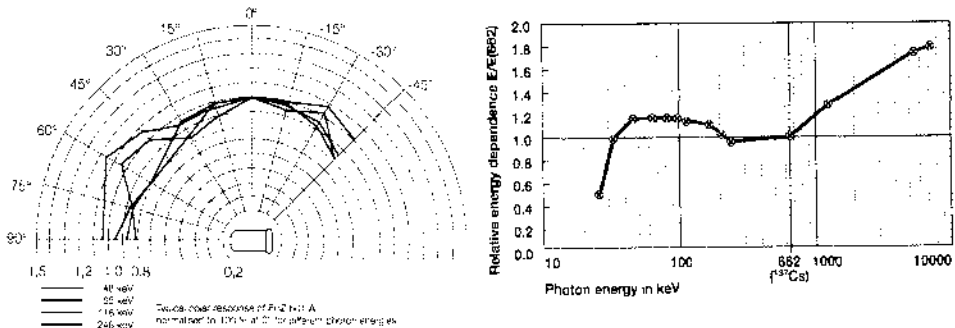

fig. 1: typical angular and energy response of the FHZ 601 A

detector as well as for the FHZ 601 A intelligent detector the approval for official calibration by German authority has been given /2/. The individual correspondence of a probe and its measuring and display instrument in a calibrated system is no longer necessary. Intelligent probes are calibrated as an independent system and can be substituted by any other one by chance without losing the calibration of the system.

THE ELECTRONICS

Modern technologies such as SMD technics, flexible printed circuits, and ASIC devices were used to build up the intelligent probe. It contains the energy filtered proportional counter, the high voltage supply, preamplifier, the whole counting electronics and an integrated microprocessor with a serial interface RS 485. The microprocessor controls the whole measurement and transmits a calibrated measuring value to the serial interface. Additionally it permanently performs self-tests for all devices and measures the operating and ambient conditions. The results are transmitted to the RS 485 interface as a status information.

The probe does not require any special display unit. For data acquisition and display a standard PC can be used. A software program for data handling in the PC is available (see below).

THE FHZ 601 A LN NETWORKS

The RS 485 interface permits the construction of local measuring networks, in which up to 32 probes can be operated from a central control station in a simple twisted pair bus system. Each probe can individually be addressed (0..31). Data transmission takes place at 2400 or 9600 bit/s via cables which may exceed even a length of 1000 m. Data transmission over distances of 3 km has successfully been tested /3/.

The measurement information is transmitted by a Level 2 protocol (ISO/OSI) listed in DIN 66348 to protect data against transmission errors. The data telegram contains not only the measured value but also an identification parameter and various status information. This telegram permits

- the identification of the source i.e. the transmitting probe
- a check of the data transfer
- a permanent control of the operating conditions and the status.

The permanent self-tests detect any ambient or operating conditions out of the normal range and report them as a status information. These tests include:

- measurement of the supply voltage for the digital electronics
- measurement of the temperature
- control of the detector amplification
- preamplifier tests by permanently injecting sets of test pulses
- control of the minimum countrate (detector failure)
- watchdog routines

Further the calibration and measuring parameters can be read out by the user and a plateau measuring routine is available that can be operated on request.

A built-in history memory stores up to 256 measuring values including time and status. The measurement is therefore independent of the connection to a central computer. On request the history data can be read out without disturbing the actual measurement.

CALIBRATION

All the calibration parameters (including two correction factors and the intrinsic background) and related information such as serial number, detector type, and software version are stored in the permanent memory (EEPROM) of each probe. The probe is calibrated at three dose rate levels. This calibration takes place once before delivery. After this initial calibration the calibration data are locked and can not accidentally be changed. For recalibration a hardware switch inside the probe has to be manipulated. Therefore by sealing the detector housing the calibration data are protected against any unauthorized changes.

THE INTELLIGENT PROBE'S FAMILY

The electronics of the FHZ 601 A is also integrated into other proportional detectors.

The probe FHZ 621 A covers the middle and high dose rate range from 50 nSv/h to 25 mSv/h. The FHZ 621 A is also PTB approved. The BIOREM FHT 750 neutron detector which uses a BF_3 proportional detector has been combined with the intelligent electronics and thus represents an intelligent neutron detector. This development allows the parallel integration of neutron and gamma detectors in the same network.

For further applications the intelligent electronics has been integrated into an ion chamber which can therefore also be used in a network together with the other detectors of the intelligent family.

MRP MONITORING RADIATION PROGRAM

As a powerful tool for analysing and interpreting the measured values a special PC-program has been designed. It allows the acquisition, storage and presentation of the measurement results from up to eight stand alone radiation monitors e.g. aerosol monitors or from up to 6 radiation monitors plus 32 dose rate probes such as e.g. the FHZ 601 A (fig. 2). According to their interactive communication with the user 3 groups of routines can be found:

1. Automatically running routines without interactive control.

These routines are automatically executed after program start up:

- The measuring values of the connected monitors and detectors are periodically acquired. Depending on preset parameters the chart of the last 1 to 31 days of the measured values is graphically displayed. Additionally another set of measured values may be displayed numerically. Fast changing values may also appear in an analogue display as a bargraph.

- Error messages from the remote monitors and exceeded alarm levels as well as transmission failures are signaled optically and acoustically.

2. Routines requiring user dialogue

Using the function keys explained on the monitor the following operations may be executed:

- Change of the time and measured value scale of the graphic display.
- Selection of the measured values to be displayed.
- Display of measured values from any time period during the last 10 months and calculating the average values of selectable regions.
- Numerical output of a complete data set for any selected time.
- Display of a protocol file containing error messages from the remote monitors and exceeded alarm levels as well as transmission failures together with the time they occurred.
- Execution of special functions e.g. control of a multi channel analyser.

All these functions do not affect the permanent data acquisition of the actual measured values.

3. Configuration Files

The preset values for the complete program (such as time period of the data acquisition, number of the monitors and detectors, scale and colours of the graphic display and many more) are stored in external ASCII files. This allows the user to modify these parameters and thus to adapt the program to new hardware configurations or to modified requirements.

HEALTH PHYSICS INSTRUMENTATION
A PROGRESS REPORT

R. Maushart

Laboratorium Prof.Dr.Berthold GmbH & Co.
Wildbad, Germany

ABSTRACT

Health Physics Instruments have changed rather dramatically in the past decade. On the one hand, technological innovations like Microprocessors, data storage facilities and imaging displays have altered shape, size and appearance of the classical devices, particularly the hand-held ones. On the other hand, instruments are increasingly being considered as an integral part of Radiation Protection procedures and organisations, supporting a smooth and reliable implementation of all necessary measures. This implies ease of operation, and extensive self-checking and performance control features.

Since there are different categories of users with quite different degrees of motivation and training, the measuring instruments of the future will have to be adapted to specific types of users. Instruments for "professional" radiation protection - for example in nuclear power plants and nuclear technology - will differ from instruments used in the radionuclide laboratory, where radiation protection will necessarily have to be done as a "side-job".

TODAY'S STATE OF THE ART IN THE DEVELOPMENT OF MEASURING INSTRUMENTS

The present state of the art in measuring technique can be illustrated by means of several types of instruments which are employed for important tasks in radiation protection in the medical field.

A large variety of portable doserate measuring instruments with digital microprocessor systems is available on the market. Their detector is usually a built-in miniature GM counter tube, and a more or less great assortment of external probes may be connected in addition.

Strangely enough, instruments with scintillation detectors have hardly been improved since they were introduced into the market one and a half decades ago; the technology change in electronics seems to have passed by these instruments.

Portable instruments using an ionization chamber as a detector are mainly supplied by US manufacturers. German manufacturers offer only two instruments, both rather obsolete.

Still hardly available - probably due to the low demand - are instruments capable of measuring the beta doserate.

Stationary doserate measuring systems used, for example, for the monitoring of accelerators are worlds apart from the first generation of analog ratemeters.

Usually, they operate, like the portable instruments, almost exclusively with digital result display. Moreover, they incorporate a significant intelligence, such as sliding time constants, dose integration, result storage over longer time periods, and autonomous programs for data transfer to a printer or computer, with data transfer option via bus lines.

The different energy and doserate ranges for specific applications are covered by a broad assortment of GM, proportional and ionization chamber probes.

Rem counters - which actually should be called Sievert counters - with BF_3 or ^3He counter tubes or even LiI scintillation counters as detectors in combination with large moderator spheres are still employed for the measurement of the **neutron doserate**. Alternative systems such as the "Dineutron" made by a French company, or tissue-equivalent proportional counter tubes (TEPC), whose development has been reported a number of years ago, have not been very successful so far.

Xenon large-area counter tubes in combination with pre-selectable nuclide-specific calibration factors for Bq/cm^2 display are fairly common in portable contamination monitors. Wall holding devices allow their application as semi-stationary units for exit control. Sophisticated calculation methods for determining the measured value have largely eliminated the slow reaction of the display of older ratemeter units. Background storage is a standard feature with most instruments.

Self-monitoring and test routines are also fairly common. However, some instruments appear to be "over-refined"; simple handling, an essential factor for the every-day use in the laboratory, is sacrificed to a large number of parameters which can be selected and edited by the user.

In the aftermath of accidents involving person contaminations one usually has to perform measurements under difficult conditions, such as high humidity or bad visibility. Many of our modern contamination monitors do justice to these requirements.

The external design of personal contamination monitors reflects the modern technology they incorporate. Detector contaminations are monitored, external radiation fields compensated, measurement times adapted to the statistics. Monitors for graphic, location-related result display are fairly common. Highly advanced data processing allows the build-up of a network of recording systems comprising contamination monitors, access control and a PC-based central evaluation station.

In the medical field, the measurement of gaseous radioactivity is required particularly in two areas: for the diagnostic use of the radioactive noble gases ^{85}Kr and ^{133}Xe , on the one hand, and for the room and waste air monitoring of accelerators, on the other hand. The monitoring systems used for this purpose usually still operate with large-area proportional counter tubes, occasionally also with surface layer semiconductors as detectors. The progress becomes obvious largely in the subsequently connected "smart" electronics.

Detectors used for **iodine measurement** which is more and more required and employed in room air monitoring on therapy stations did not change much over the last years. The noise reduction was improved, however. Specially designed low-noise instruments are capable of reaching sound levels around 50 db.

FUTURE TRENDS IN THE DEVELOPMENT OF MEASURING INSTRUMENTS

With regard to the measuring electronics the change in technology is largely completed. Microelectronics, surface mounting and hybrid technique, and the use of solid-state data memory affect the appearance and performance of the instruments.

With regard to the detectors, however, the technology has hardly changed in recent years, leaving aside the introduction of highest grade germanium detectors for high resolution gamma spectrometry. This will change in the years ahead.

Geiger-Müller counter tubes are still preferred for dose-rate measurement, particularly in portable instruments. Their weak points are the limited service life, in particular with high doserates, the measuring range which is limited to a maximum of 5 decades, and the inadequate sensitivity in the energy range below 40 keV.

These detectors will be replaced by very small proportional counter tubes in ceramic technology which can be employed in particular in the low energy range required in radiology.

Silicium-PIN-detectors offer another alternative to the GM counter tube, especially for low-priced instruments.

Large-area proportional counter tubes for contamination measurement will be constructed in plastic technology. This allows the simple electrical division of very large detector areas into small, separate counting elements.

Thus, position-resolution detectors for scanning extensive contaminated areas can be realized, for example as one square meter large mosaic of one hundred individual detectors with 100 cm^2 window area each.

The detectors will incorporate an integrated microelectronics including the HV supply. The counts will thus be stored in the detector unit itself and then transferred to the measuring electronics as a data package. Thick, shielded HV and pulse cables between detector and evaluation electronics will become obsolete.

Now that the instruments have become rather similar in performance, future improvements will mainly be concerned with the outer design, an aspect which indeed has often been somewhat neglected. Occasionally one can even notice quite "fashionable" trends which have not much to do with any progress in measuring technique.

All instruments, even the portable ones, will include computer interfaces. Thus, one can output data and analyze and display it on a PC; on the other hand, parameters in the instrument can be edited and test routines can be run via the PC. Complete programs may also be entered via a barcode reader.

The portable instruments show a distinct trend toward a universal electronics suitable for a variety of applications when using different detectors. Thus, the circle becomes complete, with the disadvantages apparent in the very first instruments, especially of American origin, being completely eliminated today. Set-up routines by the user have become redundant. The modern electronics identifies the respective detector and automatically defines all pertinent parameters, such as calibration factors and display units.

The performance test, the automatic comparison of current reference values with stored standard values via so-called utility programs, will become more common. The constant storage of data, for example background rates or the detector efficiency, and the presentation of time curves permits the user to assess the stability of the system and to recognize drifts or aging effects in time.

Modern data storage technology, the versatile combination and presentation offer nearly unlimited opportunities. Unfortunately, this has led to a trend to overload the instruments with fancy electronic features and thus to overtax the user's abilities by manifold operation options and program ramifications. Finding a reasonable compromise will be the goal of the development for the years to come.

Today we are in an integrative phase of radiation protection measuring technique development. The measuring task, i.e. the safe and reliable radiation protection, must determine the appearance and performance features of the measuring instruments. They will have to be more and more integrated into the process of operative radiation protection. The user interface, the interaction of instrument and user, will play therefore a dominant role in future Health Physics Instrumentation.

CHARACTERISTICS OF TWO GAMMA-RAY SURVEY METERS
USED FOR INFLIGHT DOSE EQUIVALENT RATE MEASUREMENTS

D. Regulla and J. David
GSF - Forschungszentrum für Umwelt und Gesundheit,
D-8042 Neuherberg, Federal Republic of Germany

U. Lauterbach and W. Peßara
Physikalisch-Technische Bundesanstalt,
D-3307 Braunschweig, Federal Republic of Germany

Abstract

Survey meters as developed for terrestrial environmental radiation dosimetry are recently also used for inflight measurements of cosmic radiation. In order to interpret the measured data correctly the characteristics of these instruments in a cosmic ray environment must be considered. The present investigations deal with established equipment, i.e., (a) a high pressure ionization chamber dose equivalent rate meter (Reuter-Stokes RSS-112) and (b) a scintillation dose-equivalent rate meter (Halle DLM 7908). Both equipment was applied during an extended GSF research programme in 1990/91 on "Radiation Exposure of Civil Aircrews and Passengers" on board of passenger aircraft of Lufthansa German Airlines (Boeing 747-400) for the major intercontinental flight routes.

The equipment was studied with respect to the following characteristics: Inherent background; linearity of the readings in low dose rate photon fields; response to cesium 137 gamma rays, high energy photons, high-energy charged particles and neutrons.

It is shown that each parameter may, under laboratory conditions, lead to significant differences in the dose equivalent rates as indicated by the two instruments. After evaluation and application of appropriate correction factors however the dose equivalent rates can be brought into good agreement. For completeness, the influence of the proposed corrections on the dose equivalent rates is quantified for cosmic ray field conditions as found on flight altitudes during the GSF inflight programme.

MULTI-COUNTER SYSTEM FOR LOW LEVEL MEASUREMENTS OF ENVIRONMENTAL SAMPLES

H.Schlösser, U.Engel, R.Ringling, M.Iwatschenko-Borho

FAG Kugelfischer, D-8520 Erlangen,
Frauenauracherstr. 98, Germany

ABSTRACT

A new multi-counter system for the measurement of environmental samples is described. The system measures simultaneously alpha and beta contaminations down to the mBq range with high accuracy. Up to 12 samples can be measured simultaneously. Individual counting times can be used and samples can be changed without disturbing the measurement of the others.

INTRODUCTION

For the measurement of environmental samples like soil, air filters or smear-tests, FAG Kugelfischer developed a variety of different detector systems^{1,2,3} during the last years. Routine measurements are usually done by automatic sample-changers or by manually operated multi-counter systems. Especially in the case of very long counting times with a great amount of samples the use of multicounter systems is advantageous. Additionally multi-counter systems are very helpful instruments, in case of incidents with a need to have a quick information about the collected samples, because they have a higher throughput as single automatic systems.

Recently we developed a new multi-counter system FHT 770 T to measure simultaneously the low level alpha and beta contamination of 6 or 12 samples. Thus it is possible to perform the measurement 6 or 12 times faster compared to a single system. Furthermore the simultaneous measurement of alpha and beta contaminations saves an additional factor of 2.

THE MULTI-COUNTER SYSTEM FHT 770 T

The FHT 770 T shown in Fig 1. is designed for laboratories in the nuclear, chemical, pharmaceutical or research industry, for analysis of foodstuff and for the use in the field of general health physics.

The system consists of the detector assembly, the lead shielding and the electronics with preamplifier, high voltage generator and counters. These components are placed in the shown box. The dimensions of the box are 615 x 650 x 455 mm³ for the 6 sample version or 615 x 650 x 530 mm³ for the 12 sample version. The total weight is approximately 950 kg or 1200 kg respectively. The system includes 3 or 6 manually operated sample slides each provided with two measuring positions with 60 mm diameter and a maximum depth of 8 mm.

The detector assembly uses 6 or 12 single proportional gas-flow counters, designed for the use with Ar-Methane 90/10 gas or Ar-CO₂ 82/18 gas. Every 6 counters are guarded by a large area proportional counter to suppress the cosmic-ray background by using an anticoincidence technique. Each counter is provided with <0.5 mg/cm² gold coated polyester window with a diameter of 60 mm.

Fig. 1 Photograph of the multi-counter system for 6 samples

The use of multi-wire technique gives a small variation of the detection efficiency over the detector surface. The detector assembly is surrounded by a lead shielding of 100 mm thickness to reduce the ambient background radiation.

The electronic system is shown as a block diagram in Fig 2.

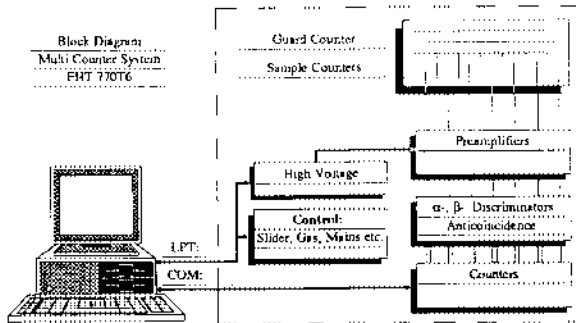

Fig 2 Block diagram of the electronics of the FHT 770 T

The signals produced by alpha- or beta-particles in the FHT 770 T are amplified by the preamplifier module and fed to discriminators which distinguish between alpha and beta signals. An anticoincidence circuit eliminates the background produced in the counters by cosmic radiation. The remaining signals are fed to counters which are controlled via one serial port by a personal computer. The high voltage of the detectors can be set by the PC via one parallel port. The control module gives information about the actual sample slide position and controls the automatic gas supply unit, which supply the detectors with gas and protects them against overpressure.

For operation of the measuring system, an IBM compatible Personal Computer is required which must be fitted with at least one serial and one parallel interface. In addition, a graphic card is necessary. A second parallel interface is required for an optional printer unit.

The measurement is controlled by a software which permits input of the most important measurement parameters, such as measuring time, nuclide, sample-id, etc., for each sample-position individually. The measurement is started after loading the samples by moving the slides into the measurement position. The measurement is finished when either a preset time, a preset count or an preset statistical accuracy is reached. When a sample slide is opened during measurement the counting for two samples is stopped. When the slide is reclosed subsequently, the interrupted measurement can either be resumed or a new measurement is started. Measurement of the other samples is unaffected thereby.

A test routine running permanently checks the detector amplification and the counting gas supply. If any significant shift in the operating points or a malfunction in the counting gas supply is detected, the system issues a warning.

The results of the measurement are stored in data-files and can thus be processed in other software programs. It is possible to quit the measurement program at any time, for example for an analysis of the measured values. After reentering the program, the data accumulated meantime are included in processing, without any loss.

FHT 770 T CHARACTERISTICS

The FHT 770 E is suitable for detection of very low alpha and beta contamination. The relevant parameters of low contamination A_{min} measurement are the measurement time t , the background n_0 and the efficiency η of the measuring assembly, according to the known formula

$$A_{min} = k \cdot \sqrt{n_0} / t \cdot (1/\eta)$$

where k represents the statistical error in terms of sigma.

In order to get a low background counting rate it is necessary to have a well designed sample-guard-counter geometry and an efficient anticoincidence circuit. In addition thoroughly selected detector and shielding materials should be used.

The variation of the background rate during long term measurement is shown in Fig 3, where subsequent background measurements over 100 min intervals are shown. The mean value for the beta background for all 6 detectors is 0.52 ± 0.08 cpm. The background variation of the individual detectors is statistically not significant within the 3 sigma level.

Fig. 3 Subsequent 100 min measurements of beta background

The FHT 770 T is calibrated for different nuclides and different sample sizes, the corresponding values for the detection efficiencies (in %) are shown in Table 1.

Table 1 Calibration data FHT 770 T

Nuclide	Planchet Ø 60 depth [mm]		Planchet Ø 30 depth [mm]	
	3	8	3	8
⁶³ Ni	7.7	3.3		
¹³² Ba	16	10	10	7.9
¹⁴ C	27	19		
⁶⁰ Co	28	22	33	28
¹³⁷ Cs	41	34	47	39
²⁰⁴ Tl	37	30	42	39
⁹⁰ Sr/ ⁹⁰ Y	42	34	51	41
²⁴¹ Am, α	28	21	32	25
²⁴¹ Am, β	9.4	6.1	11	8.7
²¹⁰ Po			40	32
geom. 100%	36	28	42	34

The radioactive sources are standard calibration sources in aluminium or stainless steel planchets. The activities are known within an accuracy of 10 %, the additional statistical errors are below 1%. The values for ⁹⁰Sr/⁹⁰Y refer to ⁹⁰Sr. Values above the geometric limits given by the source detector geometry are induced by backscattering effects.

The efficiencies decrease about 20 % by changing the distance from source to counter

from 4 to 9 mm. For the low beta energy sources, there is a decrease of about 60 %. The use of samples with 30 mm diameter in the center of the 60 mm counter gives an reasonable increase of the detection efficiency of about 15 % because of geometrical effects (solid angle and outer zones of the detector). The minimum detectable contamination in 1 hour measuring time is according to the above stated formula within an accuracy of 3 σ e.g. for ¹³⁷Cs in the order of 10 mBq.

The cross talk from alpha particles into the beta channel is < 3% measured with ²¹⁰Po and the value for beta in alpha is < 0.1 % for the above stated beta sources.

The crosstalk between neighboring detectors measured with ⁶⁰Co is less than 5·10⁻⁴, for alpha and beta emitting nuclides there is no considerable cross talk.

CONCLUSION

The new multi-counter system FHT 770 T shows extremely low and stable background counting rates: <0.35 cpm for alpha-particles and 0.5 to 0.7 cpm for beta particles. In order with the excellent counting efficiencies of the multi-detector device simultaneously up to 12 samples can be measured. Thus the fast and accurate measurement of even a great number of environmental samples with very low detection limits can be performed.

ABSTRACT

The response of contamination monitors to 589 nuclides and 44 nuclide mixtures was calculated using large-area proportional counters. Calculations were carried out for two different types, portable contamination monitors and foot detectors of hand/foot monitors. The aim was to determine those radionuclides for which surface contaminations at the level of the area contamination limits applicable in the Federal Republic of Germany can be detected. Portable devices can detect with a measuring time of 10 s contaminations at the limit level for 434 nuclides (74 %) and 41 nuclide mixtures (93 %). This is only possible for 325 nuclides (55 %) and 32 nuclide mixtures (73 %) using the foot detectors of hand/foot monitors.

INTRODUCTION

Large-area proportional counters are generally used in the Federal Republic of Germany for contamination checks at the exit of a controlled area. The surface contamination on objects, clothes and underwear must not exceed stipulated limits. Outside monitored plant areas (Betrieblicher Überwachungsbereich) these limits, averaged over a surface of 100 cm², are 0.05 Bq · cm⁻² for α -emitters with an licencing limit of 5 · 10³ Bq, 5 Bq · cm⁻² for β -emitters and electron capturers with an licencing limit of 5 · 10⁶ Bq, and 0.5 Bq · cm⁻² for other radionuclides [1]. Since no limit values are defined for persons, the above limits are generally also applied to them. The aim was to determine those nuclides for which surface contaminations at the limit level can be detected [2]. For this purpose, the response of contamination monitors and the minimum response required for the detection of a contamination at the limit level must be known. The minimum response required depends on the background and measuring time.

EQUIPMENT

Two different detectors were examined: portable contamination monitors and the foot detectors of hand/foot monitors. The detector of portable contamination monitors is a relatively small, highly sensitive detector with a surface area of 150 to 200 cm². The response of devices from different manufacturers is not very different. The foot detector of hand/foot monitors is least sensitive since it is covered by a grate. The detector surface of the foot detector is 600 cm².

Due to this large detector surface, the detector background is larger than that of portable contamination monitors. The detector voltage of large-area proportional counters can be adjusted so that either only α -radiation or α - and β -radiation are detected. Large-area proportional counters generally use hydrocarbons as the counter gas. The detector response to photon radiation is therefore small.

RESPONSE CALCULATION

The response R of a contamination monitor equals

$$R = \frac{n - n_0}{A} = \frac{n - n_0}{a \cdot F} \quad (1)$$

wherein: n = count rate
 n_0 = background count rate
 A = activity of the radionuclide to be measured
 F = contaminated surface area
 a = A : F = activity per area of contamination

Calculations of the response to 589 nuclides are based on values measured for 22 nuclides [2]. Assuming only one β -spectrum component or one energy of the conversion electrons or α -rays, these values were taken to determine the response as a function of the energy (Figs. 1 and 2) as a good approximation to experimental results. Below the lowest energy measured the response was equated to zero. Above the highest energy measured a constant response value was assumed. The response to photon radiation is smaller or equals 0.007 s⁻¹Bq⁻¹. Based on these assumptions and on the decay data specified in ICRP 38 [3] the contamination monitors' response to 589 radionuclides and 44 radionuclide mixtures was calculated both for the detection of α -rays only and for the detection of α - and β -rays. The half-life of the nuclides selected is greater or equals one hour. All important longer-lived radionuclides are covered by this investigation. For nuclides with short-lived radioactive daughter products (half-lives below one hour) the response was calculated for the nuclide mixture assuming radioactive equilibrium.

MINIMUM REQUIRED RESPONSE

The minimum response, R_{min} , required for the detection of a contamination, a, according to German DIN standards [4] is:

$$R_{min} = \frac{3.3}{F \cdot a} \left(\sqrt{\frac{n_0}{t}} + \frac{3.3}{t} \right) \quad (2)$$

Equation (2) assumes that the detector pulses are counted during the measuring time t. Furthermore, a 5 % error probability is assumed for classifying an uncontaminated surface as contaminated, and a 5 % error probability for classifying a contaminated surface as uncontaminated. R_{min} was calculated for different background values, n_0 , and for contaminations at the different limit levels for a measuring time of t = 10 s and a surface F = 100 cm². The background

assumed for portable contamination monitors was $n_0 = 0.03 \text{ s}^{-1}$ when measuring only the α -rays and $n_0 = 6 \text{ s}^{-1}$ when measuring the α - and β -rays. The background assumed for hand/foot monitors was $n_0 = 0.1 \text{ s}^{-1}$ when measuring only the α -rays and $n_0 = 18 \text{ s}^{-1}$ when measuring the α - and β -rays.

The minimum required response calculated according to (2) was compared with the response values calculated for the individual nuclides and nuclide mixtures.

RESULTS AND DISCUSSION

Contaminations at the level of the above specified limits can only be detected with portable contamination monitors for 434 nuclides (74 %) and 41 nuclide mixtures (93 %) of the 589 radionuclides and 44 radionuclide mixtures under consideration. The foot detector of hand/foot monitors can only detect such contaminations for 325 nuclides (55 %) and 32 nuclide mixtures (73 %). The specific results for all nuclides will be published in a detailed report [2]. Contamination detection is difficult, in particular, for K-capturers, pure γ -emitters and low-energy α - and β -emitters. For example, contaminations at the level of $0.5 \text{ Bq} \cdot \text{cm}^2$ cannot be detected using contamination monitors for α -emitters with energies below 4 MeV and β -emitters with average energies below 30 keV. For many α -emitters with the low limit of $0.05 \text{ Bq} \cdot \text{cm}^2$ it is difficult to detect contaminations at the limit level.

The results presented here give a survey of the state of the art concerning the direct detection of surface contaminations. Calculated response values can slightly deviate from actual values in specific cases. If the calculated response value is only slightly below the minimum response required, contamination checks are possible by prolonging the measuring time. Contamination monitoring is possible for certain nuclides using special procedures. Contaminations occurring in nuclear power stations due to low-energy K-capturers (e.g. Cr-51, Mn-54, Fe-55, Zn-65) can be detected, for example, using large-area proportional counters with xenon or argon-methane as the counter gas. Other suitable methods of contamination monitoring are available for objects (e.g. wipe test). If it is not possible to monitor the limit value using contamination monitors, technical or organizational precautions must prevent contamination from spreading.

A New CAM System on the Basis of Proportional Counter Tubes

Dr. E. Frenzel
EG&G Berthold, Wildbad, Germany

CAM systems using proportional counter tubes in combination with the AERD technique are capable of determining 1 DAC value within one hour with a high statistical safety. Air flow rates of up to 30 cfm are possible.

Introduction

When handling plutonium and other actinides, the air-borne particulate activity concentration has to be monitored to ensure optimum safety at the workplace. Lowest activity concentrations (DAC values of 40 mBq/m^3 relative to plutonium-239 = $1 \times 10^{-12} \text{ } \mu\text{Ci/cc}$) must be detected within a few hours with a high statistical safety. Usually one uses CAM systems with silicon detectors for this task. For construction reasons, however, only small dusting units can be realized, which limits the air flow to a few m^3/h (= 1 cfm).

The new CAM Monitor LB 150 RD designed by EG&G Berthold operates with large-area proportional counter tubes to ensure an extremely reliable measurement of the DAC values as well as a high representativity concerning the sample quantity (nearly $50 \text{ m}^3/\text{h}$ = 30 cfm).

The AERD technique (1) (2) (3) eliminates virtually all interference factors, such as background fluctuations, dustloading on the filter, and a high ambient gamma level.

The Principle of Measurement

The acronym AERD stands for Alpha Energy Range Discrimination, a method utilizing the relationship of α energy and range (4). It is well known that all natural air-borne alpha emitters which are daughter products of the noble gases ^{222}Rn ("radon") and ^{220}Rn ("thoron") show alpha energies above 6 MeV. On the other hand, all relevant plutonium isotopes as well as ^{241}Am and other transuranics have energies below 5.5 MeV. This fact is the physical basis of a large variety of commercially available monitors utilizing the advantages of the excellent spectroscopic properties of semiconducting detectors.

At the end of the eighties, Frenzel and Kreiner have taken up this idea to create a suitable measuring method, the alpha energy range discrimination method. The essential aspect of the AERD technique is a detector system which allows the selection of alpha sources with energies of $\alpha > 6 \text{ MeV}$ and $\alpha < 6 \text{ MeV}$ in combination with an air flow up to $50 \text{ m}^3/\text{h}$.

This application uses a two-detector system of flow-type proportional counters. In this case, however, the separation foil between the counter tubes is dimensioned such that low-energy alpha particles (artificial) can be detected in the bottom counter tube and high-energy alpha particles (natural) in the bottom and center counter tube. Through calibration and optimization one can reach an ideal cut of approx. 5.8 MeV with this detector configuration. By means of a simple coincidence stage for the alphas of the two tubes, the alphas can easily be identified as natural alphas and distinguished from artificial alphas. Oblique running high-energy alpha particles can be detected in addition in the bottom counter tube by means of a simple pulse height analyzer mechanism.

Description of the Monitor

A powerful side-channel blower ($50 \text{ m}^3/\text{h} = 30 \text{ cfm}$) aspirates the air through a $200 \text{ mm } \varnothing$ glass fiber filter located on a sinter metal support. The detector, a proportional sandwich counter tube with suitable separation foil for high and low-energy alphas, is located directly above the dusting unit. The charge-sensitive preamplifier with built-in coincidence and anticoincidence module is located directly on the counter tubes. The data logger LB 5310 is employed for evaluation; this unit includes all common interfaces used in nuclear technology.

All components are housed in a mobile 19" rack. The air flow required for calculation of the respective activity concentration is measured and calculated on-line. Since proportional counter tubes operate in the alpha plateau, no lead shielding is required (see Fig. 1).

Performance Features

A high air flow rate is imperative for achieving a high representativity of the measurement. Using the glass fiber filter and large-area proportional counter tubes one can realize a flow rate of $50 \text{ m}^3/\text{h} (= 30 \text{ cfm})$. The high efficiency of the detectors together with the high air flow rate guarantee an excellent statistics, which, as a consequence, results in a virtually negligible false alarm rate and an extremely low detection limit. The typical properties of proportional counter tubes, i.e. the fact that the efficiency curve is hardly dependent upon the alpha energy, ensure a consistent sensitivity of the monitor not only for plutonium-239 but also for plutonium-238 and uranic isotopes.

Dustloading is no problem for the AERD monitor, since the AERD compensation factor (the ratio of counting data of both detectors) is directly proportional to the air flow rate. A change in the air flow rate, on the other hand, is directly proportional to a change in the dustload on the filter; by measuring the flow rate, the correct compensation factor is determined and used. Since all alpha energies $< 6 \text{ MeV}$ are measured in the bottom counter tube, the problem of shifting thresholds and drifting ROI's does not exist for the AERD monitor.

Moreover, AERD monitors are easy to calibrate, so that recurring tests at site can be carried out within a few minutes.

As many experiments and measurements have shown, the AERD compensation factor does not change with varying radon or thoron activity concentrations or their fluctuations, so that this method may also be employed with success under difficult conditions, such as frequently changing ventilation conditions, fluctuating levels and dust-loaded air (see Fig. 2).

Conclusions

The combination of the semi-spectroscopic analysis with a high-volume technique has resulted in a monitor which is highly capable of mastering difficult measuring tasks. CAM monitors operating according to the AERD method are capable of determining a DAC hour with a very high statistical accuracy within a very short time. CAM monitors can be employed in any situation where air-borne alpha activity concentrations need to be monitored.

POSSIBILITIES OF THE MICROELECTROPHORESIS TECHNIQUE FOR THE
ASSESSMENT OF RISK AT LOW-DOSE IRRADIATION

ABSTRACT

The heterogeneity of lymphocytes in the amount of pre-existing (spontaneous) and radiation-induced DNA lesions is demonstrated using the modified microelectrophoresis technique. Irradiation of lymphocytes at 1 cGy leads to two-fold decrease in the amount of pre-existing DNA lesions 2h later. Therefore the beneficial effect of adaptive irradiation of cells is probably explained by the inducing of the repair mechanism that makes the lymphocytes less susceptible to the subsequent exposure.

INTRODUCTION

The risk of appearance of the delayed effects of radiation and other toxic agents on living cells is determined by their ability to repair DNA lesions. In turn the efficiency of DNA damage repair depends on the organization of chromatin structure and somewhat determined by the level of pre-existing (spontaneous) DNA lesions. The methods currently used to measure both the pre-existing and induced DNA damage can provide a measure of average response of the cell population according to the damage and its repair. The evaluation of pre-existing DNA lesions (recognizable by endonucleases) includes their transformation into single strand breaks (ssb) at the sites of lesions during the incubation of cells with DNA-repair inhibitors: 1- β -D-arabinofuranosylcytosine (ara-C) and hydroxyurea (HU). Thus the incubation of unirradiated cells with these inhibitors leads to their death because of double strand breaks in DNA formed as a result of ssb accumulation in opposite DNA strands. Therefore the rate of death will depend on the level of these pre-existing lesions (1,2). Recently various modifications of microgel electrophoresis technique were described which allow visualization of DNA damage and repair in individual cell (3-5). We have modified the microgel electrophoresis technique to improve the sensitivity in the evaluation of DNA damage in the single cell (lymphocyte) (6). This modified technique can provide with the most important information: whether all cells within a given population show equal amount of pre-existing DNA damage, and whether they repair the induced DNA lesions at the same rate. We have also shown that our technique of the determination of pre-existing DNA lesions in the bulk of cells permits the evaluation of the effect of irradiation at a dose as low as 1 cGy on DNA-repair functioning.

EXPERIMENTAL MEASUREMENTS

Rat blood lymphocytes and thymocytes were isolated and incubated without or with ara-C (0.1 mM) and HU (4 mM) according to the routine procedures and the number of dead cells after incubation was determined by staining. For single-cell technique measurements the cells were embedded in low melting agarose (1%) on the microscope glass slides pre-coated with 0.1% agarose, and after gelling at 4°C for 5 min were lysed in neutral salt-detergent solution (1 M NaCl, 200 mM EDTA, 200 mM Tris-HCl pH 8.0, 0.5% Triton X-100, 0.5% Sarcosyl) containing proteinase K (100 µg/ml) and ethidium bromide (20-40 µg/ml) at 20°C for 30-40 min. Electrophoresis of DNA was performed for 5 min at 5 v/cm. By use of microdensitometric system connected with computer the size of the "tail" (L) and quantity of migrated DNA (S) for single cell and the distribution of these parameters among the cells in population were determined. Cells were irradiated at a dose rate of 1.6 Gy/min by placing them in the centre of a ⁶⁰Co source, and the absorbed dose was determined with ferrous sulphate dosimetry.

RESULTS

Our modification of microelectrophoresis technique permits to increase its sensitivity and use the relatively low doses of radiation as compared with previously published results (Fig. A).

Figure. Radiation dose response for thymocytes exposed to 0-1 Gy (A). Heterogeneity in L_r for cells exposed to 0, 1, 3 and 5 Gy immediately after irradiation (B).

Interestingly, we also observed the clear heterogeneity in DNA damage among the thymocytes even at a dose 1 Gy (Fig.B). The same heterogeneity took place in DNA lesions repair (results not shown). It is noteworthy that this heterogeneity in DNA damage and its repair was not the result of technical considerations.

The next important point is the heterogeneity of control unirradiated thymocytes (Fig.B). Taking into consideration the lysis conditions this heterogeneity is explained in terms of the existence of cells with various amount of spontaneous DNA lesions. It appears that the heterogeneity in preexisting lesions observed in thymocytes within a population determines the heterogeneity in their DNA damage and repair (results not shown).

Lymphocytes that are exposed to low-doses of ionizing radiation become less susceptible to the induction of chromatid aberrations by subsequent high doses of X-rays (radioadaptive response) (7). When lymphocytes were exposed to adapting dose of 1 cGy and incubated with ara-C plus HU for 2h later, the dead cell number decreased (Table). Thus low level doses of irradiation now are seen to have a beneficial effect on the amount of pre-existing DNA lesions probably inducing the repair mechanism that makes the cells less susceptible to the effects of subsequent exposures to gamma-rays.

Table

Death of rat blood lymphocytes after irradiation at 1 cGy (0.5 cGy/min) and subsequent incubation of cells with ara-C and HU for 2h later

Incubation conditions	Dead cells,%	Increase in dead cells,%
Unirradiated	11.9 ± 1.9	16.4
Unirradiated + ara-C + HU	28.3 ± 2.3*	
Incubation for 2h after irradiation	15.2 ± 5.9	7.3
Incubation for 2h after irradiation, then + ara-C + HU	22.1 ± 3.8*	

Lymphocytes were irradiated, pre-incubated for 2h, and further incubated with or without ara-C + HU in the same growth medium for 24h. *P < 0.05; n=5.

Inasmuch the pre-existing DNA lesions plays an essential role in determining the cell susceptibility to the effects of low-dose irradiation we hope that the modified technique of their assessment in single cells will be of value for various needs especially concerning the studies on the Chernobyl accident consequences.

CONCLUSIONS

The modified microelectrophoresis technique permits to detect DNA damage induced by the dose as low as 0.2 Gy and also proved to be suitable for the assessment of the heterogeneity of lymphocytes in pre-existed DNA lesions within a population. Only a small number of cells (up to 100-200) is generally required for the analysis. The heterogeneity pattern is of the potential use in the prediction of the response of human being to the effects of low-doses irradiation and to other toxic pollutants. The resistance of blood lymphocytes to subsequent irradiation is increased after their preliminary irradiation at a dose as low as 1 cGy (adaptive response). It is noteworthy that in the cells previously irradiated at 1 cGy the decrease in the level of pre-existed DNA lesions has been observed.

**ICRP COMMITTEE 1: THE CONTINUING SAGA OF
ESTIMATES OF RISK FOR RADIATION INDUCED CANCER**

Warren K. Sinclair
National Council on Radiation Protection and Measurements
Bethesda, Maryland, U.S.A.

ABSTRACT

The estimates of fatal cancer risk which ICRP used in recommending more restrictive exposure limits for workers and for the public in 1990, were derived from the study of atomic bomb survivors. The many uncertainties in these estimates will be reduced with time as future data accrues in the Japanese study. Recent low dose studies in the Soviet Union, in the U.K. and in the U.S.A. provide tests, within broad limits, of the estimates of risk derived from the atomic bomb survivors. These form part of the continuing saga of cancer risk estimation.

INTRODUCTION

ICRP Committee 1 is responsible for advising the Main Commission of ICRP concerning the biological effects of exposure. In the 1990 recommendations of the ICRP (ICRP, 1991a) these responsibilities included reviewing Chapter 3 on Biological Effects in the main text of Publication 60, preparing the background material on biological effects used by the Commission, *i.e.*, Annex B of ICRP Publication 60 (ICRP, 1991a), and reviewing the selected papers of the Risk Task Group of Committee 1, which supported Annex B (ICRP, 1991b).

ICRP Committee 1 continues surveillance over developments in our knowledge of the biological effects of radiation and sets up working groups and task groups in selected areas as needed. This surveillance embraces all aspects of radiation-induced cancer risk, including the examination of low dose epidemiological studies for possible confirmation of risks from high dose, high dose rate studies.

NOMINAL VALUES OF CANCER RISK

ICRP appraised, for radiation protection purposes (ICRP, 1991a), recent evaluations of cancer risk from all human sources by both the UNSCEAR (1988) and the BEIR V Committee (NAS/NRC, 1990) as well as providing some additional analyses of their own. ICRP concluded that for the general public (*i.e.*, a population of all ages) the nominal risk of fatal cancer following high dose, high dose rate exposure is 10%/Sv, while for an adult (working) population it is about 8%/Sv. ICRP then applied a dose rate effectiveness factor of 2 to these numbers

to obtain the risk for low dose or low dose rate exposure, yielding 5%/Sv and 4%/Sv respectively.

SIGNIFICANT ASPECTS OF NOMINAL VALUES OF CANCER RISK

Certain features of these nominal values need to be emphasized. These include supporting estimates from other studies, projection to lifetime risk, age and sex variations and transfer between populations.

Comparison of cancer risks between different studies

The important study of the survivors of the atomic bombs has limitations, consequently confirmation would be useful. UNSCEAR (1988), (see ICRP, 1991a, Annex B, Table B-4), compared risk estimates for the ankylosing spondylitis in the U.K., and the international cervix series with those for the atomic bomb survivors. The estimates for the ankylosing spondylitis series are lower than for the atomic bomb survivors by a factor of about 2. Given the wide differences in sample, in age, in exposure circumstances, etc. (see Upton, 1991) this difference is small. For the cervical cancer series the agreement is less satisfactory, but the circumstances of exposure are even more different.

Projection of observed results to lifetime risk estimates

To estimate lifetime risk, observations of the survivors in Japan must be projected to the end of the life span of those individuals comprising over 60% of the original population who were alive in 1985. The time course of the increase in induced cancers in a number of sites has followed a multiplicative pattern well so far, consequently, the multiplicative model has been used for projection (UNSCEAR, 1988; Preston & Pierce, 1988). However for some cancer sites the multiplicative model may overestimate the risk, at least slightly. BEIR V (NAS/NRC, 1990) included a term involving time since exposure which enabled the model to be fit separately to the data for individual cancers and thus allow for a small fall-off in some cases. If this trend in the data were to continue, current estimates of lifetime risk based on multiplicative projection would be over projected. The ankylosing spondylitic study already shows a substantial fall off at longer times (Darby et al, 1987).

Recently Kellerer & Barclay (1991) have shown that if the multiplicative projection is based on attained age instead of age at exposure (and the data fit reasonably well), the projected risk is only about a half. Again, this implies over projection for current models.

Age and sex variations

Both UNSCEAR and BEIR V give substantial information on variations in cancer risk with age at exposure and sex, and still more detail, especially for individual organ risks, is available in Land & Sinclair (1991) and in summary form in Sinclair, 1992. The cancer risk is 10 times greater for the 0 to 19y ages than for the 65 to 90y age group. The sex difference is of the order of 10 to 50% depending on age, females having the larger induced cancer risk especially at young ages.

Transfer between populations

When populations other than the Japanese are considered, estimated risks must be transferred to the new population either multiplicatively using the base cancer rates in the new population or additively, independent of the spontaneous rates in the population, as in the NIH model (Rall et al, 1985). Presently it is not known which is the preferred method (Land, 1991; UNSCEAR, 1988; NAS/NRC, 1990) or whether there is a preferred method for all sites. Consequently, in deriving the contributions of the individual organs to the overall detriment, results have been averaged between the two models (Annex B, ICRP, 1991a). The total risks by the two transfer methods also differ somewhat as do results for some other national populations considered in the ICRP evaluation. ICRP averaged results for the two transfer models and for five national populations as well as for age and sex.

DETRIMENT AND ORGAN WEIGHTING FACTORS

ICRP's effective dose is based on the total detriment from a radiation exposure which includes fatal cancer in individual organs and tissues, severe hereditary effects, a weighting of each for length of life lost and a contribution for each organ or tissue from nonfatal cancer. These are listed in Table 1.

The relative contribution of the organs to this total detriment are determined as outlined in Annex B (ICRP, 1991a, Table B-20) and are then rounded to obtain tissue weighting factors. Only four weights are used (Table 2). Uncertainties due to transfer model and to characteristics of national populations have been reduced by averaging and the same weights can be used for all ages, sex and national population.

Table 1 - Nominal probability coefficients
(from ICRP, 1991a)

Exposed Population	Detriment 10^{-2} Sv^{-1}			Total
	Fatal Cancer	Nonfatal Cancer	Severe Hereditary Effects	
Adult workers	4.0	0.8	0.8	5.6
Whole population	5.0	1.0	1.3	7.3

Table 2 - Tissue weighting factors

$w_T =$	0.01	0.05	0.12	0.20					
	Skin Bone surface	Bladder Breast Liver Oesophagus Thyroid "Remainder"	Bone marrow Colon Lung Stomach	Gonads					
$\Sigma w_T =$	0.02	+	0.30	+	0.48	+	0.20	=	1.00

UNCERTAINTIES IN RISK ESTIMATES

The main uncertainties in the estimates of risk for high dose, high dose rate exposure include:

1. uncertainties in the epidemiological data,
2. dosimetric uncertainties, neutron RBE, etc.
3. uncertainty in projection to lifetime
4. uncertainties due to transfer model and
5. variations due to specific age groups or sex.

Some committees have attempted to assign magnitudes to these uncertainties (Rall et al., 1985; NAS/NRC, 1990).

Risk coefficients for low dose or low dose rate exposure are subject to these uncertainties plus those arising from the application of a dose response model or a dose and dose rate effectiveness factor, DDREF. The uncertainty in the DDREF is probably not greater than a factor of two, because the value applied by ICRP is two and the factor that could be assigned is probably not less than one nor more than about four.

FUTURE EXPECTATIONS IN THE STUDY OF THE ATOMIC BOMB SURVIVORS IN JAPAN

The study of the atomic bomb survivors will continue to acquire additional data. By the turn of the century, less than half (44%) of the study population will be surviving, four more cycles of data will have accumulated, time relationships will be better defined and the younger age groups will be further into the ages when cancer is more prevalent. Questions of fall-off (from constant relative risk) with time and overprojection of lifetime risks should be much clearer.

Significant excess of various cancer sites should extend to lower doses, to the group at 0.1 Gy to 0.19 Gy, or even to 0.06 Gy to 0.09 Gy. This will greatly influence the choice of DDREF and if the dose response curve is established at low enough doses perhaps eliminate the need for a choice.

In dosimetry, extension of the DS86 sample from 76,000 to 86,000 is expected in the 1985-89 evaluation. It may subsequently be extended a little further. Small improvements in the dosimetry can be expected and possibly a resolution of the worrisome discrepancy between calculation and measurement with distance for thermal neutrons. Further studies in high-LET radiation biology might provide additional information on neutron RBEs at low doses and permit more precise evaluation of the neutron component.

Incidence data from the tumor registries at Hiroshima and Nagasaki is just becoming available. The greater number of excess tumors, fatal and nonfatal, will improve estimates of the excess and establish better the dose response curve free of complications from treated cases. Incidence data may, in time, take over from mortality, as a superior index of the excess tumors due to radiation induction.

Overall, within not much more than a decade, improved (less uncertain) risk estimates from the atomic bomb survivors should be possible.

LOW DOSE STUDIES

In radiation protection the risk after low doses is paramount and thus direct low dose studies seem to be more relevant than high dose studies. However, most low dose studies suffer from methodological flaws which render the results questionable. Modan, in addressing this question (Modan, 1991), examined studies of fallout, occupational exposure, fetal (medical) exposure, therapeutic experience and natural background studies. Among the principal problems he identified were inadequate dosimetry, limitations on sample size and composition, lack of adequate controls, extraneous effects and sociogeographic confounders. Additional problems include the fact that studies are of too low a statistical power to demonstrate an effect, small numbers tend to increase chance associations and there is often no clear association between radiation dose and effect. Care in interpretation is also necessary if the time relationships involved are not those usually found or the cancers detected in excess are not those usually associated with radiation.

Given all these difficulties few low dose studies have been able to provide quantitative estimates of risk. Nevertheless, some have aspired to describe a range of risk and some of these are becoming of increasing importance as tests of estimates of risk derived from high dose studies.

Recent "quantitative" low dose studies

An early study of U.K. atomic energy workers (Beral et al., 1985) resulted in a broad range of risk estimates which included both the old and the new ICRP estimates. A more recent study of these workers (NRPB, 1991) is more definitive. It obtained a specific risk estimate for leukemia of $0.8 \times 10^{-2} \text{ Sv}^{-1}$, about twice the ICRP value for workers, with broad confidence limits extending to six times the ICRP value. A nonsignificant risk value for all cancers was also derived which had even broader limits.

In the U.S.A. (Gilbert et al., 1989) a study of some nuclear workers did not yield a significant association of leukemia or of all cancer with dose. The estimates ranged from below zero to an upper limit which was about the same value as that derived from the Japanese atomic bomb survivors. An initial report (Matanoski, 1991) on nuclear shipyard workers also lacked a definitive answer. Nuclear workers with exposures above 5 mSv had more leukemia and more hematopoietic cancers than those exposed below 5 mSv. However, both groups were less than for non-nuclear workers. Furthermore, within those above 5 mSv no clear association with dose was found. Further follow-up in this study may yield some more definitive contribution.

Two recent studies from the Soviet Union appear to be of greater intrinsic value, partly because the exposures in early atomic energy work were higher. The first involved workers in the atomic energy program exposed in the period 1947-58. Workers with total exposure above 1 Sv had greater cancer excess than workers below 1 Sv, from which Shlyakhter & Wilson (1991) derived a risk of all cancer expressed as $>3 \times 10^{-2} \text{ Sv}^{-1}$ similar to the $4 \times 10^{-2} \text{ Sv}^{-1}$ for workers of ICRP. In a study of residents in an area of Chelyabinsk (Degteva & Kosenko, 1990), people were exposed via their drinking water from the Techa River which for three years, 1949-52, was used for the disposal of fission products. Modeling the dosimetry appropriately, a risk estimate was derived of about $0.2 \times 10^{-2} \text{ Sv}^{-1}$ for leukemia, half the ICRP value for workers. More information on these studies would be most welcome.

Thus, in spite of the broad ranges only that can be defined, these low dose studies are within about a factor of two of the estimates derived from the atomic bomb survivors.

Possible future low dose studies

From Chernobyl useful data may emerge eventually (perhaps on leukemia only) from evacuated groups or from those in "hotspot" areas of the Ukraine, Byelorussia and Russia.

Also, a comprehensive study has been proposed of all nuclear workers in the U.S.A., possibly to include U.K. and European nuclear workers. A more positive result than any to date could result from such a comprehensive study.

CONCLUSIONS

The study of the atomic bomb survivors will continue to provide more and more data and thus to improve lifetime risk estimates. Some present and future low dose studies may help materially in testing the risk estimates from the atomic bomb survivors.

ICRP Committee 1 will continue to evaluate the situation as new information appears and relate it to radiation protection circumstances.

MORTALITY UNDER AGE 25 AROUND SIX FRENCH NUCLEAR SITES

Catherine Hill and Agnès Laplanche

Institut Gustave Roussy et Institut National de la Santé et de la Recherche Médicale Unité 287, Villejuif, France.

ABSTRACT

Mortality under age 25 between 1968 and 1987 has been studied in the population residing around the six major nuclear sites (two reprocessing plants and four power plants), in operation before 1976 in France. The population under study represents 3 million person-years. A total of 58 leukaemia deaths were observed, similar to the 67 leukaemia deaths expected from national death rates, and to the 62 leukaemia deaths observed in control communes. The risk of leukaemia did not depend on distance to the installation.

INTRODUCTION

In 1983, a British television programme reported an increased incidence of leukaemia in children in the village of Seascale, near the Sellafield nuclear reprocessing plant. Following this report, a working group, commissioned by the British government, concluded that there was an increased incidence of lymphoid leukaemia in children around Sellafield (1), and this result has been confirmed by numerous studies (2-5). Other excesses of leukaemias have been observed around the Dounreay facility, a reprocessing plant located in the North of Scotland (6), in the vicinity of the two nuclear military facilities of Aldermaston and Burghfield (7), and in the vicinity of the Hinkley point nuclear power plant (8).

France derived 75% of its electricity from nuclear energy in 1989, and the first nuclear unit producing electricity started operating industrially in 1962 (9). We have studied the main sites in operation during 1975 or before in order to have a minimum follow-up of 10 years for mortality. Before the study presented here, two studies of mortality around La Hague, French nuclear reprocessing plant had been reported (10,11); their results are summarised elsewhere in the present volume (12).

MATERIALS AND METHODS

Four geographical zones were defined around each installation according to the distance from the installation: <5 km, 5-10 km, 10-13 km, and 13-16 km. For La Hague, the farthest zone bordered the densely populated suburbs of the city of Cherbourg: an extra zone corresponding to a distance of 16-21 km has been considered for this site. France is divided into 36,500 administrative units called 'communes'. The average population of a commune is 1,500, and the average area 15 km². For each site and each zone, the 'exposed'

communes were identified, and for each exposed commune, a 'control' commune was selected as the commune in the same 'Département' having the closest total population figure. This defines, for each site, four (five for La Hague) exposed zones according to the distance to the installation, and the same number of control zones. The average distance between control communes and installation is 53 km (range 16-133 km, s.d. 24 km).

From the Institut National de la Santé et de la Recherche Médicale, we obtained the cause of each death that occurred in the population aged 0-24 between 1968 and 1987, by zone. The underlying cause of each death was coded according to the International Classification of Diseases. Census data by commune were obtained from Institut National de la Statistique et des Etudes Economiques (INSEE), for the three censuses of 1968, 1975, and 1982. The population at risk were estimated from these data.

To test the possible existence of an increase in leukaemia mortality between age 0 and 24 around French nuclear sites, we made two comparisons. First, the observed mortality was compared to the mortality expected from national rates. Second, in an attempt to control for possible systematic differences between death certification procedures in rural, sparsely populated areas and in the country as a whole, the mortality around nuclear sites was compared with the mortality in control communes, matched for total population and large geographical unit (Département).

RESULTS

The table gives the number of leukaemia deaths by type of installation (reprocessing plants versus others) and by distance from installation. The number of leukaemia deaths was 58, which is slightly less than the 66.9 deaths expected from national mortality statistics. Among the other causes considered, two significant differences (both with $p=0.02$, two-sided test) were observed between nuclear sites and national mortality: an excess of Hodgkin's disease, and a deficit of malignant brain tumors. After correction for the multiple tests due to the consideration of several causes of death, these results are no longer significant. No significant differences were observed when comparing the standardised mortality ratios in the exposed and control areas, but these comparisons are less powerful than the comparison of the exposed population to the nation as a whole. There was no effect of sex and age, no difference between reprocessing plants and reactors, and no trend with increasing distance from installation.

Table

Number of person-years, observed and expected number of leukaemia deaths, and standardised mortality ratios (SMR) by type of installation and distance from nuclear installations

Characteristics	Person-years in thousands	Observed	Expected	SMR(%)
Installation				
Reprocessing	1,576	30	36.7	82
Other	1,316	28	30.2	93
Distance in km				
< 5	260	5	6.1	82
5-9.9	982	21	22.7	93
10-12.9	373	4	8.5	47
13-15.9	748	17	17.3	92
16-21	530	11	12.3	90
Total	2,892	58	66.9	87

CONCLUSION AND DISCUSSION

Our study shows no excess leukaemia mortality in the population aged 0-24 residing near French nuclear sites. The power of this study is reasonable: when the reference is the general population, and with an expected number of leukaemias around installations equal to 60, the probability of detecting an increase of 50% is 95% (with a type I error of 5%), and the probability of detecting an increase of 23% is 50% (13). When the reference is a control group of similar size, the probability of detecting an increase of 50% is 80% (13).

Our results confirm Viel and Richardson's study of leukaemia mortality around La Hague (11), which used geographical units with populations seven times larger than in our study.

The excess leukaemia observed around nuclear sites in the United Kingdom was not observed around French nuclear sites. The amount of radioactive effluent discharged might have been higher around Sellafield and Dounreay than around French installations (11). The excess leukaemia observed in the United Kingdom could also be attributed to some characteristic common to Sellafield and Dounreay, but not shared by French installations, for instance a rapid increase of population leading to viral infections (14), or some unknown factor shared by existing and potential nuclear sites in the United Kingdom (15).

CHILDHOOD LEUKAEMIA AROUND NUCLEAR FACILITIES IN GREAT BRITAIN

R. Wakeford, K. Binks and A.J.M. Slovak

Health and Safety Directorate, British Nuclear Fuels plc,
Risley, Warrington, Cheshire, UK.

ABSTRACT

The elevated levels of childhood leukaemia incidence around certain nuclear facilities in Great Britain that have been found by epidemiological studies must be viewed with caution. The various inferential problems associated with these studies produce an uncertain interpretation. More research into the causes of childhood leukaemia is required before the distribution of cases is properly understood.

INTRODUCTION

Since the broadcast in 1983 of a television documentary which identified an excess of childhood leukaemia cases in the coastal village of Seascale near the Sellafield nuclear establishment in North-West England, there has been considerable scientific interest in whether the risk of childhood leukaemia is elevated in the vicinity of nuclear installations, and, if so, the reason for this excess risk. Since the Sellafield report, a number of other studies have been published which appear to support the interpretation of a raised risk; but detailed radiological assessments have demonstrated that radiation doses due to discharges are too low to be able to account for the excess cases. This apparent conflict of evidence has led to suggestions that radiation risks have been grossly under-estimated, or that novel leukaemogenic mechanisms are involved. However, before reaching such conclusions, the evidence for a raised risk should be scrutinised more closely.

EPIDEMIOLOGICAL EVIDENCE

The evidence for a discernible excess risk of childhood leukaemia around nuclear installations derives from various epidemiological studies. Epidemiology is predominantly an observational science that relies upon the statistical analysis of health data produced under the uncontrolled conditions of "everyday life". Causal inference based upon non-experimental data is fraught with difficulties, particularly when the health effect of interest is childhood leukaemia which is uncommon (~450 cases per year in Great Britain) and for which the major causes remain unknown (<20% of cases can be accounted for by known causes). Furthermore, childhood leukaemia is a convenient grouping of various types and subtypes of leukaemia, which may have different major causes [1].

It is in the nature of an uncommon disease that, even if the underlying risk is uniform, the distribution of cases will be heterogeneous, in much the same way as winning lottery numbers are not regularly distributed amongst the sequence of ticket numbers. It is possible that the Seascale grouping of cases has arisen purely through the vagaries of chance; but it is also possible that it reflects an excess risk, whatever the cause may be. By itself, the Seascale observation does not allow us to distinguish between these two possibilities, and independent corroborating evidence is required before an excess risk can be inferred. However, reliable supporting evidence is difficult to generate, because the "background" conditions under which further datasets are produced will differ (to a greater or lesser extent) from those experienced by the original cases, and these conditions could modify the risk of childhood leukaemia. In addition, should prior knowledge of the data available for analysis influence the structure of that analysis (eg the choice of location, geographical boundaries or time periods) then severe interpretational problems can result. [2], [3].

We would argue that the influence of prior knowledge has had a major impact upon the development of evidence in this area of epidemiology. The analysis of childhood leukaemia cases around the Dounreay installation in Northern Scotland produced an incidence rate which was ten times the national average when employing geographical and temporal boundaries which were suspiciously tight about the case data; but when more "reasonable" boundaries were used in the analysis, the rate was reduced to twice the national average, and the excess leukaemia incidence did not achieve the margin whereby it could be conventionally regarded as "statistically significant". The reported excess of cases in the vicinity of the Aldermaston and Burghfield establishments (in Berkshire, England) relies heavily upon the decision to include Burghfield (and thereby the town of Reading) in the analysis. Burghfield had featured strongly in an earlier television documentary, and the decision may have been compromised by this knowledge. Other researchers have chosen to exclude this "minor" nuclear weapons facility from their analyses. Similarly, the Hinkley Point (Somerset, England) study was undertaken with the knowledge that leukaemia rates were generally raised in Somerset, and the authors failed to point out that, unlike in previous reports, their result of an excess of cases in young persons was driven by an excess amongst young adults rather than children. However, despite these (and other) shortcomings these three studies have been disconcertingly influential in scientific circles [2], [3].

Cook-Mozaffari et al., have avoided these various selection and reporting biases by including all 15 of the major nuclear installations of England and Wales in their studies [2], [3]. These studies have not been without

weaknesses, being based unavoidably upon mortality data for largish geographical areas, but their strength lies in the comprehensiveness and coherence of analyses which have not been influenced by prior knowledge. In the latest study by this group, an elevated level of leukaemia mortality was found for young people living in areas defined as being associated geographically with nuclear installations: the adjusted mortality rate for these areas was 14% above that for England and Wales [3]. However, the authors do not conclude that this result supports a link between radioactive discharges and excess childhood leukaemia deaths, because, for example, for those areas associated geographically with the installations, rates are higher for populations living further from the installations than the rate for the population living nearest the installations. That the elevated leukaemia mortality rate might have more to do with the "background" risk factors pertaining in those areas geographically associated with nuclear facilities than with factors directly linked with the operations at the facilities is lent support by a subsequent study by Cook-Mozaffari et al. [4] in which the same analyses were performed for areas around potential nuclear power station sites. This study revealed a pattern of cancer mortality which was "strikingly similar" to that for existing sites. Similar studies in other countries (for example, USA and France) have not found any evidence of an excess risk around nuclear installations, which, at present, leaves the UK reports puzzlingly isolated.

Recently, the results of a study by Gardner et al. have indicated that the excess of childhood leukaemia cases near Sellafield may be linked to the occupational doses of radiation received by fathers prior to the conception of their children [5]. This potential explanation is of particular interest because it does not depend upon the somatic doses of radiation received from discharges, but upon occupational exposure of the paternal germ cells. However, it must be appreciated that parental exposure to radiation was only one of a large number of potential explanatory factors examined in this study, and that, under these circumstances, the effects of chance are difficult to quantify. Also, the positive statistical association is based upon four cases and a similarly small number of controls, so that results are not especially robust against minor perturbations in the data. Given the context of this study, a direct causal interpretation of the association cannot be accepted without confirmatory evidence. Presently, such evidence does not exist: a review of earlier studies of low dose preconceptual irradiation has not revealed any reliable associations with childhood cancers, and more recent studies have failed to provide strong support (for example, the excess of childhood leukaemia cases around Dounreay cannot be accounted for by preconceptual work in the nuclear industry), although the results of statistically more powerful studies are not yet available. Perhaps most

importantly, the risk of childhood leukaemia in the children of the Japanese A-bomb survivors is statistically incompatible with that suggested by the Sellafield study, a detectable excess risk being absent in the Japanese children. For these, and other, reasons it is not possible at the present time to be able to interpret the results of Gardner et al. with any confidence. [5].

CONCLUSION

Despite the extensive research that has taken place in response to the Seascale childhood leukaemia cases, a satisfactory explanation of the various reports of raised levels of childhood leukaemia incidence around UK nuclear facilities remains elusive. The interpretation of a number of these reports has been hampered by problems of statistical inference, and the results of further work on the association between childhood leukaemia and paternal preconceptual irradiation must be available before this association is properly understood. It may be that these results will be explicable only when the major causes of childhood leukaemia have been identified, and the results of Kinlen et al., eg [6], are of particular interest in this respect.

EPIDEMIOLOGY OF LEUKEMIA AMONG NUCLEAR WORKERS:

A QUANTITATIVE ANALYSIS OF RESULTS FROM 8 PUBLISHED STUDIES

Gregg S. Wilkinson (University of Texas Medical Branch)
Nancy A. Dreyer (Epidemiology Resources Inc.)

A quantitative analysis of the published results from epidemiologic studies of 8 nuclear worker cohorts in the U.S. and the U.K. was completed. Only those studies that reported data on the cumulative doses received by individual workers were selected for this analysis. The doses received by workers who were included in these studies were the result of protracted exposures to low LET ionizing radiation. A total of 87 leukemia deaths among white males from a combined total of almost 1.5 million person-years were identified. An overall relative risk of 1.6 for leukemia was calculated after adjustment for age and calendar time for workers with cumulative doses of 10 mSv or greater compared with those with cumulative doses of less than 10 mSv. When workers with doses of 10-50 mSv were compared with those who had cumulative doses of less than 10 mSv, the adjusted relative risk was 1.7. A similar comparison of workers with doses greater than 50 mSv yielded an adjusted relative risk estimate of 1.4. These combined data indicate approximately a 70 percent increased risk for leukemia at doses of 10-50 mSv and a similar (but slightly lower) increased risk at doses above 50 mSv. Empirical evidence from well characterized populations, such as nuclear workers, should be given more weight in estimating the risk of leukemia from protracted exposures to low doses of low LET radiation.

EPIDEMIOLOGICAL STUDY OF THE MORTALITY OF A GROUP OF URANIUM MINERS IN FRANCE

SUMMARY

The exposure of the French uranium miners can be considered as relatively low in comparison to most of the other groups of uranium miners (U.S.A., CANADA, CSSR) that have been published. The mean cumulated exposure of 70 WLM, observed in this French group, is linked to a long duration of underground mining, reflecting a low annual exposure rate. The excess of lung cancer deaths is studied in function of the cumulated exposure and discussed in comparison with the risk factors mentioned by the international committees.

INTRODUCTION

L'enquête épidémiologique sur les mineurs d'uranium en FRANCE est conduite depuis 1984 par l'IPSN (Institut de Protection et de Sécurité Nucléaire) avec la collaboration étroite des Services de Médecine du Travail des Mines et de Surveillance Dosimétrique de la COGEMA.

La mortalité d'un groupe de mineurs d'uranium ayant commencé à travailler au fond entre 1946 et 1972, et exposés au radon et à ses descendants pendant au moins deux ans, est analysée dans le cadre d'une étude de cohorte dont le bilan actuel s'arrête au 31 Décembre 1985. Les mineurs de la cohorte, au nombre de 1785, ont travaillé dans les mines exploitées à cette époque dans le Limousin et en Vendée.

LE SUIVI DOSIMETRIQUE

Le suivi dosimétrique des mineurs d'uranium a été assuré par le même groupe de surveillance radiologique durant la totalité de la période concernée. Les techniques de surveillance ayant cependant évolué avec le temps, il faut distinguer, pour cette étude couvrant les années 1946 à 1985, deux époques essentielles :

- 1) Depuis 1956 il existe, pour chaque année, des enregistrements de l'exposition individuelle au radon et à ses descendants ; 1956 coïncide avec la mise en place de mesures de radioprotection importantes qui ont fait baisser le niveau d'exposition au radon d'un facteur 5 à 10. La cohorte de mineurs embauchés depuis 1956

peut donc être suivie en se basant sur une dosimétrie individuelle ; ceci est un avantage certain comparativement aux études américaines et canadiennes, où la dosimétrie a dû être évaluée rétrospectivement.

- 2) L'estimation a posteriori de l'exposition individuelle a été nécessaire pour la période antérieure 1946-1955. Un niveau de concentration en radon et une valeur du facteur d'équilibre entre le radon et ses descendants ont été reconstitués par des experts.

L'historique dosimétrique de chaque mineur est donc retracé depuis sa date de début de travail au fond jusqu'à sa date de départ de la mine. La figure 1 indique la distribution de l'exposition individuelle au radon, au cours des années, exprimée en Working Level Months (le WLM est le produit d'une concentration volumique d'énergie par une durée. La concentration volumique d'énergie est le Working Level, soit $1,3 \cdot 10^8$ Mev par m^3 d'air dû au rayonnement alpha émis par le gaz radon et ses descendants présents dans l'air. La durée est le mois, soit 170 heures de travail).

Comparativement aux études menées aux U.S.A. (1, 2), au CANADA (3, 4), ou en TCHÉCOSLOVAQUIE (5) sur des groupes de mineurs d'uranium, l'étude française se caractérise par des expositions annuelles relativement faibles, aboutissant à une exposition cumulée individuelle qui vaut en moyenne 70 WLM (tableau 1). Il en ressort que cette cohorte permet d'étudier le risque de cancer pour une exposition cumulée faible obtenue sur une longue durée d'exposition longue, la durée moyenne d'exposition au radon étant de 14,5 ans.

LA RECHERCHE DES CAUSES DE DECES

En FRANCE, toute étude épidémiologique de cohorte, visant à étudier les effets à long terme et notamment le risque de décès par cancer, se heurte au problème du suivi des mineurs au-delà de leur départ en retraite à l'âge de 55 ans. C'est le Service de Médecine du Travail des Mines de la COGEMA qui est responsable de la recherche des causes de décès. En effet, à l'inverse des pays anglo-saxons et scandinaves, la FRANCE n'a pas de fichiers nominatifs nationaux des causes de décès ; cette recherche se fait donc au niveau local, grâce à la collaboration des hôpitaux et de la famille, et la cause de décès ainsi recueillie est vérifiée soigneusement.

RESULTATS

La mortalité par cancer de ces mineurs est comparée à celle de la population masculine nationale de même structure d'âge, par la méthode de standardisation indirecte. Le nombre de décès observé est comparé au nombre attendu à l'aide du rapport de mortalité standardisé (SMR). Le nombre de personnes-années est calculé jusqu'à la date de décès, et, pour ceux qui sont encore vivants, jusqu'au point actuel de fin de suivi, soit le 31 Décembre 1985. Les 1785 mineurs précités totalisent 44 995 personnes-années. Le tableau 2 indique les décès par cancer significativement en excès. La mortalité par cancer du poumon est en excès sur la totalité de la cohorte. Quand l'analyse est limitée au groupe faiblement exposé, c'est-à-dire ceux embauchés depuis 1956, l'excès de cancers du poumon reste statistiquement significatif. Pour les décès par

cancer du larynx, l'excès est principalement dû aux mineurs ayant travaillé pendant la période 1946-1955. Un excès par cancers du cerveau est observé sur le groupe faiblement exposé. Il est à noter qu'aucun excès de leucémies n'est observé.

Les cancers du poumon et du larynx sont fortement liés à la consommation tabagique et, dans un moindre degré, au niveau socio-économique. Pour qu'un facteur tel le radon puisse être incriminé, l'augmentation du risque de cancer doit être fonction de l'exposition cumulée. En admettant pour le cancer du poumon une relation linéaire entre le rapport de mortalité standardisé et l'exposition cumulée, il est possible de démontrer que la pente de la droite est proche de 0,6 % par WLM. Cette valeur, plus faible que celle de la plupart des autres études, se situe dans l'intervalle (0,5 à 1,5 % par WLM) donné dans la CIPR 50 (6).

PERSPECTIVES

Il est prévu de prolonger la surveillance de cette cohorte pour deux raisons principales ; d'une part, la cohorte est encore trop jeune pour que la totalité du risque de cancer du poumon se soit exprimée. D'autre part, la faible exposition annuelle observée présentement devrait permettre de mieux préciser le risque associé aux faibles expositions. L'enregistrement systématique de la dosimétrie est un élément favorable pour le suivi.

Parallèlement une collaboration au niveau international s'est établie pour analyser de façon conjointe les résultats d'une dizaine de cohortes de mineurs, avec l'objectif de mieux quantifier la relation entre l'exposition et l'effet.

CANCER MORTALITY OF NUCLEAR WORKERS OF CEA AND COGEMA FROM 1969 TO 1986

SUMMARY

Cancer mortality of the nuclear workers of CEA and COGEMA has been collected by the occupational health services of both firms from 1969 to 1986. The data are related only to the workers who died when in activity. Only very few workers left CEA and COGEMA before retirement ; so we consider this mortality survey as describing correctly the cancer mortality for the age groups less than 60-65 years old. Compared to the national mortality of same sex, age and calendar period, by the method of indirect standardization, the only excess observed was in the female population, linked to breast cancer mortality. The male population demonstrated a high healthy worker effect, even for cancer mortality. This study has now to be completed by an typical epidemiological cohort study in order to test cancer mortality after retirement and to discuss a possible relation with occupational exposure.

INTRODUCTION

La mortalité par cancer des agents du Groupe CEA (CEA civil et militaire ainsi que de COGEMA, à l'exception des mineurs d'uranium) a été recueillie de façon systématique par les différents services de médecine du travail. Elle est enregistrée par cause de décès par le Conseiller Médical du Groupe CEA. Le but de ce travail est de surveiller, de façon continue, au niveau de la médecine du travail, la mortalité de ce groupe de travailleurs pour la comparer à celle de la population nationale.

Le bilan réalisé sur la période 1969 à 1986 ne peut être considéré comme une étude épidémiologique dite de cohorte, car le suivi des travailleurs est limité aux seuls agents en activité et ne concerne donc qu'une population âgée de moins de 60 à 65 ans.

METHODOLOGIE

Les causes de décès par cancer des travailleurs sont transmises de façon anonyme par la médecine du travail, chaque individu étant caractérisé par sa date de naissance, sa date

d'embauche et sa date de décès. Pour le bilan actuel, la date de fin d'étude est le 31 Décembre 1986. Pour chaque cause de cancer retenue, le nombre de décès observé (O) est comparé au nombre attendu (A) qui a été obtenu en appliquant à la structure d'âge de la population active du CEA et de COGEMA, les tsux de mortalité nationaux spécifiques, par sexe et par année. Les résultats apparaissent dans les tableaux 1, 2 et 3 sous forme de rapport de mortalité standardisé O/A (ou SMR). Si le SMR est différent de 1, un test statistique, basé sur l'hypothèse que O suit une loi de Poisson de paramètre A, permet de déterminer si l'excès ou le déficit observé est significatif.

RESULTATS

La mortalité toutes causes est significativement inférieure à celle de la population nationale, aussi bien pour les travailleurs masculins que féminins.

La mortalité par cancer des agents CEA et COGEMA indiquée dans le tableau 1 pour les hommes, et dans le tableau 2 pour les femmes, est aussi significativement inférieure, si la période globale 1969-1986 est considérée. Sur le groupe féminin, un excès de mortalité par cancer est observé sur les six dernières années ; il s'explique par un nombre élevé de décès par cancer du sein : 19 observés pour 7,45 attendus (tableau 3).

DISCUSSION

Dans le groupe masculin, l'étude de la mortalité par cancer considérée globalement, ou selon les différentes causes, ne montre pas d'excès. Il est vrai que les décès par cancer apparaissent majoritairement au-delà de 60 ans. Cependant, vu le type de population suivie, un excès de décès par leucémies aurait pu être attendu [1]. Sur la période de l'étude, 3 décès par leucémies ont été observés pour 2,74 attendus et le SMR de 1,09 est non significatif. Il existe également un net déficit des décès par cancer bronchique ; ceci indique que le groupe étudié est peu exposé à des facteurs cancérigènes tels que le tabac. La mortalité toutes causes, également en déficit, reflète le fameux "healthy worker effect" des groupes de travailleurs ayant ce type d'activités professionnelles [2].

L'excès de décès par cancer du sein, observé dans le groupe féminin peut refléter la différence de niveau socio-économique entre ce groupe et la population féminine nationale. L'exposition professionnelle ne semble pas intervenir : une seule femme, sur les 19 décédées durant la période 1981-1986, a cumulé plus de 10 mSv. La possibilité d'une étude cas-témoin est actuellement envisagée afin de tenir compte des différents facteurs intervenant dans le risque de cancer du sein (nombre de grossesse, âge au premier enfant, etc...).

Parallèlement il est envisagé de réaliser, en collaboration avec le Centre International de Recherche sur le Cancer à LYON, une vaste étude de cohorte des travailleurs du nucléaire en France.

MORTALITE PAR DECES TOUTES CAUSES (CIM 8 : 1 - 999)

Population masculine (1969 - 1986)

Année	Nombre observé	Nombre attendu	SMR	p
1969 à 1980	633	1 350	0,47	
1981 à 1986	376	731,1	0,51	
TOTAL	1 009	2 082	0,48	

La mortalité toutes causes est largement inférieure à celle de la population masculine nationale ($p < 0,001$).

Population féminine (1969 - 1986)

Année	Nombre observé	Nombre attendu	SMR	p
1969 à 1980	71	107,0	0,66	
1981 à 1986	67	63,94	1,05	0,37
TOTAL	138	171,0	0,81	

La mortalité toutes causes est significativement inférieure à celle de la population féminine nationale ($p = 0,005$).

Tableau 1

MORTALITE PAR CANCER TOUTES LOCALISATIONS (CIM 8 : 140-207)

Population masculine (1969 - 1986)

Année	Nombre observé	Nombre attendu	SMR	p
1969 à 1980	213	351,9	0,61	
1981 à 1986	142	237,5	0,60	
TOTAL	355	589,3	0,60	

Pour toute la période considérée, la mortalité par cancer de la population masculine du CEA et de la COGEMA est inférieure à celle de la population nationale (différence statistiquement significative : $p < 0,001$).

Population féminine (1969 - 1986)

Année	Nombre observé	Nombre attendu	SMR	p
1969 à 1980	32	35,21	0,91	
1981 à 1986	41	24,47	1,68	0,001
TOTAL	73	59,68	1,22	0,05

L'excès de mortalité par cancer dépend de la période 1981 - 1986. Il s'explique essentiellement par une augmentation significative de la mortalité par cancer du sein.

GENDER SPECIFIC RISKS FOR FEMALE IONIZING RADIATION WORKERS

R. McFadden

Radiation Protection Service
Ontario Ministry of Labour
Toronto, Ontario, Canada

ABSTRACT

Following exposure to ionizing radiation, certain neoplastic diseases are expressed significantly more frequently in females than in males. Radiation associated ovarian cancer and the differential disease rates for thyroid cancer, breast cancer and other carcinomas lead to higher gender specific risks for female radiation workers when compared to males. This has implications for the calculation of the effective dose in both genders and for practical radiation safety procedures, especially for certain organs such as the breast and thyroid. The radiation associated fatal cancer rate in females is 60 % higher than in males.

INTRODUCTION

Tissue Weighting Factors recommended by the International Commission on Radiological Protection (ICRP) (1) are based on estimations of the adverse effects of radiation on the health of those exposed. In these calculations, which use the ICRP concept of Detriment, the gender averaged incidence of fatal cancer is aggregated with a weighted incidence of non-fatal cancer and genetic effects. Calculated below are Gender Specific Tissue Weighting Factors based on the incidence of cancer and genetic effects in both sexes. These TWF explicitly delineate the adverse effects of radiation on males and on females.

The ICRP TWF (1) are listed in their Table B-20. The development of the TWF is shown in Chapter 5 and particularly pp 120-136. The ICRP chooses to use several important averages in the development of TWF: sex, par. B99; age, par. B100; and national population par. B101-B105.

Implicit in the ICRP TWF calculation is the definition of the Detriment, a measure of the possible harm to the person exposed, par. B115 and par. B117-119. The probabilities of fatal cancer, Table B-17, on which the detriment is based, implicitly contain gender averaging. The relative length of life lost, Table B-18 and fraction of fatal cancers, Table B-19, also result from these averaging processes.

CALCULATION

An alternate approach is to carry out a calculation of a set of TWF for each gender. Gender averaging is the averaging process most at question in the ICRP approach to the calculation of TWF. There are incontrovertible differences between the two genders in their responses to ionizing radiation. At least some of these differences are biologically based:

FEMALE	MALE
ovaries	no organ
breast	female to male fatal cancer rate in range 107/1 to 150/1
thyroid	female to male fatal cancer rate 3 to 1
colon	female to male fatal cancer rate 3 to 1
oesophagus	female to male fatal cancer rate 2.4 to 1

The ICRP ovarian cancer rate results from an average over both genders. Because this organ is not present in the male, the ICRP rate must be multiplied by a factor of two to account for gender averaging and to obtain the gender specific female rate. $f = 0.20 \times (10^{-2}) / (Sv)$. The ICRP breast cancer rate also results from an average over gender. The algebraic expression to obtain the female rate is given by the following equations where: F = gender averaged fatal cancer rate; f = female fatal cancer rate; m = male fatal cancer rate; and R = f/m.

$$\text{Eq. 1} \quad f = (2FR)/(1+R)$$

$$\text{Eq. 2} \quad m = (2F)/(1+R)$$

The gender ratio R = 107 to 150 for breast cancer in the U.S. population (3) (4). This leads to a fatal female cancer rate which almost twice the ICRP rate. $f = 0.396 \times (10^{-2}) / (Sv)$.

The BEIR V preferred model for breast cancer (2) also shows an age structure of significance for the working population of females, after accounting for gender averaging. First, for females under 20 years, breast cancer is expressed 4 times more frequently than the adult female between the ages of 20 and 40 years at time of exposure to radiation. Second, for females over 40 years, breast cancer is expressed at 40 % of the rate of the adult female between the ages of 20 and 40 years at exposure.

ICRP data (1) Table B-12 and (4) may be combined to obtain an estimate of the relative probability of fatal cancer by gender and organ. These estimates of R are used with the ICRP 60 gender averaged fatal cancer incidence rates of Table B-20 to obtain gender specific fatal cancer incidence rates. These appear in the recalculations of the Gender Specific TWF below.

ICRP fatal fraction data are shown in Table B-19. However, for some organs the fatal fraction, k , differs with gender. Again choosing to use the data of (4) and 10-year cancer survival rate data, (4) Table 1 and Table 2, it is possible to estimate the fatal fraction by organ and gender. For all organs females have lower fatal fractions than do males. For example, the fatal fractions (male, female) are: Breast (0.63, 0.53), Thyroid (0.25, 0.17), and Remaining (0.77, 0.58). These data imply that females have somewhat higher cancer survival rates, at least based on the definition of 10-year survival. For expected life lost, ICRP (1) Table B-18 and B-20 data are used.

Using these data and equations a set of Gender Specific TWF can be recalculated. The calculations are shown in a format which permits simple comparison with ICRP 60 Table B-20. Results are shown in Tables I and II below. A column is added to the calculations. This column, labelled "relative contribution male" or "relative contribution female" uses the appropriate gender detriment as a basis for illustrating the sensitivity of the organs within that gender.

CONCLUSION

Gender Specific TWF make explicit that in the male the organs are equal or less in sensitivity than the ICRP reference and females are equal or greater than the ICRP reference. For the evaluation of population exposures of equal numbers of both sexes, the ICRP reference may be appropriate. However, in evaluating practical safety practices where females of various ages may be exposed to ionizing radiation, it is necessary to consider gender specific TWF. Applications may, for example, emphasise the female breast and thyroid. Finally, the ratios of fatal cancer estimates indicate that females are at a 60 % greater risk of fatal cancer than are males for cancers associated with exposure to radiation.

ETUDES EPIDEMIOLOGIQUES RELATIVES AUX CANCERS
CONCERNANT LA HAGUE ET SA REGION

P. THOMAS, Chef du Service Médical de l'Etablissement
COGEMA DE LA HAGUE

The separate investigations have been made of cancer-related deaths among the population living in the vicinity of the La Hague reprocessing plant. The results of these investigations are in agreement. They show, especially as far as leukemia is concerned, that the number of deaths recorded is no higher than the number of deaths forecast.

A la suite de la publication des premières études britanniques faisant état d'un excès de décès par leucémies dans les populations voisines des installations nucléaires de SELLAFIELD et DOUNREAY, la presse française a évoqué à plusieurs reprises la possibilité d'une augmentation des cancers en général et des leucémies en particulier dans l'environnement de l'usine de retraitement des combustibles usés de La Hague. Si, compte tenu des niveaux d'activité des rejets, une telle possibilité paraissait extrêmement réduite, elle justifiait néanmoins la réalisation d'études épidémiologiques.

L'usine de retraitement de La Hague est située dans le Nord-Ouest de la France, à l'extrémité de la péninsule du Cotentin. Cette usine, construite en 1966, a retraité depuis 1968 plus de 8400 tonnes de combustibles usés. Par ailleurs, sont implantés dans la même région une centrale nucléaire de 2 x 1300 MWE et un chantier naval construisant les sous-marins nucléaires français.

Les études épidémiologiques relatives à la mortalité par cancer dans la région de La Hague sont au nombre de trois :

1° - Etude de M. DOUSSET : "Mortalité par cancer autour des installations nucléaires de La Hague" (1).

Cette étude concerne la mortalité par cancer dans le canton de Beaumont-Hague (la France est divisée en 95 départements, eux-mêmes divisés en "arrondissements" ; ces derniers étant subdivisés en "cantons". Le "canton" peut-être comparé au "district" britannique). Le canton de Beaumont-Hague, sur le territoire duquel est implantée l'usine de retraitement compte 19 communes ; la commune de Beaumont-Hague est le chef lieu de ce canton dont la population, lors du recensement de 1982, s'élevait à 7408 habitants.

Les premiers rejets de l'usine ont eu lieu en 1968. L'auteur a considéré que le temps de latence minimum pour les leucémies était de 2 ans, et de 7 ans pour les autres cancers (valeurs généralement adoptées par les radiopathologistes). Les décès par leucémies ont été étudiés de 1970 à 1982 et, pour les autres cancers, de 1975 à 1982.

La mise à jour publiée en 1990 a permis d'étendre l'étude jusqu'en 1985.

La population de référence à partir de laquelle a été établi le nombre de cas attendus est la population du département de la Manche, auquel appartient le canton de Beaumont-Hague.

Le chiffre de population et la distribution par groupe d'âge sont déterminés tous les 7 ans par un recensement national. Les recensements pris en compte sont ceux de 1968, 1975 et 1982.

L'étude de M. DOUSSET précise par année, par sexe et par tranche d'âges les décès dus à l'ensemble des cancers sauf les leucémies, les décès dus aux cancers du sein, aux cancers de la prostate, aux myélomes multiples, aux cancers de la trachée, des bronches et du poumon et enfin aux décès dus aux leucémies.

Le tableau suivant résume les résultats de l'enquête pour la période 1968-1985 : on constate qu'il n'y a aucun excès de décès par leucémies parmi les personnes de moins de 25 ans et qu'il n'existe aucune différence significative entre la mortalité par cancer dans le canton de Beaumont-Hague et celle du département de la Manche.

2° - Etude de J.F. VIEL et S. RICHARDSON : "Leucémie de l'enfant et usine de retraitement" (2).

Cette étude portant sur les périodes 1968-1978 et 1978-1986 concerne la population habitant à l'intérieur d'un périmètre déterminé autour de l'usine. La surface ainsi définie a été divisée en 3 zones délimitées par 3 cercles concentriques de 10, 20 et 35 Km de rayon. La population de référence est la population du département de la Manche. Trois tranches d'âge ont été étudiées : 0-4 ans, 5-15 ans et 15-24 ans.

Les résultats de cette enquête figurent dans le tableau suivant : ils confirment les résultats de l'enquête de M. DOUSSET.

:	:	:	:

Il faut noter que les taux standardisés de mortalité pour l'ensemble des classes d'âges, les périodes et les zones est de 0,89 (nombre de cas observés : 21 - nombre de cas attendus : 23,6).

* Rapport standardisé de mortalité (Standardized Mortality Ratio) = nombre de décès observés/nombre de décès attendus.

3° - Enquête de C. HILL et A. LAPLANCHE : "Etude sur la mortalité par cancer autour des centres nucléaires français (3).

Cette étude fait l'objet d'une communication particulière dans le cadre de ce Congrès. Elle sera donc, ici, brièvement résumée.

Dans ce rapport, l'étude des populations de La Hague est incluse dans une étude plus vaste englobant les populations voisines de 5 autres établissements industriels nucléaires (période étudiée : 1968-1987). Les résultats confirment les résultats des 2 études précédentes : il n'existe aucune différence significative entre le nombre des décès constatés et le nombre des décès attendus.

En conclusion, aucune des enquêtes épidémiologiques, couvrant la période 1968-1986 n'a mis en évidence une augmentation de la mortalité par cancer et par leucémie parmi la population voisine de l'usine de retraitement de La Hague.

CONSISTENCY OF EXTERNAL DOSIMETRY IN EPIDEMIOLOGIC STUDIES OF NUCLEAR WORKERS

Jack J. Fix and Ethel S. Gilbert

Pacific Northwest Laboratory
Richland, Washington USA

ABSTRACT

Efforts are underway to pool data from epidemiologic studies of nuclear workers to obtain more precise estimates of radiation risk than would be possible from any single study. The International Agency for Research on Cancer (IARC) is coordinating combined analyses of data from studies in the United States, Canada, and the United Kingdom. In the U.S., the Department of Energy (DOE) has established the Comprehensive Epidemiologic Data Resource (CEDR) to provide investigators an opportunity to analyze data from several DOE laboratories. IARC investigators, in collaboration with those conducting the individual studies, have developed a dosimetry protocol for the international combined analyses.

INTRODUCTION

In the pooling of radiation exposure data, there is significant concern regarding consistency of personnel exposure records between the different epidemiologic studies. Dosimetry working groups have been formed to evaluate this issue for pooled studies for the International Agency for Research on Cancer (IARC) and U.S. Department of Energy (DOE) Comprehensive Epidemiologic Data Resource (CEDR). A protocol has been developed for the IARC study by representatives of the United States, United Kingdom and Canadian studies. Recently, a dosimetry working group has been formed to provide recommendations to CEDR regarding retrospective and prospective radiation dose records. The IARC protocol addresses concerns related to the consistency of recorded dose as obtained from personnel exposure records, and requires evaluation of historical dosimetry practices by dosimetrists for each of the contributing studies.

EPIDEMIOLOGIC EVALUATIONS

Several epidemiologic studies of workers who have been exposed occupationally to external radiation are being conducted in the United States, the United Kingdom, and Canada. U.S. studies include workers at the Hanford site¹, at Oak Ridge National Laboratory², and Rocky Flats Nuclear Weapons Plant³; the U.K. studies include workers at the Atomic Energy Authority⁴, the Atomic Weapons Establishment⁵, and at the Sellafield Plant⁶, and the Canadian study is of workers at Atomic Energy of Canada Limited⁷. Analyses of data from these studies have included tests for an

association of cumulative radiation dose and mortality from many specific diseases, and have also included the estimation of excess risk per unit of dose.

Recently, pooled analyses of data from the three U.S. studies have been conducted⁸ and pooled analysis of the international studies are underway⁹. A major objective of these pooled analyses is to obtain more precise risk estimates than could be obtained from any single study, and to compare these estimates with risk estimates obtained through extrapolation from studies of the Japanese A-bomb survivors and other groups exposed at high doses. To accomplish this objective, it is important to evaluate the consistency of dose estimates across studies and across time. In addition, because risk estimates from high dose studies are generally based on organ doses, it is important to understand the relationship between recorded whole body doses obtained from personnel dosimeters and doses to various organs.

CONSISTENCY OF RECORDED DOSE

Consistency of recorded dose between epidemiologic studies is essential to the technical integrity of the pooled evaluations. There are several potential causes, administrative and technical, of inconsistency between different facilities or through time for a given facility. These causes of potential inconsistencies should be evaluated as an integral part of the epidemiologic evaluation. Typically, there is a need for documentation of the physical meaning of the recorded dose, particularly for facilities which began operation in the 1940s and 1950s. Potential causes of inconsistency should be evaluated for systematic differences, which affect the entire dosimetry system, and for differences in administrative practices, which are generally of most significance for recorded doses near the detection level of the dosimetry system.

Potential causes of systematic differences include the dosimetry technology, calibration methodology, dose algorithms, environmental dose correction and the physical definition of the calculated dose (i.e., exposure, absorbed dose in air, deep dose, etc.). Technical, administrative and compliance considerations are involved in the determination of practices adopted by facilities to record personnel dose. Facility specific technical and administrative practices may have significant effects on the recorded lifetime personnel dose for each individual. Prior to pooling data between facilities, an evaluation of the potential causes of inconsistency in recorded dose is necessary to ensure credibility of the analyses.

DOSIMETRY ASPECTS OF IARC PROTOCOL

A protocol for "Combined Analyses of Cancer Mortality Among Nuclear Industry Workers" was published by IARC in 1989⁹. This protocol includes a discussion of dosimetry data and the consistency of dose estimates, makes specific recommendations regarding documentation of dosimetry data, and specifies the dosimetry variables that are to be included in the IARC data sets. Results of the U.S. dosimetry working group evaluation were considered along with evaluations conducted in the U.K. and Canada in the development of the dosimetry portion of the IARC protocol. The IARC protocol contains several recommendations for dosimetry data. These include the following:

- Documentation of procedures and practices used to record dose
- Report external whole body dose as currently recorded
- Report external whole body dose components (i.e., penetrating photon and beta, neutron and tritium)
- Flag records with monitoring for internal depositions
- Flag records with confirmed plutonium, uranium or other nuclide internal depositions
- Comparison of recorded dose to deep dose
- Determination of organ dose as feasible

Prior to inclusion in the IARC study, a representative for each participating study completed a questionnaire on specifics of dosimeter design, dose assessment, monitoring and recording practices, radiation fields to which workers were exposed, etc. This information was used by IARC and the dosimetry subcommittee to conduct a preliminary evaluation of consistency of dose estimates used in different studies, and whether the reported doses can be converted to "deep dose", and to doses to various organs. More detailed documentation by the respective studies is encouraged. Recently, documentation of historical personnel dosimetry practices was published for Hanford¹⁰. This document describes dosimeters, calibration and dose recording practices for hanford facilities from 1944 through 1989.

ABSTRACT

The chelating effect of natural polymers on the radiostrontium was investigated on a single ingestion with chitosan and a long day pre-feeding diet with alginate in rats. After dosing of chitosan, Sr-85 was ingested orally to the rats and the whole-body retention of Sr-85 was investigated. The whole-body retention of the chitosan treated rats was lower than that of non-treated control.

INTRODUCTION

The radiostrontium, one of the nuclear division products flown out to the environmental area by the nuclear power plant accident and nuclear weapon accident. It brings out of a serious genetic disease like Bone Cancer, Hypocemia, etc. Therefore, it has been discussed out an important human health problem that the chelating of radiostrontium and the removing out of the body before or after accumulating to the bone. Chitosan derived from chitin which is a cellulose-like biopolymer distributed widely in nature, especially in shell fish, insects, fungi and yeast, is known to be one of the natural chelating agents. The purpose of the present study is to investigate whether chitosan can be applied to the animal and human body and the long day pre-feeding effects of alginate in order to reduce the bioavailability of radiostrontium in foods. Many chelating agents—that is, DTPA, CDTA, EDTA, etc were reported as effective medicines. But they have some toxicity. So, we need a serious check to use of them at the real clinic experiment. Therefore, the discovery of non-toxic natural chelating polymer is quickly needed.

MATERIALS AND METHODS

Experimental animals used were male rats of the adult wister strain and 8 weeks of age, weighing about 250-300g, bred and supplied by the animal and plant supply section of National Institute of Radiological Sciences were used in this experiment. The rats were provided with a standard cubed diet(Fubashi Farm co. Fubashi, Chiba, Japan). Radiostrontium chloride ($^{85}\text{SrCl}_2$) with a specific activity of 430MBq/mg Sr was obtained from England Nuclear, U.S.A through Radioisotope Association, Japan. This was diluted to 15KBq/ml of solution with normal saline solution and administered 0.5ml per one rat. Chitosan (Hwasung K.K, Tokyo, Japan) is slightly soluble in distilled water and alkali, it is soluble in some organic acids. 0.8, 2, 3% of chitosan solution was prepared by dissolution in 1N acetic acid. And also 0.8, 2, 3% of water soluble chitosan (Hwakwang K.K, Tokyo, Japan), the chemical form of 45-55% deacetylated chitin, solution was prepared by dissolution in distilled water. Chitosan solution was orally given and immediately after than $^{85}\text{SrCl}_2$ was administered to rats using a stomach tube. The whole-body retention of Sr-85 was determined by in vivo counting. The percent of alginate food was given to rats during 10days and Sr-85 was administered orally.

CONCLUSIONS

The whole-body retention of Sr-85 determined by in vivo counting was lower than that of control rats which were not given chitosan.(Fig.1) And the effects were differented along the concentration variation of chitosan.(Table1) The activity ratio in urine and feces for chitosan-treated rats was higher than control rats.(Fig.2) The whole-body retention of Sr-85-alginate treated rats was decreased sharply compared with control rats.(Fig.3) These results suggested that chitosan and alginate can be used as a drug to reduce bioavailability from gastrointestinal of ingested radiostrontium.

NONSPECIFIC CELLULAR RESISTANCE DISORDERS
INDUCED BY LOW DOSES OF RADIATION

I. Voltchek, E. Kostyushov, L. Filyov, V. Dyachek, I. Izyumtsev,
A. Tyaptin, I. Popov, Yu. Medvedev, L. Goncharova

Department of Extreme Medicine, Leningrad Institute of
Advanced Medical Studies; All-Union Research Institute of Highly
Pure Biopreparations, Leningrad, USSR

Some integral proofs of nonspecific cellular resistance was studied at liquidators of the consequences of Chernobyl AES crash 4-4,5 years ago radiation influence in doses 20-25 rem. The share of blood mononuclears with viral inclusion bodies and degree of its viral affect, metabolic and phagocytic monocyte activity in NBT-test (L. Filyov et al., 1985) were appraised. Lysosomal-cationic test was used for the revealing of functional state of granulocytes.

It was established that at all patients influenced by low doses of radiation there were increased proofs of viral affect of mononuclears in comparison with control group of healthy donors. At the same time most liquidators had functional defects of monocytes and granulocytes.

Consequently, there may occur nonspecific (antiviral) cellular resistance disorders under the influence of radiation low doses which in its turn may lead to development, unfavourable course, chronization of infection diseases, forming of immunocomplex pathology, neoplastic processes. The perspective way of prophylaxis radiation low doses induced unfavourable consequences is the correction of nonspecific cellular resistance disorders (Olifen, Interlock).

RADIATION PROTECTION - IS IT SCIENCE?

Dr B M Hartley

**Physicist in Charge, Radiation Health Section
Health Department of Western Australia**

Radiation Protection brings together a variety of disciplines which would claim to be sciences. The amalgamation of these into radiation protection is done under the guise of Scientific Committees and by Scientists. Can the result of this amalgamation still be described as a science? If not, our perception of the discipline and attitude to its practice may need to change. The attitude of the media and that of the public to our profession may also change if radiation protection is recognised not to be a science.

An analysis of the basis of science would indicate that Radiation Protection is not a science. The question is then posed; What is the discipline of Radiation Protection?

INTRODUCTION

Whether radiation protection is 'science' or not should affect the way it is practised and the way it is considered by the public at large. If it is science there is an expectation of accuracy, precision and consistency and therefore the possibility of widespread acceptance of decisions based on its application. If it is not science the public at large, and especially those who may be affected by its practice, may have a role in determining how it is practised. Radiation protection may then become subject to political, philosophical and practical pressures which influence decisions on the application of its systems.

WHAT IS SCIENCE?

It is common to distinguish between two types of conventions which control our actions. The first of these are the natural laws which define such properties as the law of gravity or the laws of thermodynamics; these are laws which can be investigated by the scientific method. Other conventions are the so called normative laws which are the conventions by which people control their lives and in which society has exercised a choice. Such laws often cannot be rationalised by scientific investigation.

Such a classification is not precise as there are some natural laws which, for a variety of reasons, cannot be investigated whilst normative laws imply that an option or choice has been exercised. Some normative laws of behaviour may, however, arise from natural laws or be required for survival. The distinction between normative and natural can, as a result, become blurred.

Without being too precise science could be defined as being the process of investigating natural laws. In investigating natural laws a common procedure is to devise a hypothesis and test it by experiment. The linear hypothesis of radiation protection may be considered such a hypothesis, but it is not testable at certain doses and dose rates. As it cannot be investigated scientifically it is an invalid scientific hypothesis.

A more scientifically justifiable hypothesis would be one of no effect at low doses and dose rates. Such an hypothesis is falsifiable by application of scientific methodology and is therefore scientifically valid hypothesis.

WHAT IS RADIATION PROTECTION?

The principal foundations of radiation protection are the disciplines of epidemiology, modelling and laboratory studies. These disciplines are identifiable as sciences since they seek to investigate natural laws by the testing of hypotheses through experiment. The phenomenon which is being investigated in these studies is that which relates the effect of radiation exposure to the level of exposure on the ensemble of the human population; an identifiable natural law.

The syntheses of the results of epidemiology, modelling and laboratory studies has given us some confidence about the relationship between radiation exposure and response. The International Commission of Radiological Protection has, as a result, devised a system of radiation protection with its basis being exposure control by justification, optimisation and limitation.

These three tenets of radiation protection do not evolve readily from natural laws. Justification and optimisation, require a judgement of the community value placed on the detriment which exposure to radiation imposes on the community. The limitation of exposure to an individual is derived from the ensemble of human responses. It may not be appropriate to apply a dose-response law to an individual when it is derived from grouped data. Its application departs from the normal practices of science. All three involve ethical considerations.

The setting of standards for Radiation Protection is clearly in the area of public policy and ethics although its basis is scientific.

An alternative to optimization would be a policy of "Prudent Avoidance" of exposure and this would be more in keeping with the adoption of the null hypothesis for effects of radiation at low doses.

Since radiation protection is commonly pursued by persons who have scientific training there is a tendency to confuse the application of scientific method with science. Attempts have been made to adopt a scientific approach to justification by placing a value on a human life and assessing the loss of life or health against the benefits to be had by others. A similar paradigm is used to optimise a practice.

In giving advice the ICRP could confine themselves to statements of the known data on levels of radiation which produce known biological effects. Such levels are well above those which are used as annual occupational radiation limits. By adopting the non falsifiable linear hypothesis the ICRP alters the profession of radiation protection from purely scientific to pseudo-scientific.

SETTING OF RADIATION STANDARDS

The means by which standards for radiation exposure are set should depend on whether the process is one which set natural or normative laws i.e. scientific or conventional. Even the necessity to establish radiation protection standards in law would indicate that they are normative laws and not natural ones. Recommendations for limits can derive either from an expert group or from community based groups. Included among the community groups may be workers groups with representatives on decision making bodies.

It is normally considered to be the role of politicians to determine policy but in this instance their input has been small or non-existent. In some countries there is a growing call for tripartite agreement on occupational limits with the persons occupationally exposed having a major role in determining limits. Participating workers often call for exposure limits lower than those recommended by the ICRP taking the determination of limits further away from the scientifically verifiable.

The groups making recommendations will nevertheless consider matters which are, in the above definitions, not scientific. If the matters are scientific the uncertainties are often such as to render their consideration by scientists inappropriate. If recommendations are only made by scientists, the public expects greater precision than can be given. Radiation protection cannot respond adequately through science alone.

Bodies setting radiation protection standards should understand that they are setting policy not science. Optimisation and justification tend to demand the use of a scientific method which is inapplicable in a policy area. When effects are so uncertain a policy of either acceptance or avoidance of exposure could be adopted instead of optimisation.

At levels where effects are quite uncertain a policy of acceptance could be adopted. Such a method of radiation control is clearly then a policy matter but is based on the proper scientific hypothesis of no effect of radiation exposure at low doses. Optimisation would only be applicable where radiation effects were known and demonstrable.

THE FUTURE FOR RADIATION PROTECTION STANDARDS

As the ICRP and Regulatory Bodies have, as a policy matter, set exposure limits outside the bounds of scientific evidence, one may question whether this should continue. The success of such a process should be a determining factor in deciding.

The ICRP can point to many successes in its long history including the evidence of low exposures and health risks in most radiation industries. The cost of the reduction in exposures must however be balanced by the benefits derived. It is certain that the ICRP's assumption of continuing detrimental effects of radiation at low levels has caused the expenditure of considerable effort which could have been directed at more tangible and direct hazards. To balance this, however, emphasis on radiation has led to reductions in other industrial hazards.

A new Radiation Protection System could be considered to replace the current system of radiation exposure control.

- (1) Radiation exposure at high levels has been shown to produce detrimental health effects. Limits of exposure of single persons should be set to be below such levels.
- (2) Where large numbers of persons may be exposed to radiation as a result of a practice and where individuals may be exposed to levels which are a significant fraction of the limit, radiation exposure should be controlled by optimisation.
- (3) Where individual radiation exposures are low a policy of prudent avoidance of exposure should be employed. At levels at which it is unfeasible to demonstrate harmful effects on individuals or groups a policy of acceptance of the radiation exposure may be adopted where the use of radiation is shown to produce other positive benefits.

This system of radiation protection is based on a scientifically valid hypothesis and includes explicit to the statement on formation of policy implicit in setting of any standards.

Training and Retraining of Radiation Protection Technicians

L. Warming, J. Søgaaard-Hansen, B. Lauridsen and P. Hedemann Jensen
Risø National Laboratory, DK-4000 Roskilde, Denmark

Abstract

A new training programme for health physics technicians has been based on a textbook on health physics (700 pages in Danish). Two technicians have been trained according to the programme. Following this an extensive programme was initiated for the retraining of all technicians. Both programmes consists of lectnres, theoretical problems and practical exercises.

Introduction

Risø National Laboratory was founded in 1956 and in the following years several nuclear facilities were build. Today, two reactors, several nuclear laboratories and a nuclear waste treatment plant are in operation.

A section for applied health physics is responsible for radiation protection at the nuclear facilities and at other laboratories at Risø, where radioactive materials, ionizing radiation and lasers are used. The section consists of four health physicists (HPs) and 13 radiation protection technicians (RPTs). A few of the technicians have been with the section for about 30 years.

New comprchensive programmes for both basic training and retraining of RPTs have been made. All training is done by the HPs and senior RPTs. The main part of the teaching is based on the first draft of a textbook on health physics (approximately 700 pages in Danish). The book has been tailor-made for the RPTs. It is comprehensive and self-contained; a good basic school education is needed to read the textbook. The textbook is suitable as a handbook in the daily radiation protection work for both the HPs and RPTs. The authors of the book are the HPs (also authors of this paper), and the retired senior RPT who previously was in charge of training of the RPTs.

Basic training

The basic training takes 8 months. Trainees are recruited among people with a technical background such as laboratory assistants or mechanical technicians. The basic training consists of lectures (400 h), theoretical problems and laboratory exercises (200 h) and on-the-job training (400 h). The lectures give the theoretical basis of radiation protection and cover the subjects of the textbook, such as: atomic physics, interaction of ionizing radiation with matter, dosimetry, radiation biology, radiation protection philosophy, legislation and local rules. Further the various nuclear installations at Risø are described with emphasis on radiation protection matters. The laboratory exercises introduce measuring techniques and data analysis. The lectures are given by the HPs, who also formulate the theoretical problems, while senior RPTs are in charge of the laboratory exercises and the on-the-job training. The training is not identical for all new trainees, but it is adjusted slightly to fit the educational background of the individual.

The aim of the basic training is to reach a level of education that enable the RPT to act independently and:

- give advice in work-situations both on-line and in the planning phase
- perform standard analysis on samples (γ -spectrometry, gross α - and β -counting)
- report results and evaluations in writing
- present problems for the HPs
- answer questions on radioactivity and radiation protection from the staff of the installations
- handle emergency situations.

The trainees are evaluated by a written (4 h) and an oral (1-2 h) examination. The man-power required for running a basic training programme including preparatory work is approximately 1000 HP hours and 500 senior RPT hours.

Retraining.

An extensive retraining programme was initiated for the first time in 1990 and will run for a period of two years. It is an assembly of teaching sessions, and each session has three parts:

- two double lectures on separate subjects, lasting a morning (3 hours),
- a set of theoretical problems
- a practical exercise.

The programme has about 20 sessions in total (one session a month). Most subjects are dealt with in several sessions (months) depending on their importance. During the programme the technicians will become familiar with the different chapters of the health physics textbook.

The two set of lectures are always dealing with two separate subjects and they are given by two different teachers. The level of the teaching is set rather high and is higher than needed for the RPT's daily work.

With each lecture follows a set of theoretical problems to be solved and the answers to be handed in before the next lecture. An example is the calculation of the internal dose, the tritium concentration in the body as well as the concentration in the urine at different times after two separate intakes of tritiated water.

The practical problems aim at making the technicians familiar with all health physics instrumentation available at the health physics laboratories. This is among others, survey instruments, γ -spectrometers, α - and β -counters. The problems chosen for the practical exercises are specifically selected to be closely related to the daily use of the instruments. An example of a practical exercise is calibration of an air-monitor for a specific radionuclide. When the RPTs have made the measurements they have to write a report. The report should present the purpose of the exercise and describe the work carried out together with the measured data, the calculations and a discussion of the results. The report should be written in a manner that can readily be understood by their colleagues. Also this report should be handed in before the next session.

From reading and correcting the problems and reports handed in, it is easy for the teachers continuously to get an impression of the educational level of the technicians.

Experience - Results.

The training programme has been used once for two new RPTs and has proved very effective, although some minor corrections were needed. The new RPTs have now been working for two years and accomplish their work satisfactorily. During the teaching period parts of the draft of the health physics textbook were written in parallel with the teaching which helped to make the content directly aimed at the RPTs.

The extensive retraining programme runs for the first time and we are now about half-way through the programme. All the RPTs have expressed a need for retraining before the programme was initiated and they appreciate the information they are presented with. The two "youngest" RPTs do also participate in the retraining programme. Although it is only two years ago they finished their basic training, they find the repetition useful. The practical experience they have gained in these two years has clarified for them some of the theoretical aspects in the training programme.

The educational level of the "old" RPTs has increased considerably. They are now able to make better use of the different instruments in the laboratories. Measurements and observations during important operations are being very well documented. This is essential both for record keeping and for communication to and from the RPTs working in shifts and in reports to the HPs. The RPTs find themselves with a better background for their advice to those workers, they supervise.

The teaching has been done in an informal way, and the enthusiasm of the teachers(!) seems to have spread to the RPTs. During the lectures the RPTs have contributed with practical examples from their local working area. This helps linking the theoretical subjects with the practical work and it is a good exchange of information among the different working places. This also makes it more easy for the RPTs to help their colleagues at other installations. During the teaching sessions and the following discussions the HPs and the RPTs have got to know each other better and the HPs have now a much better knowledge of the capabilities of the individual RPT.

The teachers have also benefitted both from writing the book and from the teaching itself. As always, teachers gain a deeper knowledge of a subject when they have to teach it.

So far the retraining seems to be so much a success that it is being discussed to let it continue in a less intensive manner.

COST-EFFECTIVE RADIATION PROTECTION FOR SCHOOLS AND COLLEGES
IN THE UNITED KINGDOM

K W Bowker

Hinton & Higgs (Consultants)
Abingdon, Oxon
United Kingdom

ABSTRACT

This paper describes how schools and colleges in the United Kingdom can meet the requirements of the Ionising Radiations Regulations 1985 in a simple and cost-effective manner.

INTRODUCTION

In the United Kingdom, the storage, handling and use of radioactive materials is controlled by the Ionising Radiations Regulations 1985. Students, usually in the 16-18 age group studying Advanced Level Physics in schools and colleges carry out a number of practical experiments using radioactive sources. The sources are principally closed sources of low activity and their usage is of corresponding low risk. Nevertheless, there is a need for the school or college to comply with the legislation and this paper describes how this can be achieved in a cost-effective way.

SOURCES USED

Appendix 1 shows typical closed sources used in the Advanced Level Physics course, together with their activities. In addition, cloud chamber sources are of very low activity (740 Bq). Thoron generators typically use 100 grams of thorium carbonate powder in polythene squeeze bottles. Radioactive rocks sets are a mixture (usually for four different rocks) of naturally occurring minerals containing radioactivity.

MAIN POINTS OF THE LEGISLATION

An essential aspect of the legislation is the requirement for the employer to appoint a Radiation Protection Adviser (RPA) who, as the title implies, provides advice on all aspects associated with the safe use of radiation sources in the school or college. In addition, each establishment must appoint a Radiation Protection Supervisor (RPS) to oversee the day to day arrangements for the radiation sources. The person usually appointed as RPS is the head of physics in the school, occasionally the head of science.

The main duties of the RPS in a school or college are principally to ensure that:

- 1 The list of sources is kept up to date and to notify the RPA of any changes;
- 2 Sources are kept in a locked, fire-proof cabinet, properly signed;
- 3 A log book is kept with the sources and that details of source movements are being maintained;

- 4 Local rules have been formulated and are kept up to date;
- 5 Leakage tests on appropriate closed sources are carried out;
- 6 To arrange, usually via the RPA, for the safe disposal of unwanted sources.

LEAKAGE TESTING

The Regulations require that all closed sources with a surface dose rate greater than 100 microsieverts per hour and with any dimension greater than 5mm are tested for leakage every twenty-six months. The method of test is a wipe followed by counting the activity removed onto the wipe. The limit of leakage test activity is 185 Bq. A sensible and cost-effective arrangement that can be adopted in schools involves an initial in-house screening process which is followed, but only where necessary, with testing by an appropriate external organisation. The RPS carries out the wipe test using a moistened paper and counts the wipe using school counting equipment. Where a significant quantity of activity is found on the wipe, the RPA is notified and arrangements for quantitative testing made. Schools must keep records of the test in a format laid down by the Regulations.

Most Radium-226, Strontium-90 and Cobalt-60 sources used in schools require leakage testing. In the author's experience, an insignificant few are found to have any measurable leakage activity. Thus, for the main part, this requirement of the Regulations can be carried out in-house by the school at a time to suit their convenience and at minimal cost.

TRAINING

The Regulations require that a RPS is not appointed until such time as he/she is aware of the Regulations such as they affect their particular work activity. Training is therefore essential. All RPS's are expected to attend a training course, typically of one half day's duration. A syllabus for a school/college RPS training course is shown in Appendix 2.

RADIOACTIVE WASTE DISPOSAL

In addition to commercially purchased sources, schools and colleges often 'acquire' additional sources, usually from well-meaning parents or teachers themselves. These 'acquired' sources tend to be either naturally occurring ores/minerals or apparatus containing luminising material. Many contain more activity than the commercially bought sources. In most cases, the teacher in charge is pleased to see such sources put for disposal. A collection of unwanted sources, including those commercial sources that have decayed to a level where they are no longer useful, is most cost-effective when carried out on a basis involving as many schools as possible in an area. Disposal by individual schools is not recommended on cost grounds.

CONCLUSION

Perhaps with the exception of thoron generators, the use of radioactive sources in schools is of a low order of risk. Compliance with the UK regulations can be achieved simply and in a cost-effective manner. There is a further positive benefit in that schools and colleges are able to demonstrate to their students, whose opinions are at a critical stage of development, a sensible radiation protection regime.

APPENDIX 1

CLOSED SOURCES USED IN SCHOOLS AND COLLEGES

SOURCE	TYPICAL ACTIVITY (kBq)
Americium-241	185
Cobalt-60	185
Strontium-90	185
Radium-226	185
Plutonium-239	3.7

APPENDIX 2

SYLLABUS FOR RADIATION PROTECTION SUPERVISOR TRAINING

Radiation harm.
Radiation protection objectives and methods by which objectives are achieved.
Dose limits - units of activity and dose.
Methods of dose reduction.
Summary of typical sources used in schools and associated doses and risks.
Thoron generators, cloud chamber sources.
Naturally occurring radioactive sources used in schools.
Ionising Radiations Regulations 1985 - main points of legislation as they affect the school.
Role of the Radiation Protection Adviser and Radiation Protection Supervisor.
Duties and responsibilities of the Radiation Protection Supervisor.
Local rules.
Waste disposal requirements.
Leakage test - demonstration - records to be kept.

EDUCATIVE HEALTH PHYSICS

R J VETTER⁽¹⁾, M C O'RIORDAN⁽²⁾

⁽¹⁾ B-31 Medical Sciences, Mayo Clinic,
Rochester MN 55905, USA
Fax Number: 0101 507 284 0150

⁽²⁾ National Radiological Protection Board
Chilton, Didcot, Oxon OX11 0RQ, UK

There is more to education in radiation protection than curricula, courses and certificates. In a broader sense, education implies the provision of knowledge, the development of competence, and the promotion of understanding. These purposes are served by Health Physics, the journal of radiation protection. The leading role of the journal is supported by an Advisory Board composed of members of the IRPA Publications Commission.

A review is presented of the diversity of material in Health Physics throughout the last few years and set against the historical background. Expansion in the range of topics is described as well as the increase in didactic content both theoretical and operational. The global range of contributions is noted as is the attempt to provide an international perspective on developments in the discipline. Plans for the future are discussed.

ELECTRICITE DE FRANCE - Comité de Radioprotection
PARIS - FRANCE

COMPARED RISKS AMONG ELECTRICITY GENERATING ENERGIES

ABSTRACT

When comparing risks among the different electricity generating energy sources, demonstration has been made that nuclear electricity "performance" is comparable to that of natural gas and far better than oil and coal's. The greenhouse effect must of course be taken into account. Nuclear and hydro power stand out as non-contributing to this effect. We must keep in mind that energy requirements will increase in the next years, because of demographic development and economic growth in the Third World. Therefore, a large-scale use of nuclear power will become necessary.

INTRODUCTION

Les comparaisons des risques des diverses énergies utilisées pour produire de l'électricité ont commencé il y a environ 20 ans.

Leur but est de "situer" l'importance des risques dus à l'emploi du "nucléaire" par rapport à ceux dus à l'utilisation d'autres énergies : elles concluent toutes que pour produire de l'électricité les risques de l'industrie nucléaire sont moindres que ceux du charbon ou du pétrole et du même ordre de grandeur que ceux du gaz naturel [1].

Leurs faiblesses sont cependant nombreuses :

- manque ou insuffisance de données,
- absence de dénominateur commun pour juger des effets sur la santé.
- variabilité très grande des résultats suivant les conditions d'exploitation.
- etc...

Les publications récentes [2,3,4] affirment que malgré Tchernobyl la hiérarchie indiquée ci-dessus est toujours valable bien que l'évaluation des conséquences de l'accident soviétique ne soit pas encore terminée.

PRISE EN COMPTE DE L'EFFET DE SERRE

Cependant le bilan de telles études doit être complété par la prise en compte de l'effet de serre et, par extension, de tous les problèmes d'environnement ayant une dimension à l'échelle de plusieurs pays ou d'un continent : pluies acides, dépérissement des forêts, pollutions transfrontières par les dérivés soufrés et azotés.

Le meilleur exemple est celui de l'effet de serre.

Il est dû essentiellement au CO₂ mais aussi au méthane, aux oxydes d'azote, aux chlorofluorocarbones ou CFC et aux hydrocarbures imbrûlés.

Il concerne toute l'atmosphère terrestre ; ce n'est donc pas un problème à résoudre au plan local ou régional. Il implique une politique énergétique commune.

C'est un problème dont l'évolution est lente et qui oblige à une politique à très long terme.

Cette évolution paraît difficilement réversible puisque les quantités de CO₂ produites paraissent supérieures à celles qui peuvent être éliminées par les étapes suivants du cycle du carbone.

Tous les combustibles carbonés y contribuent : charbon, lignite, produits pétroliers, gaz naturel mais encore le bois et, plus généralement la biomasse, la combustion des déchets et en particulier des ordures ménagères.

C'est une pollution différente des pollutions classiques ; elle modifie l'environnement et agit par le cumul de substances modifiant le climat. Elle n'agit pas directement sur l'homme.

Parmi les énergies actuellement utilisées à grande échelle seuls le nucléaire et l'hydraulique ne sont pas concernés. Ceci est la première conclusion.

QUELLES SONT LES CONSEQUENCES DE L'EFFET DE SERRE

L'augmentation progressive du taux de CO₂, de méthane et d'oxydes d'azote dans l'atmosphère est certaine. L'élévation lente mais réelle de la température atmosphérique paraît très vraisemblable. Les conséquences pour l'environnement semblent n'être que partiellement prévisibles mais elles ont peu de chances d'être réversibles dans les conditions actuelles de croissance de la consommation d'énergie. Les conséquences pour la santé sont inconnues mais des modifications des conditions de vie, du climat, de l'agriculture sont à peu près certaines.

Tout ceci devrait amener à réviser les politiques énergétiques : d'ailleurs les producteurs d'énergies fossiles qui à énergie égale produisent le moins de CO2 revendiquent déjà un rôle accru : c'est le cas du gaz naturel par rapport au charbon. L'essentiel et c'est notre deuxième conclusion est que la nécessité de développer l'électronucléaire est ainsi devenue évidente pour un nombre croissant d'hommes politiques et surtout de scientifiques de disciplines diverses [5].

SOLUTIONS

En effet on propose de réduire (ou de stabiliser) la consommation d'énergie pour diminuer la production de ces gaz favorisant l'effet de serre. On ne peut qu'être sceptique sur la réussite de telles mesures et on peut même se demander si ce n'est pas une façon de refuser de poser les vrais problèmes.

. L'augmentation de la population mondiale est extrêmement rapide (population 91 : 5,4 milliards d'habitants - prévision 2025 : 8,6 milliards d'habitants) et ceci en raison essentiellement de l'accroissement de la population du Tiers Monde.

. Or l'évolution du tiers monde passe par le développement économique donc par le développement de la consommation d'énergie ; le manque de moyens financiers de ce pays fait que la protection de l'environnement n'est pas une de leurs priorités ; les économies d'énergie sont soit imposées par le manque de ressources d'un pays, soit un luxe de pays riches.

. Cependant il sera évidemment nécessaire de freiner l'augmentation de la consommation d'énergie puisque les réserves sont limitées ; elles représentent quelques dizaines d'années de consommation pour le pétrole, entre 60 et 100 ans pour le gaz naturel, plusieurs siècles pour le charbon, et certaines énergies non encore exploitées comme les asphaltes et les schistes bitumineux sont encore plus polluantes que le charbon. La consommation de la biomasse et du bois augmente l'effet de serre de deux façons : la déforestation et la production de CO2.

. Il sera évidemment nécessaire d'utiliser toutes les énergies disponibles tant qu'une révolution technologique ne permettra pas de révolutionner la production d'énergie, et l'électronucléaire, en particulier dans les pays économiquement développés, sera amené à se développer et ceci paradoxalement, n'en déplaise à certains, pour des raisons sanitaires et, deuxième paradoxe pour que ce développement ait une influence significative il faudra qu'il soit très important. Ceci est notre troisième

conclusion. Le surgénérateur est peut-être la seule filière à la mesure des besoins d'autant qu'il est peut-être aussi la solution pour éliminer les nucléides à très longue période.

**RADIATION PROTECTION TRAINING
AT ELECTRICITE DE FRANCE**

**Evelyne Guinard
Deputy Training Division Manager
Nuclear and Fossil Generation Division**

ABSTRACT

Training in radiation protection is a part of EDF's general risk prevention training program. Operating personnel who work in controlled areas receive specific training focused on ensuring awareness of the risks involved at each phase of an operation. Specific training actions also have been designed for specific target populations. The program calls on an innovative tool : a simulator is used for training of operators in managing accidents following steam generator tube breaks. This simulator is linked to a special training-oriented expert system in order to generate key parameters, including graphs showing changes in dose equivalent at the site boundary.

During the development of France's PWR nuclear plants, radiation protection was taught as a specific subject. Today, we feel that it can be integrated within a broader context, i.e. training in risk protection, which encompasses both radiation protection and so-called conventional safety training. This thinking has led to preparation of a training plan which targets all personnel -- operating staff, supervisors and managers -- who might take actions in a controlled area.

This plan starts with an initial training segment, which is in turn divided into two parts:

- The first 5-day session takes place no later than several weeks after a new employee has joined a nuclear power plant. This session provides the basic knowledge required to issue level one personnel certification (level one means operating personnel taking action either alone or under the supervision of a supervisor with level two certification).
- The second session lasts four days and takes place one year later.

The objective of this initial training is to ensure that all persons who will subsequently work in controlled areas are aware of the need for:

- integration of all components of safety information, particularly those related to radiation protection, within a coherent whole during every phase of workplace action: preparation, execution and experience feedback;

- knowledge of the reasons for which regulations have been defined and are applied;
- improved ability to implement behavior aimed at risk prevention during all workplace actions, with an emphasis on cooperation within the work team.

In order to achieve these objectives -- which are directly linked to awareness of the importance of the issues involved -- the acquisition of information strictly speaking has been accorded secondary importance. Rather, the training courses emphasize reflection, situational exercises, tours of work sites and case studies.

Following this first training program, a second program has been developed within the same context. This program is designed specifically for personnel with the following functions in controlled areas:

- work preparation manager,
 - supervisor,
 - safety supervisor,
 - safety instruction manager,
 - shutdown manager,
 - supervisor,
- as well as certain other categories.

The goal of this action is to ensure that all these staff take risk prevention into account during preparation of their work, as well as during actions taken before, during and after the tasks they perform in controlled areas. The training course seeks to develop their ability to:

- analyze work situations, especially in terms of identifying potential risks;
- apply the operating procedures and resources required to control risks and prevent any member of the work team from having an accident during all three shifts (particularly for work on a given site with other teams);
- explain to team personnel the risks inherent to the tasks to be performed in a controlled area.

Before taking this second session, all participants must have first completed the initial training course.

The training tools are based on the same approach as the initial module: studies of accidents or near-accidents to gain awareness of responsibilities and obligations, exercises in organizing a work site, case studies, situational exercises and group work. These different elements build awareness among participants of the different aspects of team leadership and communications.

It is important to note that these two programs never replace specific training provided for risks related to individual jobs. These risks are covered during initial professional training, as well as in "refresher" courses for each job category.

The training program calls for two "refresher" modules three years after completion of the two initial training courses.

After this training program for employees who work in controlled areas, specific training actions have been developed for distinct target populations.

1 - RADIATION PROTECTION SAFETY TEAMS AT NUCLEAR PLANTS

These training sessions last a total of four weeks. The objectives are:

- increase skills in regulatory and theoretical areas;
- enhance inter-personal relations expertise, i.e. dialogue and listening skills, problem analysis and resolution, etc.
- provide the technical skills required for detection and calculation of risks (principles for using various detectors, adjustment and calibration, qualitative and quantitative measurements), as well as knowledge of ionizing radiation (effects on materials, appropriate means of prevention).

2 - ENGINEERS ASSIGNED TO NUCLEAR PLANTS

There are two successive courses on radiation protection. The first, lasting two weeks, is for engineers who have been at a plant for at least one year and who have acquired basic knowledge of radiation protection. The second training session (four days) is a refresher course given one year after the initial session.

Both modules share a common goal: strengthen and add to understanding of the main radiation protection issues linked to normal and accident mode operation at nuclear power plants. The content covers both theory and the reasons behind rules and regulations applied.

3 - OPERATING MANAGERS

The position of operating manager was recently created in the face of two major challenges: increased safety and availability of EDF's PWR reactors, and enhanced career development of the company's managers.

The operating manager is specialized in plant operation, and has in-depth knowledge of all aspects of safety and security.

He or she is in charge of managing the operating team and is a member of the plant operating management team. A specific training program has been prepared for shift supervisors seeking to take up this new position. The program provides them with the technical knowledge required to carry out this position. Radiation protection has been identified as a central component of the course and covered both as a separate subject and indirectly through related subjects:

- generation and management of gaseous and liquid effluents and wastes;
- processing of gaseous and liquid effluents -- discharge conditions and regulatory requirements;
- "safety during accident mode operation". One of the subjects covered is the radiological consequences of incidents both at the site and off-site (magnitude of radioactive releases and dose equivalents at site boundaries for different types of accidents, criteria proposed by the International Commission on Radiological Protection, etc.);
- "radiation protection during normal operation", focusing on knowledge and control over the main risks (particularly radiological). This part of the course also covers the Alara optimization concept and containment principles.

Independent of the training programs and courses described above, radiation protection is taken into account whenever possible during training actions. For example, the SG tube break/SEPIA training tool has a simulator linked to an expert system. There is an independent system at each nuclear site (installed near the control room), available to operators at any time.

This tool simulates all types of SG tube breaks, combining in particular the initial state, unavailability of ancillary and safety systems, as well as the type of break. During the initial simulation phase, the operators manage the accident. The Sepia artificial intelligence system records operator actions and shows their impact on some one hundred different parameters. The system then analyzes the management performance of the operator during the session and generates results in learning-feedback form, acting as a trainer. One of the functions of the Sepia system is display of graphs showing changes in different parameters over time. Two of these parameters are the dose equivalent at the site boundary (500 meters), with one set of worst case scenarios and one set of realistic hypotheses.

This training policy, based on both course work and specific training, is designed to help reduce the doses recorded at nuclear sites despite the ageing of the installations.

RADIATION SAFETY TRAINING FOR URANIUM WORKERS

Bhawani Pathak

**Canadian Centre for Occupational Health and Safety
Hamilton, Ontario, Canada**

ABSTRACT

In cooperation with Denison Mines and the Atomic Energy Control Board (AECB), the Canadian Centre for Occupational Health and Safety has developed an interactive computerized radiation safety training program for uranium mine and mill workers. It consists of modules designed to provide the radiation safety training required by the Uranium and Thorium Mining Regulations (1988) of the AECB. The style and the technical level of the subject matter in these modules is appropriate for communicating scientific information to people in the "real-world" workplaces - the employers and the employees.

INTRODUCTION

Employee education and training are essential parts of any radiation protection program. The purpose of such training is to ensure that radiation workers perform their tasks in accordance with an established code of practice and in a way which poses no danger to health and safety.

The Uranium and Thorium Mining Regulations of the Canadian Atomic Energy Control Board (AECB) require that employees in uranium mines and mills receive appropriate radiation safety training. The scope of the subject matter of the training is also specified in these regulations. We developed and produced computerized training modules to fulfill the above training requirements. These modules serve two basic purposes. First, the trainer can use them as a training aid in a class room situation. Second, the trainees can use them at their own pace to review the subject matter and update themselves. In this way these modules provide the trainee an opportunity for interactive learning.

The modules were developed by the Canadian Centre for Occupational Health and Safety (CCOHS) in collaboration with the staff and Joint Health and Safety Committee at Denison Mines and the Atomic Energy Control Board.

LEARNING OBJECTIVES

The objective of this training package is to develop a heightened awareness about radiation protection among employees and enable them to take remedial action in their day-to-day work and in the event of an accident.

The modules are not intended to serve as a substitute for a trainer. Instead, they are intended to serve as a learning aid for the trainees and an instructional tool for the trainer. Movement and development of ideas and images on the screen encourage the trainees to talk about their own work situations. The trainer plays the role of an organizer and discussion leader as well as a source of technical information.

For persons with basic radiation protection training, the modules serve as a resource for self study and periodic refresher training. As well, the "Test Your Knowledge" module can be used for a quick review and self evaluation.

CONTENTS

The subject matter of this training package is designed to address the radiation safety issues of uranium miners, including the distribution of radioactive material in the mines and techniques for the evaluation and control of radiation exposure.

The training is divided into four modules which combine colourful graphics, animation and text in a comprehensive training package.

A fifth module called "Test Your Knowledge" is presented in a question and answer format. The purpose of this format is to guide the trainee through a review of the four modules.

An illustrated Glossary of technical terms is included for reference as the sixth module.

The contents of modules are outlined below.

Module I: An Introduction to Radiation

- What is radiation
- Types of radiation
- Sources of radiation
- How people are exposed
- How radiation is measured
- Harmful effects
- Exposure in mines
- Protecting ourselves

Module II: Properties and Hazards of Radiation

- Radiation emission
- The atom
- Half-life
- Types of ionizing radiation
- Radioactive dust
- Radiation exposure of uranium workers
- Lungs and dust
- What is risk

Module III: Principles of Radiation Protection

Dose limit
Minimizing external dose
Minimizing internal dose
Monitoring radiation
Workers' radiation doses
Monitoring methods
Units of measurement
Personal protective equipment
Medical surveillance

Module IV: Uranium and Thorium Mining Regulations

Uranium mining and the AECB
Regulatory control
Uranium and Thorium Mining Regulations
Joint employer-employee responsibility
Code of practice
Compliance procedures
Employer and worker obligations
Whom to contact

Module V: Test Your Knowledge

This module contains review questions on the first four modules. The questions are presented as multiple choice. When the user provides his answer, the computer displays whether or not the selected answer was correct and also displays the correct answer with appropriate illustration.

Module VI: Glossary

This module provides an illustrated definition of technical terms in a simple and non-technical language.

COMPUTER CONFIGURATION REQUIREMENTS

All the modules utilize the videotex technology based on the NAPLPS (North American Presentation Level Protocol Standard).

Equipment requirements are as follows:

- ° IBM or compatible PC, XT, 286, 386 or 486 with at least 640K RAM and either a) or b) of the following:
 - a) EGA interface card with 256K on card and an EGA colour monitor or
 - b) Norpak PCD6 or PCX6+ card and a RGB colour monitor

NEEDS FOR FUTURE DEVELOPMENT

Recent advances in computer technology enable the production of multimedia and multilingual training modules with text, sound, photo scanned images, animation and high resolution graphics.

The CCOHS plans to upgrade and convert the existing training modules for both the Macintosh and IBM platforms and standards. Work is in progress to develop radiation safety training modules specific to other selected occupational categories. These training modules will provide the user with the fundamentals necessary for working with radiation emitting equipment and radioactive materials. All these training modules will be available from CCOHS on a compact disc along with other training packages.

RADIATION PROTECTION TRAINING AT IEN/CNEN

Patricia Wieland Fajardo

Jesse James Gomes da Silva

Instituto de Engenharia Nuclear

CP 68.550 - CEP 21945 - Rio de Janeiro - BRAZIL

FAX 55/21/590-2692

ABSTRACT

Training in radiation protection is one of the most hard and important task in an occupational radiation protection program. The Radiological Protection Service of the Nuclear Engineering Institute of the Brazilian Nuclear Energy Commission (IEN/CNEN) organized several radiation protection courses suitable for research personnel, radiation workers, radiation protection specialists and non-radiation workers. All of the courses have practical exercises, simulating real situations. It has been noted the general necessity of inicial basic training on foundations of atomic and nuclear physics.

INTRODUCTION

The main activities and researches developed at the Nuclear Engineering Institute (IEN), involves the operation of an Argonaut research reactor, a CV-23 cyclotron, a radioisotope production laboratory, radiochemistry laboratories, a radwaste treatment laboratory and a type test laboratory. IEN has a staff of about 200 non-radiation workers and about 170 radiation workers. According to the activity, the associated radiological risks involve exposure to beta, gamma and neutron radiation of wide energy spectrum and external and internal contamination. From 1984 to 1990, the highest collective dose of IEN workers belongs to the cyclotron laboratory workers mainly due to the handling of the cyclotron activated parts during its maintenance⁽¹⁾.

The occupational radiation protection program consists⁽²⁾, as usual, of individual monitoring, surface, air and area monitoring, radiation protection equipment testing, decontamination and training. In order to implement this programa, the Radiological Protection Service of IEN has an infrastructure that includes a radiation measurement laboratory,

equipment testing laboratory, decontamination laboratory, laundry, radwaste provisory deposit, liquid effluent treatment installation and a staff that consists of 1 MSc, 2 physicists, a chemistry engineer and 7 technicians, all with specialization in radiation protection.

In Brazil, there are very few schools or universities that provide training in radiation protection. The courses on radiation protection at IEN are based on a standard curriculum, and depending on the worker category, relevant subjects are emphasized or included, or some subjects can be omitted. Beside the training courses, every worker receives the "IEN's Internal Regulation on Radiation Protection" that informs about responsibilities, attributions, classification of areas and operational limits.

STANDARD CURRICULUM

The basic curriculum consists of the following subjects. It is also indicated the duration of each lecture. All theoretical lecture ends with exercises and at the end of the course there is an evaluation. Those who are not successful have another chance by an oral interview. The on-the-job follow up is very important in a sense that it helps to evaluate the efficiency of the training and is a opportunity to correct any failure.

- PRACTICE ON DECONTAMINATION (1h)
- RADIOACTIVE WASTE - VISIT TO THE PROVISORY DEPOSIT (2h)
- RADIOACTIVE MATERIAL TRANSPORTATION (1h)
- RADIOLOGICAL ACCIDENTS (1h)

RADIATION PROTECTION BASICAL COURSE

The purpose of this course is to prepare technicians in charge of radiation survey and also to provide basic technical knowledge essential for those who develop activities in restricted areas. The curriculum is the standard one described above.

FOUNDATIONS OF NUCLEAR ENERGY COURSE

This course is offered by IEN for those students that must have a six month practical experience to complete the technical college. One of the subject of this course is radiation protection. The curriculum is the standard one but dose calculation and theory of radiation detection is not so deeply explored.

INTRODUCTION TO NUCLEAR ENGINEERING COURSE

This course is offered by IEN for those who have finished a technological graduation course and will begin to research in the nuclear area. One of the subject of this course is radiation protection. This subject is offered for IEN research personnel. The curriculum is the standard one without notion of radioactivity. A lecture on Optimization of Radiation Protection and an Emergency Planning are included and the exercises are mathematically more complex.

SEMINAR ON RISKS AND BENEFITS OF NUCLEAR ENERGY

This seminar is given to non-radiation workers. It is explained in a simple way what is ionizing radiation, the biological effects of irradiation, the pacific uses of nuclear energy, practical rules of radiation protection, basic emergency training and a brief description of the restricted areas of IEN. The main purpose is to divulgate de benefits of nuclear energy and avoid misunderstandings such as "the individual dosimeter is a radiation protector" or "X-ray contaminates" or

panic in case of an unusual event inside a restricted area.

PRESENT SITUATION AND THE ROLE OF THE RADIATION CONTROL EDUCATION FOR HEALTH PERSONNEL BEFORE LEAVING SCHOOL

T. Orito, *S. Koga, S. Suzuki and *M. Nakamura

Department of Health Physics, School of Health Sciences, *Department of Radiology, school of Medicine, Fujita Health University, Toyoake, Japan

ABSTRACT

For purpose of investigating the present situation of radiological technologist education for radiation protection and control before leaving school, questionnaires were sent out to 28 school for radiological technologist in Japan.

For purpose of characterizing each school, it is permitted by the "Designation rules for schools and training schools for radiological technologist" to use 500 school hours for any of the subject, mainly special subjects, that are selected by the school. In investigating the 500 school hours which are left to the discretion of each school for characterization, some of these hours are used for radiation control-related subjects in 20 schools from which answers to questionnaires were obtained. Briefly, 15 to as many as 210 hours are spent for lessons regarding such subjects.

INTRODUCTION

Utilization of radiation in medical treatment has made a large contribution to society as a whole. On the contrary, radiation may bring about serious social problems not capable of being solved within the field of medicine, if used in an inappropriate manner. In this paper, the present status of radiation protection and control education for radiological technologist as health personnel before leaving school is investigated from the standpoint of the curriculums being taught and the results of a questionnaire for finding out the present situation of such education in individual schools are described.

METHOD AND DETAILS OF THE QUESTIONNAIRE

A total of 29 schools for radiological technologist exist in Japan. The students received until the year of completion are present in 28 of them. The questionnaire was sent out to the teachers in charge of radiation control in these 28 schools, with 20 of the answering the

questionnaire.

RESULTS OF THE QUESTIONNAIRE

For purpose of characterizing each school, it is permitted by the " Designation rules for schools and training schools for radiological technologist " to use 500 school hours for any of the subjects, mainly special subjects, that are selected by the school. Table 1 shows the proportion of these school hours assigned to the subjects related to radiation control. Only six of the schools had no classes in radiation control-related subjects. A varying number of school hours are assigned to these subjects in the remaining 20 schools.

Tables 2, 3 and 4 show the subjects which are also taught by teachers of radiation control, radiation health and related laws, respectively.

Table 1 Of the 500 Hours Left to the Discretion of Each School, the Following Number of Hours are Assigned as Extra Hours to Radiation Control-related Subjects.

Radiation control-related subjects are not included	Number of school
15 hours	1
21 hours	1
30 hours	5
45 hours + 120 hours (only for students who selected the subjects)	1
50 hours	1
60 hours	1
70 hours	2
120 hours	2

The teachers of radiation control-related subjects are also in charge of various other subjects as well.

DISCUSSION

As leading experts to apply radiation to the field of medical treat-

radiation protection and control before they leave school, they would tion control, radiation health and related laws directly related to them were investigated from the standpoint of curriculums by means of carrying out a questionnaire in the present study. In investigating the 500 school hours which are left to the discretion of each school for characterization, some of these hours are used for radiation control-related subjects in 20 schools from which answers to questionnaires were obtained. Briefly, 15 to as many as 210 hours are spent for lessons regarding such subjects. These results suggest that radiation protection and control are considered very important by teachers actively engaged in the education of students who want to be radiological technologist. Radiation protection and control are expressed more clearly in curriculums for radiological technologist than for any of the other kinds of medical professionals. Moreover, many hours are used to lecture on these subjects. It is conceivable

from these findings that the role of radiological technologist in radiation protection and control is one of their most important tasks. To our surprise, however, the lessons on radiation control, radiation health and related laws are given by teachers who are also in charge of other subjects. The absence of true professionals may be seen by the fact that lessons on radiation control-related subjects are given by teachers who are in charge of a wide range of subjects. Taken altogether, it must be said that the content of education for radiation protection and control is seriously lacking, though these subjects are deemed important in the education of students who want to be radiological technologist. Accordingly, it may also be an urgent necessity to bring up the level of teachers specializing in subjects related to radiation protection and control. Taking this need into consideration, education for radiological technologist must be conducted not only in training schools and junior colleges but also at the university level as well. It is necessary to actively introduce these subjects into university education and to develop a system of radiation protection and control.

CONCLUSIONS

For purpose of investigating the present situation of radiological technologist education for radiation protection and control before leaving school, questionnaires were sent out 28 schools for radiological technologist. Based on the answers obtained from 20 of them, the following conclusions were able to be obtained.

(1) Of the 500 school hours left to the discretion of each school, 15 to 120 hours are assigned to radiation control-related subjects in 14 of the 20 schools.

(2) Since many teachers are in charge of classes of radiation control, radiation health and radiation-related laws as well as other classes, it is necessary to increase the number of teachers who are actually specializing in radiation control-related subjects.

(3) The range of related laws actually taught is wider than prescribed in the designation rules.

EDUCATIONAL PROGRAMME ON RADIATION PROTECTION FOR
VETERINARY MEDICINE SPECIALISTS

G. Djuric and D. Popovic

Department of Radiology and Radiation Hygiene and Department
of Physics, School of Veterinary Medicine, Belgrade,
Yugoslavia

ABSTRACT

The education of radiation protection for veterinary medicine specialists on the University of Belgrade is integrated both in regular graduate studies and in postgraduate studies. Within the graduate studies, students attend courses in physics and biophysics and in radiation hygiene. During postgraduate or specialistic veterinary medicine studies, veterinary medicine specialists expand their knowledge in radiation protection through a number of courses on radiation biophysics, radioecology, nuclear instrumentation and environmental protection.

INTRODUCTION

Radioactive contamination of the environment became a very serious problem during the age of nuclear energy exploitation. As the radiocontamination of the biosphere includes the contamination of the cattle breeding process and the live stock production and eventually the man exposure to radiation through food, the radiation hygiene in animal and food production was developed as a new educational and scientific discipline in veterinary medicine. Together with radiation protection it obtained an important role both from medical and technological point of view, in scientific as well as in practical sense, in the field of activity of a modern veterinary medicine specialist. The knowledge that such a specialist should obtain through these courses, together with basic knowledge in physics, is intended to enable him to undertake necessary measures of radioprotection and radio-decontamination if the radioactive contamination endangers the animal or food production process. The nuclear accident in Chernobyl and the situation that followed, confirmed that this matter is of invaluable importance for veterinary medicine specialists, especially those involved in the inspection of cattle and food production.

EDUCATIONAL PROGRAMME ON RADIATION PROTECTION IN THE GRADUATE STUDIES

During the first year of veterinary medicine studies, students obtain basic elements of radiation biophysics through courses of elementary physics and biophysics. The educational programme is carried out within a course of 2 theoretical lessons and 2 laboratory lessons per week during 15 weeks. The programme comprises:

- atom and nuclei structure, nuclei forces and bond energy;
- stable and unstable nuclei, radioactive disintegration and the law of radioactive decay;
- emission of alpha and beta particles and gamma and neutron rays and their interaction with matter;
- nuclear reaction, production and properties of radioisotopes, their application in medicine and biology;
- ionizing radiation: sources, detection and dosimetry, biological effects.

Laboratory lessons comprise detection of radioactive radiation and its absorption in matter with Geiger-Muller nuclear instrumentation, as well as calculation exercises on the matter.

Within the fifth year of veterinary medicine graduate studies, students attend a course on radiation hygiene including 15 lectures and 30 laboratory exercise hours. The programme comprises basic elements of radiation hygiene in animal production and food technology, including:

- basic principles of radioecology in animal production;
- distribution of natural and technologically produced radionuclides in different phases of cattle breeding process and food chains;
- internal radiocontamination of animals;
- radiopathology: radiation sickness in animals, methods of internal and external radiodecontamination;
- basic principles of radiation protection: units, standards, recommendations, permissible doses for occupational and nonoccupational exposures, accidental doses;
- radiohygienic control of food and fodder;
- nuclear accidents and protective measures in animal and food production;
- exposure and radiation risk for agricultural workers in accidental situations due to radiocontamination of the environment.

The laboratory exercises are especially emphasized within the framework of the course; students are acquainted with some of the methods for fast evaluation of radionuclide contents in food and fodder. The methods are developed for radiometric laboratories with GM counter detector. The exercises include detection of ionizing radiation and absorption of beta and gamma radiation in different materials, exposure

rates measurements in the field, mass activity determination of food and fodder including sampling, transport and storage procedures, fast evaluation of radionuclides contents in food and fodder in accidental situations, undertaking of protective measures and recommendations in food and fodder usage in accidental situations.

EDUCATIONAL PROGRAMME ON RADIATION PROTECTION IN POST-GRADUATE STUDIES

During postgraduate or specialistic veterinary medicine studies, veterinary medicine specialists expand their knowledge on radiation protection through a number of courses on biophysics, radioecology, nuclear instrumentation and environmental protection. The programmes discuss biophysical, radiobiological and biomedical aspects of the effects of ionizing radiation on cellular and molecular level, as well as some aspects of radiation diseases and post irradiation recovery.

The special course on environmental radiation protection considers:

- sources of ionizing radiation in the environment,
- translocation of radionuclides from the source of radiocontamination to man;
- radioecological parameters, concentrations, translocation and discrimination factors;
- models of radionuclides migration in the biosphere;
- instrumentation and methods for radionuclides detection and identification in the environment;
- aspects of dose and risk evaluation for animal and food production and eventually, population on the whole.

Some of the courses are specially organized for veterinarian inspectors. They provide important informations about legal regulatives in production of animal and food regarding radioactive contamination, especially in accidental situations. There are also training courses in methodology of fast evaluation of radioactive contamination of food and fodder in the field.

CONCLUSIONS

In the field of activity of a modern veterinary medicine specialist radiation protection plays an important role, both from medical and from technological point of view. The possibility of occurrence of large nuclear accidents demands that one obtains basic theoretical knowledge in radiation physics and biophysics, as well as to be acquainted with methods of detection of radionuclides in the environment, methods of radiodecontamination of animals and food and legal regulatives in this area. Radiation protection should be therefore considered an integral part of the educational

process in graduate and in postgraduate studies of veterinary medicine.

DEVELOPMENT OF AN EFFECTIVE DOSE EQUIVALENT DETECTOR
HAVING ANGULAR RESPONSE OF HUMAN BODIES

M.Tsutsumi, K.Saito and S.Moriuchi

Department of Environmental Safety Research,
Japan Atomic Energy Research Institute,
Tokai-mura, Ibaraki-ken, Japan

ABSTRACT

In order to estimate effective dose equivalent due to external photon exposures, a new shape of NaI(Tl) scintillation detector was developed which has an angular response similar to that of adult human bodies. Further, the detector utilized a spectrum-dose conversion function for compensating accurately the difference of energy response. The accomplishment of this detector made it possible to estimate effective dose equivalent easily from direct measurement without assuming irradiation conditions.

INTRODUCTION

ICRP ¹⁾ introduced effective dose equivalent (H_E), being a better indicator of stochastic effect of radiation, for radiation protection. In practice, quantities proposed by ICRU such as $H^*(10)$ have been used since they give conservative values for H_E under arbitrary exposure conditions. In case H_E is estimated, conversion factors assuming an irradiation condition have been multiplied to a measurable quantity. One of the reasons why such indirect procedures have been taken is the difficulty of acquiring the information of irradiation condition, that is, the angular distribution of incident radiations on human bodies. This information is needed because human body's sensitivity depends strongly on the incident angle of radiation.

This study intended to develop a detector which has responses similar to human body. In order to meet this requirement, we used the following two methods in this study: (1) letting the detector have the angular sensitivity similar to human bodies, for the irradiation geometry problem; (2) making the energy weighting $G(E)$ function applied to this detector for the compensation of energy response.

DETECTOR

The scintillation detector which incorporates 75 mm in diameter x 210 mm long NaI(Tl) crystal was constructed. The shape is circular cylindrical with the both ends spherically cut, as shown in Photo 1. The shape and size were determined from empirical estimate of

Photo 1 Effective dose equivalent detector.

change of absorbed energy in the crystal due to the incident angle. The sensitivity difference around the body axis, which is not significant under usual exposure conditions, is not considered.

On the characteristics on angular sensitivity, we compared H_E with this detector at 3 points of energies, 124 keV, 514 keV and 1836 keV. The comparisons are shown in Fig. 2(a)-(c). Both are in good agreement except for the direction of photomultiplier tube. Judging from the solid angle extended by the photomultiplier tube, the effect of the difference is considered not significant. Both curves coincide within 10% except for this direction.

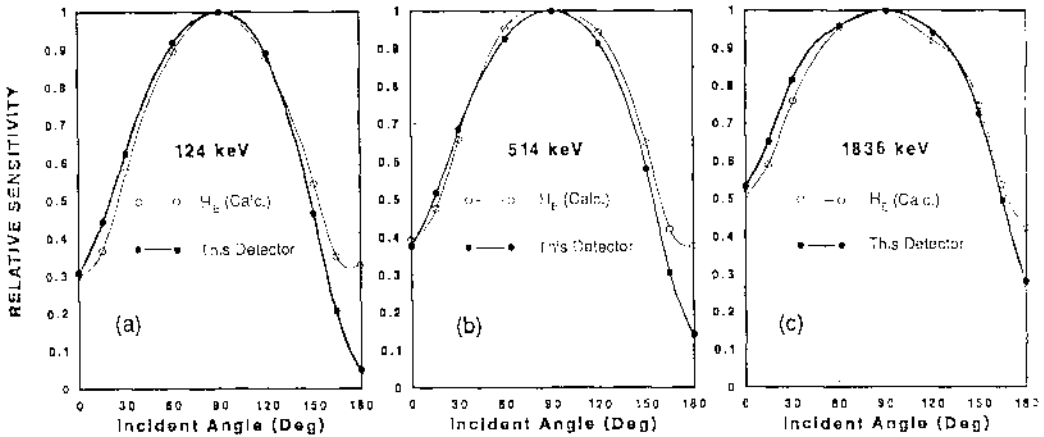

Fig.2 Comparison of angular sensitivities of this detector to H_E . Energies are (a) 124 keV, (b) 514 keV and (c) 1836 keV. Head: 0 Degree.

The effect of detector dimensions was discussed from detector responses calculated with the Monte Carlo code MARTHA. The results from this simulation are shown in Fig.3. Here, the ratio of detector response to gamma rays coming from 0 deg. direction over that to gamma rays from 90 deg. direction was considered. The axis of ordinates represents the relative deviation of the ratios between the detector and human bodies, the axis of abscissas the ratio of the length to the diameter of detector. At low energy the angular profile of the detector is mainly deter-

Fig.3 Relationship between detector dimensions and angular sensitivity. $DET(x)$: Detector sensitivity at angle x. $H_E(x)$: H_E at angle x.

mined by the ratio of the length to the diameter. The higher the energy is getting, the more critical the diameter becomes. It is desirable that the zero crossing point on this figure does not change much for a wide range of energy. From this view point, the optimum diameter should preferably be about 80 mm, the optimum length being about 2.8 to 3.0 times the diameter of the detector. From this figure, the dimensions of the detector constructed were confirmed to be fairly close to the optimum ones.

G(E) FUNCTION

A spectrum-dose conversion function ²⁾ called "G(E) function" is defined by the following equation,

$$\int_{E_{\min}}^{E_{\max}} F(E, E_j) \cdot G(E) dE = D(E_j)$$

where $F(E, E_j)$ and $D(E_j)$ are a measured pulse-height spectrum and an interested dose quantity due to a certain number of photons with energy E_j , E_{\min} and E_{\max} being lower and upper energy limits. Here, E_{\min} and E_{\max} were taken to be 40 keV and 10 MeV, respectively. The $G(E)$ function is usually determined by polynomial fitting from several tens of $F(E, E_j)$ and the corresponding $D(E_j)$ covering energies considered.

Response functions $F(E, E_j)$ were calculated by MARTHA. Here, the $G(E)$ function was determined for planar isotropic irradiation, and the $D(E_j)$ are taken from data of GSF ^{3,4)}, which present the H_E per unit fluence as a function of photon energy. These factors have been derived from calculations using a Monte Carlo computer code and associated anthropomorphic phantoms. The $G(E)$ function can calculate doses within 2% over the whole energies. $G(E)$ values are expressed in $\text{nSv} \cdot \text{h}^{-1} / \text{cpm}$.

Fig.4 G(E) function applied for this detector.

APPLICATION IN NATURAL ENVIRONMENT

Applying this detector to natural gamma rays, we examined variability of conversion coefficients from air dose to H_E in Sv per Gy. Generally, a constant of 0.7 ⁵⁾ is used as this conversion coefficient. Furthermore, H_E may also depend on the posture of the body. Measurements were performed at indoors and outdoors, changing the orientation of detector to simulate body postures; standing (detector axis = 0 deg) and lying (axis = 90 deg). Air dose (free-in-air) measured by a 3 in. diam. spherical NaI(Tl) detector was used as a normalizing quantity. Obtained results are shown in Table 1. The results are a

little higher than the conventional value 0.7. However, these are in good agreement with our former results^{6,7)}. It was observed that the conversion coefficients do not depend much on human posture for natural radiation.

CONCLUSIONS

The method introduced in this paper made it possible to estimate H_E easily from direct output of the detector without assuming angular and energy distributions of incident photons. Angular responses of the developed detector are in good agreement with H_E , and errors induced from dose conversion using $G(E)$ function is very small. Consequently, overall systematic errors are within 10%, up to 2 MeV except for its particular incoming angle. Moreover, the posture of the body exposed, for example, standing or lying, is able to be easily accounted by changing the orientation of the detector.

It is believed that the H_E detector is a useful device to estimate H_E for radiation workers as well as for the public in the environment.

Dosimétrie - Ministère de l'Industrie

STUDY OF A RADIATION SOURCE FOR THE SIMULATION OF REALISTIC
NEUTRON SPECTRA FOR CALIBRATING

A set-up intended to replicate neutron spectra encountered at workplaces is presented. Such a facility can provide means of calibrating dosimeters in spectral conditions similar to those of their use for radiation protection purposes. Results of a computational approach are compared with Bonner Multisphere Spectrometer measurements.

I - INTRODUCTION -

La simulation de spectres neutroniques réalistes constitue, actuellement, l'un des domaines d'étude de la radioprotection. Son but principal, est d'obtenir, avec l'instrumentation en usage, une meilleure estimation des doses "neutron" auxquelles sont soumis les personnels en activité dans l'industrie nucléaire. L'importance de ce projet, déjà reconnue en raison des performances limitées des dosimètres de surveillances individuelle et d'environnement, s'est amplifiée avec la publication des Nouvelles Recommandations de la CIPR (Rapport 60) en raison de l'abaissement des limites primaires de doses et du changement des facteurs de qualité des neutrons.

Pour l'étalonnage des instruments, la panoplie des spectres de référence recommandés est assez pauvre (4 spectres disponibles) et leur représentativité ne fait pas l'unanimité, par exemple : réacteurs, conteneurs de transport.

Il s'avère donc indispensable de compléter les moyens d'étalonnage actuels par d'autres dispositifs, mieux adaptés, délivrant des spectres neutroniques plus variés, dont la conformité aux situations effectivement rencontrées soit établie. Ceci a justifié l'action conjointe de plusieurs laboratoires dans le cadre du contrat CCE Bi7-0031-C, afin de recenser ces situations réelles, puis de les simuler en laboratoire.

Le principe d'un montage expérimental a été défini et ses caractéristiques ont été calculées puis optimisées à l'aide du code MCNP.

II - PRINCIPE DU MONTAGE -

II.1 - Généralités sur les spectres neutroniques réalistes

Une description générale simple représente de façon satisfaisante l'ensemble des cas rencontrés en radioprotection. 3 zones énergétiques composent un spectre réaliste (1,2) :

- a) la zone "thermique" (TH) : $E_n < 1 \text{ eV}$
- b) la zone "intermédiaire" (INT) : $1 \text{ eV} < E_n < 10 \text{ keV}$
- c) la zone "haute énergie" (HE) : $10 \text{ keV} < E_n < 15 \text{ MeV}$

Les données consultées résultent, en général, de mesures multisphères (ou sphères de Bonner) pour lesquelles les informations spectrométriques doivent être considérées avec précaution (3).

Les différents "spectres" étudiés, ont montré que :

- a) les contributions relatives en fluence dans les zones TH, INT et HE peuvent varier dans de larges proportions,
- b) pour la zone HE, l'énergie moyenne de la distribution constitue un paramètre supplémentaire dépendant :

Pour la radioprotection, la loi de variation avec l'énergie de $h_\phi(E)$, facteur de conversion fluence-équivalent de dose, modifie notablement les "poids" dosimétriques respectifs des différentes zones.

II.2 - Éléments fondamentaux de montage -

Le concept choisi est celui d'un dispositif de laboratoire produisant un faisceau de rayonnement non perturbé par l'environnement (Fig. 1).

Figure 1

Schématiquement, les parties principales de l'option choisie sont :

- une source de rayonnement, constituée d'un convertisseur d' ^{238}U irradié en son centre par la cible d'un accélérateur,
- une chambre de diffusion, associant un canal cylindrique en polyéthylène et des écrans complémentaires,
- une zone d'étalonnage, assimilée à un orthocylindre ($h = \varnothing = 30$ cm), situé à 30 cm du plan de sortie du canal de $(\text{CH}_2)_n$.

L'étude des spectres neutronique et photonique, produits dans la zone d'étalonnage, a été effectuée à l'aide du code MCNP-3A, pour 2 énergies de la source primaire :

* Configuration (I) : $E_n^1 = 14,6$ MeV [Réaction (d,T)]

* Configuration (II) : $E_n^2 = 2,8$ MeV [Réaction (d,d)]

L'homogénéité de la fluence dans la zone d'étalonnage a été vérifiée aux distances 5, 10 et 15 cm de l'axe. Les variations relatives sont $< 2\%$ pour l'ensemble des cas étudiés.

III - ETUDE DE LA CONFIGURATION (I) : $E_n^1 = 14,6$ MeV -

III.1 - Atténuation de la composante "neutron" parasite de 14,6 MeV -

Afin de réduire cette contribution, une coquille de fer de 15 cm d'épaisseur entoure le convertisseur, et une 1/2 sphère d' ^{238}U , de rayon 5 cm, est placée au contact de la cible. Dans ces conditions, la contribution parasite résiduelle est :

- en fluence $\Phi_{14,6}/\Phi_{total} \approx 0,2\%$
- en équivalent de dose $H_{14,6}/H_{total} \approx 1,7\%$

La géométrie de base du système est représentée par $[E_n^1 + U + Fe]$.

III.2 - Caractéristiques des spectres produits -

Quelques exemples de spectres calculés pour le dispositif expérimental considéré sont tracés sur la figure 2 et regroupés dans le tableau 1.

TABLEAU 1

CONFIGURATION (I) - $E_n^1 = 14,6$ MeV										
Numero du spectre	Caractéristiques du montage	θ_m (%)	θ_{av} (%)	θ_{ca} (%)	E_1 (MeV)	θ_{1m} (%)	θ_{1av} (%)	θ_{1ca} (%)	E_1^1 (MeV)	Débit d'équivalent de dose moyen ($\mu Sv/h$)
I	$[E_n^1 + U + Fe]$ sans canal	0	1	99	0,42	0	0	100	0,71	2850
II	$[E_n^1 + U + Fe]$ + canal (13) θ_{1ca} $l = 90$ cm	36	20	44	0,15	6	3	91	0,61	1700
III	$[E_n^1 + U + Fe]$ + canal (13) θ_{1ca} $l = 90$ cm	21	18	61	0,13	2	2	96	0,63	1000
IV	$[E_n^1 + U + Fe]$ + canal (13) θ_{1ca} $l = 90$ cm + Fe de 10 cm	45	27	28	0,08	12	7	81	0,50	1700
V	$[E_n^1 + U + Fe]$ + canal (13) θ_{1ca} $l = 90$ cm + Fe de 10 cm	10	28	42	0,14	5	1	90	0,62	1500
VI	$[E_n^1 + U + Fe]$ $l = 90$ cm + (13) θ_{1ca} + Fe de 10 cm	41	26	31	0,09	10	7	83	0,56	2100

IV - ETUDE DE LA CONFIGURATION (II) - $E_n^2 = 2,8$ MeV -

Le même dispositif expérimental de diffusion peut aussi être associé à une source de neutrons de 2,8 MeV produits par réaction (d,d). Dans ce cas, la composante monocinétique transmise appartient au domaine "haute énergie" du spectre. La géométrie de base du système est donc : $[E_n^2 + U]$.

Quelques résultats des calculs sont rassemblés dans le tableau 2 et tracés dans la figure 3.

TABLEAU 2

CONFIGURATION (II) - $E_n^2 = 2,8$ MeV										
Numero du spectre	Caractéristiques du montage	θ_m (%)	θ_{av} (%)	θ_{ca} (%)	E_1 (MeV)	θ_{1m} (%)	θ_{1av} (%)	θ_{1ca} (%)	E_1^1 (MeV)	Débit d'équivalent de dose moyen ($\mu Sv/h$)
A	$[E_n^2 + U]$ sans canal	0	0	100	0,71	0	0	100	1,05	420

C	$[E_n^2 + U]$ + canal (13) θ_{1ca} $l = 90$ cm + (13) θ_{1ca} $l = 90$ cm	36	16	48	0,19	4	2	94	0,96	600
D	$[E_n^2 + U]$ + canal (13) θ_{1ca} $l = 90$ cm + (13) θ_{1ca} $l = 90$ cm	23	15	60	0,16	2	1	97	1,00	510

V - COMMENTAIRES SUR LES SPECTRES NEUTRONIQUES CALCULES -

Les résultats présentés ont pour objectif principal de traiter des situations courantes de l'industrie nucléaire où les protections biologiques et l'environnement contribuent à produire des spectres dégradés : conteneurs de transport, laboratoires de fabrication de combustibles...

A partir de ces résultats, on constate que 2 groupes de spectres neutroniques de basse énergie peuvent être produits à l'aide de ce montage : $\bar{E}_1 \approx [0,10 \text{ à } 0,20] \text{ MeV}$ et $\bar{E}_2 \approx [0,25 \text{ à } 0,35] \text{ MeV}$.

Deux exemples de simulation sont présentés ci-dessous. Ils correspondent, d'une part, au spectre de fuite d'un conteneur LK100 de transport de combustibles (spectre 28, réf. 1), et d'autre part, à une zone de passage dans un laboratoire de retraitement de combustibles (spectre E, réf. 2).

VIII - CONCLUSIONS -

Un dispositif d'irradiation destiné à reproduire dans un laboratoire d'étalonnage des spectres neutroniques réalistes rencontrés en radioprotection a été présenté. A l'aide du code MCNP, les caractéristiques de plusieurs spectres disponibles dans la zone d'étalonnage ont été calculées. Enfin, le domaine d'application de ce dispositif a été précisé par le biais de comparaison à des données expérimentales.

A RADON EXPOSURE CHAMBER IN HONG KONG

John K.C. Leung, D. Jia and Man-yin W. Tso

Radioisotope Unit,
University of Hong Kong,
Hong Kong.

ABSTRACT

A radon exposure chamber was constructed. Both ^{222}Rn and ^{220}Rn can be injected independently or simultaneously into the chamber from separate dry sources. The air flow in the chamber can be adjusted manually in a 100% flow-through mode, 100% recirculate mode or flow-through/recirculate mode. Water vapour and aerosol particles of variable sizes are injected into the chamber through computer controlled mechanism. The continuous radon and radon progeny concentration and working level, and aerosol concentration are constantly monitored by the microcomputer.

INTRODUCTION

The Radioisotope Unit (RIU) of the University of Hong Kong has had a programme of research on radon and its decay products started a number of years ago. Surveys on radon concentration and working levels have been conducted which indicated that the arithmetic means of both indoor radon concentration¹ and working level² are higher than most other countries and the world average³.

Because of the special geological conditions and tropical monsoon climate, Hong Kong deserves special attention to the adaptability and response of radon detectors which were otherwise proved to be good in Continental or high latitude countries. With the experience gained and quality of measurements assured through participating in the Asian/Australasian Regional Intercomparison Programme in 1987/88⁴ and a similar programme in China in 1989, the RIU has successfully constructed a radon exposure chamber which is essential for calibrating radon and radon progeny measuring instruments over a range of temperature, humidity and aerosol concentration likely to be experienced in this region of the world. In addition to calibrating instrument and detectors, the chamber will also provide service for interlaboratory comparison studies (one such programme is being conducted during the writing of this paper), and for other research and development projects.

THE RADON EXPOSURE CHAMBER

A schematic diagram of the exposure chamber is shown in Fig. 1. The chamber is made of stainless steel and has a volume of 1.4 m^3 ($1.3\text{m} \times 1.2\text{m} \times 0.9\text{m}$). A smaller conditioning chamber having a volume of 0.056 m^3 is attached to the side of the main chamber. Radon gas, recirculated gas, water vapour and aerosols are injected into the conditioning chamber where they are mixed before being passed into the main chamber. The gas diffuses into the main chamber through a series of perforated tubing laid at

the bottom of the chamber to ensure an even mixture. The air flow in the chamber can be adjusted manually in a flow-through, recirculate or flow-through/recirculate mode so that a wide range of environmental condition can be simulated. The maximum air exchange rate (including recirculated air through the conditioning chamber) is about 1 hr^{-1} . The various flow modes are illustrated in Fig. 2.

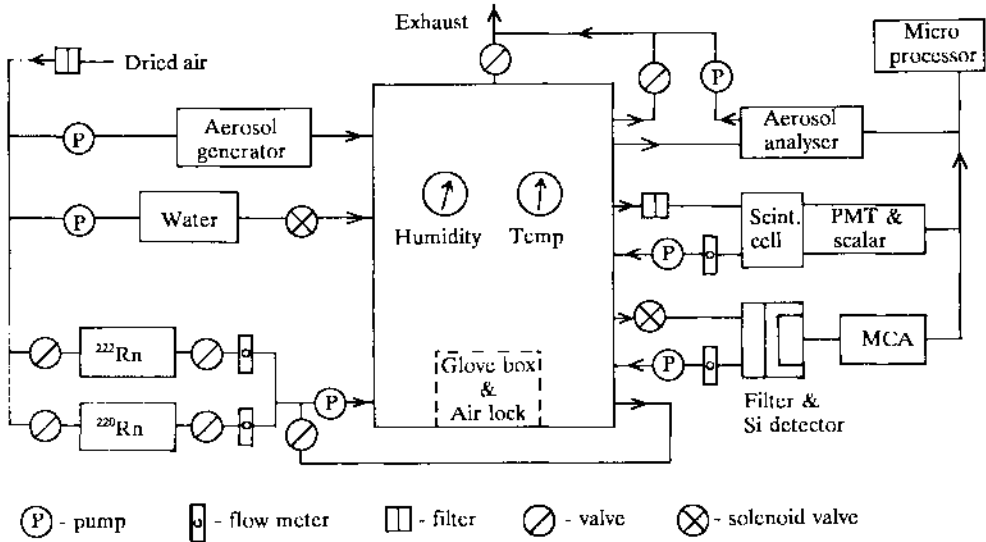

Fig. 1 Schematic diagram of the radon exposure chamber

Fig. 2 The air flow mode of the radon chamber

The chamber is totally heat insulated from the surrounding by 1/2 inch foam insulator which allow it to operate in a temperature other than room temperature. On the front of the chamber is a viewing glass which can be opened for putting large equipment into the chamber. Smaller piece of equipment can pass through an airlock at the side of the chamber without having to shut down the system completely. A pair of long armed glove is provided for easy access of the inside of the chamber. The following is a brief description of the peripheral equipment installed to the chamber.

1. Radon source. Flow through type dry source of ^{222}Rn and ^{220}Rn (RN1025 and TH1025, Pylon Electronic Development Co., Canada) of various activity are used to provide a wide range of radon concentration. Dry and filtered air carries the radon gas and is mixed with the recirculated gas before being pumped into the conditioning chamber. The radon concentration inside the chamber depends on the source strength and the circulation mode. The nominal range is from a few hundred Bq m^{-3} to 10^5Bq m^{-3} . It is to be noted that the flow rate through the radon source becomes critical when the chamber is operating at low concentration under a 100% flow through mode.

2. Aerosol generator. To maintain a steady aerosol size and concentration, a high output atomizer (Model 3076, TSI Inc, USA) together with a diffusion dryer (Model 3062, TSI) is installed. The aerosol particle size can be altered by changing the amount of solute in the solution. Typical particle size is from $0.02 \mu\text{m}$ to $0.3 \mu\text{m}$. The pump for the atomizer is computer controlled to turn on and off intermittently. By adjusting the ejection duration and interval, a wide range of aerosol concentration can be achieved.

3. Water source. Water is sprayed into the conditioning chamber through pressure exerted to a reservoir of water by a pump. The pump and the solenoid valve which gates the water pathway are controlled by the computer to maintain the desired humidity.

4. Temperature control. A simple heating coil inside the conditioning chamber is used to warm the chamber gas to above room temperature. For low temperature, the gas is circulated through a freezer by a coil of copper tubing outside the chamber. By using the heater and freezer independently or simultaneously, a temperature range of about 0°C to 60°C can be achieved.

5. Radon gas measurement. The gas inside the chamber is continuously pumped through a scintillation cell connected to a photomultiplier tube and a counter. The radon daughters are first removed by a filter and the radon gas that decays inside the scintillation cell is recorded. The continuous radon concentration is then calculated by an algorithm which takes into account of activities of previously deposited radon daughters and also corrects for different humidities and flow rates.

6. Radon daughter measurement. The radon daughters are sampled intermittently by a filter and Si α -detector assembly. The complete α spectrum of the radon daughters collected in the filter paper can be recorded in a computer controlled multichannel analyzer (PCA-II, Tennelec Inc, USA). Alternatively, three count method, five count method or similar algorithm are also being used to determine the daughter activities and working levels. The gas flow through the filter is governed by a solenoid valve and a pump which are again controlled by the computer.

7. Aerosol measurement. A condensation nuclei counter (Model 3760, TSI) is used to count the aerosol concentration. A variable number of stainless steel wire screens can be added to

the front of the analyzer to discriminate the size of aerosol particles inside the chamber. The analyzer will be operated intermittently and the data can be communicated to the computer. A maximum of 2.5×10^4 particle per cc can be measured.

AN INTERCOMPARISON PROGRAMME

Despite of the small area of Hong Kong, at least five organisations (higher institutions including RIU and Government Departments) are doing investigations on radon in one way or the other. It is noted that a wide range of detectors are being used by different organisations. Most of them were commercially bought and therefore the calibration factors rely solely on the manufacturers. Because of the lack of locally available calibration standards, some inconsistency has already been observed among detectors owned by different organisations. As the best equipped and experienced laboratory in Hong Kong on the radon issue, the RIU of the University of Hong Kong is conducting a territory radon intercomparison programme with this newly built radon exposure chamber. The result of the programme will be reported in due course. Hopefully, the exercise will assure the quality of measurement done by all the participating organisations.

CONCLUSION

A radon exposure chamber has been built which can be operated at various simulated environmental conditions. Studies on ^{222}Rn , ^{220}Rn or a mixture of them can be done precisely. Calibration of detectors and some form of intercomparison are other applications of the chamber.

A CONTROL SYSTEM FOR STANDARD ALPHA AND BETA RADIOACTIVE SOURCES

Simone K. Dias and Linda V.E. Caldas

Instituto de Pesquisas Energéticas e Nucleares
Comissão Nacional de Energia Nuclear
São Paulo

ABSTRACT

A system of alpha and beta radiation detection was designed and constructed, using a plastic scintillator, in order to control the sources used for the calibration of contamination detectors. The obtained results of the short and medium-term stabilities, linearity and energy dependence using three different measurement systems were compared.

INTRODUCTION

The systematic routine monitorations have to be conducted using sensitive detectors in any area where radioactive materials are handled and specially where the possibility of surface contamination exists. The normally used instruments for surface contamination detection are scintillators, proportional counters, semiconductor detectors and Geiger-Müller detectors provided with thin entrance windows. The calibration process of such monitors involves the use of different radioactive sources^{1,2,3}. In the case of alpha radiation, the sources are unsealed, requiring special care during their handling. In order to check these sources periodically a control system was developed.

DESIGN AND CONSTRUCTION OF THE CONTROL SYSTEM

The developed detection system is constituted mainly by a plastic scintillator, a light pipe (Lucite) and a photomultiplier tube. This arrangement can be seen in Figure 1. Three different measurement assemblies were tested: an electrometer Keithley 616 (System 1), an electrometer Keithley 610C (System 2) and a timer-counter (System 3).

The secondary standard set in the case of alpha radiation for calibration of surface contamination monitors is composed by ^{239}Pu , ^{238}Pu , ^{244}Cm , ^{233}U and ^{241}Am sources, with certificates of the Laboratoire de Metrologie des Rayonnements Ionisants and by ^{241}Am sources produced and calibrated at the Nuclear Metrology Laboratory of IPEN. In the case of beta radiation,

the secondary standard sources are $^{90}\text{Sr} + ^{90}\text{Y}$, ^{137}Cs , ^{14}C and ^{36}Cl , all calibrated at LMRI.

RESULTS

a. Short and medium-term stabilities

A source of ^{241}Am (2305 s^{-1}) was used for this study. The best short-term stability (repeatability test) was shown by the System 3: the obtained variation coefficient was lower than 0.11%, while in the case of Systems 1 and 2 it was respectively 0.95 and 0.19%. For the medium-term stability (10 daily measurement series) the obtained variation coefficient was 0.18% for the System 1 and 0.14% for both Systems 2 and 3.

b. Linearity

Two different methods were carried out in this test. First, an ^{241}Am source (2305 s^{-1}) was used and the irradiation time was varied between 0 and 300 seconds. In the second case the control system was exposed to several ^{241}Am sources, with the emission flux varying between 55.3 and 11100 s^{-1} . In both cases a linear behaviour was observed for all three systems.

c. Energy dependence

Alpha and beta radiation sources with different energies were utilized, in order to obtain calibration factors for the control system and to study its energy dependence.

In the case of alpha radiation, in the energy interval of 4.7 and 5.8 MeV, the obtained energy dependence was 31.0 and 37.6% for the Systems 1 and 2 and only 5.3% for the System 3. Exposing the developed instrument to beta radiation, the energy dependence showed values of 19.6, 14.0 and 12.2% for respectively Systems 1, 2 and 3, in the energy interval of 511 keV and 2.0 MeV. Comparing these results, it can be verified that the arrangement with the timer-counter (System 3) demonstrated the lowest energy dependence, a desirable characteristic of such an instrument.

The efficiency of System 3 was determined: 91.8% for alpha radiation (^{241}Am) and 55.9% for beta radiation ($^{90}\text{Sr} + ^{90}\text{Y}$).

Table 1 presents the calibration factors of the control system for ^{241}Am and $^{90}\text{Sr} + ^{90}\text{Y}$ in the case of the three different measurement assemblies.

CONCLUSION

The studied characteristics of the developed control system for alpha and beta sources, ie, the short and medium-term stabilities, the linearity and the energy dependence indicate the system composed by the radiation detector and the timer-counter measurement assembly as the most suitable, although the other two systems showed their usefulness also.

ABSTRACT

Both fixed-filter and step-filter monitors can be used for the on-line surveillance of airborne fission products and trans-uranium elements in the environment. In this paper the specific benefits and drawbacks of these monitoring concepts are discussed. The network of the German Meteorological Service takes advantage of the complementarity of both sampling techniques. The comparability of the data received by different methods is demonstrated by some typical results of environmental measurements.

INTRODUCTION

In Europe the radiological consequences of the nuclear accident at Chernobyl have stimulated the design and the configuration of extended networks for the continuous surveillance of the environmental radioactivity. Nevertheless not all of the radiological features that have been observed in Western Europe can be taken for granted in respect to potential events in the future. But even an analysis of published data concerning the isotopical composition of the Chernobyl-fall-out clearly reveals the necessity of nuclide specific measurements at different locations:

In Germany the observed activity-ratio of Plutonium- to Cesiumisotopes had been in the order of 10^{-5} /1/. This means that the insignificant amount of transuranium elements had been detectable by off-line radiochemical methods only. On the other hand the official russian IAEA-report /2/ states an Pu/Cs activity ratio of $1.7 \cdot 10^{-3}$ for the emitted core material. This discrepancy can be explained by the different processes of emission, transportation and deposition for non-volatile and volatile elements: A comparison of soil samples taken in distances of up to 100 km from Chernobyl and those taken in Western Europe showed a derichment of the heavier particles of the nuclear fuel material by three orders of magnitude with increasing distance to the emittent. Additionally great differences in the isotopical composition of the various contaminated clouds depending on the time of emission at Chernobyl have been found /3/. Taking into account that the inhalation dose factor of $^{239,240}\text{Pu}$ is $3 \cdot 10^4$ higher than for ^{137}Cs /4/ it can be concluded that in the area around Chernobyl α -emitters played an important role in respect to the potential inhalation risk. Since the inhalation of these radioactive particles can be reduced quite effectively by the use of masks or by staying indoors the instantaneous knowledge of the airborne presence of α -emitters can thus be quite essential for the authorities.

REQUIREMENTS FOR ENVIRONMENTAL ALPHA AND BETA MONITORING

Keeping the radiological features of the Chernobyl accident in mind, the following aspects of environmental α - and β -monitoring have to be considered:

- The activity concentration of fission products (β -emitters) can be expected to exceed that of transuranium elements (α -emitters) by several orders of magnitude. Thus the β -sensitivity of the α -measurement has to be very small.

- Transuranium elements often occur as part of 'hot particles', i. e. the spatial distribution of the activity concentration can be quite inhomogeneous. Thus the volumina of the air under investigation should be sufficiently large in order to get a reliable result.

- According to the fact, that the required detection limits of artificial α -activity concentrations are typically two orders of magnitude below the natural background an effective suppression and compensation of the ^{222}Rn -daughters is very essential. Here an on-line discrimination can be performed via an energy analysis of the emitted α -particles, while the most efficient separation technique (simply waiting for the Rn-daughters to decay) yields delayed results only.

- Due to the preferential short-ranged transportation behaviour of non-volatile radionuclides the relative presence of artificial α -activity can be expected to be quite different at different locations of a network. Additionally the higher deposition rate in comparison to the volatile elements leads to a more transient time behaviour as well. Thus an on-line measurement of the α -activity concentration at selected sites of the network is desirable.

- Depending on the kind of nuclear accident the presence of artificial α -activity is related with the observation of other specific radionuclides, for example ^{144}Ce /3/, which might be identified via Γ -spectroscopy. Thus on-line Γ -spectroscopy also yields a first indication concerning the presence of small airborne α -contaminations which might remain below the detection limit of the α/β -monitor.

- Of course the design of the monitoring techniques must fit to the specific requirements of the network. For example the desired minimum response time for an alarm or the availability of skilled crews at the individual stations have to be taken into account.

ENVIRONMENTAL MONITORING CONCEPTS

Different off-line (1,2) and on-line (3,4,5) methods can be applied for the detection of airborne α - and β -contaminations in the environment (see table 1):

- 1) Using high-volume samplers combined with a subsequent radiochemical analysis detection limits in the order of several $\mu\text{Bq}/\text{m}^3$ for a sampling periode of one week can be reached. Though being the only technique for the detection of these (radiologically irrelevant) traces of radioactivity, this

method cannot supply instantaneous data which might be required in a network designed for an early warning. Depending on the distance to the laboratory and the kind of analytical method, a typical delay of at least one day between the end of the sampling periode and the final result can be assumed.

2) The off-line application of the alpha beta pseudo coincidence (ABPD) method /5/ represents a much faster evaluation technique which can be applied in the stations by unskilled personal as well. Here α - and β -detection limits of several mBq/m^3 for a sampling periode of 24 h can be reached.

3) Due to an excellent discrimination behaviour against natural radioactivity the α -energy range discrimination (AERD) method /6/ allows the on-line detection of α - and β -emitters. The detection limit is typically 50 mBq/m^3 for an integration time of two hours. According to the great volume under investigation ($\Phi = 40 \text{ m}^3/\text{h}$) an instantaneous response to the presence of hot particles can thus be combined with a very low detection limit for small but persistent concentrations. The presence of personal is required for the change of the filter only.

4) Much larger service intervals (up to 6 month) can be reached by the use of step-filter monitors /7/ involving silicon detectors. Here typical detection limits for averaging times of several hours are similar to those of AERD-monitors since the much smaller flow-rate ($8 \text{ m}^3/\text{h}$) approximately balances the improved discrimination against natural radioactivity. On the other hand smaller concentrations might remain undetected since the accumulation process is restricted by the filter transportation mechanism.

5) Isotopes which are Γ -emitters as well can be identified by an on-line Γ -spectroscopical step-filter monitor.

	high volume sampler radiochem. analysis	sampler, ABPD - analysis	On-line AERD monitor	On-line α, β step-filter-monitor	On-line γ step-filter-monitor

AN APPROVED PERSONAL DOSIMETRY SERVICE BASED ON AN
ELECTRONIC DOSEMETER

T.O. Marshall, E.A. Pook, D.T. Bartlett and J. Hallam

National Radiological Protection Board,
Chilton, Didcot, Oxon, OX11 0RQ, UK

ABSTRACT

An electronic dosimeter has been developed in the U.K. by the National Radiological Protection Board (NRPB) and Siemens Plessey Controls Ltd. It has been designed to measure the quantities $H_p(10)$ and $H_s(0.07)$ for photons and beta-rays and is suitable for use by approved personal dosimetry services.

The specification of the dosimeter and the operational features it provides are described and a summary of the type tests and the dosimeter trials is also given.

INTRODUCTION

Personal dosimetry services, approved by their national authorities for category A workers, invariably use passive dosimeters incorporating photographic film or thermoluminescent detectors. However, for several years the NRPB has felt that the next major development in personal dosimetry should be an electronic dosimeter mainly because the instantaneous indication of radiation levels to the wearer should lead to improved control of exposures and a reduction in individual doses. This became a possibility when an arrangement of solid state detectors and filters was developed at NRPB⁽¹⁾ which was suitable for the measurement of individual dose equivalent penetrating, $H_p(10)$ for photons.

Since then further development has taken place at NRPB⁽¹⁾ for the measurement of individual dose equivalent superficial, $H_s(0.07)$ for beta-radiation. The quantities $H_p(10)$ and $H_s(0.07)$ have been recommended by ICRU⁽²⁾ for individual monitoring.

NRPB and Siemens Plessey Controls agreed to develop jointly the device which will, in due course, be manufactured and distributed by Siemens Plessey.

THE DOSEMETER SPECIFICATION

It is the intention that the device is suitable for use as a legal dosimeter, i.e., one which in the U.K., for example, could be the basis of a dosimetry service, approved by the Health & Safety Executive (HSE) for "Classified" workers.

The dosimeter will measure $H_p(10)$ and $H_s(0.07)$ for photons and beta-rays both as the accumulated dose or instantaneous dose rate and the wearer is free to choose at any time which of these is displayed. The dose range which can be displayed for $H_p(10)$

and $H_p(0.07)$ is 1 μSv to 999.9 mSv. On its own this range is insufficient but the dosimeter will store up to 10 times this value, which will be accessible with an external reading unit. The dose rate ranges which can be displayed for $H_p(10)$ and $H_p(0.07)$ are 1 to 9999 $\mu\text{Sv h}^{-1}$ and 0.01 to 99.9 mSv h^{-1} respectively.

For photons and beta-rays the dosimeter can cover the energy ranges 20 keV to 7 MeV and 250 keV to 1.5 MeV (mean energies) respectively. Over the more important regions of these ranges the response is constant to within about 30% and the variation of response with angle of incidence will be contained within these limits.

Audible and visual alarms are provided, the setting up of which is restricted to authorised persons. The wearer, using keypads provided on the unit, can cause dose rate, or accumulated dose, or the alarm settings or his personal unique identifier to be displayed. Warning signals such as battery low or calibration required are automatically displayed. An essential feature for a legal dosimeter is that the accumulated values of $H_p(10)$ and $H_p(0.07)$ are stored securely. This security will be maintained even if the battery is discharged or the unit is damaged providing the storage chip is intact.

Important internal features are the use of semi-conductor detectors together with state of the art electronics. A customised battery will have a life of at least 1 year under normal conditions. Each dosimeter has a unique identifier and authorised stations (i.e., approved dosimetry services in U.K.) will be able to read and reset the stores for $H_p(10)$ and $H_p(0.07)$ prior to re-issue to a different person. The dosimeter is shown in Figure 1.

TYPE TESTING THE DOSEMETER

The dosimeter is being type tested in order to demonstrate its overall performance characteristics. Central to these tests is an investigation into the way its response varies with radiation type and energy and with the angle of incidence of the radiation. The dosimeter is intended for the measurement of $H_p(10)$ and $H_p(0.07)$ for photons and beta-rays. The above tests are being carried out with ISO reference radiations with energies between 17.4 keV and 7 MeV for photons and with beta particle spectra from ^{204}Tl , $^{90}\text{Sr}/^{90}\text{Y}$ and ^{106}Rh . In all cases the dosimeters will be exposed at angles of incidence 0° , 20° , 40° and 60° . The dosimeters are being exposed on the phantom expected to be recommended by the ICRU for this type of test namely a slab of dimensions 30 x 30 x 15 cm. Appropriate conversion coefficients, recommended by ICRU, are used to convert the air kerma intensity in the radiation beam to $H_p(10)$ and $H_p(0.07)$ in the phantom, i.e., the quantities against which the reading of the dosimeter is compared. The results will be presented in the form of a family of 4 curves being the energy response for each of the angles of incidence. To gain acceptance the mean of these curves at each energy should be within $\pm 30\%$ of that at the calibration energy over the whole energy range. So far this work has been

completed for photon radiations. Figure 2 shows the photon energy response for the dosimeter at angles of 0°, 20°, 40° and 60°. It can be seen that all values of the combined energy and angular response are within the range $1.0 \pm 30\%$.

In addition the dosimeter has been tested against the Draft IEC Standard for pocket alarm dosimeters and the tests have been successful for all requirements of major importance. This standard prescribes an extensive range of tests which includes the following:

- i) effects of temperature and humidity
- ii) effects of electromagnetic and electrostatic fields
- iii) effects of shock, vibration and immersion in water
- iv) the ease of radioactive decontamination

The dosimeter has also been shown to meet the requirements for personal dosimeters given in the Draft CEC document on Technical Recommendations for Monitoring Individuals Occupationally Exposed to External Radiation.

THE WEARER TRIALS

Wearer trials are in progress and are being largely limited to NRPB staff at its centres in Chilton, Leeds and Glasgow using the system described above. The service will be operated from Chilton and the trials at Chilton are being used to simulate an ADS serving its own on-site staff. The staff at Leeds are being used to simulate a remote customer linked to the dose record keeping system by an interactive computerised system and those at Glasgow to simulate a remote customer transferring data by means of some computer compatible medium. During the trials staff are, of course, continuing to wear their current passive dosimeters.

SUMMARY

An electronic personal dosimetry service has been described. The NRPB considers this to be the next logical development in personal dosimetry and it has been shown that the device offers a number of advantages for this purpose.

GRAPHITE MIXED $\text{CaSO}_4:\text{Dy}$ TL DOSEMETERS FOR
BETA RADIATION DOSIMETRY

L.L.Campos

Instituto de Pesquisas Energéticas e Nucleares
Comissão Nacional de Energia Nuclear
São Paulo - Brasil

ABSTRACT

Sintered pellets of $\text{CaSO}_4:\text{Dy}$ of different thickness with graphite contents from 0 to 10% were investigated for application for beta dosimetry.

INTRODUCTION

During the last few years many attempts have been made to develop detector devices for assessment of radiation doses from low energy beta rays to the unprotected skin⁽¹⁻³⁾. The Dosimetric Materials Production Laboratory of IPEN developed thin pellets of $\text{CaSO}_4:\text{Dy}$ (0.20 mm thick) for beta radiation detection⁽⁴⁾. This type of dosimeter shows good sensitivity but high energy dependence for beta mean energies below 100 keV. In this work it was investigated the TL characteristics of the sintered $\text{CaSO}_4:\text{Dy}$ dosimeters with graphite contents from 1 to 10% for application for personnel dosimetry.

EXPERIMENTAL MEASUREMENTS

TLD pellets were obtained from a homogeneous mixture of $\text{CaSO}_4:\text{Dy}$ (0.1% mol) phosphor (35% by weight), Teflon powder and graphite (0; 0.5; 1; 2; 5 and 10% by weight). Pellets of this mixture, with a diameter of 6.0 mm and thickness between 0.20 mm and 0.80 mm were first cold pressed and then sintered.

The TL response of these pellets were determined using the Harshaw TL Reader model 2000 (AB). Prior to irradiation, the samples were subjected to an annealing at 300°C for 3 h. They were irradiated under the same conditions. Each reported value corresponds to the average of five measurements.

The beta irradiations were carried out using the beta Secondary Standard System of the Calibration Laboratory of IPEN, with $^{90}\text{Sr} - ^{90}\text{Y}$ (74 MBq), ^{204}Tl (18.5 MBq) and ^{147}Pm (0.5 GBq) sources (manufactured by Buchler & Co., Germany). The detectors were always placed on a 12 mm thick phantom (Lucite) and covered with a 15 μm thick (2.1 $\text{mg}\cdot\text{cm}^{-2}$) polyethylene terephthalate (Hostaphan) foil during the irradiation.

The gamma irradiations were carried out using a ^{60}Co source (1.0 GBq). The samples were always irradiated sealed in Hostaphan foil 15 μm thick and under electronic equilibrium conditions.

RESULTS

The CaSO₄:Dy Teflon pellets with different graphite contents were exposed to 2.58×10^{-5} C.kg⁻¹ (100mR) of ⁶⁰Co gamma radiation. The decrease of the TL sensitivity with increasing graphite content is observed. Pellets with thickness of 0.20 mm showed the highest TL response when exposed to 10 mGy of ²⁰⁴Tl radiation.

The individual reproducibility of the dosimeters was investigated for each dosimeter type by calculating the standard deviation from ten successive dose measurements. The average reproducibility obtained for ten pellets irradiated with 10 mGy (⁹⁰Sr - ⁹⁰Y) under identical conditions was 3% (1σ) for all type of dosimeters.

The dose threshold defined as three times the standard deviation of the zero dose reading of the dosimeters expressed in terms of dose units, was calculated for each type of dosimeter. From Table 1 it can be seen that the dose threshold for dosimeters 0.20 mm thick with graphite content of 10% is approximately 23.0 μGy for gamma radiation of ⁶⁰Co, which is an acceptable level for application for personnel dosimetry.

The TL response of all type of CaSO₄:Dy dosimeters was measured for ⁹⁰Sr - ⁹⁰Y, ²⁰⁴Tl, and ¹⁴⁷Pm beta sources normalized to ⁶⁰Co radiation. The energy dependence for 0.20 mm thick pellets is shown in Table 2. It can be seen that the beta ray response of CaSO₄:Dy dosimeters with a graphite content of 10% gives an optimal response curve when compared with the response curve of pellets without graphite.

After a storage period of one month at room temperature, the results from the stored dosimeters were compared with dosimeters annealed, immediately irradiated, stored for 24 h and then read out: only 3% fading was found in the TL response.

CONCLUSIONS

The graphite mixed CaSO₄:Dy Teflon pellets produced at IPEN appear attractive for beta as well as mixed beta-gamma dose measurements. The reduced energy dependence to beta rays with average energy between 100 and 800 keV makes them useful in personnel monitoring.

A PARALLEL PLATE IONIZATION CHAMBER FOR ELECTRON DOSIMETRY

Cleber N. de Souza* and Linda V.E. Caldas

Instituto de Pesquisas Energéticas e Nucleares
Comissão Nacional de Energia Nuclear
São Paulo, Brazil

ABSTRACT

A parallel plate ionization chamber for electron dosimetry was developed and tested in relation to the metrological characteristics: short and medium-term stabilities, leakage current and response to electron beams up to 13 MeV. The polarity effect was also investigated. The obtained results show that they are within the international limits recommended for a secondary standard chamber.

INTRODUCTION

The increasing utilization of linear accelerators in radiotherapy treatments has imposed the necessity of use of parallel plate ionization chambers for dosimetry of the electron beams with energies lower than 15 MeV, as recommended by the dosimetry protocols^{1,2,3}. In the present work an ionization chamber of this kind was designed and constructed at the Calibration Laboratory of IPEN. Such chambers may be calibrated in future by comparison with cylindrical ion chambers in a phantom irradiated by ⁶⁰Co gamma rays⁴, without the need for an electron fluence correction.

DESIGN AND CONSTRUCTION OF THE IONIZATION CHAMBER

The parallel plate ionization chamber developed in this work has a circular shape, is mainly made of Lucite and presents an active volume of 0.06 cm³. The entrance window consists of a thin polyethylene foil coated with graphite (0.84 mg.cm⁻²); the collecting electrode is made of a graphite block (3 mm thickness) and a graphite coated slice of Lucite (0.15 mm). The distance between the electrodes is 2 mm; the external diameter and height of the chamber are 54 and 17.5 mm respectively. A schematic diagram of the chamber is shown in Figure 1.

* Fellowship from Conselho Nacional de Desenvolvimento Científico e Tecnológico, Brazil.

EXPERIMENTAL MEASUREMENTS

The chamber was connected to a Keithley model 617 electro meter in order to allow measurements with both polarities. The tests were made in electron beams up to 13 MeV, using a phantom made of Lucite slices.

The short-term stability was determined through 10 consecutive measurements using a check source of ^{90}Sr . The percentual standard deviation showed values between 0.14 and 0.34%. For the medium-term stability test 15 series of measurements were performed at different days. The response presented a variation lower than 0.5% in relation to the mean value: Figure 2.

The leakage current was measured several times during 1 h with intervals of 5 min and showed always values lower than 0.4%. The chamber presented an ion collection efficiency higher than 99%, when operated at a collecting potential of 250 V.

The polarity effect of the chamber was investigated in a 10 MeV electron beam, taking measurements for both polarities and varying the Lucite absorber thickness (z) up to the practical electron range (R_p). The polarity effect was lower than 1% at the maximum ionization depth and it increased for greater depths: Figure 3. All standard deviations of these measurements were lower than 0.25%.

According Goswami and Kase⁵ the replacement factor for parallel plate ionization chambers in electron beams above 13 MeV is approximately 1 and probably not significant. In the present work the chamber response was compared to that of a calibrated thimble chamber (Capintec-C II model 66080, 0.6cm^3) in a electron beam of 13 MeV. The obtained calibration factor was 1.04 cGy/s.u. (s.u.: scale unit).

CONCLUSION

The developed parallel plate ionization chamber presented metrological characteristics, as short and medium-term stabilities, leakage current, ion collection efficiency, polarity effect and calibration factor comparable to those of commercial ionization chambers. The obtained values, within the recommended ones for this kind of radiation, demonstrate the usefulness of the chamber for electron dosimetry.

ACKNOWLEDGEMENTS

The authors wish to express their thanks to Mr. Marcos Xavier for technical assistance.

THORIUM BIOASSAY OF MINERAL SANDS WORKERS

G S Hewson¹ and J J Fardy²

1. Department of Mines, 100 Plain Street, East Perth, Western Australia.
2. Australian Nuclear Science and Technology Organisation, Lucas Heights, New South Wales.

ABSTRACT

The concentration of thorium in the blood serum and urine of Western Australian mineral sands workers was studied to complement estimates of radiation dose derived from air sampling measurements. The measured levels were significantly lower than the values predicted from the application of ICRP biokinetic models to air sampling data. In many cases, the levels were of the same order as background levels measured in occupationally unexposed persons.

AIM OF PROJECT

The study was designed to enable comparisons between measured values of thorium in the blood and urine of mineral sands workers and:

1. measured values for unexposed persons;
2. values reported in the literature for other worker groups exposed to thorium; and
3. predicted values based on air sampling measurements undertaken by the industry.

It was considered that such comparisons would facilitate a comparative assessment of the relative level of exposure.

BACKGROUND

Workers in the mineral sands industry are exposed to varying concentrations of the radioactive mineral, monazite, which contains 6-7% by weight of the radioactive element thorium. The principal radiation exposure pathway is thought to be through inhalation of alpha radiation associated with airborne dust. Estimates of internal radiation dose using the assessment protocols and data contained in ICRP Publications 26 and 30 indicate that up to 15% of the approximately 1500 workers in the mineral sands industry may exceed the formal investigation level of 15 mSv⁻¹.

The existing radiation dose assessment method is based on air sampling, which requires assumptions to be made concerning a number of environmental factors, including the size of the dust particles, the solubility of the dust, the incorporation of dust into the body and the effectiveness of respiratory protective equipment in reducing exposure to dust.

Bioassay monitoring for thorium will assist in improving knowledge of its metabolic behaviour. The blood and urine samples provide an indication of the amount of thorium circulating in the body and being cleared from the body, respectively. Such bioassay studies assist in refining our estimates of radiation dose following inhalation of thorium.

STUDY GROUP AND METHODS

The project commenced in April 1991 and involved thirty four (34) mineral sands workers across five processing plant sites. In addition, a number of samples were collected from unexposed persons to obtain an indication of background levels of thorium.

The cumulative internal exposure history for each worker was obtained from industry records of airborne radioactivity (gross alpha activity) measurements submitted to the Department of Mines. It was assumed that workers were exposed to class Y (i.e. avidly retained) Th ore dust with an AMAD of 10 μm . Twenty five millilitres of blood and 1 L of urine were collected using rigorous collection protocols to minimise the possibility of contamination. The samples were analysed using chemical/radiochemical neutron activation analysis procedures.

RESULTS

The results of testing are summarised in the attached figure. The measured average levels for the industry are compared with the expected level, based on industry monitoring of the workplace atmosphere, and also average background levels. The levels of thorium in urine and blood are expressed in parts of thorium per billion parts of either urine or blood.

The following observations are made on the results obtained in this study:

1. The levels of thorium in urine are very low and typically more than ten times lower than those expected based on air sampling measurements.
2. The levels of thorium in blood are typically more than two times lower than those expected based on air sampling measurements.
3. The urine results for many workers are not substantially different from those reported for members of the public and are lower than those reported for other groups of workers exposed to thorium.

Results of Bioassay Measurements

(a) Urine Sampling

(b) Blood Sampling

- * *Expected Level Based Upon Application Of ICRP Biokinetic Models To Airborne Radioactivity Measurements.*

4. The level of thorium in blood are higher than some reported background levels.

The blood testing is considered to be more reliable than urine testing since varying intake of fluids such as water and alcohol, or loss of water by perspiration, will cause significant differences in the amount of urine excreted.

CONCLUSIONS

This testing program indicates that the absorption of thorium is much less than has been previously assumed. This result suggests:

- (1) present industry monitoring procedures may overstate the radiation doses received by workers. The lower results could arise if respirators have been worn for "dusty" jobs and no allowance has been made for their protective effect; or
- (2) thorium may be much less soluble than expected and only a small amount passes into the blood or urine. If this is so, then thorium will not be carried to sensitive organs such as bone.

It is likely that, on the basis of this study, average radiation doses in the industry may only be about one-half of those reported.

While this monitoring has indicated that existing protective measures are effective in controlling radiation exposure to low levels, it is still important to maintain radiation exposures As Low As Reasonably Achievable.

THE N-16 GAMMA RADIATION RESPONSE OF GEIGER-MUELLER TUBES

D. J. Allard, A. M. Nazarali and G. E. Chabot

Arthur D. Little, Inc., Acorn Park, Cambridge, MA 02140; WIPP, P.O. Box 2078, Carlsbad, NM 88220; University of Lowell, 1 University Ave., Lowell, MA 01854

ABSTRACT - This paper describes an evaluation of various Geiger-Mueller (GM) tubes for N-16 gamma radiation response. The work is an extension of investigations regarding the various radiation response characteristics of these devices. Previously acquired photon energy response data were from 10 keV to 1.25 MeV. Utilizing the 6 MeV gamma ray of N-16, the pair production interaction response with different GM tube styles was studied. The new relative response ratios of N-16 to Cs-137 are presented with a discussion of results. Additionally, two full energy response curves are presented.

INTRODUCTION AND METHODS

Recently, evaluations for radiation response characteristics of GM tubes with respect to beta energy, dose rate, photon polar and photon energy response have been performed in conjunction with the NRPB in the UK (Allard 1987). That work investigated photon energy response from 10 keV to 1.25 MeV. The dominant interactions in this energy range are photoelectric and Compton scattering. An investigation presented herein extended the photon energy testing into the 6 MeV range using an N-16 source. At this energy the pair production interaction will become more apparent with respect to detector response. Various styles of "pancake", mica end window, thin wall, thick wall and energy compensated GM tubes were included in this study. The mechanical aspects of the various styles are noted in Table 1 and TGM Detectors' product specifications. In this evaluation a portable high voltage supply/digital scaler was set up adjacent to the N-16 source at the University of Lowell's research reactor facility. This source has been fully characterized for the specific purpose of measuring response of portable radiation protection instruments (Neault, 1980). It should be noted that a 1.5 inch thick iron plate was placed in front of the source to attenuate the high energy beta component and provided secondary electron buildup. This arrangement also furnished an exposure scenario that is similar to what is encountered in a nuclear power plant. The various GM tubes were irradiated with the N-16 source at known exposure rates, and observed counts and times recorded. Efforts were made to obtain at least 10,000 counts for statistics. Similarly, the same detectors were irradiated with a calibrated Cs-137 source. The background was measured in each area and corrections applied. Collected data were then used to determine a count rate per unit exposure rate value. A response ratio of N-16 to Cs-137 was then calculated in order to fold this information into the previously acquired photon energy response measurements made at NRPB.

RESULTS AND DISCUSSION

Table 1 is a summary of the N-16 to Cs-137 response ratios. As noted, the relative response ratio varied from nearly unity to about two. Considering the interactions and number of secondary charged particles produced, this would be expected. If one were to plot of photon fluence versus photon energy, a peak would be observed below 200 KeV. This is mentioned in that GM tubes are basically photon counters, and will more or less exhibit the same generally shaped curve. However, differences in GM tube construction does cause notable discrepancies at high photon energies and variable peak spread at low photon energies. Figures 1 and 2 are energy response curves for a bare and energy compensated version of a GM tube. The data presented are a combination of the NRPB and this study's results (i.e. N-16 data point).

GM tubes will respond to any charged particle that enters their sensitive volume. A discharge may be produced by charged particles directly entering the tube through a mica window or thin cathode wall. Alternately a discharge may result from secondary electrons; thus, the construction of any given GM tube will greatly influence an energy response curve by the complex contribution of primary photon transmission/attenuation and secondary particle production/attenuation at various depths in the GM tube window, wall or outer energy compensation filter. Again, the data shown in Figures 1 and 2 are the relative response values for the GM tube on an exposure rate basis. Because Cs-137 is a very common calibration source, by convention 662 keV is used as the normalization point. This allows comparison of tubes that may have quite different gamma ray sensitivities due to overall size.

As can be noted in Figure 1, the "thin wall" style GM tube with an 80 mg/sq. cm window provides excellent transmission for low energy photons below 100 keV. However, relative to Cs-137 it does over-respond by nearly a factor of 13 at 70 keV. This results from the high photon fluence being transmitted through the cathode wall, a high interaction probability, and the subsequent discharge events being counted. In the intermediate energies the response is relatively flat, but does begin to increase slightly above 1 MeV. The latter is due to the increase in number of secondary charged particles from pair production. Over-response below about 200 keV may be reduced by adding a thin layer filter of high atomic number metal over the tube with an appropriate open area. This effectively attenuates a portion of the low energy photon fluence. With proper engineering, one can easily obtain a +/-20% response from 50 keV to 1.25 MeV using a "thin wall" GM tube and energy compensation filter. However, as can be noted by comparing the response curves in Figures 1 and 2, the high atomic number filter actually causes an increased over-response in the 6 MeV range compared to the bare tube. This is no doubt due to energetic secondaries produced in the energy compensation filter, passing through the GM tube cathode wall and causing a discharge.

**"THE ENVIRONMENT" AND THE MONITORING
OF RADIOACTIVITY IN AIR**

The french company, SAPHYMO-PHY, presents two state of the art products for "the Environment" and the monitoring of radioactivity in air :

- The **RAM 900** : Aerosol (Alpha and Beta) activity measurement.
- The **SIAM 9000** : - Aerosol (Alpha, Beta, Gamma) activity measurement
- Gaseous Iodine Gamma volumic activity measurement
(High resolution gamma spectrometry)
- **RAM 900** :

La RAM 900 est une balise de surveillance de la radioactivité de l'air : elle mesure l'activité alpha et bêta des aérosols.

La mesure est faite par pompage de l'air à travers un filtre déroulant séquentiel et par spectrométrie alpha/bêta en ligne à l'aide d'une diode Silicium. La spectrométrie permet d'une part de discriminer les alpha des bêta, et d'autre part, de mesurer l'énergie de chaque alpha.

La RAM 900 peut ainsi mesurer et compenser l'activité alpha bêta naturelle - due aux descendants solides des radons - quelle que soit la situation radon, situation extrêmement variable suivant la météorologie et le lieu d'implantation de la balise. Un détecteur gamma permet de mesurer l'ambiance gamma et de compenser son influence sur la voie bêta. Les limites de détection en isotopes artificiels atteignent :

- 1 mBq/m³ pour les alpha
- 100 mBq/m³ pour les bêta.

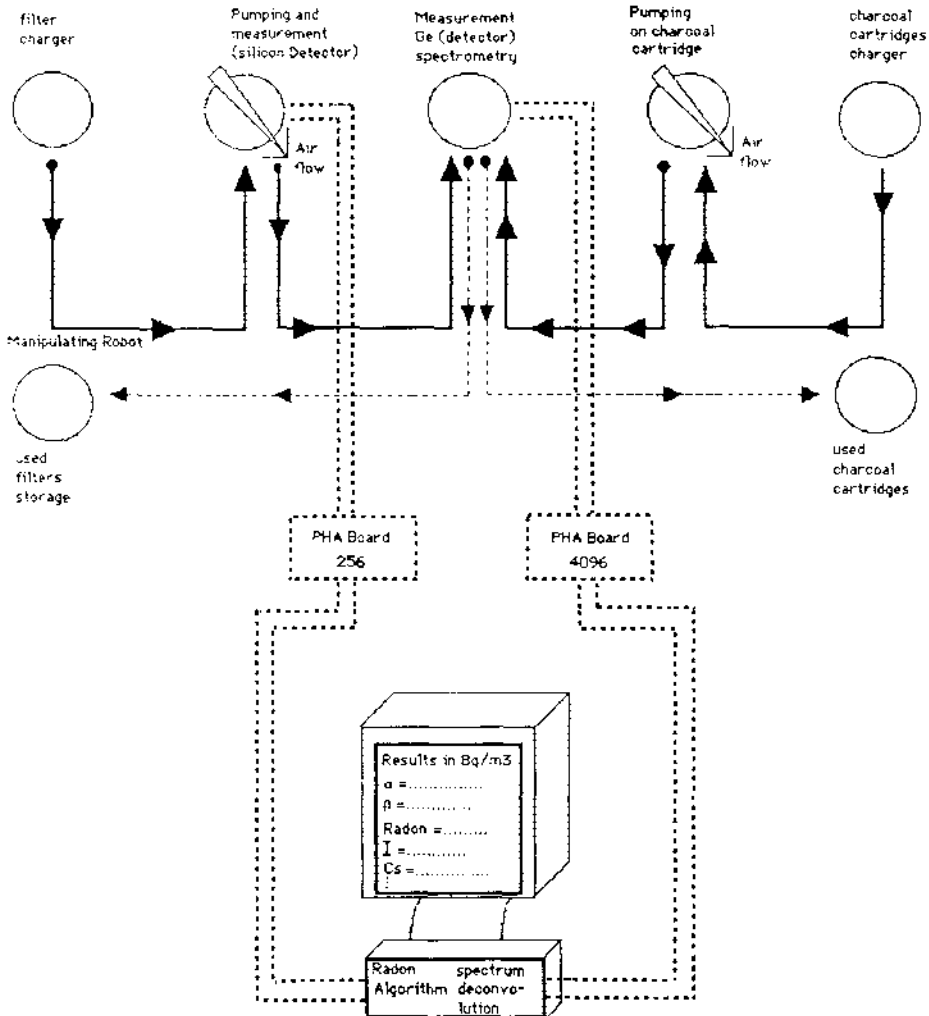

- SIAM 9000 :

La SIAM 9000 intègre une voie de mesure type RAM 900 avec des filtres individuels et effectue une spectrométrie gamma haute résolution (grâce à un détecteur au Germanium refroidi à l'azote liquide) sur les aérosols et sur les iodés gazeux, ce qui lui permet d'identifier et de quantifier les éventuels contaminants.

Les deux détecteurs (Germanium et Silicium) sont placés dans des enceintes en plomb hermétiques afin de les protéger de l'effet de l'ambiance gamma.

Le prélèvement d'iode est effectué par pompage de l'air à travers une cartouche au charbon actif.

Un bras manipulateur robotisé manipule les filtres et les cartouches.

COMPARAISON DE TECHNIQUES DE MESURE DU RADON 222 (COMPTEUR
PROPORTIONNEL, DIODE SILICIUM (P.I.N.) ET DETECTEURS SOLIDES DE
TRACES NUCLEAIRES)

AN INTERCOMPARISON OF TECHNIQUE TO MEASURE RADON 222
(PROPORTIONAL COUNTER, SILICON DIODE AND SOLID STATE NUCLEAR
TRACK DETECTOR)

An intercomparison in laboratory conditions was made between three different methods to measure radon 222. One instantaneous technique based on the use of a proportional counter and the others by integrating method base on the use of diode silicium (P.I.N.) and Solid State Nuclear Track Detector. The test was performed in a standard source in L.M.N. at Besançon. Good agreement was obtained between all the techniques.

INTRODUCTION

Le radon 222, gaz radioactif de la famille de l'uranium 238 est le principal composant de la radioactivité atmosphérique. Le suivi de sa concentration est donc fondamental dans le domaine des Sciences de la Terre et dans le domaine de la radioprotection, que cela soit dans les habitations ou sur les sites miniers.

Dans le but de disposer d'une instrumentation adaptée à l'ensemble des conditions de terrain (maison, mine, site géologique, etc...), le Laboratoire de Microanalyses Nucléaires a développé différentes techniques de mesure.

Ces techniques sont : des détecteurs solides de traces nucléaires (LR 115 et CR 39), un compteur proportionnel et un détecteur à diode silicium.

LES TECHNIQUES DE DETECTION

- Le compteur proportionnel

Le compteur proportionnel a été spécialement développé au Laboratoire de Microanalyses Nucléaires pour la mesure en continu du radon 222 avec la possibilité de fonctionner sur des terrains très hostiles tels que les volcans.

Cet ensemble de détection est autonome et portable. Sa limite de détection inférieure à 40 Bq.m⁻³ et son temps de réponse immédiat permet son utilisation pour de nombreuses applications.

Cet appareil a déjà été utilisé et a montré son efficacité pour différentes applications en radioprotection (mesure de

concentration dans des mines et des habitations) et dans le domaine des Sciences de la Terre (caractérisation des mouvements terrestres, prospections géologiques, étude des fluides géothermiques et suivi des variations de radon aux édifices volcaniques).

- Diode silicium (P.I.N.)

Utilisant les effets de l'irradiation des particules alpha sur les semi-conducteurs, un détecteur de radon est en cours de développement. Il utilise en base de détection du matériel Hamamatsu standard et une électronique associée qui est développée au Laboratoire de Microanalyses Nucléaires pour son utilisation aux mesures de terrain.

Cette technique est en cours de développement et nous présentons ici les premiers résultats obtenus à partir du prototype de laboratoire qui vient d'être développé et qui donne une mesure intégrée directement accessible sur le terrain par connexion d'un micro-ordinateur portable sur une eprom de stockage intégrée à l'électronique de détection.

- Les Détecteurs Solides de Traces Nucléaires (D.S.T.N.)

L'utilisation de D.S.T.N. pour la mesure de l'émanation radon, s'est imposée pour de nombreuses applications. Deux types de détecteurs sont utilisés au Laboratoire: le LR 115, nitrate de cellulose commercialisé par la Société KODAK, sensible aux particules alpha d'énergie comprise entre 0,5 et 4 MeV et le CR 39, polycarbonaté commercialisé par la Société TASTRAX, sensible pour toutes la gamme des énergies de particules alpha.

Pour cette technique, les détecteurs sont placés dans des cellules de mesure de géométries spécifiques développées pour des mesures de terrain et ensuite après un temps d'exposition variant de 10 à 60 jours les détecteurs sont analysés au laboratoire par traitement d'image automatique.

- Utilisation des appareils sur le terrain

Pour réaliser des mesures sur le terrain, la méthode que nous utilisons actuellement repose sur l'utilisation complémentaire du compteur proportionnel et des détecteurs de traces nucléaires. Le compteur proportionnel est placé en un point du site et son information permet de suivre les variations de la concentration radon par pas de trente minutes et de choisir le temps d'exposition des détecteurs nucléaires en fonction de la concentration en radon au point de référence. Les détecteurs nucléaires quant à eux sont placés sur l'ensemble de la zone d'intérêt et leur analyse permet d'accéder à la cartographie en radon de toute la zone.

En ce qui concerne le détecteur à diode silicium, il n'a pas été encore utilisé en routine sur le terrain, mais leur utilisation est appelée à remplacer à court terme les détecteurs polymériques.

RESULTATS EXPERIMENTAUX

Pour réaliser l'intercomparaison deux chambres sont utilisées. La première (Figure 1) permet la mesure de la concentration en radon dans un flux d'air sec, la seconde (Figure 2) permet la mesure dans un atmosphère humide.

Figure 1

2. compteur proportionnel
3. pompe
4. électronique associée
5. portoir

La mesure en continu de la concentration en radon est accessible par le compteur proportionnel en impulsion par seconde, en ce qui concerne la diode silicium (PIN) et les détecteurs solides de traces nucléaires, la mesure est réalisée par intégration sur une période de 5 jours et les résultats sont exprimés en trace par centimètre carré ou impulsion par heure. La figure 3 présente l'ensemble des résultats.

Figure 3 : Principaux résultats

CONCLUSIONS

Le tableau suivant donne l'ensemble des avantages et inconvénients des techniques utilisées

	Avantages	Inconvénients
- Compteur proportionnel	- mesure en continu - autonome et portable - sensibilité < 40 Bq.m ³	- coût - encombrement
- Diode silicium (PIN)	- bonne sensibilité - mesure directe sur site	- mesure intégrée - coût
- Détecteur Solide de Traces Nucléaires	- coût - facilité de mise en oeuvre	- mesure intégrée - traitements en laboratoire post-exposition

Les résultats obtenus sont en accord et il est à noter que l'avantage principal de la mesure intégrée obtenue par la diode silicium est la rapidité d'acquisition de l'information qui ne nécessite aucun traitement en laboratoire.

ABSTRACT

By measuring the Radioactivity in the air of a Radionuclide Therapie - Unit it could be observed that the changes of the radioactivity concentration are closely related to the functional state of the patient's thyroid. In patients with thyroid carcinoma the organification of administered J-131 depends on the size and function of the postoperatively remaining thyroid tissue and this in turn influences the exhalation of J-131 by the patient. In a patient with a relatively large amount of remaining thyroid tissue the shape of the observed time activity curve shows an ascending slope reaching a maximum at 7,5 h. After the maximum the curve follows a monoexponential decrease with a disappearance half-life time of 10,7 h. In patients suffering from hyperthyroidism several cyclic changes of radioactivity concentration could be observed as a result of the organification and the release of J-131 after deiodination of endogenous labelled thyroid hormones.

INTRODUCTION

Since radioactive Iodine and its stable isotopes have the same chemical and physiological properties, it can be used for diagnosis and treatment of various thyroid disorders. J-131 is used for therapy because of its β -emission (606 keV, directly ionising radiation, small range). The gamma-radiation (364 keV, penetrating radiation) on the other hand can be used for diagnostic procedures like uptake measurements and scintigraphy of the thyroid gland. Mainly two types of thyroid disorders are subject for therapy with J-131:

Carcinoma of the thyroid and hyperthyroidism. The Radioactivity administered for treatment of thyroid cancer ranges from 1850 to 5550 MBq (50-150 mCi). The corresponding Radioactivity for treatment of hyperthyroidism ranges from 185 to 1110 MBq (5-30 mCi) corresponding to an absorbed organ dose of 100 - 200 Gy for therapy of so called Grave's disease and up to 400 Gy for treatment of toxic thyroid nodules. The estimation of the individual dose for treatment is made using a formulation which contains the 24 h J-131 uptake in % of a standard-dose and the effective J-131 half-life time.

Since the patient after treatment can be considered as a radioactive source, he has to stay 3 - 4 days in a special designed therapy Unit for radiation protection of the nursing personal. Within 48 h J-131 is mostly excreted (65 %) in the urine. About 30 % of the administered dose are excreted by stool, the remaining 5 % are excreted by sweat and exhalation.

Due to the fact that J-131 is also exhaled from the patient, a monitoring of the radioactive concentration in the air has to be done using aerosol monitors.

The aim of our study was:

1. to investigate the activity concentration of exhaled J-131 in the room air
2. to investigate whether the time course of activity concentration is specific for a certain type of thyroid disorder after J-131 treatment.

MATERIAL AND METHODS

In order to measure the concentration of radioactive iodine in the air with acceptable accuracy, it is necessary to suck the air through a filter. The activity absorbed on the filter is measured with a NaI-crystal coupled with a photomultiplier.

Assuming that all the concentration of activity is uniformly distributed in the air of the room and is only time-dependent, the infinitesimal change of absorbed activity $dA(t)$ during the time-interval dt comes up to

$$dA(t) = C(t) \cdot Q \cdot F \cdot dt - \lambda \cdot A \cdot dt$$

- A(t) activity on the filter
- C(t) concentration of activity (activity / volume)
- Q sucking rate
- λ decay constant
- F efficiency of filter

The relation between the activity in the filter and the concentration of activity in the air yields

$$\frac{dA}{dt} + \lambda A = Q \cdot F \cdot C(t)$$

For finding a solution of the above equation the assumption was made that the concentration between two data points was considered to be constant.

(A_i, A_{i+1} ...activity at the time t_i, t_{i+1}) With $C(t)=C_i$ the solution of the differential equation can be written as

$$A_{i+1} = A_i e^{-\lambda(t_{i+1} - t_i)} + \frac{QF}{\lambda} C_i (1 - e^{-\lambda(t_{i+1} - t_i)})$$

With respect to $x = \lambda(t_{i+1} - t_i) \ll 1$ we can approximate the concentration of activity to

In our carcinoma patients 1,2 the half-life time of whole-body retention was 22,6 h (large amount of remaining tissue) and 19 h (small rest of remaining tissue) respectively. The blood disappearance half-life time in patient 1 was 14,4 h and 15,3 h in patient 2.

Regarding the concentration of J-131 in air after administration of the therapeutic dose to patient 1 a single peak of maximum activity at 9,9 h with a disappearance half-life time of 10.7 h could be observed. After treatment of patient 2 the maximum activity was reached at 3,0 h. The disappearance half-life time was 3,1 h.

In hyperthyroidism 3 peaks of radioactivity with a mean disappearance half-life time of 1,6 h could be registered.

DISCUSSION

In our investigations we compared the whole-body retention curve (% of administered dose), the course of the activity concentration in the blood (% dose/L blood) and the course of the radioactivity concentration in the air of the therapy Unit (nCi/m³) of patients with different types of thyroid disorders.

In patients with carcinoma of the thyroid a single peak of radioactivity could be detected. The organification of anorganic J-131 depends on the volume and the function of the remaining thyroid tissue. If this volume is relatively small, low uptake of administered J-131 and rapid whole-body clearance will take place. If the volume of the remaining thyroid tissue is comparatively large, considerable uptake of J-131 by the thyroid gland and labelling of endogenous thyroid hormones will take place.

The deiodination of these organic compounds leads to another rise of activity in the air exhaled by the patient. So, a second lower peak of activity in the air is registered. The same phenomenon will take place in the treatment of hyperthyroidism. Due to the rapid J-131 turnover up to 3 activity peaks can be detected in the air of the room.

LEVELS OF POLONIUM-210 IN SOME BEVERAGES AND IN TOBACCO

C. H. Colangelo, M. R. Huguel, M. A. Palacios and A. A. Oliveira

Gerencia de Seguridad Radiológica y Nuclear
Comisión Nacional de Energía Atómica
Buenos Aires -República Argentina

ABSTRACT

The objective of the present work is the estimation of the Polonium-210 content in some beverages and in tobacco, in order to assess the corresponding collective doses to the population in Argentina. Yerba mate, an autochthon plant of South America, tea leaves, their infusions and ground coffee were analyzed as well as tobacco. Collective doses due to annual consumption of the beverages described, resulted in values from 6 man.Sv to 1200 man.Sv. Results for Polonium-210 in tobacco ranged from 10 Bq kg⁻¹ to 80 Bq kg⁻¹. Doses due to the use of tobacco were not assessed since an appropriate metabolic model was not found.

INTRODUCTION

Polonium-210 is a naturally occurring radionuclide in the environment and it is considered one of the highly toxic radioisotopes. It is an α emitter, T_{1/2} 138 days, but in spite of its relatively short half life it is maintained in the atmosphere due to longer lived precursors. Polonium-210 in food is an important route of intake [1].

ANALYTICAL METHOD

Solid samples were homogenized, spiked with Polonium-208 as a tracer, and wet ashed with concentrated nitric acid and hydrogen peroxide [2]. The insoluble was discarded because of negligible levels of activity [3].

Yerba mate infusions were prepared with 25 g per liter of boiling water and filtered five minutes later; tea infusions were done in the same way but 10 g of tea leaves were used. The chemical procedure was the same as before, but less insoluble remained.

Nitrates were eliminated, the solution was adjusted to a hydrochloric acid concentration of 0.5 N, ascorbic acid was added to keep iron reduced and Polonium was deposited on silver disks, 25.4 mm in diameter, with constant stirring during 3

hours at 85°C [2] [4].

The deposited activity was measured by α spectrometry with a Si surface barrier detector (1000 mm²) and a Canberra Series 30 Multichannel.

The radiochemical yields for Polonium-208 were quite low and widespread, mainly in the solid samples, with values fluctuating between 20 % and 50 %.

The results obtained are shown in TABLES I to IV.

DISCUSSION

If we compare levels of Polonium-210 in yerba mate and tea leaves with values published for different vegetables [5] [6], a higher bioconcentration in the former is noticeable. Nevertheless, the fraction of Polonium-210 actually extracted into the infusions was between 15 % and 63 %, representing an annual dose by ingestion between 28 $\mu\text{Sv y}^{-1}$ and 86 $\mu\text{Sv y}^{-1}$ (TABLE I). The values corresponding to tea leaves and its infusions are shown in TABLE II. Dose estimations were performed by applying representative consumption rates [7] and dosimetric factors [8] [9]. We assumed f_1 as 0.2 in our calculation.

The annual doses due to yerba mate infusions are six times higher than the doses for tea infusions.

Collective doses, estimated considering the consumption rate during 1990 for Argentina, were 1200 man.Sv. and 6 man.Sv for yerba mate and tea infusions, respectively. As a matter of fact, if we compare the annual collective dose in Argentina due to the consumption of yerba mate with the corresponding collective dose due to previously published data of Polonium-210 in the Argentine diet [10], it results that the former is almost 3 times greater than the latter. It must be taken into account that the beverages analyzed are not included in the total diet, in spite of their important levels of consumption.

Besides, phosphate fertilizers may be discarded as a source of Polonium-210 [11] since their use in yerba mate and tea production in Argentina is insignificant [12].

As the activity levels of Polonium-210 for ground coffee (TABLE III) were negligible, their infusions were not considered for the estimation of the annual doses by ingestion.

Regarding tobacco, only activity levels are given in TABLE IV, since it is difficult to adopt a simple respiratory model in order to calculate the annual doses. Anyway, the results obtained are much higher than the corresponding values for Indian tobacco, but close to U.S.A. data [13].

ABSTRACT

Dose equivalent estimate of workers in a Brazilian monazite sand plant, due to concentration of thorium in the air is presented, using in air monitoring program and utilizing calculation model described in publication nº 30 of the International Commission on Radiological Protection (ICRP).

The sample area, the number of measurements and the results evaluation were made using the experimental design techniques. The results of the dose equivalent estimation due to internal and external radiation exposure indicate the existence of operation areas, for example mill and magnetic field separation, where the dose values surpassed the recommended limits, demanding improvement in radiological protection and the modification of the engineering process, in order to obey the international standards.

INTRODUCTION

The Nuclear Energy National Commission (CNEN) has been developing for many years programs of accompanying of radiological conditions at installations that use ores with reasonable thorium and uranium tails, as those that processes monazite sand mill to produce rare earth and trisodic phosphate. The Brazilian industry analysed, processes monazite with the following sequences of operation: magnetic field separation, milling, alkaline treatment, trisodic phosphate filtration and thorium and uranium cake filtration.

The radiological conditions evaluations were performed by an area monitoring program in the various processes steps location. The results obtained from monitoring were considered as input data in the dose equivalent calculation model, recommended by ICRP publication nº 30⁽¹⁾.

METHODOLOGY

The use monitoring program performs the sampling of measurement in the positions of major occupation of workers, inside of a process area. The permanence time used was the time of labour agreement, i.e., 40 hours/week.

The evaluation of the dose was given by the sum of the doses due external and internal exposure. The dose due to external exposure was estimated by direct measurement in the radiation field, using a Geiger Muller detector, and considering the quality factor for gamma radiation equal to 1. The dose due to internal radiation was estimated by indirect method, measuring the portion that was inhaled through the determination of the concentration of radionuclides in the air, sampling the air and total alpha counting, and multiplying by permanence time, and using models for internal dose calculation.

The main difficult in the monitoring program is to find the distribution representative value or values of the results. It was resolved by using the technique of statistics planning. The planning took into consideration that the main source of fluctuation would be the measurement of the sample point and time/day of its execution.

Therefore, the value of an individual measurement was expressed by:

$$Y_{ijk} = \bar{Y} + P_i + D_j + PD_{ij} + \varepsilon_{(ij)k}$$

where:

Y_{ijk} - individual measurement value

\bar{Y} - distribution mean value

P_i - measurement influence in a "i" point

D_j - measurement influence in a "j" day

PD_{ij} - combined influence in a "i" point and in a "j" day

$\varepsilon_{(ij)k}$ - variation due random error and other influences.

Using this equation we obtain the number of measurement, the measurement points and sampling days. Hence, we draw lots the days and points sequence to be monitored, to obtain an statistics planning of the type "totality random". The obtained results were submitted to variance analysis.

Using the results distribution of the gamma exposure rate and radionuclide concentration in air, we estimate the dose equivalent using the dosimetric model for the determination of internal and external dose.

RESULTS AND DISCUSSIONS

The estimates of the dose equivalent due to external exposure are presented in table 1. The results do not present higher risks to the workers.

Table 1 - Annual dose equivalent due to external exposure to gamma radiation in several areas of the installation.

Processing area	Dose (mSv)
Monazite mill	15,4
Magnetic separation	35,0
Light fraction deposition	21,0
Autoclave (alkaline treatment)	8,0
Filter-press	10,5

The dose equivalent results due to internal exposure to radiation are presented in table 2. All the results are higher than the limits set by safety series n° 82. That indicates the need for improvement in the radiation protection and the modification in the industrial process.

Table 2 - Annual dose equivalent due to internal exposure.

Processing area	Mean Concentration (Bq/m ³)	Dose (mSv)
Monazite mill	0,25	150,6
Magnetic separation	0,56	300,0
Light fraction deposition	0,43	259,0
Autoclave (alkaline treatment)	0,20	120,5
Filter-press	0,13	78,3

The total dose equivalent are presented in table 3.

Table 3 - Total annual dose equivalent.

Processing area	Dose (mSv)
Monazite mill	166,0
Magnetic separation	335,0
Light fraction deposition	280,0
Autoclave(alkaline treatment)	128,5
Filter-press	88,3

The results in table 3 show that all the values are higher than the primary limits (50 mSv/year). To avoid those doses it was adopted the following remedial actions: reduction of working journey; the use of masks for radioactive particulate; and modifications in the processing, like deactivation of the magnetic separation.

CONCLUSIONS

1) The monazite processing to obtain rare earth trissodic phosphate, in areas that have associated thorium, can yield doses equivalents up to 335,00 mSv a year, mainly during milling and magnetic separation.

2) According to the results from mean concentration given in table 2 and considering the limits for thorium associate ore dust, $0,082 \text{ Bq/m}^3$, by safety series 82, we conclude:

a) For free air sampling one should use techniques to retain particles of breathing size such as Cyclones.

b) The total alpha technique is not adequate to apply those limits for concentration. It is necessary a additional technique that allow discriminat the contribution from thorium, radium and uranium.

c) Since the dose equivalent values are greater than 3/10 of the primary limit, it is recommended a individual monitoring program using personal air sampler and/or bioanalysis.

3) The Company should execute cost-benefit analysis to obtain a conclusive solution for the radiological problems.

MESURES DANS UNE MINE D'URANIUM DE LA GRANULOMETRIE DES AEROSOLS ET DES DESCENDANTS DU RADON

D. BOULAUD, J.C. CHOUARD

CEA/Institut de Protection et de Sûreté Nucléaire
DPEI/SERAC/LPMA, BP 6, 92265 FONTENAY-AUX-ROSES CEDEX, France

SUBMICRON-SIZED AEROSOL AND RADON PROGENY MEASUREMENTS IN A URANIUM MINE

Submicron-sized aerosol was studied in a uranium mine using an Electrical Aerosol Analyzer and a Differential Mobility Particle Sizer. In addition radon progeny particle size distributions were measured using a prototype instrument developed by us (SDI 2000). The number weighted mean electrical mobility diameters and the geometric standard deviations ranged respectively from 0.05 to 0.1 μm and 1.8 to 2. The gross alpha activity weighted mean thermodynamic diameters ranged typically from 0.1 to 0.2 μm .

INTRODUCTION

La seconde campagne européenne d'intercomparaison des méthodes de mesure du radon s'est déroulée du 29 juin au 7 juillet 1989 sur le siège minier de Bellezane (Division Minière COGEMA de La Crouzille, France) [1]. La section de la galerie est de 10 m² avec des vitesses moyennes d'air de l'ordre de 1,3 m/s. Au cours de cette campagne, la caractérisation de la granulométrie des aérosols était assurée ainsi que la mesure de la distribution en dimension de l'activité alpha globale. L'objet de cet article, outre la caractérisation de l'aérosol d'une mine d'uranium, est de montrer comment ces deux mesures peuvent être reliés.

METHODES DE MESURE - APPAREILLAGES

Mesure de la distribution en dimension de l'aérosol

Deux dispositifs fondés sur les propriétés électriques étaient utilisés :

- l'analyseur électrique d'aérosol (EAA modèle 3030 de TSI, St Paul, Mn, USA),
- l'analyseur différentiel de mobilité électrique (DMPS modèle 3932 de TSI, St Paul, Mn, USA)

EAA : Le principe de comptage et de sélection en dimension de ce dispositif est basé, premièrement sur un processus de charge des particules par un nuage d'ions unipolaires, deuxièmement sur une mesure de la distribution en mobilité électrique des particules ainsi chargées. La connaissance de la loi de charge permet alors de remonter à la distribution en dimension de l'aérosol. Le domaine effectif de mesure s'étend de 0,01 à 1 μm . Dans notre application, cet appareil fonctionnait automatiquement, une mesure étant effectuée toutes les 15 minutes. Un PC assurait à la fois la commande, l'acquisition et le stockage des données. L'EAA nous fournissait l'évolution au cours du temps de la distribution en dimension numérique de l'aérosol, caractérisée principalement par le diamètre médian numérique, l'écart type géométrique et la concentration en nombre.

DMPS : Le principe de sélection en dimension de ce dispositif est basé, premièrement sur un processus de mise à l'équilibre de

Boltzmann des particules par passage au travers d'un nuage d'ions bipolaires, deuxièmement sur une mesure de la distribution en mobilité électrique en utilisant un analyseur différentiel qui permet une meilleure résolution que l'EAA. La détection des particules est assurée en aval de l'analyseur par un compteur de noyaux de condensation (CNC, TSI, 3030, St Paul, Mn, USA). Ce dispositif permet de couvrir un domaine s'étendant de 0,008 à 0,4 μm . Le DMPS nous fournissait le diamètre médian numérique et l'écart type géométrique de l'aérosol.

Mesure de la distribution en dimension de l'activité alpha globale

Nous avons utilisé un prototype développé par nos soins et dénommé SDI 2000 (Spectromètre Diffusionnel et Inertiel). Il permet de couvrir un vaste domaine de dimensions s'étendant de 0,0075 à 15 μm en diamètre. Une description complète du SDI 2000 a déjà été publiée [2, 3]. Ci-dessous, on trouvera une description succincte des principaux composants et du fonctionnement. La partie inertielle est constituée d'un impacteur en cascade de huit étages (ANDERSEN mark II) dont les diamètres de coupure s'échelonnent entre 0,35 et 7,5 μm pour un débit nominal de 28,3 l/min. La partie diffusionnelle est constituée par six tubes disposés en parallèle qui contiennent des lits granulaires ayant des hauteurs et des diamètres de billes différents. Dans notre application particulière, l'impacteur était réduit aux trois derniers étages et un canal de la batterie de diffusion était neutralisé. De plus, un ensemble de grilles, dimensionné pour piéger la fraction libre des descendants du radon était placé en amont du SDI. Dans ces conditions, le domaine couvert s'étendait de 0,01 à 2 μm . Pour ce type de dispositif associant un impacteur à une batterie de diffusion, les dimensions caractéristiques sont soit aérodynamique (impacteur), soit thermodynamique (batterie de diffusion). Ceci signifie que pour un dépôt majoritairement dans l'impacteur on détermine un AMAD (Activity Mean Aerodynamic Diameter) et que pour un dépôt majoritairement dans la batterie de diffusion on accède à un AMTD (Activity Mean Thermodynamic Diameter). Après la mesure, l'ensemble des filtres et des plaques de collection étaient récupérés et analysés par comptage alpha. Les chaînes de comptage se composaient d'un détecteur de silicium implanté et d'une échelle de comptage multivoie couplée à un calculateur. Du fait des délais dans le démontage du SDI et la récupération des différents échantillons, la distribution en dimension des descendants du radon est représentée en activité alpha totale, car il n'est pas possible d'accéder à la distribution des différents descendants du radon.

RESULTATS EXPERIMENTAUX

Noyaux de condensation

La concentration en noyaux de condensation a été mesurée en continu durant toute la durée de l'intercomparaison. Celle-ci a varié entre 30 000 et 200 000 particules/cm³ avec des valeurs moyennes par demi-journée comprises entre 60 000 et 90 000.

Distribution en dimension de l'aérosol

Pour une journée représentative, on a représenté sur la figure 1 les variations du diamètre moyen numérique de l'aérosol

à partir des mesures effectuées avec l'EAA et le DMPS. On constate que l'amplitude de ces variations est faible et qu'elles sont bien reproduites simultanément par les deux dispositifs. Néanmoins, un léger écart est observé entre les deux appareils. Les variations de l'écart type géométrique sont très faibles et celui-ci est typiquement compris entre 1,8 et 2.

Distribution en dimension de l'activité alpha globale

A titre d'exemple, on a représenté sur la figure 2 une distribution en dimension de l'activité alpha globale obtenue au cours de la même journée (mesure à 16 heures) à partir des prélèvements effectués avec le SDI 2000. Au cours de cette étude, les mesures au SDI et au DMPS étaient simultanées.

DISCUSSION

Afin de relier les deux types de mesures décrites dans le paragraphe précédent, on peut, à partir de la distribution en dimension numérique obtenue au DMPS, calculer la distribution en dimension de la fraction attachée des descendants du radon, en utilisant les éléments théoriques permettant de décrire l'attachement. Ces développements théoriques ont fait l'objet de nombreux travaux que nous ne rappellerons pas ici [4, 5]. Le coefficient d'attachement utilisé est celui introduit par Porstendorfer [6], avec comme valeur du coefficient de diffusion de la fraction libre pour le ^{218}Po , celle qui est couramment admise (0,068 cm^2/s [5]). Sur la figure 3, on a donc porté les valeurs des diamètres moyens en activité alpha globale obtenus directement avec le SDI et les diamètres moyens de la distribution en dimension de la fraction attachée des descendants du radon calculée à partir de la distribution en dimension numérique obtenue au DMPS. On constate que pour nos conditions expérimentales, l'accord est très satisfaisant et que le calcul de l'attachement des descendants du radon à partir d'une distribution en dimension numérique permet de restituer une distribution en dimension tout-à-fait comparable à celle de l'activité alpha globale obtenue avec le SDI.

MANAGEMENT OF OCCUPATIONAL EXPOSITION
OF CONTRACTORS' WORKERS

Abstract :

In order to improve the dosimetric follow-up of the contractors' workers and for a fair application of the ALARA principle, EDF has developed a computerized file for occupational doses (collected by electronic dosimeters). Contractors will be associated to the use of the system. In its contracts, EDF is also providing for an improved quality and supervision of the workers' education and training.

I - LE PROBLEME DES TRAVAILLEURS DES ENTREPRISES
EXTERIEURES DANS LE CYCLE ELECTRONUCLEAIRE FRANCAIS

Entre 1985 et 1990, on peut estimer que le bilan de l'exposition collective des travailleurs dans le cycle électronucléaire français est passé de 110 à environ 150 H.Sievert. La part des travailleurs des entreprises extérieures qui était inférieure à 50 % de l'exposition totale en 1985 s'est accrue progressivement pour atteindre près de 70 %, soit environ 100 H.Sievert en 1990.

La quasi-totalité de cette exposition apparaît concentrée dans deux maillons du cycle : les centres de retraitement et les centrales nucléaires. La part de ces dernières est prépondérante dans l'exposition des travailleurs des entreprises extérieures, plus de 90 % en 1990. Cette situation n'est pas surprenante lorsque l'on sait que les travaux de maintenance des réacteurs sont réalisés pour l'essentiel par ces entreprises et que le volume des travaux s'accroît avec le vieillissement du parc (révisions quinquennales, décennales, remplacement de générateurs de vapeur...). Ainsi en 1990, les travailleurs de ces entreprises ont reçu 82 % de l'exposition collective engagée dans les réacteurs à eau pressurisée d'EDF, soit 92 H.Sv sur 113 au total.

En France, du point de vue réglementaire, le contrôle des doses reçues par les travailleurs des entreprises n'est pas du ressort de l'exploitant mais de la responsabilité de leur employeur. Ces contrôles se font par

films dosimétriques mensuels dépouillés par des laboratoires contrôlés par le Ministère de la Santé. Mais l'exploitant n'est pas habilité à connaître les doses, qui sont couvertes par le secret médical et ne peuvent être communiquées qu'à des médecins. Si l'on ajoute à cela les délais de dépouillement de la dosimétrie réglementaire, la mobilité des travailleurs, le rattachement de certaines entreprises à des Services communs de médecine du travail, et il faut le dire la fraude qui peut être le fait d'employeurs peu scrupuleux comme d'ailleurs de travailleurs -surtout intérimaires- plus soucieux de conserver un emploi bien rémunéré que de protéger leur santé, on prend la mesure de la méconnaissance des doses réelles.

Une enquête du CEPN réalisée en 1989 auprès d'un échantillon d'entreprises a permis d'estimer la distribution des doses individuelles des travailleurs extérieurs sur la période 1985-1988. Le pourcentage, d'opérateurs exposés dont la dose annuelle dépasse 15 mSv fluctue entre 25 et 45 % ; celui des opérateurs dont la dose annuelle dépasse 20 mSv fluctue entre 16 et 32 %. Les spécialités concernées par ces fortes doses sont aussi bien celles d'opérateurs très qualifiés amenés à opérer dans des zones pénalisantes (boîtes à eau de générateurs de vapeur) que d'opérateurs beaucoup moins qualifiés comme les calorifugeurs ou les agents de servitudes.

II - MOYENS MIS EN OEUVRE PAR EDF

Face à cette situation préoccupante*, EDF a été conduite à prendre un certain nombre de mesures de sa propre initiative, en dehors du contexte réglementaire ; d'une part afin d'assurer aux travailleurs le même degré de protection qu'à son propre personnel, d'autre part en vue de se doter d'outils lui permettant de mettre en oeuvre une véritable politique d'optimisation de la radioprotection.

Par ailleurs, l'abaissement futur des limites de dose en application de la CIPR 60 (révision de la Directive CCE/EURATOM 80/836) est un motif supplémentaire d'améliorer le suivi dosimétrique des agents d'entreprises extérieures.

EDF a généralisé depuis plus de 10 ans l'usage des dosimètres électroniques. Tout agent -EDF ou entreprise- pénétrant en zone contrôlée en est doté ; la dose est lue automatiquement quand l'agent sort de la zone et lui est affectée par un système informatique. Ceci permet la gestion des doses du personnel fixe de la centrale, et du

* La Commission des Communautés Européennes s'est d'ailleurs saisie du problème au plan européen et a publié une Directive (90/641 EURATOM) pour améliorer la surveillance dosimétrique de ces travailleurs.

personnel d'entreprises pendant son séjour sur un site de centrale. Mais le système est actuellement limité car :

- 1 - la gestion est locale : un travailleur qui change de site repart à zéro ; seules sont contrôlées les doses reçues sur le site (sachant que c'est l'employeur -avec son médecin du travail- qui est responsable du respect des limites annuelles).
- 2 - quand on tente des recoupements avec les résultats obtenus sur plusieurs sites, on se heurte fréquemment au problème de l'identification correcte des travailleurs ; les sources d'erreur sont en effet nombreuses.

Un premier pas vient d'être franchi avec la mise en place d'un *fichier national* (DOSINAT) regroupant les données de dosimétrie opérationnelle*. Ce fichier pourra être interrogé par toutes les centrales. Le système comprend des procédures de contrôle et de validation des identités pour éviter les écueils mentionnés ci-dessus. Ce fichier mis en service en 1992 sur 2 sites pilotes, va être très rapidement étendu à tous les sites.

Mais cette démarche est encore insuffisante. En effet, EDF n'est pas le seul exploitant nucléaire en France. Des contacts ont été pris pour étendre la portée du fichier en y incluant les sites du groupe CEA (Commissariat à l'Energie Atomique).

Ce fichier présente aussi un grand intérêt pour les entreprises prestataires elles-mêmes confrontées au problème de connaître rapidement les doses pour pouvoir gérer leur personnel ; elles sont également sollicitées par leurs clients étrangers pour fournir l'état des doses reçues par les travailleurs et se trouvent souvent dans l'incapacité de le fournir.

III - GENERALISATION DE LA DEMARCHE : L'ASSURANCE DE LA QUALITE - DEVELOPPEMENT DES RELATIONS CONTRACTUELLES

Pour aller plus loin dans la démarche d'optimisation de la radioprotection des travailleurs

* Nota : la dosimétrie opérationnelle ne donne pas nécessairement les mêmes valeurs que la dosimétrie réglementaire par film (seule légale en France), et pourrait être -dans le contexte français- une source de conflits. En fait, il faut comprendre que la dosimétrie opérationnelle restera un moyen de gestion, capable de permettre l'optimisation des doses et d'attirer l'attention sur les travailleurs approchant d'un "niveau d'investigation" à définir avec les services médicaux.

extérieurs, il faut pouvoir compter sur des partenaires industriels sérieux ; les abus liés à l'utilisation d'intérimaires sans formation sont en effet connus.

Pour obtenir des progrès sensibles, il faut un personnel sensibilisé et bien formé. Et cette formation doit être soumise aux règles d'assurance de la qualité, donc contrôlée*. Par ailleurs, l'abaissement des normes de radioprotection va conduire à accroître le nombre des travailleurs pour certains postes plus particulièrement exposés -si des moyens de réduction de doses (robots par exemple) ne peuvent être mis en oeuvre. On ne peut exiger des entreprises cet effort de formation sans leur garantir en contre-partie un volant de travail suffisant même pour les travailleurs ayant atteint un seuil de dose déterminé : ces travailleurs devront être employés en zone non nucléaire. Ceci conduit à développer les relations contractuelles avec les entreprises, ce qui devrait se traduire par une amélioration des conditions de formation et une réduction des doses individuelles.

Les acteurs seront en effet bien identifiés, les temporaires sans formation ne pourront plus être employés pour les travaux les plus exposés ; les clauses contractuelles -avec risque d'exclusion- seront claires sur ce point.

Conclusion :

En résumé, la création d'un fichier national, associant progressivement les principaux exploitants nucléaires français, et auquel auront accès -sous certaines conditions- les entreprises prestataires qui le souhaiteront, devrait permettre de mieux connaître les doses de la plupart des travailleurs et d'assurer correctement leur suivi dosimétrique en temps réel. L'association avec des clauses contractuelles, "moralisant" les relations avec les entreprises, donnant une importance essentielle à l'assurance de la qualité, devrait permettre globalement une meilleure protection des travailleurs extérieurs, objectif conforme aux vœux de la Communauté Européenne. On pourrait en outre souhaiter qu'un fichier communautaire voit rapidement le jour.

* Les moyens prévus dans cette optique sont développés dans la communication n°350 de M. MARILLIER sur le CEFRI.

NUCLEAR POWER IN SWEDEN - DOSES, RELEASES AND ACTIONS

J.Valentin, P.Hofvander, C.Hägg, L.Malmqvist, B.Å.Persson

Swedish Radiation Protection Institute (SSI),
Box 60204, S-104 01 Stockholm, Sweden

ABSTRACT

Some 5,000 workers at 12 units get a mean annual effective dose of 2-3 mSv corresponding to a collective dose of c. 2 man Sv per GW. Annual critical group doses from environmental releases are 0.001-0.015 mSv, public collective doses c. 5 man Sv per GW. A steam generator replacement, 1989, did not change this picture. During the 1980ies, filtered containment venting systems were installed and an organisation for local measurements of gamma dose rate established.

BACKGROUND

The Swedish nuclear programme consists of 12 light water reactors producing about half of the electric power in Sweden. Nuclear power is scheduled for phaseout by 2010, but no starting date is fixed for the phaseout.

The energy availability factor has been in the range of 75-90 %. Some years, utilisation has been about 10 % lower than availability, due to well-filled water reservoirs and low power demand in mild winters. The low annual number of scrams per reactor decreased further in 1990 to 1.7, with no triggered scram at all at 3 reactors. Most scrams originated in conventional systems, not the reactor process system.

THE SYSTEM OF DOSE LIMITATION

Current regulations are based on ICRP 26 (1). However, for workers supplementary dose limits enacted 1989 for age 30 (180 mSv) and lifetime (700 mSv) correspond to a mean of 15 mSv annually. As a level of ambition the annual collective worker dose should not exceed 2 man Sv annually per GW installed capacity. Releases must not cause annual doses exceeding 0.1 mSv to members of critical groups. The annual collective dose should not exceed 5 man Sv per GW installed.

A common centralised dose registration system is operated and used by all nuclear power plants. Internal exposure, checked at the plants by whole-body measurements, has so far been insignificant compared to external exposure.

ANNUAL OCCUPATIONAL EXPOSURES

Data on the nuclear programme and average effective doses are given in Table 1. For individual doses, utility employees have slightly but significantly lower doses than

contractors. No dose since 1981 exceeds 50 mSv per year. Normalised collective doses to staff are consistently in agreement with the regulatory level of ambition, 2 man Sv per year. Internationally, the doses are low, cf. (2).

Table 1. Occupational exposure data at Swedish light water reactors, 1981 - 1990

Year	Number of reactors	Installed capacity (Gw)	Energy generated (Gwa)	Number of exposed workers(a)	Annual individual mean dose (mSv) for utility	Annual individual mean dose (mSv) for contractors	Annual collective dose (man Sv) per reactor	Gwa(b)	Gw(c)
1981	9	6.4	4.5	4,154	2.9	3.3	1.5	3.2	2.1
1982	9	7.3	4.3	3,766	2.3	2.6	1.1	2.3	1.5
1983	10	7.4	4.6	4,774	2.6	3.2	1.5	3.2	2.0
1984	10	7.4	5.8	4,584	2.5	2.5	1.2	2.0	1.6
1985	12	9.5	6.7	4,674	1.8	2.6	0.9	1.7	1.2
1986	12	9.5	8.0	5,688	2.1	3.4	1.4	2.1	1.5
1987	12	9.7	7.7	5,815	1.9	2.9	1.3	2.0	1.5

1989	12	9.9	7.5	5,449	2.0	3.2	1.3	2.1	1.6
1990	12	10.0	7.4	5,138	2.1	3.1	1.2	1.9	1.4

Notes: (a) Workers with recorded doses only
 (b) Energy generated
 (c) Installed capacity (ambition level: annual collective dose < 2 man Sv)

The steam generators at Ringhals unit 2 were replaced in 1989. The replacement took 72 days and caused a collective dose of only 2.9 man Sv (3). All doses due to this big project are included in Table 1. As can be seen, the project has not changed dose statistics compared to other years.

ACCUMULATED OCCUPATIONAL EXPOSURES

Accumulated effective doses at age 30 are recorded, and predicted lifetime doses shown, in Table 2. Two discriminators were used for lifetime dose prediction: 1) Only workers with a current accumulated dose exceeding 100 mSv were included (their number is given in Table 2), and 2) The dose had to be distributed over 5 or more years.

Lifetime doses were calculated as $E = (D_r + D_c)$, where D_r is the recorded dose during n years including 1990 at the latest, and D_c is the expected dose from 1991 up to age 65 calculated as $D_c = (t * D_r / n)$ where $t =$ years from 1991 to age 65, i.e. with the very conservative assumption of the same average annual dose all years as in past years.

Doses at age 30 have not exceeded the new 180 mSv limit since 1976 (but one foreign contractor was refused to work for this reason in 1991). A score of workers are predicted to hit the lifetime 700 mSv limit, but the prediction is not very realistic. Also, steps taken in response to the limit

Table 2. Accumulated effective dose (E) in mSv at age 30, currently and predicted for lifetime for Swedish nuclear industry workers

Occupational group	Dose at age 30			Current dose	Predicted total lifetime effective dose				
	Number with E >50	E >180	E max	Number with E >100	Number with E >700	E mean	E max	E median	SD E
Health physicists	33	2	222(a)	36	3	430	820	380	163

(b) Total number of workers with recorded dose >0.1 mSv in the underlying central dose register is 27,479

decrease doses further. Although ICRP disfavours lifetime dose limits, the new 100 mSv per 5 years limit (4) will also limit lifetime doses to 900 mSv. Few Swedish workers could accumulate 900 mSv, but several predicted mean lifetime doses exceed 400 mSv, the German lifetime dose limit (5).

EXPOSURES OF THE PUBLIC: RELEASES FROM NORMAL OPERATION

The left part of Figure 1 compares Swedish and international normalised activity releases, excluding air releases of H-3 and all C-14. On average, Swedish BWR releases are similar to other countries, while Swedish PWR releases are smaller than in other countries. The high BWR releases in 1980-1982 are mainly due to fuel damage at the Ringhals BWR unit and at Oskarshamn, causing large noble gas releases.

The right diagram shows effective doses to critical groups from Swedish plants including H-3 and C-14. All doses are far lower than the limit, 0.1 mSv. However, 3 of the 4 Ringhals units are PWRs, all other Swedish units are BWR. While PWR releases are smaller, PWR doses are higher, mainly due to lower smoke stacks causing a higher C-14 dose.

C-14 dominates the collective dose. Using a truncated 500-year time integral, the calculated C-14 collective dose is c. 48 man Sv annually, or up to c. 1.2 times the level of ambition of 5 man Sv per GW. All other releases together

give less than 0.1 man Sv.

EMERGENCY PREPAREDNESS

Since 1981, an extensive programme has introduced mitigating devices and a new severe accident handling strategy at the plants. For each reactor containment, filtered venting systems can be activated manually or automatically, in order to avoid heavy ground contamination even in severe accidents. There is a regulatory limit on accident releases through the filter of 0.1 % of the core inventory of particulate activity, normalised to an 1800 MW (thermal) reactor.

After Chernobyl, all counties and all 284 urban and rural districts in Sweden were equipped with gamma dose rate instruments with a range of 0.1 uSv/h to 10 mSv/h. Some 500 persons have been taught to use these and measurements are practiced at 7-month intervals at about 800 local reference points. Thus reference data with seasonal variations are obtained and handling proficiency retained. This supplements other means of rapid determination of radiation conditions. It would provide an important background for information to the public in accidental fallout situations.

Trombay, Bombay-400 085

ABSTRACT

Staff handling Radioluminous Paint (RLP) have been monitored for internal burden for the past ten years. The annual collective dose equivalent is found to vary from 20 to 268 man mSv in case of ^3H . The collective dose per TBq activity of ^3H is ranging from 0.54 to 7.72 man mSv. In case of ^{147}Pm the bioassay results indicated pulmonary burden in some of the workers. The effective dose equivalent is found below 0.1 mSv.

INTRODUCTION

Use of RLP in the country in past seven years has increased from 37 to 185 TBq in case of ^3H paint and 2 to 3.7 TBq in case of ^{147}Pm . Watch manufacturers import ^3H paint with specific activity varying from 0.07 to 18.5 TBq/kg. ^{147}Pm paint is manufactured in the country with specific activity of 70 GBq/kg. There are sixteen institutions actively using RLP with a work force of 100. These institutions use RLP in large quantity. At one place the paint is used in powder form. Their workplaces were routinely inspected and modified to reduce air, surface and personnel contamination. The luminizing jobs are now done in ventilated boxes (VB) & glove boxes (GB) installed in a ventilated room⁽¹⁾. Workers engaged in luminizing job, work with RLP in rotation for fixed interval of time varying from 15 to 90 days. The workers engaged in painting job are monitored continuously for internal burden.

METHOD/PROCEDURE OF MONITORING

Tritium concentration in air as HTO is measured by cold strip method and total tritium using continuous tritium monitor⁽²⁾. To remove tritium in particulate form, air was filtered through absolute filter paper and counted for ^3H concentration. ^3H workers are monitored before commencement and soon after stopping the work with RLP. ^3H burden is estimated by urine analysis, by taking biological half life $T_b=7$ days or actual T_b of the workers. The urine samples from outstation institutions are received by post at regular intervals. ^{147}Pm concentration present in particulate form in air is measured by filtering large volume of air through absolute filter paper and counting ^{147}Pm betas on it with a calibrated end window type GM counter. ^{147}Pm workers are called to Trombay for monitoring once in a year soon after stopping the work with RLP. ^{147}Pm body burden is measured by estimating activity in liver using Phoswich Detector⁽³⁾ (counting the bremsstrahlung) and also by carrying

out bioassay. RLP workers have been monitored continuously over a period of 10 years.

RESULTS AND DISCUSSION

Regular personnel monitoring, periodic inspection of the workplaces and modifications carried out in working areas have resulted in a significant reduction of annual dose to radiation workers. In institution 'A' where the luminizing operation is dusty, the annual Dose Equivalent (ADE) in the year 1981-82, was in the range 8.2 to 16.2 mSv, is now, in the range 0.07 to 3.5 mSv (Table I). The use of GB/VB for luminizing job and the improvement in ventilation system to create 5 to 12 air changes in the workshop was recommended. This change has brought down the HTO concentration during working hours to 40 kBq/m³ from 1200 kBq/m³ of air. A worker in this air concentration would receive ADE of about 2.5 mSv. It can be seen in the table I that in most of the workers, the ADE in 1988 is less than 3 mSv. During the monitoring programme, ³H concentration in urine samples indicated the concentration varying from 3.7 to 370 kBq/l of urine. There were instances when ³H concentration in few workers exceeded the level of 370 kBq/l of urine. The maximum ³H concentration in urine which was detected at any time in any subject was 2.5 MBq/l of urine. The investigations revealed that the ventilation system was not operative during the period of higher internal burden. It was evaluated that with the ventilation system OFF, the HTO concentration can rise to 330-370 kBq/m³ of air⁽⁴⁾. This may increase the urine concentration by a factor of ten. In institution 'B' large quantity of RLP (92.5 TBq) with specific activity 18 TBq/kg is in use and is currently being modified. The monitoring programme was started in 1987 and systematic studies were initiated in 1988. The ADE in these workers ranged from 4.35 to 23.53 mSv (Table II). In 1990 the ADE received by most of the workers was in the range of 0-10 mSv whereas in 1988-89, it was 10 to 20 mSv. Here HTO concentration in urine was usually in the range of 10 to 100 kBq/l. There were also instances when HTO concentration was higher than the usual level. In two cases the levels were estimated to be 2.58 & 3.8 MBq/l. Air monitoring results showed HTO concentration at this place to be in the range of 101 to 210 kBq/m³ of air. This contamination also has

Table III: Level of fecal activity detected.

Range of act. Bq/24 h	0-1.0	1.0-2.0	2.0-3.0	3.0-4.0	4.0-5.0
No. of workers	8	1	1	2	2

been brought down by improving ventilation system and use of GB/VB. This relatively higher internal burden in these workers is probably due to two reasons. Firstly, the period of rotation is as long as 90 days. Secondly, the quantity and the specific activity of paint used is large.

Whole body counting of ^{147}Pm did not show any liver burden in workers. However fecal analysis indicated some activity in a few workers. Activity was not detected in any urine sample. Repeat measurements after five days did not show reduction in fecal activity. Lung burden was evaluated from fecal activity assuming $T_b=500$ days in lung. It was found to range from 0.4 to 5.2 kBq (Table III). In all other cases the pulmonary burden was below the detection limit of the counting set-up which is 0.89 kBq. The ^{147}Pm paint supplied to the institutions is an oxide compound which is insoluble in body fluid. The activity in fecal samples is the activity which is being eliminated from the lung. In most of the cases the exact date of intake is not known, as they reported for monitoring very late after stopping the work with paint. After the improvement in ventilation system the air concentration is 1.2 MBq/m^3 . Some times when the room is dry swept, the air contamination rises to a level of 2.3 MBq/m^3 , higher than DAC for ^{147}Pm (2 kBq/m^3).

CONCLUSION

Use of RLP in the country is safe. The internal burden in the workers is well within the limit provided the radiation safety procedures are followed. There are about 76 workers engaged in tritium work and collective dose evaluated from monitoring data of two institutions works out to be 20 and 268

man mSv. There were two cases of excessive exposure due to ^3H . In one subject it was 120 mSv and in the other it was 210 mSv. However these workers were laid off from the radiation job. The annual internal dose received per person due to ^3H in year 1988 was 0.24 mSv which is one eighth of the annual dose received per year in USA(5). In 1989 it was 3.5 mSv. The main contribution is due to institution 'B' which is under modification. In case of ^{147}Pm paint, the number of workers are less and have insignificant lung burden. The collective dose is much less. Internal burden can further be brought down by improving the ventilation system as per the activity handled and allotting the painting job in rotation to workers. Surface contamination was observed in all the workplaces, therefore cleanliness and periodic decontamination of the workplace will also reduce the annual dose to workers. No liver burden was observed in recent years, but in 1982 there were three cases with liver burden ranging between 10.7 to 27.4 kBq(6). ^{147}Pm workers receive external exposure mainly due to bremsstrahlung but well within the limit. These results will be presented separately.()

ACKNOWLEDGEMENT

Authors gratefully acknowledge the help given by Dr. R.C.Sharma, Head of the Internal Monitoring Section of Health Physics Division in providing the Whole Body Monitoring results from 1980 and sincere thanks are due to Mr. M.Rathnakaran of Environment Assessment Division for loaning the tritium monitor.

---000---

The plutonium recycling in LWR was adopted by several european countries right from the early 70's. At that time, France elected to develop the breeders. Some years later, when the economic conditions led to postpone the building of breeders, recycling in PWR was decided in France.

MOX fuel was introduced firstly in Saint-Laurent-des-Eaux 900MWe reactor (unit 1) as an industrial product. Since five reactors are dedicated to plutonium recycling; the core management scheme consists of reloads containing 16 MOX fuel (i. e. a third of the renewed assemblies). Sixteen PWR units are authorized to such a recycling and could be used by the year 1997.

As far as radioprotection is concerned, the fresh MOX fuel emits neutron and gamma rays when enriched uranium fuel emission is almost negligible.

In files established to obtain a generic authorization for MOX use it has been demonstrated that the collective doses corresponding to the complete fuel cycle were quite similar for MOX and for enriched uranium fuel. This fact has been confirmed by experience; MOX fuel fabrication and handling do not induce penalty in comparison with uranium mining and implementation.

To reduce doses for operators in the EDF power plants, a new handling system of fresh fuel has been conceived. the controls concerning fresh fuel receipt have been modified to make shorter the operator exposition time and screens are used to decrease the level of radiations.

---000---

Dès le début des années 1970, plusieurs pays européens optaient pour le recyclage du plutonium dans les réacteurs à eau légère. La France, en choisissant le développement des réacteurs surrégénérateurs, trouvait là une voie d'utilisation du plutonium issu des usines de retraitement provenant des Réacteurs à Eau sous Pression (REP) et des réacteurs de la filière Uranium Naturel Graphite Gaz (UNGG). L'évolution différée de la filière des réacteurs surrégénérateurs a conduit la France en 1985 à s'engager dans la voie du recyclage du plutonium dans les réacteurs REP. Cette possibilité avait été prise en compte dès la conception du palier REP 900 MW, tant sur le plan technique qu'administratif. Seize tranches REP 900 MW sont actuellement disponibles pour ce type de fonctionnement. Dans l'avenir, 12 tranches REP 900 MW et quelques tranches REP 1300 MW pourraient compléter ce parc. La première tranche REP 900 MW a été chargée en 1987 et aujourd'hui, cinq tranches fonctionnent de manière industrielle en cycle mixte, selon une stratégie de rechargement par tiers de coeur. Deux de ces tranches ont un coeur à l'équilibre. La stratégie de rechargement par tiers de coeur conduit à renouveler le tiers des éléments combustibles lors de chaque campagne, en les remplaçant, en cycle mixte par un tiers de combustible MOX (4,5 % de PU) et deux tiers de combustible standard (3,25 % d'U5). Les irradiations de décharge des lots de combustible sont de l'ordre de 33.000 MWj/t, ce qui correspond à 300 JEPP.

Le tableau qui suit donne le bilan comparatif de la dosimétrie engagée selon les deux voies, combustible standard (cycle UO₂) et combustible mixte (cycle MOX).

Transport Assemblages		0,13	
Réacteur	87,00	90,10	
Retraitement	16,40	19,70	
BILAN TOTAL	190,69	190,13	

* Ce chiffre résulte:

- du coût dosimétrique de l'extraction d'uranium naturel,
- et d'une part du coût dosimétrique du retraitement pour le plutonium.

Avant d'analyser les chiffres présentés dans ce tableau, un rappel élémentaire des données radiologiques s'impose.

Le combustible standard est constitué d'uranium enrichi à 3,25 %. Provenant directement de l'uranium naturel,

Le MOX est actuellement fabriqué à partir de plutonium provenant du retraitement du combustible UNGG. Sa composition isotopique évoluera donc lorsqu'il sera utilisé en aval du retraitement du combustible REP. Enfin le MOX est actuellement élaboré à partir d'uranium naturel appauvri lors du processus d'enrichissement (et non d'uranium de retraitement).

Le Plutonium sous ses différentes formes isotopiques :

- est un émetteur alpha. Il émet 10 à 100 fois plus de rayonnement alpha que l'uranium,
- est un émetteur bêta par l'intermédiaire de l'isotope 241 lors de sa désintégration en américium,
- est un émetteur gamma par la présence d'américium 241 provenant de la désintégration du plutonium 241,
- et est enfin un émetteur neutron par les fissions spontanées de la plupart des isotopes ou par les conséquences des réactions nucléaires qui se produisent lorsque des atomes d'éléments plus légers sont bombardés par des particules alpha de haute énergie (provenant par exemple du plutonium 238 et plutonium 240).

Les rayonnements alpha et bêta ne sont nocifs que lorsque le plutonium s'introduit dans le corps humain, ceci ne concernant que les situations accidentelles d'inélançabilité de stockage qui ne sont pas traitées dans cet exposé. En fin de cycle (33.000 MWj/t) le Mox ne se distingue pas significativement du combustible standard qui contient alors 1% de plutonium provenant de la transformation de l'Uranium 238.

Les émissions de rayonnements gamma ou neutrons obligent à prévoir

- une protection physique supplémentaire à certains stades du processus industriel,
- une automatisation ou des techniques d'examen ou de maintenance adaptées afin de limiter les temps d'exposition.

Il ressort donc, malgré les incertitudes entachant les valeurs présentées, que les doses collectives engagées par tonne de combustible irradié sont du même ordre de grandeur pour les deux cycles de combustible.

Les doses intégrées dans les réacteurs et les usines de retraitement sont voisines pour les deux types de combustible.

Les doses plus importantes dans les usines de fabrication du combustible MOX, relativement aux usines de fabrication du combustible standard, sont compensées par les doses économisées dans les mines et les usines de conversion.

Si l'on fait abstraction de l'enrichissement pris ici au titre du retraitement du combustible standard irradié, le bilan dosimétrique pour le MOX s'établit à 150 mSv par tonne de combustible. L'analyse des écarts par rapport au cycle du combustible standard fait apparaître des postes en augmentation. Ce sont les étapes de fabrication, d'exploitation en réacteur et de retraitement (toutes activités confondues).

La fabrication de ce combustible se fait actuellement dans l'usine BELGO-NUCLEAIRE située à DESSEL en BELGIQUE. Cette usine ne pouvant assurer la fabrication de la quantité de combustible suffisante, sera à terme relayée par l'usine française MELOX implantée à MARCOULE. On peut considérer que les chiffres de dosimétrie ne changeront pas de manière significative dans la mesure où deux paramètres agiront de manière antagoniste. Cette usine mettra en oeuvre un processus de fabrication qui diminuera le bilan dosimétrique, cependant, il est probable que la dégradation qualitative du plutonium de retraitement (augmentation du burn-up) réduira les gains escomptés.

S'agissant de la phase d'exploitation en réacteur, l'écart peu significatif (3 mSv par tonne de combustible) a pour principale origine la manutention du combustible MOX en centrale nucléaire lors de sa réception. Le combustible MOX est livré par transport routier spécial, accompagné. Deux livraisons sont nécessaires pour un rechargement du coeur (16 éléments MOX). Chaque livraison comprend en général quatre containers renfermant chacun deux éléments combustibles. Chaque container est instrumenté afin de mesurer avant son ouverture l'éventuelle occurrence de chocs lors du transport. L'effectif du personnel présent lors des opérations de réception est limité à 8 personnes. Des contrôles dosimétriques gamma et neutrons sont effectués sur le container avant l'ouverture. Après ouverture, un contrôle dosimétrique gamma et neutron est effectué au contact des éléments combustibles MOX. Les éléments combustibles sont ensuite basculés en position verticale et manutentionnés un à un, afin de réaliser une opération de contrôle élémentaire avant l'immersion en piscine. Un poste d'examen a spécialement été conçu afin que tout le chemin effectué par l'élément combustible ne se fasse pas à une hauteur supérieure à 70 cm (2,3 feet). Cette disposition permet de prévenir les risques en cas de chute de l'élément combustible. Le contrôle élémentaire a pour seul objectif de s'assurer qu'aucun corps étranger ne se trouve entre les crayons combustibles. Les contrôles de qualité et dimensionnels sont effectués en usine de fabrication du combustible, cette stratégie étant validée par les résultats. Le poste d'examen en centrale nucléaire est blindé afin de réduire les effets des rayonnements gamma et neutrons. Il est équipé d'un poste d'observation optique par binoculaire et miroirs coulissant de bas en haut afin d'examiner les quatre faces de l'élément combustible. Après ce contrôle, l'élément combustible MOX est immergé en piscine avant son transfert dans le coeur du réacteur. Le stockage sec est exclu.

La phase complète d'ouverture d'un container, de contrôle, et d'immersion des deux éléments combustibles MOX dure en moyenne xx minutes.

Les appareils de mesure utilisés par Electricité de France pour ces opérations sont :

- le compteur FAG FH 40 (SOCIETE NARDEUX) pour le débit de dose gamma,

- le compteur DINEUTRON (SOCIETE NARDEUX) pour le débit de dose neutron. Ce compteur effectue directement la conversion neutron-gamma sur la base de la courbe de la CIPR (gamme d'énergie de 0,025 ev à 15 Méga ev).

Seize réceptions de combustible ont déjà été réalisées dans la centrale nucléaire de Saint-Laurent-des-Maux. la valeur moyenne des doses mesurées est de 3,3 mSv par tonne de combustible.

Le retraitement enfin fait apparaître un bilan dosimétrique plus fort en ce qui concerne le MOX. Cet aspect est directement lié à la composition du combustible MOX en fin de cycle. Le combustible MOX contient, à burn-up égal (33.000 MWj par tonne) 4 % de plutonium, alors que le combustible standard ne renferme que 1 % de plutonium. Les deux pourcentages cités étant à pondérer dans leurs effets radiologiques par la composition isotopique qui est défavorable pour le MOX.

Le dossier de faisabilité établissait que les doses collectives par tonne de combustible chargé en réacteur, pour le combustible standard à l'uranium enrichi et pour le MOX, devaient être comparables. L'expérience acquise confirme donc ce point. Les doses résultant de la fabrication du MOX en usine et de sa manutention en centrales nucléaires sont compensées par les doses liées à l'extraction et à la conversion de l'uranium naturel.

SPECIFICATIONS DE BLINDAGE PRIMAIRE ET SECONDAIRE POUR
LES SALLES DE RADIOGRAPHIE INDUSTRIELLE MUNIES
D'IRIDIUM 192 SELON LES LIMITES DE DOSES
EFFECTIVES ANNUELLES D'ICRP 60

Jean-Marc Légaré

Ministère de l'Environnement du Québec,
6072 est, rue Sherbrooke
Montréal, Québec, Canada H1N 1C1

PRIMARY AND SECONDARY SHIELDING SPECIFICATIONS FOR INDUSTRIAL
RADIOGRAPHY ROOMS WITH IRIDIUM 192 ACCORDING TO ICRP 60
ANNUAL EFFECTIVE DOSE LIMITS

The correlation between the HVL of large fields coming out of various shielding thicknesses of exposure rate transmission curves and the conversion coefficients [Effective dose equivalent/100 Exposure] for an AP anthropomorphic phantom (ICRP 51, 1987) is first determined. These factors are then applied to free air primary, scatter and leakage exposure dose rates and transmission fractions for lead, steel and concrete. The results are then used to obtain the table of shielding specifications for primary, scatter and scatter with 0,1% 1% and 10% leakage for various distances and weekly workloads to meet the average yearly effective dose limits of 20 and 1 mSv per year of ICRP 60 (1991).

INTRODUCTION

Le but de ce travail est d'établir les spécifications de blindage pour l'iridium 192 afin de rencontrer les limites de doses effectives annuelles moyennes de 20 et 1 mSv par année de ICRP 60 (3) pour l'exposition AP d'un mannequin selon ICRP 51 (2).

PROCÉDURE

La procédure utilisée est la suivante:

1. Faire sur la figure ci-jointe le graphique des CDA expérimentales de plomb, d'acier et de béton pour des grands champs très filtrés en fonction de l'énergie équivalente des rayons (4, 5 et 7). Ajouter sur cette figure le graphique de la fraction [Equivalent de dose effective en Sv/100 Exposition en R] d'un mannequin AP selon ICRP 51 (2). Ceci nous donne donc les facteurs de conversion [EDE/100 Expos.] pour diverses CDA à la sortie de diverses épaisseurs de blindage présélectionnées sur toute courbe de transmission.
2. Choisir une charge de travail hebdomadaire donnée de 4800 Ci h (640 000 TBq s) par semaine pour l'iridium 192 et calculer à 1,0 m de distance pour ces épaisseurs de blindage présélectionnées, les produits [Débit d'exposition primaire de 500 mR/h Ci (7) ou diffusé de 22 mR/h Ci x Fraction d'exposition primaire (1) ou diffusée (6)] pour le plomb, l'acier ou le béton selon l'épaisseur de blindage présélectionnée x

Figure - Couches de demi-atténuation (CDA) de grands champs traversant le plomb, l'acier et le béton (4 et 7) en fonction de l'énergie équivalente d'exposition (5); coefficients de conversion [Equivalent de dose effective/100 Exposition] de grands champs sur un mannequin AP (2) en fonction de l'énergie (keV). L'EDE s'appelle maintenant la dose effective E (3).

Facteur de conversion [EDE/100 Expos.] pour les CDA au-delà des épaisseurs de blindage présélectionnées. On a fait les mesures au moyen de compteurs Berthold LB 1200 et Keithley 36150 étalonnés par sources radioactives (5). Les rayons diffusés à 90° avec l'axe central provenaient d'un mur de béton exposé à 45° alors que les rayons diffusés à 95° avec l'axe central provenaient du plancher de béton exposé perpendiculairement. La moyenne des rapports des débits d'exposition [diffusé (2 m)/ primaire (2 m)] était de 0,044 pour le cône de 60°, soit 1,7 fois le résultat d'un cône de 46° utilisé dans un autre projet relié aux expositions (6).

3. Faire pour chaque matériau, une figure de courbes de ces valeurs mSv/sem. en fonction de l'épaisseur des matériaux.
4. Répéter l'étape 2 pour les rayons de fuites dont les CDA s'obtiennent pour chaque épaisseur de blindage donnant 10%, 1% ou 0,1%, ajoutée des épaisseurs présélectionnées.
5. Additionner, pour chaque épaisseur présélectionnée, les équivalents de doses effectives par semaine de diffusion de l'étape 2 et de fuites (10% 1% ou 0,1%) de l'étape 4. Ajouter ces trois lignes sur la figure (non illustrée).

Spécifications de blindage pour l'iridium 192 pour réduire les doses effectives primaires, secondaires et diffusés à 90°-95°, à 0,40 et 0,02 mSv par semaine (20 et 1 mSv/année)

0,40	Piom b	16	14	13	11	9	7	5	4	3	
0,02	Piom b	24	22	20	19	17	15	13	11	9	
0,40	Acier	99	90	81	72	63	55	46	38	29	
0,02	Acier	136	128	119	110	102	93	84	75	66	
0,40	Béton	386	352	320	288	253	224	191	160	127	
0,02	Béton	528	496	461	428	397	364	330	297	265	

6. Lire, pour chacune de ces cinq courbes pour un matériau donné, les épaisseurs de blindage donnant 0,40 et 0,02 uSv par semaine à 1,0 m de distance et le double de uSv par semaine à chaque multiple de $\sqrt{2}$ m de distance.
7. Inscrire ces épaisseurs de chaque matériau dans le tableau ci-joint des spécifications de blindage puisque sur une base de 50 semaines de travail par année, elles correspondent aux limites de doses effectives annuelles moyennes de 20 et de 1 mSv/année de ICRP 60 (3) pour le mannequin AP (2).

DISCUSSION

Les facteurs de conversion [EDE/100 Expos.] trouvés et utilisés dans ce travail sont pour les courbes primaires de plomb, d'acier et de béton successivement de 0,92-0,96 0,90-0,93 et 0,89-0,95 selon l'épaisseur de matériau. Pour les rayons diffusés, elles sont 0,97-1,09 0,99 et 0,92-1,05. La procédure utilisant la figure ci-jointe peut s'appliquer dans l'obtention des spécifications de blindage pour rencontrer les valeurs d'ICRP 60 (3) pour le mannequin, tant pour les rayons X que pour les sources radioactives si les données d'exposition (ionisation) de base sont adéquates. Dans l'utilisation du tableau, il y a lieu d'inclure un facteur de sécurité surtout lorsqu'on utilise de grandes épaisseurs de blindage en raison des extrapolations dans les données utilisées (1 et 6). Dans le cas de la courbe de transmission primaire à travers le plomb utilisée (1), elle est plus exigeante qu'en 1958 (8). Quant aux installations sans plafond, on peut trouver ailleurs (6) des données utiles sur l'effet de ciel (skyskine) et sur le blindage (hauteur x épaisseur) optimal pour l'iridium 192 et le cobalt 60.

ABSTRACT

The communication presents the main evolutions of the collective and individual exposures within pressurized water reactors. Results are based on the analysis of a database developed at CEPN since 1986 for Electricité de France including about 1 100 reactor-years in nine countries. So far the impact of new reactors integrating the benefit of past experience and improvement in exposure-control has balanced the tendency to increasing doses associated with the ageing of installations. This evolution will only remain if on-going efforts to control and reduce exposures are strengthened.

**ANALYSE RETROSPECTIVE DE L'EXPOSITION PROFESSIONNELLE
DANS LES REACTEURS A EAU PRESSURISEE**

I - LA BASE DE DONNEES

Depuis 1986, à la demande d'Electricité de France, le CEPN développe une base de données, mise à jour annuellement, sur l'exposition professionnelle dans les réacteurs à eau pressurisée (REP). Cette base intègre les réacteurs mis en exploitation depuis juillet 1974 dans les neuf pays suivants : Belgique, Espagne, Etats-Unis, Finlande, France, Japon, République Fédérale d'Allemagne, Suisse et Suède. Au total, en prenant en compte les données relatives à 1989, la base contient 147 réacteurs, ce qui représente une expérience de près de 1 100 années réacteurs.

Le Tableau 1 présente les principales caractéristiques des réacteurs introduits dans la base de données pour les différents pays. Les parcs des Etats-Unis et de France sont les plus importants et représentent respectivement 37 % et 33 % du nombre total de réacteurs de la base, et 38 % et 34 % de la puissance totale installée. Les parcs les plus jeunes sont ceux de l'Espagne et de la France ; les plus anciens ceux de la Finlande et de la Suisse.

Tableau 1 : Caractéristiques des parcs REP en exploitation en 1989 pris en compte dans la base de données.

PAYS	Nombre de réacteurs	Puissance électrique (GW _e)	Nombre d'années d'exploitation (ans)	Age moyen (ans)
Belgique	7	5,8	65	9,3
Espagne	6	5,7	27	4,5
Finlande	2	0,9	22	11
France	48	50,3	297	6,2
Japon	14	11,5	126	9
R.F.A	11	13,9	78	7,1
Suède	3	2,8	29	9,7
Suisse	1	1	10	10
USA	55	57	442	8
Ensemble	147	149	1096	7,5

II - L'EVOLUTION DE L'EXPOSITION COLLECTIVE

La **Figure 1** qui présente l'évolution depuis 1975 de la dose collective moyenne par réacteur, montre une réduction régulière de cette dose entre 1982 et 1988 et une légère remontée des valeurs en 1989 avec des résultats comparables à ceux de 1987.

Figure 1 : Evolution de la dose collective annuelle moyenne par réacteur (1975-1989)

L'analyse selon le nombre d'années d'exploitation met en évidence une nette augmentation de la dose collective moyenne par réacteur au cours des huit premières années d'exploitation.

La tendance se poursuit ensuite mais des écarts importants apparaissent d'une année sur l'autre dans la mesure où cette moyenne correspond à un nombre de réacteurs de plus en plus réduit.

Figure 2 : Evolution de la dose collective moyenne par réacteur en fonction du nombre d'années d'exploitation.

L'examen des évolutions par pays montre des résultats assez différenciés dont l'explication ne peut reposer que sur une bonne connaissance des travaux effectués dans les réacteurs, en liaison avec des analyses de la structure par âge et par génération des différents parcs.

III - LA REPARTITION DE L'EXPOSITION ENTRE LES TRAVAILLEURS DES EXPLOITANTS ET CEUX DES ENTREPRISES EXTERIEURES

Le mode d'exploitation des REP induit qu'une part importante des travaux de maintenance est confiée à des entreprises extérieures. En moyenne, sur l'ensemble des pays, l'exposition des agents de ces dernières est passé de 67 % de l'exposition totale annuelle en 1980 à 74 % en 1988. Toutefois comme l'indique la Figure 3 la contribution des travailleurs des entreprises extérieures à l'exposition totale varie assez sensiblement selon les pays.

Figure 3 : Part de l'exposition des travailleurs des entreprises extérieures dans la dose collective annuelle selon les pays.

En ce qui concerne l'exposition individuelle moyenne annuelle, la situation est clairement appréhendable pour le personnel des centrales. L'évolution sur la période 1975-1989 montre une tendance à la baisse depuis 1980 où la valeur moyenne était de 2,6 mSv, alors qu'elle n'est plus que de 1,6 mSv en 1989. En revanche, pour le personnel des entreprises extérieures, la situation est beaucoup plus confuse. Les seules données disponibles, à quelques exceptions près, ne concernent que les expositions associées à chaque réacteur. Une fraction non négligeable de ce type de personnel intervient sur plusieurs réacteurs chaque année. Il est donc impossible en l'absence de systèmes centralisés, de reconstituer les doses annuelles individuelles moyennes.

IV - CONCLUSION

L'évolution générale de la dosimétrie professionnelle dans les REP est la résultante de deux tendances contradictoires. D'un côté, le vieillissement des installations conduit à un accroissement des travaux de maintenance qui pèsent de plus en plus lourd dans les bilans dosimétriques. A ces travaux viennent souvent s'ajouter ceux engagés pour améliorer la sûreté. De l'autre côté, les efforts entrepris pour mieux contrôler les sources, le développement d'outillages spécialisés et de la robotique, les progrès au niveau des protections et de l'organisation du travail en milieu irradiant permettent de maintenir, sinon de réduire, les niveaux d'exposition des travailleurs.

Globalement, au vu des résultats présentés ci-dessus, il semble que les effets positifs associés au retour d'expérience aient permis une évolution favorable de l'exposition. L'introduction de nouveaux réacteurs beaucoup plus performants sur le plan de la dosimétrie semble plus que compenser les effets négatifs du vieillissement.

Compte tenu de la diminution des mises en service de nouveaux réacteurs dans les années à venir il est difficile d'assurer que la tendance passée se poursuivra sans envisager d'accroître la maîtrise des sources et des interventions du personnel dans les réacteurs mis en service dans les années quatre-vingt.

Dans ce contexte, l'analyse approfondie des données du retour d'expérience et leur mise en commun, associée à la mise en oeuvre plus systématique de la démarche ALARA apparaissent comme indispensables pour s'assurer, d'une part que toutes les potentialités de réduction des expositions ont été exploitées et, d'autre part que les efforts de radioprotection consentis sont compatibles avec les conditions d'exploitation des installations.

FRENCH NUCLEAR POWER PLANTS ACCUMULATED DOSE
INTERNATIONAL COMPARISONS

J. STAIMESSE (*), A. BRISSAUD (**), J.L. TROMBINI (***)

(*) EDF/UTO, BP 129, 93612 NOISY LE GRAND CEDEX - FRANCE

(**) EDF/SEPTEN, 12-14 avenue Dutriévoz, 69628 VILLEURBANNE CEDEX - FRANCE

(***) EDF/DSRE, 6 rue Ampère, 93203 SAINT DENIS CEDEX 1 - FRANCE

After ten years of operation, the accumulated dose of the PWR french nuclear power plants is generally positive. In comparison to countries having an important number of nuclear power plants, like JAPON or US, the french results are better.

More or less, the tendency to an increase of certains indicators, like the annual average dose by reactor, or the dose by product energy, obliged us to follow our efforts to continue our goods results.

BILAN DOSIMETRIQUE DU PARC REP FRANCAIS
Comparaisons Internationales

Après une dizaine d'année de fonctionnement, le bilan dosimétrique du parc REP français est globalement positif. Par rapport à des pays ayant un parc électronucléaire important, comme le JAPON ou les USA, les résultats français sont meilleurs. Néanmoins, la tendance à la hausse de certains indicateurs, comme la dose moyenne annuelle par réacteur ou la dose par énergie produite, nous impose de poursuivre nos efforts pour conserver de bons résultats.

INTRODUCTION

Entre la première divergence de FESSENHEIM 1 en 1977 et aujourd'hui, ce sont 34 tranches REP 900 MW et 17 tranches REP 1300 MW qui ont été couplées au réseau. L'âge moyen du parc est d'environ 8 ans.

DOSIMETRIE MOYENNE PAR REACTEUR (figure 1)

La dose moyenne annuelle du parc REP par réacteur oscille autour de 2,3 h.Sv, avec une tendance à la hausse depuis 1989.

Cette augmentation est causée en particulier par :

- le plus grand nombre des arrêts de tranche pour rechargement et l'allongement de leur durée,
- la réalisation des premières visites décennales de tranches 900 MW longues et plus coûteuses en dose qu'une simple visite pour rechargement.

Il est à noter un meilleur comportement des tranches du palier 1300 MW dont la moyenne annuelle est voisine de 1,5 h.Sv, ce qui est dû aux valeurs plus faibles de débit de dose dans les locaux et au voisinage des matériels (les moindres teneurs en cobalt des tubes de générateur de vapeur et l'application, dès le démarrage de ces tranches, de spécifications radiochimiques lors des mises en arrêt en froid ne sont pas étrangères à ces meilleurs résultats).

COMPARAISON INTERNATIONALE (figure 2)

Alors que la dose moyenne annuelle par réacteur oscille aux environs de 2,3 h.Sv avec une tendance à la hausse depuis 1989 en FRANCE, on constate une tendance inverse continue à la baisse pour les USA, le JAPON et l'ALLEMAGNE.

Il en est de même pour l'indicateur de dose collective divisée par l'énergie produite.

Ces pays appliquent depuis plusieurs années le principe ALARA dans le domaine de la radioprotection.

Il faut noter également qu'à l'étranger, de plus en plus de tranches réalisent aujourd'hui des campagnes longues de 18 à 20 mois contrairement au parc REP français, où pour des considérations économiques de combustible un cycle dure environ 1 an. Le calcul de la dose moyenne annuelle est fortement influencé par l'espacement des arrêts de tranche, la dose d'arrêt de tranche étant environ 3 fois la dose prise au cours d'une année de fonctionnement.

DOSE PAR ENERGIE PRODUITE (figure 3)

La dose par énergie produite oscille aux environs de 3 h.mSv/MW.an pour l'ensemble du parc REP.

Elle est voisine de 2 h.mSv/MW.an pour les centrales REP 1300 MW qui sont plus récentes et où les débits de dose tant ambiants que sur les matériels, sont plus faibles ; les doses reçues par le personnel sont donc plus réduites.

COMPARAISON INTERNATIONALE (figure 4)

Par rapport aux pays étrangers comparés précédemment (USA, JAPON, ALLEMAGNE), le parc français présente un bilan dose/énergie produite satisfaisant.

CONCLUSION

Le bilan dosimétrique du parc REP est satisfaisant. Cette situation est la combinaison de facteurs favorables :

- abaissement de la teneur en cobalt des tubes GV,
- application d'un conditionnement chimique rigoureux,
- application d'une procédure de mise en arrêt à froid performante,
- gestion rationnelle des assemblages combustibles pour maîtriser la contamination par produits de fission,

et défavorables :

- "maladies" génériques : jet de baffle, broches, tubes guides, tubes GV, piquages pressuriseurs, ...,
- augmentation de la durée des arrêts de tranche,
- augmentation des contrôles.

Pour conserver et peut-être améliorer ces résultats, il est nécessaire de persévérer et d'améliorer nos conditions d'interventions.

ABSTRACT

An investigation was carried out on properties of radioactive aerosol floating in the air at several workplaces in a nuclear power plant.

The principal results are as follows:

- (1) The aerosol particle size distributions consisted of two particle groups, whose aerodynamic diameters ranged from 4 to 7 microns and from 0.4 to 0.6 microns.
- (2) The radioactive aerosol particle size distribution were unimodal. The mean activity median aerodynamic diameter (AMAD) was 6 microns, with geometric standard deviation 1.9 microns.
- (3) The average density of the aerosol was about 2.2g/cm^3 .

INTRODUCTION

Knowledge of the particle size distribution of radioactive aerosol floating in the environmental air at workplaces in a facility handling radioactive materials is essential for estimating the internal radiation exposure dose of workers, caused by respiration and for monitoring the concentration of radioactive aerosol.

Task Group on Lung Dynamics of the ICRP has proposed a lung model for estimating the dose, following inhalation of radioactive aerosol.^{1,2} This model takes particle size into account and also defines three classes of retention, which, in part, reflect the chemical form of the aerosol. This model shows that the pattern of deposition can be related to the activity median aerodynamic diameter (AMAD) of the aerosol, for a log-normal distribution of diameters, which seems typical distribution of aerosol. Therefore the particle size distributions of radioactive aerosol are important and have been studied in detail in the present work.

Aerosol particles floating in the air at several workplaces were sampled during the maintenance period of a nuclear power plant. Analysis were carried out for the samples and particle size distributions of total aerosol and radioactive aerosol were determined.

MEASUREMENTS AND DATA ANALYSIS

Samples of aerosol floating in the environmental air at several workplaces in a nuclear power plant were collected with a cascade impactor (Andersen sampler model AN200). The Andersen sampler consists of 8 stages and a backup filter, and flow rate was regulated at 28.3 l/min. The height of sampling position was about 1.2 meter above the working floor, corresponding to the worker's respiratory zone. The sampling time was 60 to 90 hours at a workplace. After sampling, the weight of the aerosol particles taken at each sampler plate (stage) were measured with a micro balance (minimum detectable weight is 0.01mg) and gamma radioactivity of the each plate (stage) were measured with a Ge-detector and a multichannel pulse height analyser.

Data analysis for particle size distribution of aerosol were made with the method proposed by Fujimura and Hashimoto⁽³⁾. In this method, at first, a cumulative distribution curve $F(D)$ for aerosol particle diameter D is drawn by plotting the percentages of cumulative weight (or radioactivity) on a semi-logarithmic graphpaper. Then, the $F(D)$ curve is differentiated to obtain a frequency distribution curve $f(D)$, by plotting the gradient $dF(D)/d(\log D)$. It is suitable to obtain an intuitive image of the size distribution for aerosol particles.

The "Floating Method" was used to determine particle density. In this method, aerosol accumulations were soaked into a liquid and the liquid density was changed by mixing two other liquids whose densities were different from each other. If the aerosol density was equal to the liquid density, the aerosol particles float in the liquid. So, by measuring the liquid density, the aerosol density can be obtained.

RESULTS

The aerosol size distribution (mass frequency distribution) was found to be bimodal, as shown in Fig.1, consisted of two particle size groups, whose aerodynamic diameters were 4 to 7 microns and 0.4 to 0.6 microns. The particle size distribution for each aerosol group closely resembled to logarithmic normal distribution. Their average mass median aerodynamic diameter was 6 microns and 0.5 microns, with geometric standard deviations of 1.9 and 2.1 microns, respectively.

On the other hand, the particle size distribution for radioactive aerosol were found to be unimodal, as shown in Fig.2. The mean activity median aerodynamic diameter (AMAD) was 6 microns with geometric standard deviation of 1.9 microns. As shown in Fig.3, the concentration of radioactive aerosol particles in the air strongly depended on the concentration of larger particle group, whose aerodynamic diameters were 4 to 7 microns.

The radioactive nuclides, included in the aerosol,

were Cr-51, Mn-54, Fe-59, Co-58, Co-60, Zn-65 and Ag-110m. These radioactive nuclides were activation products of structural materials by neutrons. The main radioactive nuclides were Mn-54 and Co-60.

The densities of aerosol, measured by the "Floating Method", is shown in Table 1. Measured densities for aerosol were ranged from 1.8 to 2.6 g/cm³ in place by place, and average aerosol density was about 2.2 g/cm³.

Other observed properties of the aerosol were chemical elements. The main chemical element included in the aerosol was iron.

CONCLUSION

An investigation was carried out on properties of radioactive aerosol floating in the environmental air at workplaces of a nuclear power plant.

The results are as follows:

- (1) The aerosol particle size distributions consisted of two particle groups, whose aerodynamic diameters ranged from 4 to 7 microns and from 0.4 to 0.6 microns.
- (2) The particle size distributions for each aerosol group closely resembled to logarithmic normal distribution. Their mean mass median aerodynamic diameter (MMAD) was 6.0 and 0.5 microns with geometric standard deviations of 1.9 and 2.1 microns, respectively.
- (3) The particle size distribution of radioactive aerosol were unimodal. The mean activity median aerodynamic diameter (AMAD) was 6 microns, with geometric standard deviation of 1.9 microns. The radioactive aerosol concentration in the air strongly depended on the concentration of the larger particle group, whose aerodynamic diameters ranged from 4 to 7 microns.
- (4) Other observed properties were:
 - (a) The average density of the aerosol was about 2.2g/cm³.
 - (b) The main radioactive nuclides, included in the aerosol were Mn-54 and Co-60.
 - (c) The main chemical element, included in the aerosol was iron.

RISK MODELS FOR ESTIMATING LIFETIME CANCER PROBABILITY: ALTERNATIVE TO RELATIVE RISK MODEL BY UNSCEAR/ICRP

M. KAI and T. KUSAMA

Department of Radiological Health, Faculty of Medicine,
The University of Tokyo, Tokyo, JAPAN

ABSTRACT

Based on the carcinogenesis model as proposed by Moolgavkar et al., time-dependent relative risk models were derived for projecting time variation in excess relative risk. If it is assumed that each process is described by time-independent linear dose-response relationship, the time variation in excess relative risk is influenced by the parameter related with the promotion process. Its parameter was discussed by analyzing spontaneous cancer incidence data. The model predicts larger variation in relative risk with time for younger ages at exposure.

INTRODUCTION

The ICRP adopted relative risk models for radiation-induced lifetime cancer probability in the 1990 recommendation(1). The application of the relative risk projection model mainly causes higher lifetime cancer probability than the ICRP 1977 recommendation(2). The main background why the ICRP adopted the relative risk model is based on the epidemiological data of A-bomb survivors in Japan. The atomic bomb data indicate that the variation of relative risk with time is constant for a given age-at-exposure, but the transfer of the constant relative risk to population other than the Japanese cannot be verified by the statistical models based only on the data fitting. However, there is no biological basis for projecting excess hazard rate of radiation. The carcinogenesis model as proposed by Moolgavkar et al.(3,4) can give a good fitting and interpretation for the age-dependent spontaneous cancer incidence rate of a specific population data. In this paper a risk projection model will be derived from the carcinogenesis model as biological basis. Moreover, the time variation in relative risk for age at exposure will be discussed.

CARCINOGENESIS MODELS

Moolgavkar et al.(2,3) proposed the two-stage carcinogenesis model, which will be referred to as MVK models below. The two-stage carcinogenesis model assumes that stem cells change to initiated cells by first mutation and furthermore tumor cells are induced by second mutation. In addition, the MVK model is a stochastic model which deals with a homogeneous filtered Poisson process of initiated cells. In the case of epidemiological data, the approximation of the hazard rate as an expected value is as follows:

$$r(t) = u_2(t) \int_0^1 \left\{ u_1(s) X(s) \exp\left(\int_s^1 [a(u)-b(u)] du \right) \right\} ds. \quad (\text{Eq.1})$$

DERIVATION OF MATHEMATICAL MODELS

It is assumed that each process is described by linear dose-response relationship which is time-independent. Furthermore, it can be assumed that a single exposure to radiation acts as an initiator. On these assumptions, if the stem cell population is constant, the hazard rate of spontaneous cancer ($R_s(t)$) and excess hazard rate ($R_r(t)$) due to a single exposure can be derived as:

$$R_s(t) = N_0 ac/g \{ \exp(gt) - 1 \} \quad (\text{Eq.2})$$

$$R_r(t) = N_0 bcx \exp[g(t-t_0)], \quad (\text{Eq.3})$$

using the expressions as $u_1(t)=a+bx$, $u_2(t)=c$ and $a(t)-b(t)=g$.

In addition, N_0 , x , t and t_0 represent the number of normal cells, dose, attained age and age-at-exposure, respectively. The parameter g is the net rate of proliferating initiated cells and plays an important role in projecting the variation in relative risk. The above expressions are the most simple form with minimum unknown parameters.

If the growth of the normal stem cell population is modeled by an exponential function until t_1 , the hazard rate of spontaneous cancer is then described by the summation of hazard rates that originate from the numbers of cells which are initiated until t_x and are initiated after t_x . The expression can be given by:

$$R_s(t) = \begin{cases} \left\{ \frac{ack}{(L-g)} \right\} \{ \exp[L-g)t_x + gt] - \exp(gt) \} \\ \quad + (acN_0/g) \{ \exp[g(t-t_x)] - 1 \} & \text{if } t > t_x \quad (\text{Eq. 4}) \\ \left\{ \frac{ack}{(L-g)} \right\} \{ \exp(Lt) - \exp(gt) \} & \text{if } t < t_x \quad (\text{Eq. 5}) \end{cases}$$

where it is assumed that $X(t)=k\exp(Lt)$ ($t < t_x$). The excess hazard rate due to a single exposure can be obtained as:

$$R_r(t) = \begin{cases} (kbcx)\exp[g(t-t_0)+Lt_0] & \text{if } t_0 < t_x \quad (\text{Eq. 6}) \\ (N_0bcx)\exp[g(t-t_0)] & \text{if } t_0 > t_x \quad (\text{Eq. 7}) \end{cases}$$

The expression of hazard rates involving time-dependent processes can be derived by dividing the age into two or more age groups in which the parameters are assumed to be time-independent. In the case of two age groups, the expression for the hazard rate of spontaneous cancer shown in Eq.2 must be rewritten into:

$$R_s(t) = \begin{cases} (N_0a_1c/g_1) \{ \exp[g_2(t-t_1)] \} \{ \exp(g_1t_1) - 1 \} \\ \quad + (N_0a_2c/g_2) \{ \exp[g_2(t-t_1)] - 1 \} & \text{if } t > t_1 \quad (\text{Eq. 8}) \end{cases}$$

where the parameters of g_1 and g_2 are the net rates of proliferating initiated cells in each age group, and those of a_1 and a_2 are mutation rates per cell per year of one normal cell into one initiated cell. If $t_0 < t_1$, the excess hazard rate due to a single exposure can be obtained as:

$$R_r(t) = \begin{cases} (N_0bcx)\exp[g_1(t-t_0)] & \text{if } t < t_1 \quad (\text{Eq. 9}) \\ (N_0bcx)\exp[g_1(t_1-t_0)+g_2(t-t_1)] & \text{if } t > t_1 \quad (\text{Eq. 10}) \end{cases}$$

MODEL FITTING TO SPONTANEOUS CANCER DATA

The cancer incidence data from 20 to 80 years of age in Japan in 1985(5) were used for the parameters by model fitting. By using Eq.2 and Eq.8, in which $t_1=60$, the results of data fitting to the incidence rates of lung cancer and stomach cancer of males were obtained as shown in Fig.1 and Fig.2, respectively. These organs have higher cancer probabilities in ICRP Pub.60. The MVK model agrees with the spontaneous cancer data.

PREDICTED TIME VARIATION IN EXCESS RELATIVE RISK

The reduction in excess relative risk can be predicted by the g parameter which is obtained by data fitting to spontaneous cancer incidence rates. Figure 3 illustrates the excess relative risk in stomach for a single exposure at adult age or young age. The excess relative risk for the young age decreases more rapidly with time than that for the adult age. This is

influenced by the age-dependence of the growth of radiation-induced initiated cells and spontaneously induced initiated cells.

CONCLUSION

It was suggested that the MVK model is a useful tool as a carcinogenesis model for projecting the time variation in excess relative risk. The reduction rate in excess relative risk can be obtained by the data fitting to spontaneous cancer incidence data. For adult exposure, the excess relative risks are approximately constant for some cancers such as lung, colon and stomach. However, for breast cancer, the excess relative risk decreases with attained age. In applying the above risk model to epidemiological data for estimating lifetime cancer probability, the parameters related with the time variation in relative risk can be estimated by analyzing the spontaneous cancer incidence data.

EPIDEMIOLOGY OF PLUTONIUM WORKERS

G. L. Voelz, L. D. Wiggs, and W. A. Galke

Los Alamos National Laboratory
Los Alamos, New Mexico, U.S.A.

ABSTRACT

Workers at several U.S. plutonium (Pu) processing or research facilities are subjects of the National Plutonium Workers Study. Mortality from all causes and all cancers has not been elevated in these cohorts compared with rates in the general U.S. population. Mortality from all causes and blood cell neoplasms was statistically elevated in Pu-exposed workers at Rocky Flats compared with those not exposed to Pu. Linear dose-response trends were not observed. Bone sarcoma in a Los Alamos Pu exposed worker is noteworthy because bone tumors are an important cancer found in Pu exposed dogs.

INTRODUCTION

The National Plutonium Workers Study uses a historical cohort mortality design to study the long term health experience of four worker populations: Los Alamos National Laboratory and Zia Co., Los Alamos, NM; Rocky Flats plant near Denver, CO; and Mound facility near Dayton, OH. About 54,300 workers have been employed at these facilities from the onset of operations until 1979. The cohorts include over 80% of all persons with occupational exposures to Pu in the U.S. Seventy seven percent of the workers are white males. Vital status of white males in these cohorts is known with about 95% completeness thru the end of 1983.

Monitoring for internal Pu deposition, primarily by measurement of Pu in one or more urine samples, has been done on 13,750 (25%) of the 54,300 workers. Selection is based on the potential for exposure in work assignments. About 1800 workers are estimated to have Pu depositions of more than 74 Bq. The majority of these depositions are ^{239}Pu , but some ^{238}Pu exposures are also present. Estimates of depositions below the arbitrary value of 74 Bq Pu are considered to be too uncertain to be included in the exposed category. Regarding higher depositions, only fifty workers are estimated to have depositions above 1480 Bq Pu, which is the lifetime maximum permissible body burden guideline used during the years under study.

Eighteen percent of the white males in these cohorts have cumulative external doses in excess of 10 mSv. External radiation exposure is a potential confounding factor in these studies. Plutonium work involves exposure to external gamma and neutron doses. The contribution from neutron exposures is either not known or has large uncertainties in the personnel dosimetry data from the 1940s into the 1970s.

MORTALITY OF PLUTONIUM WORKERS

Using mortality rates of the U.S. general population for comparison, the standardized mortality ratios (SMR) for deaths from all causes in the cohorts (unexposed and exposed workers) studied to date are all significantly less than 100.¹⁻⁵ A ratio below 100 means the mortality rate of the study cohort is less than that of the comparison group. The low SMRs are attributed to a large healthy worker effect, which is frequently observed in studies of employed populations when occupational health impacts are absent or small. The SMRs for deaths from all cancers are also low in these cohorts.

Rate ratios comparing mortality rates of Pu-exposed workers with those of unexposed workers were calculated for the Rocky Flats workers.¹ If the mortality rates of exposed and unexposed workers are equal, the rate ratio is 1.0. If the mortality rate of the exposed exceeds the unexposed, the rate ratio is above 1.0. This type of internal comparison has an advantage over external comparison with state or national rates, because employment procedures for the exposed and unexposed persons are the same. The use of internal comparisons essentially eliminates the healthy worker effect. Using 5-year and 10-year induction times, the stratified rate ratios for all causes of death for Rocky Flats workers exposed above 74 Bq Pu are significantly elevated at 1.33 (90% confidence intervals (CI) = 1.05, 1.68) and 1.39 (CI = 1.04, 1.87) respectively. Persons exposed to external radiation (>10 mSv) did not exhibit elevated rate ratios. Interpretation of this observation will be strengthened if the finding is confirmed in other studies. The stratified rate ratios for all cancer deaths were 1.24 (CI = 0.75, 2.07) and 1.61 (CI = 0.88, 2.93) for 5- and 10-year induction times respectively.

CANCERS OF SPECIAL INTEREST

Experimental studies in rodents and dogs have shown plutonium concentrations to be highest in lung and tracheobronchial lymph nodes after inhalation of insoluble Pu particulates. Soluble Pu compounds are distributed primarily to bone and liver. It is thus not surprising that animal experiments showed excess cancers primarily in lung (after inhalation exposures only), bone, and liver. Bone tumors in dogs were most frequently osteogenic sarcomas arising in trabecular bone. Leukemias and myeloproliferative disorders were not prominent findings in the dog studies.

The following sections describe selected findings to date in studies of workers. It is anticipated that the induction time for Pu-induced cancers is likely to be very long, perhaps in excess of 30 years. These epidemiologic research studies should continue and will record such events as they unfold.

Bone Cancer. In a clinical study of 26 workers exposed at Los Alamos in 1944-5, one individual died of an osteogenic sarcoma in 1990.⁵ The latent period from exposure to the time

of initial clinical symptoms was 43 years. It appears that this is the first case in which a bone tumor has been observed in a person exposed to Pu. The estimates of ^{239}Pu deposition in this case, using urine excretion measurements, range from an initial maximum of 740 Bq to 560 Bq at the end of his life. These depositions are somewhat lower than current radiation protection guidelines would allow. The cumulative dose to bone surface is estimated to be 0.44 Gy. This estimated dose is similar to the lowest skeletal doses in Pu exposed dogs that have developed bone tumors.

The incidence of bone cancer in humans is ordinarily low. In a group of 26 adult males over a 40+ year period, the likelihood is only about 1% that a bone cancer would occur.

Blood Cell Neoplasms. This term is used here to describe a group of neoplasms originating from a variety of cell types in lymphatic and hematopoietic tissues, including all leukemias, lymphomas, and multiple myeloma. This group (ICDA 8th Revision, Codes 200-209) is convenient to use for epidemiologic analyses when the number of observed cases is too small to evaluate specific diseases. It has frequently been used in studies of radiation health effects to evaluate potential effects on lymphoid and hematopoietic tissues. Several of these diseases have had an increased frequency associated with doses of external radiation.

The Rocky Flats study¹ indicated a 5 to 10 fold increased rate of blood cell neoplasms in Pu exposed workers compared to unexposed workers using 2-, 5-, and 10-year induction times. The rate for the 5-year induction time was 9.86 (90% CI = 1.26, 94.03). A linear dose-response trend was not present. It is interesting that the rate ratio for blood cell neoplasms in workers exposed to external radiation was not similarly elevated. This interesting group of diseases bears close watching as Pu epidemiology studies unfold.

Lung Cancer. Lung cancer mortality for the cohorts studied thus far in Pu handling facilities is not increased compared that in the U.S. general population. For example, the SMR for lung cancer of 64 (90% CI = 46, 87) in the Rocky Flats study¹ is significantly low. The same study indicates ratios of lung cancer rates for Pu exposed and unexposed workers are not significantly different using induction times of 2-, 5-, and 10-years. Analysis of the 10-year induction time gives a rate ratio of 1.4 (90% CI = 0.33, 4.65) based on the three lung cancer deaths in the exposed group.

An earlier study of 224 white males with the highest Pu exposures at Los Alamos observed an SMR of 20 (95% CI = 0, 110) for lung cancer.⁴ Only one death from lung cancer occurred over a 33-year follow-up period. In the study of 26 Manhattan Project Pu workers⁵, three lung cancers have been observed over a 44-year period, which is a higher incidence than expected but is still within the limits of expectation. All three men had a long history of cigarette smoking, which is an important confounding risk for lung cancer.

Liver Cancer. Mortality rates for cancers of the liver and gallbladder have not been elevated in the cohort studies to date.

Other Cancers. A two to three fold increase of brain tumors--benign and malignant combined--in Rocky Flats workers has been reported.¹ A case-control study of brain tumors showed no association between these tumors and radiation doses--either internal Pu depositions or external radiation.⁶ The reason for the excess brain tumors in this cohort is unknown, but it is clearly not from Pu deposition.

In the Pu-exposed worker cohort at Rocky Flats, six cancers of all digestive organs combined gives a rate ratio of 1.68 (90% CI = 0.58, 4.71) relative to the unexposed monitored workers using an induction time of 5 years. The ratios for 2- and 10-year induction times are 1.31 and 1.46. Wide confidence intervals suggest these results may well be due to chance, but elevated central values were not observed in the same study for workers exposed to external radiation .

ABSTRACT

The effect of time and dose rate on cancer risk from protracted irradiation by internally deposited radionuclides forms a three-dimensional mathematical dose-rate/time/response relationship. Data were reviewed from lifetime studies with beagles exposed by injection, ingestion, or inhalation to either beta emitters or alpha emitters. The cumulative absorbed dose required to yield a specified level of cancer risk was found to be less at lower dose rates than at higher dose rates, but the time required for tumors to manifest tends to be much longer at lower dose rates and can exceed the natural life span, yielding a virtual threshold for fatal radiation-induced cancer. The $RBE(\alpha/\beta)$ was found to vary from about 1 at high dose rates to above 50 at low dose rates. These results can be scaled by life-span normalization to predict similar relationships in people.

INTRODUCTION

This report focuses on risks associated with radiation-induced cancer from internally deposited radionuclides with respect to the separate and independent risks of death associated with natural aging. Precise data obtained in lifetime studies utilizing beagles provide the basis for understanding the relationship of these risks.

The effect of time and dose rate on cancer risk from protracted irradiation by internally deposited radionuclides forms a three-dimensional mathematical dose-rate/time/response surface in which the coordinates for protracted exposure to the ionizing radiation are time-weighted average dose rate, elapsed time after intake, and risk given as the independent probability of death with radiation-induced cancer (1-2). Raabe et al. (3) used life-span normalization to scale response relationships from laboratory animal species to human risks.

METHODS

Selected data were reviewed from published reports of lifetime studies of internally deposited radionuclides in young adult beagles at four laboratories: University of California, Davis (4), Lovelace Inhalation Toxicology Research Institute, ITRI (5), University of Utah (5), and Battelle Pacific Northwest Laboratory, PNL (6). Data were reviewed for skeletal burdens of Sr-90 via ingestion at Davis, via injection at Utah, and via inhalation at ITRI, for lung burdens of inhaled Ce-144, Y-91, and Sr-90 in fused aluminosilicate particles (FAP) at ITRI and of inhaled Pu-239 dioxide at PNL, skeletal burdens of inhaled

Pu-238 at ITRI and of injected Ra-226 at Davis and Utah, and skeletal burdens of injected Ra-228, Pu-239, and Am-241 at Utah. Throughout this report, doses refer to average absorbed doses from parent and decay products in their appropriate proportions, where all X-ray and gamma emissions are ignored, and beta emissions are ignored when in combination with alpha emitters.

Because of an observed pattern of linearity between the logarithm of time to radiation induced cancer deaths and logarithm of lifetime average dose rate, standard log-linear survival models and maximum likelihood regression methods were used to describe the response functions (7). In terms of the natural logarithms, the log-linear regression line is thus given by:

$$\ln t_m = \ln K_m - s \ln \bar{d} \quad (1)$$

where \bar{d} is the time-weighted average dose rate, t_m is the median value of survival time, s is the negative slope of the regression line for the specified effect, and K_m is the coefficient describing the median risk. This regression line is equivalent to the power function:

$$t_m = K_m \bar{d}^{-s} \quad (2)$$

which describes the median survival time after intake.

RESULTS AND CONCLUSIONS

The results of these analyses are summarized in Fig. 1. The alpha emitting radionuclides all yielded cancer risk distributions with negative slopes of 1/3 and the beta emitting radionuclides all yielded cancer risk distributions with negative slopes of 2/3, showing that two beta particles are needed to cause the same cellular transformations produced by one alpha particle. Also, the underlying slope of 1/3 indicates that the distance between these events controls the response as a function of survival time as discussed by Raabe (2).

Because of the negative slopes of these distributions, the cumulative absorbed dose required to yield a specified level of cancer risk is less at lower dose rates than at higher dose rates, but the time required for tumors to manifest is much longer at lower dose rates and can exceed the natural life span, yielding a virtual threshold for fatal radiation-induced cancer.

This threshold occurs at about 0.08 Gy for Pu-238 and Pu-239 in bone, 0.2 Gy for Am-241 in bone, 0.5 Gy for Ra-228 in bone, 0.9 Gy for Pu-239 in lung, 1.4 Gy Ra-226 in bone, 28 Gy for Sr-90 in bone, 70 Gy for Y-91 in lung, 110 Gy for Ce-144 in lung, and 130 Gy for Sr-90 in lung.

Because the slopes of the response curves for alpha emitters differ from those for the low LET beta emitters, the

Figure 1: Median bone and lung cancer risks for beagles.

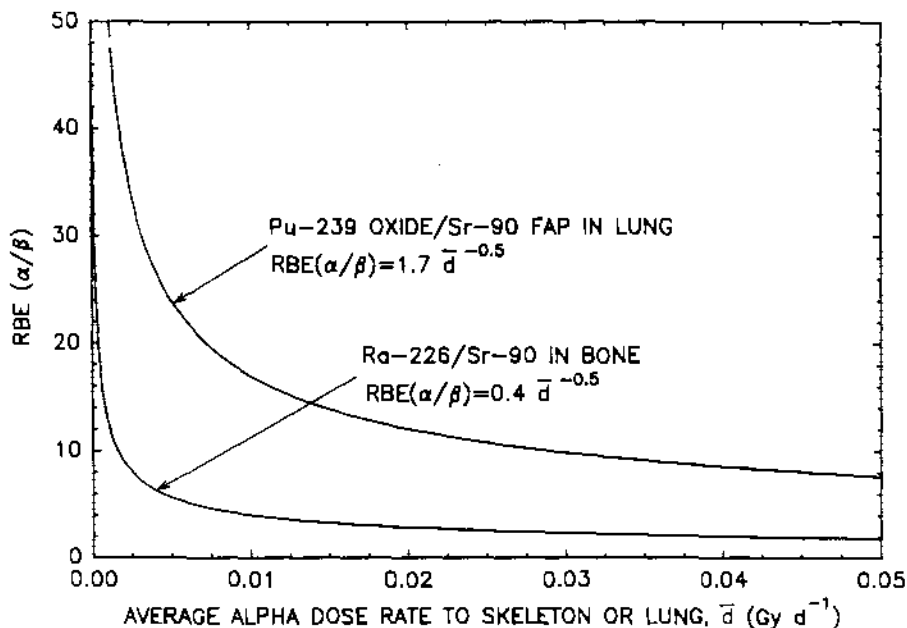

Figure 2: Apparent relative biological effectiveness, $RBE(\alpha/\beta)$, for beagle deaths with radiation-induced cancer.

observed relative biological effectiveness, $RBE(\alpha/\beta)$, varies as a function of dose rate, and rises as dose rate decreases. The $RBE(\alpha/\beta)$ contrasting Pu-239 dioxide with Sr-90 FAP at the median risk for fatal radiation-induced lung cancer in beagles and for Ra-226 versus Sr-90 bone cancer in beagles are shown in Fig. 2.

At high dose rates this radiation-induced cancer $RBE(\alpha/\beta)$ is small and rises to large values at low dose rates. As dose rate goes down the fatal radiation-induced cancer $RBE(\alpha/\beta)$ rises without limit; actually the beta effectiveness for producing radiation-induced cancer approaches zero. For example, for Pu-239 dioxide in lung at 0.1 Gy/day the $RBE(\alpha/\beta)=5$, while at 1 mGy/day $RBE(\alpha/\beta)=50$. The bone cancer $RBE(\alpha/\beta)=30$ at 1 mGy/day for Ra-226/Sr-90 in bone. Since Pu-238 and Pu-239 are about 10 times more effective than Ra-226 in producing bone cancer, the apparent $RBE(\alpha/\beta)=300$ for plutonium in bone at 1 mGy/day.

RESUME

Les espèces activées de l'oxygène sont mises en cause dans de nombreux phénomènes inflammatoires, dans la transformation cellulaire et la carcinogénèse. Toutes les expériences qui ont étudié : (i) leur influence directe; (ii) ou indirecte *in vivo*, et/ou, sur culture de cellules se sont révélées positives.

A contrario, les réactions, ou les produits, qui diminuent le taux de ces espèces activées, soit directement, soit indirectement par une augmentation des activités SOD, catalase, et peroxydase, limitent les anomalies énoncées ci-dessus. C'est le cas du domaine "2" (porteur du cuivre) de l'hémocyanine du scorpion (i) qui possède les trois activités de défense cellulaire, (ii) dont les activités oxyphorique, SOD, catalase et peroxydase résistent à au moins 4000 Gy, et qui de ce fait, participe à la radiorésistance exceptionnelle de cet animal.

ABSTRACT

H₂O₂ and free radicals are correlated with inflammatory diseases, cellular transformation and carcinogenesis. Experiments studying their direct or indirect influence (*in vivo*, and/or, in cell cultures were still positive.

In the contrary, reactions or products, which decrease level(s) of free radicals/H₂O₂ (i) directly, (ii) indirectly by an increase of SOD, catalase and peroxydase activities zeroed the above described phenomena. It is the case of the domain number 2 (that contains copper) of the Scorpion's blood pigment (hemocyanin), (i) which possesses SOD-, catalase- and peroxydase-like properties, resistant, at least, at 4000Gy, furthermore explaining the especially high radioresistance of scorpions.

INTRODUCTION

La majeure partie de l'oxygène respiré est consommée durant la phosphorylation oxydative des mitochondries. Cependant 8 à 10% échappent dans un métabolisme normal, à la réduction totale à 4 électrons (H₂O). Les radicaux libres (O₂^{•-}, OH[•]) et les molécules d'H₂O₂ ainsi obtenus sont potentiellement très toxiques pour la cellules. D'autres réactions biologiques normales conduisent également à la production, dans le cytosol, les mitochondries et près du DNA, de ces espèces activées .O₂^{•-}, OH[•], H₂O₂ sont également produites par l'action des radiations ionisantes naturelles ou artificielles qui selon l'énergie distribuée conduisent à une radiolyse totale ou partielle de l'H₂O. Des systèmes enzymatiques présents dans les cellules/tissus peuvent minimiser leurs dommages (1-5) : ce sont les peroxydases, les catalases et les superoxydes dismutases. Ces

enzymes ne fonctionnent plus lorsque le taux de leurs substrats respectifs excède leur capacité enzymatique. et ne pourront assurer qu'un service réduit en cas de débordement pathologique.

D'où l'intérêt de travailler sur des systèmes cellulaires, et/ou, pathologies humaines bien définies, où la production/ accumulation anarchique d'une ou plusieurs de ces différentes espèces est soupçonnée. Parmi quelques exemples, je citerai certains de nos propres travaux qui ont mis en évidence certaines des relations pouvant intervenir entre différents systèmes défaillants, (DNA repair, activité catalase anormale) et les tentatives de réparation spontanées par le biais d'une augmentation de l'activité d'une autre enzyme (par exemple l'activité glutathion peroxydase). Cette présentation n'est évidemment pas exhaustive et ne choisit que certains exemples portant sur certaines étapes de la cancérogénèse humaine. En contre partie, je citerai brièvement un exemple de radiorésistance naturelle exceptionnelle, l'hémocyanine du scorpion) pour laquelle nous avons mis en évidence, aussi bien dans la protéine purifiée que dans ses sous-unités (monomères et domaines 75 et 50 KDa) des activités de type SOD, catalase et peroxydase, résistant à au moins 4000 Gy .

RESULTATS

I) AGENTS EXTERNES /CONDITIONS produisant des espèces activées de l'oxygène .L'oxygène hyperbare, les peroxydations lipidiques, les intermédiaires quinoniques, des mimétiques des réactions de type-Fenton, des modifications dans le transport des électrons le long de la chaîne des cytochromes, des réactions redox en présence de métaux, des molécules chimiques utilisées dans les traitements des obésités, la fumée de cigarette, les extraits de cafés, les radiations ionisantes (UV, X, γ , α , β , électrons) sont tous générateurs des espèces activées de l'oxygène.(6)

II) EFFETS DES RADICAUX LIBRES ET DE L'H₂O₂ (7-25)

Les premiers effets remarquables ont été sur les chromosomes/DNA. Je citerai aussi, les corrélations naturelles qui existent entre la carcinogénèse humaine , les dommages du DNA et les maladies héréditaires radiations-ionisantes dépendantes que sont *Xeroderma pigmentosum*, *Ataxia telangiectasia* , le Syndrome de Bloom, l'anémie de Fanconi, le syndrome de Cockayne .Les effets des espèces activées de l'oxygène et de leur protection par addition de SOD, et/ou catalases,et/ou, peroxydases, ont été étudiés sur des cultures de cellules, sur des organes *in toto* ,(duodénum de rat)(9) etc....Dans tous les cas, un effet inhibiteur de la "transformation " a été constaté lorsque les systèmes enzymatiques cités ci-dessus pouvaient fonctionner normalement; des coupures sur les DNA et jusqu'à la formation de tumeurs cancéreuses dans le cas contraire. Parmi les maladies génétiques non radiations dépendantes, on peut citer la trisomie 21; en effet, Sinet *et al* ont, en 1975,(12) montré que les fibroblastes, lymphocytes et monocytes de ces malades produisent une overdose de CuZnSOD . Cela a été considéré comme une des origines possible de l'accroissement de stress oxydatifs conduisant aux nombreuses anomalies métaboliques qui atteignent ces malades (rappelons que les mongoliens font un taux anormalement élevé de leucémies).

Le fait que l'activité catalase (i) ne s'effondre pas ; (ii) que l'activité glutathion peroxydase augmente dans un bon nombre de composés sanguins, paraît cependant assez peu compatible avec cette théorie.

Les relations entre "production de radicaux libres, de peroxyde d'hydrogène et d'oxygène singulet" ont été également envisagées dans bon nombre de cas.(15). Nous mêmes avons démontré qu'une maladie génétique récessive et autosomale, (16-17) UV-dépendante, *Xeroderma pigmentosum*, est caractérisé par une chute très précoce et progressive de l'activité catalase de la peau : de 20% dès l'âge de 6 mois et sans signe clinique d'apparition de la maladie, à 95% au moment de la formation des premières tumeurs cancéreuses (dès l'âge de 2-3 ans). Ce phénomène s'accompagne, après irradiation UV des extraits acellulaires, d'une augmentation par 2-3 du taux normal de l' H_2O_2 . Un traitement externe avec de la catalase de mammifère gèle l'évolution de la maladie.(18-19).

Fort de ces résultats établis sur des malades et leur famille après un suivi de 6 ans, nous avons voulu savoir si cette chute de l'activité catalase était caractéristique :

(1) de la peau, et/ou, des ses fibroblastes et kératinocytes en culture de XP, d'autres maladies génétiques sensibles aux radiations ionisantes (*Ataxia telangiectasia*, syndrome de Bloom ...); (20-22)

(2) d'autres systèmes de même origine embryonnaire, mais non-radiations dépendants (cancers du col de l'utérus, du vagin et de la vulve) contaminés ou non par Papillomavirus; (23)

(3) de fibroblastes et kératinocytes en culture, transformés par différents virus à DNA; (24)

(4) de cancers d'origines inflammatoires (vessie, maladie de Lapeyronie).

Dans tous les cas nous avons trouvé une diminution très précoce (même dans les cellules en culture d'origine embryonnaire) de cette activité (70-95%) et une augmentation très marquée de la quantité d' H_2O_2 formée (2-3 fois la normale) après irradiation UV. Un point remarquable est qu'il n'y a pas de parallélisme entre l'effondrement de l'activité catalase et le degré de possibilité de réparation du DNA. Par contre, il paraît y avoir :

(a) **synergie** entre les % de diminution de ces deux activités, la précocité d'apparition de la maladie et le pronostic de survie, mais, de toutes façon

(b) **cancérisation**, seulement un plus tard dans la vie de l'individu lorsque seule l'activité catalase est diminuée;

III) ENZYMES DE DEFENSE ET RADIORESISTANCE. (25-26)

Une pigment transporteur d'oxygène, l'hémocyanine de scorpion, est depuis longtemps mis en cause dans la radiorésistance exceptionnelle de cet animal. Nous avons montré que cette protéine multimérique, à Cu^{2+} et Zn^{2+} de $2 \cdot 10^6$ Da de PM, ainsi que ses sous-unités possèdent : une **activité de type catalase**, une **activité de type SOD** qu'elles conservent même après irradiation de 4000 Gy.

L'étude moléculaire de l'hémocyanine dans le cadre de la radioprotection a été abordée par le biais des travaux actuels sur les séquences d'hémocyanines d'Arthropodes:

a) la réalisation d'une sonde spécifique au(x) gène(s) hémocyanine a demandé la recherche d'une séquence conservée dans les différentes sous-unités protéiques. La séquence:His-His-Trp-His-Trp-His remplit ces caractéristiques et semble, de plus, impliquée dans la structure du site actif. Une séquence de DNA complémentaire au mRNA a donc été synthétisée afin de servir de sonde pour rechercher le messenger de l'hémocyanine.

b) La purification des RNA messagers et leur hybridation avec la sonde oligonucléotidique spécifique, a permis de déterminer la taille du (ou des) messenger (s) de l'hémocyanine. Le cDNA correspondant à l'hémocyanine a été cloné. Son expression dans des systèmes eucaryotes devrait permettre :

1) l'étude de la "réparation" éventuelle des systèmes déficitaires cités ci-dessus par un fragment de petit poids moléculaire,

2) ainsi que de l'éventuel transfert de la radio-résistance de l'hémocyanine à différents systèmes cellulaires.

CONCLUSIONS

Les produits de réduction de l'oxygène obtenus aussi bien au cours du métabolisme normal que lors de réactions pathologiques paraissent entrer très activement en jeu dans la mise en place de la transformation cellulaire, et/ou de la cancérisation. En contre partie, la radio-résistance naturelle du scorpion qui est de plus de 1000 fois supérieure à celle de l'Homme est en majeure partie portée par son pigment sanguin natif (l'hémocyanine, protéine de 2.10^6 KDa) et ses sous-unités (75 et 53 KDa) qui possèdent tous des activités de type catalase, SOD et peroxydase, dépendant du Cu^{2+} dans le site actif du domaine 2; Ces activités résistent à au moins 4000 Gy. L'obtention en grandes quantités de ,

TRANSFER OF RISK COEFFICIENTS ACROSS POPULATIONS¹

Len R. Rasmussen

Radiation and Industrial Safety Branch
Whiteshell Research Laboratories
Pinawa, Manitoba Canada

ABSTRACT

The variation of lifetime risk projections for a Canadian population caused by the uncertainty in the choice of method for transferring excess relative risk coefficients between populations is assessed. Site-specific projections, varied by factors up to 3.5 when excess risk coefficients of the BEIR V relative risk models were transferred to the Canadian population using an additive and multiplicative method. When the risk from all cancers are combined, differences between transfer methods were no longer significant. The Canadian projections were consistent with the ICRP-60 nominal fatal cancer risk estimates.

INTRODUCTION

Current lifetime risk estimates of cancer mortality following exposure to ionizing radiation are based almost entirely on the Life Span Study of the Japanese survivors of the atomic bombings of Hiroshima and Nagasaki. As a result of the latest follow-up of cancer mortality of the cohort (1950-1985), the relative risk model has become preferred over the absolute risk model for projecting lifetime cancer risks following radiation exposure (ICRP 1991, NRC 1990, UNSCEAR 1988, Shimizu et al. 1988). The use of the relative risk model introduces the question of how to transfer excess relative risk coefficients to other populations, such as Canada, where baseline cancer rates are substantially different from those in Japan.

There are two plausible risk transfer methods. The first is a multiplicative method whereby excess relative risk coefficients are transferred directly and applied to the baseline cancer mortality rates of the population of interest. The second is an additive method whereby the excess relative risk coefficients are first applied to the baseline rates of Japan and then the resulting excess absolute risk coefficients transferred to the population of interest. Presently, there is no general agreement on which, if any, transfer method should be used or whether the same method should be used for every cancer site (ICRP 1991).

The purpose of this paper is to assess the variation in the projected lifetime risk of fatal cancer per unit dose for a Canadian population caused by the uncertainty in the choice of risk transfer method. Variations are compared with statistical errors in the excess relative risk coefficients caused by sampling variation. In addition, Canadian projections are compared with the nominal fatal cancer risk coefficients derived in ICRP publication 60, the 1990 Recommendation of the ICRP (ICRP 1991).

¹This paper is based on a M.Sc. thesis report (Rasmussen 1991) commissioned by the Atomic Energy Control Board of Canada.

METHODS

Lifetime risk projections for the Canadian population are performed using the excess relative risk coefficients of the modified relative risk models developed by the BEIR V Committee (NRC 1990) of the respiratory tract, female breast, digestive system, and other remaining organs and tissues. Projections are performed for a single hypothetical whole body exposure of 1 Sv and projections are averaged over the life-table age distribution of a 1982 and 1988 Canadian population with equal number of male and females. A dose and dose rate effectiveness factor of 2 is assumed.

The additive risk transfer method uses the baseline cancer mortality rates of the 1984 Japanese population² to compute the conditional absolute excess risks. The multiplicative method uses the baseline cancer rates of 1982 Canada (StatCan 1985) and 1988 Canada³. A Canadian life-table is constructed using age-specific mortality rates for all causes of death in Canada for 1980-1982 (StatsCan 1985b) and 1988. Approximate 90 percent confidence intervals representing the uncertainty due to sampling variation are calculated indirectly by multiplying the ratio of the upper and lower 90% confidence interval of the excess lifetime risk point estimate given in the BEIR V report (NRC 1990) to the Canadian projected lifetime fatal cancer risk. The Canadian projections are compared to the ICRP-60 nominal risk factors by combining the ICRP site specific values to give the corresponding groupings in the BEIR V report⁴.

COMPARISON OF BASELINE CANCER MORTALITY RATES IN CANADA AND JAPAN

Table 1 shows the standardized⁵ sex and site specific cancer mortality rates for Canada and Japan. The annual background risk of cancer mortality are similar between Canada and Japan for leukemia, Canadian rates being higher by about a factor 1.07. For other cancers, baseline rates differ substantially between the populations. Cancers of the respiratory tract, female breast, and other remaining cancers are greater in Canada than Japan by factors of about 2, 4, and 2 respectively. For digestive cancers, the Canadian baseline mortality rate is about half the rate in Japan. The differences in site-specific baseline rates between Canada and Japan tend to be offsetting so that overall, the rate for all cancers combined is similar between Japan and Canada (Canadian rates higher by a factor of 1.2).

RESULTS

Table 2 shows the age- and sex averaged⁵ site-specific risks of fatal cancer per Sv for the Canadian population. Given is the lifetime fatal

² Supplied by Dale Preston of the Radiation Effects Research Foundation

³ The 1988 Canadian rates were calculated using data from 1988 causes of death tables and population estimates supplied by Statistics Canada

⁴ Standardized to the age distribution of the 1988 Canadian population.

⁵ Averaged over a Canadian life table population (ages 0-85) and equal number of males and female

cancer risk averaged over transfer methods (the nominal risk estimates) the variation with transfer method, the 90% confidence interval of the nominal estimates, and the nominal values given by the ICRP. For cancers of the respiratory tract, female breast, and other remaining cancers the multiplicative transfer method gives a significantly higher projected risk than additive method by factors of 1.8, 3.5, and 2.4, respectively. For digestive cancer, the fatal cancer risk projected by the multiplicative method is almost half that of the additive method. These variations are comparable to the uncertainty caused by sampling variation (i.e. 90% confidence intervals). The projected lifetime risk for radiation induced leukemia is similar between transfer methods, differ by a factor of 1.14. The site-specific differences between transfer methods tends to be offsetting so that when the lifetime risk from all radiation induced cancers are combined, there is little difference between transfer methods (transfer methods differing by a factor of 1.18).

The site-specific lifetime risk projections for the Canadian population are in good agreement with the nominal fatal cancer risk factors given in ICRP publication 60 (ICRP 1991). For specific cancer except leukemia, the ICRP risk factors within the range projected by the two transfer methods for Canada. The ICRP risk factor for radiation-induced leukemia mortality is lower than that for Canada (ICRP: 50×10^{-7} per Sv, Canada: 70 to 80×10^{-4} per Sv). However, this is not significant in view of the uncertainty due to sampling variation and the ICRP do not use the BEIR V risk coefficients.

CONCLUSION

The choice of method for transferring excess relative risk coefficients is a significant source of uncertainty in lifetime risk projections of fatal cancer resulting from radiation exposure. Canadian site-specific projections can be expected to vary up to a factor 3 or more, depending on the transfer method and cancer site. In view of the difficulty in choosing between transfer methods and the significant effect on site-specific risks, it would seem the appropriate approach is to carry out lifetime risk projections using both methods and then average the results.

TABLE 1

NATIONAL CANADIAN AND JAPANESE STANDARDIZED* MORTALITY RATES
BY CANCER SITE (DEATHS PER 100,000 PERSONS PER YEAR)

Augmentation of Proliferative Responses of Mouse
Splenocytes by Low Dose X Ray Irradiation

ABSTRACT

To elucidate the hormetic effect on the immune system, we studied the mitogen induced proliferation of mouse splenocytes after low-dose X irradiation. Major results obtained were as follows; Proliferative response of mouse splenocytes induced by Con A or PHA was augmented by a single whole-body irradiation with 2.5 or 5 cGy, and its optimal concentration of Con A rose to 4 $\mu\text{g/ml}$ from 2 $\mu\text{g/ml}$ in the sham irradiated control group. Furthermore, irradiation with 5 cGy prevented mouse splenocytes from declining of mitogen responses by subsequent 4 Gy irradiation.

INTRODUCTION

Radiation hormesis is a new concept for radiation biology. The concept is that low-dose irradiation stimulates bio functions¹. A phenomenon in which low-dose irradiation stimulates mitogen-induced proliferation of human T-cells in in vitro experiments has been reported². In general, however, it was well known that immune cells are easily injured by X-ray irradiation, since they are highly sensitive to X-ray. To verify the hormetic effect of low-dose whole-body X-ray irradiation, in vivo, in cells of immune system, we studied effects on the proliferative responses of mouse splenocytes induced by various mitogens. The results obtained are reported in this paper.

METHODS

Male BALB/c mice of 7 weeks old were given a single whole body X ray irradiation of 2.5 or 5 cGy at an irradiation dose rate of 1 cGy/min. SHIMADZU X ray irradiator MBR-1505R was used. Another experiment was made, where the dose was divided over 5 days, 1 cGy/day. Spleen was taken out 4 hours after the single irradiation or 4 hours after the final irradiation in the divided irradiation case. Cell suspensions were prepared.

Splenocytes were cultured on RPMI-1640 medium containing 5% fetal bovine serum under an environment of 37°C and 5% CO₂, in the presence of 1-16 µg/ml of Concanavalin A (Con A) or 25 µg/ml of Phytohemagglutinin (PHA) or lipopolysaccharide (LPS), for 44 hours. Next, ³H-thymidine was added to the culture, and cultivation was continued for 4 hours. Radioactivity taken into the cells was measured by a liquid scintillation counting system.

Some animals were irradiated with 4 Gy 21 days after the low-dose whole body irradiation of 5 cGy. Spleen was taken out 4 hours or 24 hours after the last irradiation. Response of splenocytes to mitogen was examined in the same manner.

The controls of these experiments were mice for which the low dose irradiation operation was substituted with a sham operation.

CONCLUSIONS

To conclude, our major results are as follows;

(1) As shown in Fig. 1, proliferative response of mouse splenocytes induced by Con A or PHA was augmented by a single whole-body irradiation with 2.5 or 5 cGy, whereas the proliferation induced by LPS was augmented only by irradiation with 2.5 cGy. And, the fractionated whole-body irradiation

exhibited less effect on PHA-induced proliferation than a single irradiation.

(2) Although the data is not shown in the paper, low-dose whole-body irradiation with 5 cGy prevented mouse splenocytes from declining of mitogen-induced proliferation by subsequent high-dose irradiation with 4 Gy.

(3) As shown in Fig. 2, Con A-induced proliferation of mouse splenocytes was augmented by an irradiation with 2.5 cGy over the range of 1-16 $\mu\text{g/ml}$ of Con A. Its optimal concentration of Con A rose to 4 $\mu\text{g/ml}$ from 2 $\mu\text{g/ml}$ in the sham-irradiated control group.

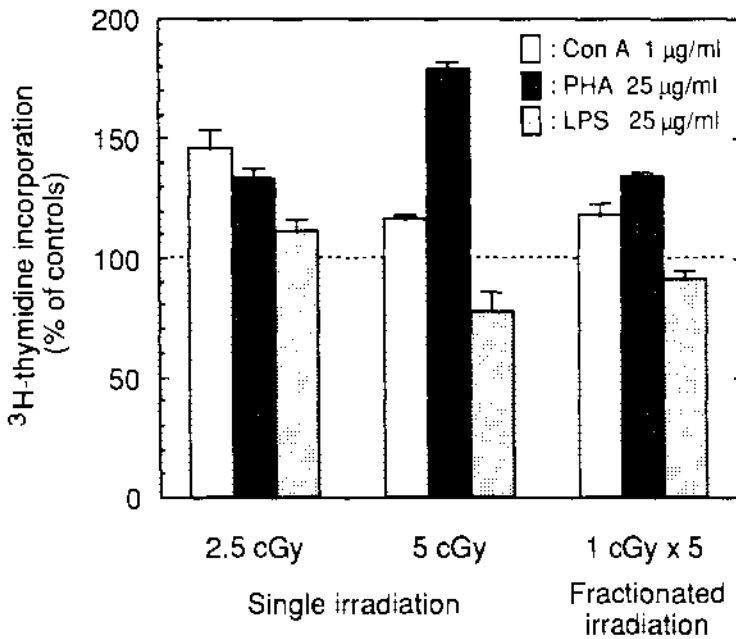

Fig. 1. Effect of a single whole-body X-ray irradiation and fractionated irradiation on mitogen-induced proliferation of mouse splenocytes. The number of mice per experimental point is 13.

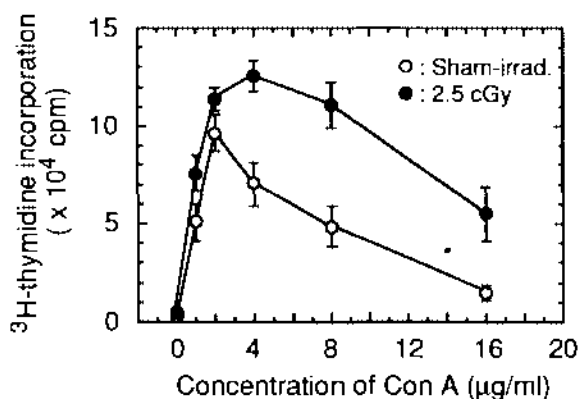

Fig. 2. Effect of a single whole-body X-ray irradiation (2.5 cGy) on Con A-induced proliferation of mouse splenocytes, as a function of concentration of Con A. The number of mice per experimental point is 12.

The augmentation of the response to mitogen in mouse splenocytes this time was also observed in F344/NSlc rats in the past³. We considered significant augmentation of mitogen-induced proliferation of mouse splenocytes by low-dose whole-body X-ray irradiation is one of hormetic effects. And, our finding suggests some functional alteration in splenocytes from low-dose irradiated mice.

STUDY ON LEUKOCYTIC ENZYMES ACTIVITY INFLUENCED
BY IONIZING IRRADIATION

Snežana Milešić

Institute of Occupational and Radiological Health,
University clinical center of Belgrade

and

M. Jančić., S. Dodić

ABSTRACT

Both alkaline phosphatase (APL) and myeloperoxidase (MPO) activities in neutrophilic granulocytes influenced by different doses of ionizing irradiation were studied.

In individuals professionally exposed to the low doses, the enzyme activities were repeatedly determined during the period from 1986-1989. The activities of APL and MPO in patients exposed to the therapeutic irradiation were presented before, during and after the therapy.

Both alkaline phosphatase and myeloperoxidase activities were evidenced by cytochemical staining of capillary blood smears.

INTRODUCTION

Hematopoietic tissue is, according to its radiosensitivity classified into the first group.1 Therefore, routine peripheral blood analysis is a method of choice in irradiation effects monitoring. Intermittent, low doses induce no depression of bone marrow stem cells (when single doses not higher than 0.5mGy/0.5 mSV/) even during longer time intervals 2. Therefore, numeric changes of peripheral blood elements are not indicative of initial impairment in routine monitoring of patients. Intracellular enzymes are the most sensitive substances to ionizing irradiation 3. They are closely related to hematopoietic cells differentiation

and maturation 4. Alkaline phosphatase (APL) and myeloperoxidase (MPO) found in secondary and primary granules of neutrophilic granulocytes are of particular importance 5. Ionizing irradiation induces the inhibition of these enzymes in mature cells as well as its synthesis discontinuation in the course of granulocytopenia 6.

MATERIAL AND METHODS

The influence of small doses of ionizing irradiation was examined in professionally exposed workers (radiologic technicians, N= 27). The irradiation extent was evaluated according to the mean annually absorbed dose calculated on the basis of dosimetric control using thermoluminescent pastilles (TLD) for the whole period of the exposure.

The influence of high doses of irradiation may be evaluated in human model only in accidental situations, which are infrequent and unpredictable. Therefore, we conducted our study in cases of therapeutic application of high doses. In order to approximate local therapeutic application of high doses and accidental situation, we had performed experimental dosimetric evaluation of patient's total body dose by thermoluminescent dosimeters (TLD) as well as by dose measurement on Rando phantom's surface.

Alkaline phosphatase (APL) and myeloperoxidase (MPO) activities were determined by cytochemical staining of capillary blood smear 7. The activity was calculated according to the intensity of staining and expressed as a score of cell count product and stain index per 100 neutrophilic granulocytes, i.e. semiquantitatively 7, 8.

The activity of the examined enzymes in workers exposed to low-dose irradiation was determined repeatedly during the period from 1986 till 1989, and in patients therapeutically exposed to the irradiation, APL and MPO values are presented before, during and

after the therapy 8.

RESULTS AND DISCUSSION

The mean annually absorbed dose obtained for ten-year exposure period was 4.5 mGy, while for thirteen-year exposure period it was 5.59 mGy. Accordingly, professionally exposed workers continually and absorbed approximately the same, low doses.

The estimated effective equivalent therapeutical dose for the whole 6-week period of therapy was 2.6 Sv, with 1.3 Sv for the 2-week period.

AFL scor values in professionally exposed workers after 10 and 13 years of exposure were mutually compared, and also compared with the controls having 10 and 13 years of service. The results are presented at Table 1.

Table 1.

AFL scor in exposed and control groups

Observed groups	N	<u>Years of Service</u>	
		10 yrs	13 yrs
E	27	39,93	39,53
C	16	45,50	47,81
		0.62NS	0.11NS

Mean RBC scor values are identically compared and presented at the Table 2.

Table 2.

MFO scor in exposed and control groups

Observed groups	N	Years of Service	
		10 yrs.	13 yrs.
E	27	132.29	91.79
C	16	168.0	170.0
p		0.001 S	0.001 S

As it may be seen from labels 1 and 2, there was no significant difference in AFL scor in controls. Duration of exposure had no statistic significance.

MFO scor was significantly lower in the exposed workers, decreasing with the duration of exposure (Figure 2).

Table 2 reviews mean AFL and MFO scor values obtained from 18 patients, therapeutically irradiated due to the tumor for 6 weeks, before, during and after the therapy:

Table 3.

AFL and MFO scor in Therapeutically Irradiated Patients

AFL, MFO	N	Before RTh	During RTh	After RTh
X SCOR AFL	18	66.61	85.11	34.17
X SCOR MFO	18	141.77	109.20	73.0

The analysis using Paired T-test revealed: the difference between mean values of both enzymes showed significance of p 0.05, before, during and after the therapy. AFL values significantly increased during the

Figure 1.
APL SCOR in exposed and control group after 10 and 13 years

Figure 2.
MPO SCOR in exposed and control group after 10 and 13 years

Figure 3.

APL and MPO scor tendencies influenced
 by high doses during the 6-week
 irradiation therapy

therapy, with sudden decrease after the irradiation, while significant decrease of MFO values was observed both during and after the irradiation when compared to pre-irradiation values (Figure 3).

CONCLUSION

Our results revealed significant decrease of MFO values under the influence of irradiation, while APL values decrease, influenced by low doses was insignificant. After the initial increase, significant fall was observed induced by high doses.

PERCUTANEOUS ABSORPTION OF TRITIATED OIL AND DOSIMETRIC CONCERNS

A. Trivedi

Dosimetric Research Branch, AECL Research, Chalk River Laboratories
Chalk River, Ontario, Canada.

ABSTRACT

Tritiated oil deposited on the skin provides an intake route for organically bound tritium (OBT) and tritiated water (HTO). The kinetics of tritium excretion in the urine of hairless rats exposed to tritiated vacuum-pump oil have shown a much shorter effective time constant for OBT, compared to HTO. However, the detection of long-term tritium activity in urine indicates that there is also long-term retention in the body. This is attributed to metabolism and assimilation of tritiated compounds into the body.

INTRODUCTION

Tritium has been measured in pump oils within the vacuum pump reservoirs in tritium handling facilities [1]. A high-performance vacuum pump operating in the tritium handling facilities can retain significant amounts of tritium activity in oil and lubricants [2]. Tritium activities in the pump oils from a D-T neutron generator facility are being detected and reported as a possible source of internal contamination during maintenance of the pump systems [3].

Tritium contamination of vacuum-pump oil can result in radiation-induced polymerization of the oil. Thermal degradation and tritium radiolysis of pump fluids are considered to be critical factors in generating specific tritiated impurities. Also, tritium gas in the oil may convert to tritiated water by the catalytic effect of the emitted β -rays. This conversion becomes an important factor in contamination evaluation.

The absorption of tritium through the skin has long been recognized as a possible route of intake. Our earlier study on the skin-contact exposure to tritium-gas-contaminated metal surfaces has increased the awareness of the radiological consequences of such tritium exposures [4]. To enable improved assessment of the risk from skin contaminated with tritiated oil, the urinary excretion of tritium following the skin-contact exposure of hairless rats has been investigated. The analysis of urinary excretion of tritium is performed to evaluate the possible radiological consequences from this mode of contamination.

EXPERIMENTAL PROCEDURE

Tritiated oil was prepared by the Chemical Engineering Branch at Chalk River Laboratories. The tritium content of the oil was $31 \pm 1 \text{ mCi} \cdot \text{g}^{-1}$ ($1.2 \times 10^3 \text{ MBq} \cdot \text{g}^{-1}$). To prevent abrasion to the skin, six-month old male hairless rats (Sprague-Dawley:hy,hy) were used. The contaminated oil (28 MBq in 0.05 mL) was applied against the dorsal skin (4 cm²) to expose the animal percutaneously. The application was short (less than a minute), but the oil remained on the skin. Urine samples were collected before exposure to provide

background specimens, and were subsequently collected at regular intervals to determine HTO and OBT rates of excretion.

RESULTS AND DISCUSSION

The application of contaminated oil on the skin does not represent an acute exposure, as a thin film of contaminated oil on the skin was detected in the post-exposure examinations (within 24 h). This situation may represent a continuing exposure for the period in which a gradient of the contaminated oil exists across the skin.

Tritium in pump oil has been identified as existing in two distinct chemical states: one is tritiated organic impurities or nonexchangeable tritium (95%), and the other is tritiated water (5%).

Tritiated water in the oil should behave similarly to HTO from skin exposed to HTO vapour [5]. Thus HTO absorbed through the skin from contaminated oil should distribute uniformly throughout the body, and be excreted with a dominant single time constant. However, the urinary excretion of HTO from contaminated animals was best fit in terms of two exponentials: a fast- and a long-term component (Fig. 1). The fast component of HTO excretion was represented with an average half-life of about 3.3 ± 0.4 days (Table I). This half-life value is identical to the value of clearing component observed after skin exposure to HTO, suggesting that the HTO excreted in this component originated predominantly from the oil. The presence of a second component with half-lives of 25.5 ± 3.5 days was attributed to the fact that the turnover of HTO in the body is initially influenced by rapid absorption of tritium through the skin as tritiated water with subsequent excretion in the same form, followed by the delayed excretion of HTO as a result of catabolism of stored OBT in the body.

TABLE I Urinary Excretion of Tritium ($\text{MBq}\cdot\text{d}^{-1}$) and Biological Half-Lives (days). Values are mean of four independent animal experiments ($n=4$), and the standard deviation (S.D.) for each value is in parentheses.

Component	$U_{0,1}$	$U_{0,2}$	$U_{0,3}$	$T_{0,1}$	$T_{0,2}$	$T_{0,3}$
HTO	$2.7\text{E-}02$ ($1.5\text{E-}02$)	$2.0\text{E-}05$ ($4.7\text{E-}06$)		3.3 (0.4)	25.5 (4.0)	
OBT	$9.0\text{E-}02$ ($4.5\text{E-}02$)	$6.1\text{E-}04$ ($3.0\text{E-}04$)	$1.3\text{E-}05$ ($4.1\text{E-}06$)	1.0 (0.1)	5.4 (0.6)	31.4 (1.9)

A significant amount of OBT was also observed in urine (Fig. 1). The excretion of OBT elevated sharply and reached a maximum at 12 h. The OBT excretion in urine was analyzed in terms of three exponentials: fast-, medium- and long-term components. As shown in Table I, a much faster OBT (compared to HTO) clearing was noticed with a half-life of 1.0 ± 0.1 day. The slower

components were represented with 5.4 ± 0.6 days and 31.4 ± 1.9 days of half-lives. The amount of OBT excreted in the urine during the experimental period (for 112 days) accounted for about 75% of the total tritium excreted, whereas HTO concentration ranged between 20% and 30%.

The urinary concentrations and kinetics of tritium not only reflect the degree of percutaneous absorption of tritiated oil, but also exhibit a function of the distribution and elimination characteristics of the tritium in the body. The majority of tritium (~80%) is cleared in the urine in very early periods post-exposure (within five days). However, that fact does not account for the total applied activity on the skin. The excretion of total tritium in urine accounts only for 1% of the applied activity. The unaccountability of a large portion of tritium in urine suggests that a significant portion of tritium has: (i) been retained in the body, (ii) been lost through exhalation, (iii) been evolved from the skin, or (iv) may never have entered the body. The last seems most likely; however, the estimation and accountability of such large portions of tritium are prerequisites in developing a proper metabolic understanding.

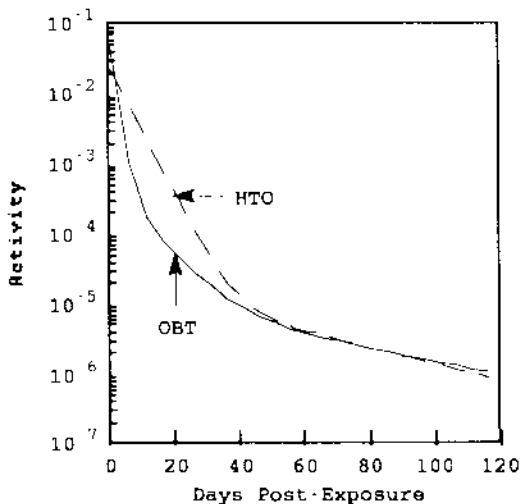

Figure 1. Urinary excretion (MBq.d^{-1}) of tritium following skin-contact exposure to tritiated oil.

The skin forms a complex barrier to external contaminants. The knowledge of the skin penetration of tritium contaminants is important. In predicting the rate at which tritiated contaminants penetrate the skin, it is necessary to consider the fundamental physiology of the skin and relate this to the possible rate-limiting steps in the permeation process. It would be useful to learn quantitatively the absorption and retention of tritium in

skin. It is thought that tritium diffuses passively in all its forms across the skin. This assumption is necessary if a simple mathematical representation of the experimental results is required for dosimetric interpretations.

Comparing the current data with our earlier work on tritium-gas-contaminated metal surfaces [4], it is apparent that the mode of contamination from two different sources results in similar tritium excretion kinetics in urine. Such observations support (but do not prove) the notion that tritium contamination from metal surfaces is due to the transfer of tritium impurities that originated external to the body and are then assimilated into the body.

CONCLUSION

It is apparent that skin-contact exposure to tritiated oil results in HTO uptake and OBT accumulation in the body. The accumulation of OBT at the point of contact in the skin and in various tissues influences the kinetics of tritium excretion in urine. The long-term retention of tritium in the body can contribute to doses to the skin and other tissues. It is therefore important to illustrate the significance of long-term retention of tritium in the body and its influence on dosimetry.

ABSTRACT

The functional state of blood antioxidant system (AOS) was studied at liquidators of Chernobyl AES crash 4-5 years ago irradiation (200-250 mSv). The increasing SH/SS ratio in protein and non-protein thioldisulfide system, the prevailing of ascorbic acid oxiforms in plasma, changes activity of catalase, glutathionreductase and superoxidedismutase, rising of the intensity of peroxide lipid oxidation and nucleotides degradation have been revealed. Thus, the adaptational failure of the AOS may be regarded as one of the leading links in low dose irradiation injuring effect.

INTRODUCTION

It is now evident that one of the most common manifestations of the effect of stressor agents on man's organism is the intensification of free-radical oxidation processes. Obviously, this fact is to be regarded as a side effect of the growing intensity of biochemical reactions in response to the action of extreme factors, including radiation through neuro-endocrine regulation mechanisms [1]. As known, these processes are capable of exercising multiplan injuring effect on living cell.

The manifestation of the injuring effect of free radicals and peroxide compounds is hindered by the complex multicomponent antioxidant system (AOS) providing binding and modification of radicals, the prevention of peroxides formation or their destruction. In its composition are included bioantioxidants of different nature and antiperoxide enzymes [2,3]. So, pro- and antioxidant systems exist in dynamic equilibrium and provide in their interaction the adaptive reactions in response to the effect of extreme factors, ensuring radioresistance of organism [4].

MATERIALS AND METHODS

Complex clinical examination employing modern functional and biochemical methods was conducted with 35 men-liquidators of the consequences of Chernobyl AES crash 4-5 years ago radiation influence in doses 200-250 mSv per 1-2 months. The observed patients were suffered from different internal diseases (neurocirculatory asthenia, hypertensive and

ischemic heart diseases, stomach and duodenum ulcers, chronic gastroduodenitis) which have been revealed after their work in Chernobyl. The control group consists of 104 healthy donors. We studied contents of sulfhydryl (SH) and disulfide (SS) groups in whole blood [5], concentrations of ascorbic acid (AA) and its oxiforms (OF) in plasma [6]. Activity of superoxidodismutase (SOD), catalase and glutathionreductase (GR) was determined [7]. Intensity of peroxide lipid oxidation was estimated by accumulation of malone dialdehyde (MDA) in whole blood [8]. Valuing of lymphocyte products of nucleotides degradation (PND) was executed by the spectrofluorimetric method [9].

RESULTS

As the analysis of data obtained has demonstrated changes were observed in the non-enzymatic link of the AOS in low dose irradiated patients (Table).

TABLE Values of AOS in low dose irradiated patients

PROOFS	CONTROL GROUP	PATIENTS
Protein		
SH (mM/l)	13.00 ± 0.20	12.30 ± 0.20 *
SS (mM/l)	4.80 ± 0.10	3.79 ± 0.18 **
SH/SS	2.70 ± 0.20	3.81 ± 0.22 *
Non-protein		
SH (mM/l)	1.14 ± 0.01	1.35 ± 0.10 *
SS (mM/l)	0.41 ± 0.01	0.42 ± 0.10

SOD (% of inhib.)	29.6 ± 0.9	17.2 ± 1.6 *
MDA (μ H/l)	76.8 ± 5.1	101.8 ± 2.5 *
PND (%)	50.0 ± 8.5	70.7 ± 1.5 *

* - differences with a control group are significant (* - p<0.05, ** - p<0.01) by Fisher test

In particular, the significant disorders were observed in thioldisulfide system which displayed by increasing of SH/SS ratio both in protein and non-protein fractions of the solid blood. And if in protein part it was connected with the reducing value of SS-groups then in non-protein part it was due to significant increasing value of SH-groups.

At the same time the functional state of ascorbic redox system was characterized by the great prevailing of its oxiforms in plasma.

Changes of enzymatic function were exclusively individual: the activity of catalase and GR more often has

been increased than decreased but overall there weren't differences between the enzymatic activity of low dose irradiated patients in comparison with a control group. At the same time SOD was depressed in all observations.

On the background of data obtained the level of MDA and FND were significantly rised.

DISCUSSION

The increasing of non-protein SH-groups and enzymatic activity may testify the hormetic influence of low dose irradiation on the nonspecific resistance in the process of adaptation. From the one side, unproportional decreasing of protein SS- (to a considerable extent) and SH- groups (to a smaller extent) may be limited by structural protein alteration which are accompanied by changes of correlation between camouflage and accessible for determination protein thiol and disulfide groups. From the other side, the rising of protein SH/SS ratio may be regarded as the protective reaction at the more low adaptational level in the conditions of the oxidizing agents excess which is realized at non-protein group expence.

Even under conditions of AOS adaptative activation there aren't abilities to prevent the increasing of peroxide lipid oxidation, DNA degradation and reducing of ascorbic acid oxiforms. So, our data give reason to suggest the significant role of antioxydant insufficiency in the launching mechanisms of disease in low dose irradiation.

At the level of cell metabolism it is manifested in peroxidation reactions, whose biochemical substrate are practically all biomolekules, which leads to injuring their practically. Its consequence is disturbance of biological activity, synthesis, transport and inactivation of enzymes, hormones, vitamins, mediators and other substances, as well as change of receptivity, membrane permeability, energetic deficit, disturbance of hemoglobin transport of oxigen and its utilisation by tissue. This leads to proliferation and differentiation disorders, disintegration of humoral and cellular defence mechanisms, including the immune [10].

In its turn, the result of the changes indicated is disturbance of circulatory homeostasis system, vessel reactivity and microcirculation, heart activity, as well as disorder of pulmonary gas exchange leading to hypoxia of tissues and organs. Subsequent hemocirculatory disturbances together with tissue and cell hypoxia lead to functional and morphological modifications in organs and lifesecuring systems and to development of various organ's pathology in low dose irradiated persons.

CONCLUSIONS

For our opinion, the adaptational failure of the antioxydant system may be regarded as one of the leading links in pathogenesis of damage by radiation low doses.

The methods employed can be recommended for the estimation of radiation danger, standartization and elaboration of the directions for radioprotection. Achived results enable us to propose a pathogenetically founded metabolic therapy of injuries induced by low dose radiation with the employment of antioxidants.

MOLECULAR LOCALISATION OF AMERICIUM , TECHNETIUM
AND CESIUM IN EDIBLE MARINE ANIMALS.
THEIR METABOLIC BEHAVIOR AND THEIR CONSEQUENCES

We show the molecular behavior of americium, technetium and cesium on the chromatographic pattern of each cytosol in the digestive gland of eel and lobster.

The contamination by cadmium seems to compete with americium in the fractions of MW 10,000.

Cesium shows an ionic behavior.

Il est actuellement connu que le radiocésium présente un comportement ionique lorsqu'il est disséminé dans l'environnement.

Notre but a été d'étudier le comportement de ce radioélément au niveau moléculaire chez un animal comestible, l'anguille, et de comparer ces résultats avec ceux obtenus pour le Tc-95m et l'Am-241 chez des animaux marins comestibles.

Le fractionnement subcellulaire a été fait sur le foie et le muscle de l'anguille, selon une méthode utilisée précédemment (Galey et al, 1986 ; Goudard et al, 1991). La radioactivité du césium se trouve essentiellement dans le cytosol : 87 % pour le foie et 79 % pour le muscle.

Le fractionnement chromatographique du compartiment cytosolique est obtenu sur Séphacryl S300 : Fig. 1 et 2.

Fig. 1 et 2 - Chromatographie en gel filtration (Séphacryl S300) de cytosols de cellules de foie et de muscle d'anguille contaminés au Cs 137.

Les figures 3 et 4 nous montrent les chromatogrammes de cytosol de homards contaminés par l'Am-241 et le Tc-95m.

On note :

1 - L'activité pour les deux radioéléments est reportée sur les fractions détectées à 280 et 250 nm entre le V_0 et le V_1 , c'est à dire là où les molécules présentent un coefficient de partage.

2 - L'Am-241 est lié de façon répétitive sur la ferritine. On relève un pic très net d'activité dû au Tc-95m dans la zone de masse 10 000 (métallothionéines). Au niveau des masses molaires 10 000, la courbe d'activité de l'Am-241 présente une dépression accentuée par une induction de métallothionéine (injection de Cd-109), Fig. 5 et 6. et 7.

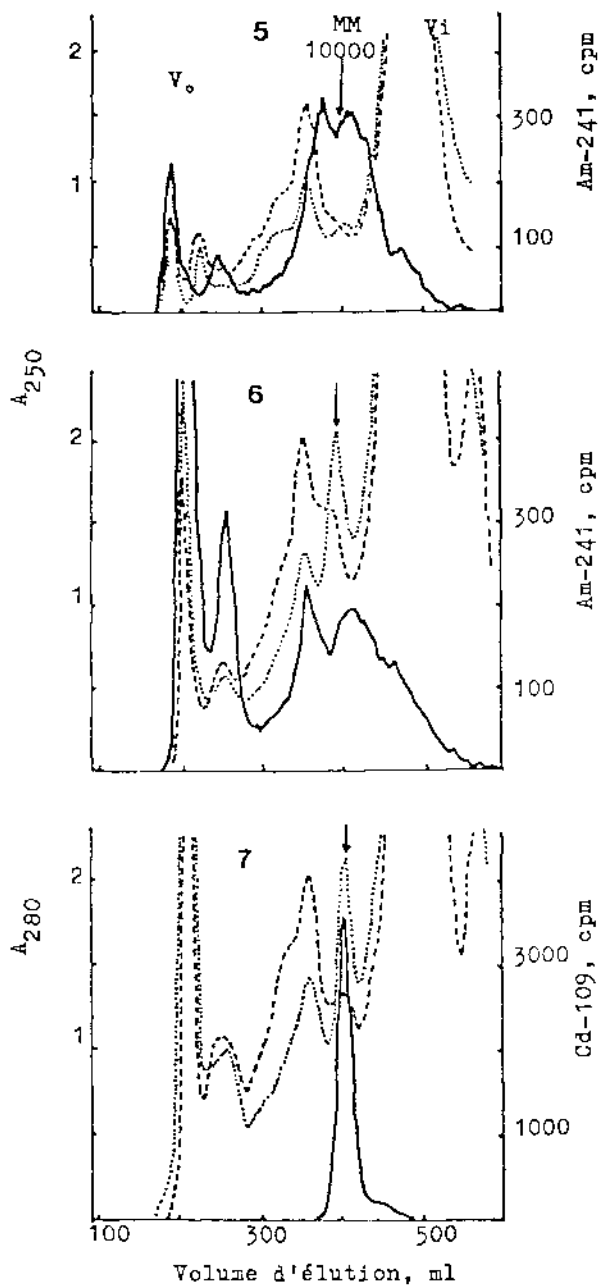

Fig. 5, 6 et 7 - Courbes d'activité de l'Am-241 dans des fractions cytosoliques sans (fig.5) et avec (fig.6) injection de cadmium chez le homard. La fig. 7 montre la place du cadmium.

L'Américium présenterait une compétition défavorable avec le métal inducteur.

Sachant que toutes les petites molécules et les ions ont une diffusion libre dans la phase stationnaire, le Vi représente ce volume. Le rapport entre l'activité dans la zone chromatographique où les protéines présentent un coefficient de partage et l'activité après le Vi peut être considérée comme un rapport de localisation métabolique. Ce rapport est assez représentatif de la diffusion d'un radionucléide dans l'organisme d'un animal contaminé. Il est très bas dans le foie de l'anguille pour le césium, ce qui montre la tendance très limitée du radiocésium à se fixer sur les protéines cytosoliques de cet organe. En comparaison, ce rapport est 500 fois plus élevé pour le Tc-95m et 2500 fois plus élevé pour l'Am-241 dans l'hépatopancreas du homard.

En d'autres termes, deux radionucléides peuvent montrer la même radioactivité au niveau cytosolique dans le foie, mais présenteraient un comportement différent selon ce rapport. Il est possible que la contamination des parties comestibles des animaux correspondrait à ces différences de rapport.

MANAGEMENT OF RADIO FREQUENCY RADIATION EXPOSURES IN TELECOM AUSTRALIA

K.H. Joyner and B. Hocking
Telecom Australia Research Laboratories
770 Blackburn Road Clayton Victoria 3168 Australia

ABSTRACT

Telecom Australia is the largest non-military user of radio frequency radiation (RFR) in Australia and the management of risks to health from RFR exposure are discussed. The Australian RFR Exposure Standard forms the basis of risk assessment. Risk assessment and control procedures including the health surveillance of workers, other special occupational groups and members of the general public are outlined.

INTRODUCTION

Risk management principles regarding safety of workers and public were originally developed in the nuclear industry. They have been recently applied to the use of chemicals in the UK code on Control of Substances Hazardous to Health and the Worksafe Australia code on Workplace Hazardous Substances. Essentially employers are required to identify and assess risks to the health of their workforce, contractors, visitors and public arising from substances and processes, and where appropriate to control any risks. Control should mainly be by engineering or administrative actions rather than relying on protective clothing. Health surveillance is part of the control strategy. This paper extends these ideas to RFR and is based on the authors experiences in Telecom Australia, the Royal Australian Air Force and some small industries.

In order to thoughtfully assess risks from RFR it is essential to be aware of the range of possible health effects [1]; to have an understanding of the mechanisms of interaction of RFR with the human body [1] and to know the relevant safety standards that have been set. The limits permitted by the Australian RFR Exposure Standard [2] are shown in Figure 1.

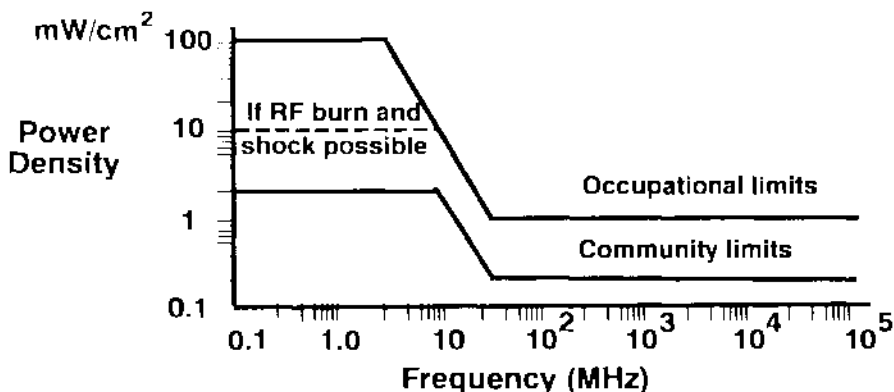

Figure 1: Australian RFR Exposure Standard

RISK ASSESSMENT AND CONTROL - OCCUPATIONAL EXPOSURES

Evaluation

The first step is to measure the exposure. Appropriate measurement procedures and instrumentation are covered in detail in [3]. Any person planning to measure RFR levels should refer to this or similar publications as there are a number of issues with which the "would be surveyor" should be familiar prior to the commencement of the survey. The results of any surveys should be recorded and updated with changes to plant or equipment. The results are then compared to the occupational level of the Australian Standard.

Control Procedures

Where the Standard is exceeded, the levels of exposure should be reduced (to at or below the relevant limit) by various control procedures. Expert advice may need to be sought. Control procedures include:

- Shield or restrict access to the source.

Shielding or isolation of the source through the use of metallic enclosures is the preferred control procedure. Where shielding is not an option, such as in the case of radio and TV broadcast antennas, access restrictions are generally the only control option.

- Reduce power.

During maintenance, a reduction in transmitter power may be an option to achieve compliance with the limits. Indeed the transmitter may have to be turned off in instances where maintenance on antennas and plant is required. Specific procedures for down-power or power-off will have to be included with safe working practices (see below).

- Safe working practices.

All safe working practices such as down-power or power-off procedures, as well as a map of restricted zones should be located in a central position. All staff should be aware of the procedures and the need to up-date this record when changes are made to the site.

- Warning signs.

Warning signs should be installed to identify areas which are off limits to the general public or to personnel, and to identify sources of RFR.

- Protective clothing.

Protective clothing should only be provided where other methods have been shown to be ineffective and where it has been established that the protective clothing is effective.

- Supervision and co-ordination.

The responsibility for supervision and coordination all of these approaches should be given to a unit or person within the organization.

To complement these procedures, training is required for staff about the hazard of RFR and the safe working practices. Special training may be required for the coordinating staff and those persons involved in the survey of RFR levels. Where contractors are working on sites with RFR sources the operator has a responsibility to inform contractors of any risks and the safe working practices to be followed.

Health Surveillance

Health surveillance of workers should be instituted if there is a significant risk of exposure above the community limits. Medical surveillance has various aims:

- At pre-employment it provides a baseline on health status and detects conditions which may be adversely affected by RFR exposures. The latter include electromagnetic interference to, and heating of medical implants (see below).

- At periodic examinations it is intended to detect adverse health effects, (such as changes in the lens of the eye).
- It should also provide medical data for epidemiological studies. (This should be in parallel with documentation on work exposure).

The Australia Standard [2] details the medical examination required for RFR workers. The records of examination need to be stored for durations set by regulatory authorities. Special occupational groups may require further management. Such groups include workers with medical implants, pregnant workers and staff accidentally over-exposed. RFR workers who have medical implants should be evaluated prior to commencing, or on resuming work [4]. Devices such as cochlear implants or pacemakers may be subject to EMI in high field strengths or at certain frequencies. Other devices such as orthopaedic prosthesis or skull plates may act as antennas and cause heating of adjacent tissue. Individual advice should be provided regarding any restrictions on duties or alterations to the work environment.

The specific absorption rate of the foetus may exceed community exposure levels when a pregnant worker is exposed to the occupational exposure limits at certain frequencies [5]. Therefore, it is prudent to reduce exposure of pregnant RFR workers to below the community exposure limit as soon as reasonably practicable for the duration of the pregnancy to ensure maximal protection of the unborn child and to ensure potential legal liabilities are met.

In the event of accidental over-exposure to RFR the following should occur:

- The circumstances causing the over-exposure should be determined and corrected.
- A biophysical investigation should proceed to determine the extent of over-exposure.
- Medical examination should be conducted utilising data on the over-exposure to direct detailed examination [6].

Good occupational risk management requires monitoring all of the above to ensure documentation of exposure levels, auditing of work practices and integration of health surveillance and accident data.

RISK ASSESSMENT AND CONTROL - PUBLIC EXPOSURES

The community may be exposed to RFR due to their proximity to transmitting antennas, industrial sources of RFR, or their use of radiocommunications products. Possible exposures should be measured and evaluated, and where required appropriate control procedures introduced.

- Community Exposure Limits

At the boundary of transmitting sites and areas within transmitting sites open to visitors the RFR levels must comply with the community exposure limits (see Fig. 1). For industrial sources of RFR (eg RF welding) barriers and warnings should be place at the boundaries where community exposure limits may be exceeded.

- RFR Products.

Radiocommunication devices or equipment, where required, will also have to comply with the community exposure limits (see Fig. 1). Clear instructions on the appropriate use of the equipment and the placement of antennas will need to be included.

- Electromagnetic Interference (EMI)

EMI generally manifests itself as the visible or audible degradation of TV or radio reception. EMI is irritating but in general, not life threatening. However, there are instances where EMI may have serious consequences, such as the disruption of air navigation services and electronic systems of aircraft, the inadvertent detonation of electro-explosive devices and ignition of flammable atmospheres. In hospitals where patients may have susceptible medical devices it is particularly important RFR fields be controlled to avoid EMI.

- Town Planning

In Australia some State Government Departments have developed guidelines for town planners in order to protect the public and to avoid disruption of RFR transmissions. These require that where development is proposed it should be critically assessed if it is within 500 m of VHF, UHF broadcast services and 1000 m of radar and HF sources, or if transmission paths may be interrupted. In addition, it has been recommended that planning authorities not approve new transmission sources which would expose the surrounding community to levels in excess of relevant Australian Standards.

- Education and Information

In addition it is desirable the public be provided with information on RFR and good public relations be fostered through the use of videos [7] booklets [8] and the lay and scientific media. McKlveen & Blitz have described a community consultation process for ionising radiation concerns [9] and Morgan & colleagues [10] have outlined the level of knowledge of lay groups about extremely low frequency radiation as a starting point for education programs. These approaches should be considered when communicating about safety of RFR between the public, generators and regulators of RFR.

CONCLUSION

Health risk management for RFR requires a coherent approach to the safety of workers and public. It is desirable that users of RFR adopt a high standard of management and risk mitigation and that personnel are aware of, and adhere to safe working practices. This paper sets out the authors experiences within Telecom and other industries. It is suggested that this paper could form a basis of a code of practice. However, it is recognised that the authors own experience is limited to certain aspects of RFR usage and therefore a wider input is needed for a code to be formed. It is also noted that the above paper is broader than some existing codes, (by inclusion of information on the management of pregnancy or accidents) and thereby indicates ways other codes may be extended to improve risk management.

RESULTS FROM AN AUSTRALIAN SOLAR UVR MEASUREMENT NETWORK AND IMPLICATIONS FOR RADIATION PROTECTION POLICY

C.R.Roy and H.P.Gies

Australian Radiation Laboratory
Yallambie, Victoria, Australia

ABSTRACT

Growing evidence of global depletion of stratospheric ozone has emphasised the need to establish an ultraviolet radiation (UVR) status and trends network, to increase our knowledge of human health effects and to better educate the public about the need to modify personal behaviour in order to minimise UVR exposure. The results presented highlight some of the difficulties that will be faced in developing a consistent approach to solar UVR protection in Australia.

INTRODUCTION

Recently there has been considerable concern over the likely depletion of the stratospheric ozone layer due to the effect of trace gases released to the atmosphere as a result of man's activities. Reports have suggested that a depletion of 2 to 3% occurred in the Northern Hemisphere during the last decade and atmospheric model calculations^{1,2} indicate possible depletions of up to 15% in the coming decades.

The development of the ozone hole in the stratosphere over Antarctica during winter^{3,4} is almost certainly due to reactions involving organochlorine chemicals⁵. Model calculations, which suggested that the breakup of the ozone hole in late spring may result in the transportation of ozone-depleted air into the mid-latitudes, have been confirmed^{6,7}.

There are indications that the numerical models are underestimating ozone loss and that ozone depletion is increasing at a rate greater than that predicted above. We are undoubtedly entering a period of increased ambient UVB with scant knowledge of the implication for plant and marine systems and for human health.

The Australian Radiation Laboratory has been making spectral measurements of UVR in Melbourne since the early 1980s. In addition broadband measurements are now made at a total of twenty locations in Australia and at the permanently-manned Australian bases in Antarctica. The aim of these measurements is not necessarily to determine long-term trends in UVR but to provide data on ambient UVR and input into epidemiological studies as well as information to help educate the public about the dangers of overexposure to UVB. Some results from the network will be presented.

EXPERIMENTAL METHOD

The radiation calibration of the network is underpinned by the spectroradiometer (SRM) system at Yallambie (38°S). This PC-

controlled system incorporates a Spex 1680B double grating monochromator with an integrating sphere input optic. The noise equivalent spectral irradiance at 300 nm is less than $1 \mu\text{W}\cdot\text{m}^{-2}\cdot\text{nm}^{-1}$. Global and diffuse horizontal terrestrial UVR over the spectral range 280-400 nm is measured at 1 nm steps with a bandpass of 1 nm on cloud-free days. Radiation calibrations are performed in-situ using a calibrated (traceable to the US National Institute of Standards and Technology) 1000 W quartz halogen lamp. Ideally an Australian network of 5 or 6 spectroradiometers would provide data to satisfy all research interests. However, available resources (both financial and human) dictated a network comprising a permanent SRM in Melbourne, a network of broadband detectors and a portable SRM for the regular field calibration of the broadband detectors.

The broadband measurement system has four radiometers each responding to the regions of the solar radiation spectrum indicated: solar radiation [0.285 - 2.8 μm], solar UVR [295-385 nm], UVB [280-315 nm] and erythemal UVR [280-340 nm].

RESULTS

The 5-day average daily total UVB for Melbourne (38°S) and Darwin (4°S), which provide the extremes of latitude on the Australian mainland, is shown in Figure 1. The data reflect the fact that Darwin has small annual changes in the solar zenith angle and ozone while Melbourne has much larger variations in both. As expected, in winter, Darwin and the other tropical locations experienced significantly higher UVB (up to a factor of eight) than the midlatitude locations. In

Figure 1. Daily total UVB for Melbourne and Darwin

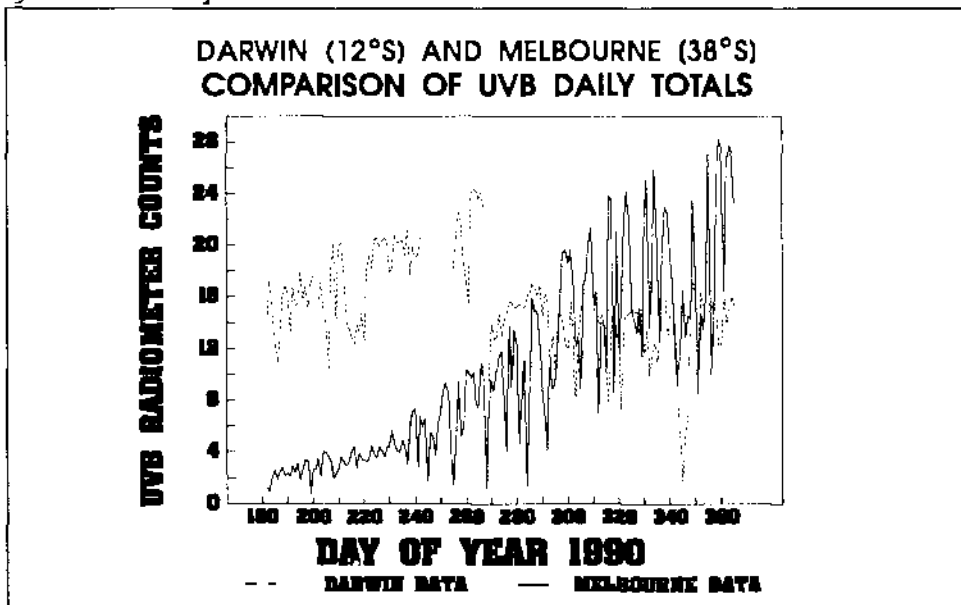

Figure 2. Melbourne solar UVB

summer there is little difference between the various sites. In Figure 2 daily total UVB for Melbourne is plotted for the 3½ year period indicated (1 count is approximately 1.6 kJ m^{-2}).

Antarctic ozone depletion can influence Melbourne ambient UVB during November/December⁷. However, total ozone measured in Melbourne during February 1991 were the lowest values on record for this period. This same period also had low cloudcover compared with recent years. These two important parameters reinforce each other and result here (Figure 3) in large increases in UVB - substantially greater than long-term ozone trends would suggest. In fact, the February 1991 UVB is 37% and 27% higher than that for 1990 and 1989 respectively.

DISCUSSION

In developing radiation protection advice for both outdoor workers and the public the considerable differences in the seasonal profiles of ambient UVB make a uniform approach impossible and advice needs to be tailored to the location.

Estimates of future ozone depletions of 3-4% per decade are alarming but if correct should provide time to pursue critical research and to develop appropriate strategies. Although short-term ozone variations have always been a natural phenomenon effects such as that seen in Figure 3 suggest that either ozone depletion is occurring at a rate substantially greater than the models are predicting or that other atmospheric processes are capable of producing substantially reduced ozone for periods of a month or more. If similar

Figure 3. Comparison of Melbourne UVB for the years 1989-91.

periods of reduced ozone become a regular occurrence then it may be necessary to develop criteria on which public warnings could be based.

The current extremely high skin cancer rates in Australia is the result of past exposure to UVR. Ozone depletion will result in large increases in skin cancer rates unless the public can be convinced of the need to modify their behaviour. A national educational program is required which takes into account not only current behaviour but acknowledges that the public resides in vastly different ambient UVR regions.

**EXPOSURE OF ONTARIO WORKERS TO RADIOFREQUENCY FIELDS
FROM DIELECTRIC HEATERS**

Maurice E. Bitran, John M. Nishio, and David E. Charron

**Radiation Protection Service
Occupational Health and Safety Branch
Ontario Ministry of Labour**

ABSTRACT

As part of a program to assess and reduce the exposure of Ontario workers to non-ionizing radiations, stray electric and magnetic fields from 383 dielectric heaters were measured in 71 industrial establishments from 1988 to 1990. This represents a population of over 800 workers potentially exposed to radiofrequency (RF) electromagnetic fields. Electric and magnetic field strengths at the head, waist, and thigh levels of the operators, corrected by duty cycle, are presented for the different heater types surveyed. Worker exposure data and compliance with Ontario radiofrequency exposure guidelines are discussed.

INTRODUCTION

Electromagnetic energy in the radiofrequency range (1 - 100 MHz) is used in industry to heat dielectric materials such as plastics, woods, glues, fabrics, etc. Dielectric heaters, also known as RF heaters or plastic welders, usually operate at a frequency of 27.12 MHz and have output powers approximately ranging from 0.2 to 100 kW. The dielectric material to be processed is placed between the heater's electrodes, and held under mechanical pressure while the RF field is applied (usually between 0.5 and 10 seconds). The dielectric material is efficiently heated by the energy dissipated when its polar molecules oscillate under the influence of the external RF field.

Dielectric heaters are a significant source of occupational exposure to RF fields. This is the result of the intense stray fields emitted by the habitually unshielded electrodes, the close proximity of the operators to the electrodes, and a standard operating frequency very close to the resonant absorption range of an electrically-grounded adult. A number of surveys have shown that a significant fraction of RF sealer workers are exposed to field strengths in excess of applicable guidelines or standards (1, 2, 3, 4, 5). Overexposure to radiofrequency fields is known to result in a variety of health effects (6, 7, 8, 9). The Ontario Ministry of Labour guidelines limit worker exposure to $900/f^2[\text{MHz}]$ [mW/cm^2] for frequencies between 3 and 30 MHz and to 1 [mW/cm^2] between 30 and 100 MHz, averaged over 1 hour; and to 25 times the 1 hour guideline averaged over 1 second.

MATERIALS AND METHODS

Operator exposure to stray fields from dielectric heaters takes place in the reactive near field, it is intermittent, and the actual RF frequency often differs from the nominal value. In order to take these factors into account, both the electric and the magnetic fields were measured, the "on time" and the production rate of each machine were recorded, and the operating frequency was measured. Measurements were taken at approximately 10 to 15 cm from the left and right sides of the operators at the head, waist, and thigh levels. The measurements were taken while the operators carried out their normal duties at their working positions.

The field strength measurements were carried out with Narda 8616 and 8716, and Holaday HI-3001, meters equipped with broadband, isotropic electric and magnetic field probes. The frequency was measured with a Global Model 5000 frequency counter, and the "on time" was measured with a stop watch. Other information recorded included the type of heater, the nominal power output, the hourly production rate, the presence of shielding, and reports of contact electric shocks.

RESULTS

In total, 383 dielectric heaters were surveyed. The average output power and operating frequency for the different RF heater types are presented in Table I. The corresponding minimum and maximum values are listed below in parenthesis. Most of the heaters surveyed were either of the "Turntable" type (30.5%) or of the "Shuttle Tray" type (24.3%), but enough devices of each type were surveyed to ensure representative exposure averages. "Standard" heaters (general purpose heaters with a fixed work table without attachments) were divided according to the number of operators (one or two). The electric and magnetic field exposure data are presented in Table II, expressed in equivalent power densities to facilitate comparison. This table presents mean exposure levels at the head, waist, and thigh of the operators, corrected for duty cycle, for the different RF heater types. The corresponding minimum and maximum values are listed below in parenthesis. Table III presents the fractions of RF heaters found to produce operator exposure in excess of the Ontario Ministry of Labour RF exposure guidelines.

DISCUSSION

The results of this survey agree with previous findings indicating that a significant fraction of RF heater operators are exposed to high electric and magnetic field levels. Exposure levels were found to depend more on the type of heater used than on their power output. "Standard, 2-Operator" heaters produced the highest exposure levels, with exposure to the magnetic field being higher than to the electric field. Most of these heaters are used in the manufacture of pool liners or water beds. They have relatively high output powers, long "on times", and the electrodes are normally unshielded. In addition, the operators may have to support the material during

processing, and thus stand close to the sides of the electrodes and to the RF feed cables. The proximity of the operator to current-carrying cables and straps may contribute to the larger magnetic field exposure produced by this type of heater. Half of the "Standard, 2-Operator" heaters surveyed exceeded the 1 hour exposure guideline and 38.9% exceeded the 1 second guideline.

The lowest exposure levels were produced by the "Conveyor" heaters (only 3.6% exceeded the 1 hour guideline, and none the 1 second guideline). This is probably due to the greater distance between electrodes and operators allowed by automated feeding. Comparable fractions of the rest of the heaters exceeded the guidelines: 17.6% to 26.5% exceeded the 1 hour guidelines, and 2.5% to 7.8% exceeded the 1 second guideline. In general, the electric field exposure to the head was higher than to the waist and thighs, while magnetic field exposures to the waist and thigh were higher than to the head.

Control measures used to reduce worker exposure included shielding of the interaction area, reducing the production rate, and increasing the distance between the operator and the electrodes. If the material does not have to be held by hand during processing, increasing the distance is a simple and effective way to reduce exposure. This can be facilitated by relocating the controls further from the interaction area, adding a time delay to the cycle, and painting a line on the floor to indicate the high exposure areas. Compliance with the Ministry of Labour RF exposure guidelines is enforced in Ontario workplaces under a general duty clause of the Occupational Health and Safety Act.

ELF Magnetic field distribution around power lines in an urban area

B. Heaton and H.M. McCallum
Department of Bio-medical Physics,
University of Aberdeen, Foresterhill,
Aberdeen AB9 2ZD, SCOTLAND.

Abstract

A number of epidemiology studies have drawn attention to an increase in incidence of leukaemia and other cancers among children living close to sources of ELF magnetic fields. By comparing the studies a lower limit for such an effect was estimated to be $250\text{mA}\cdot\text{m}^{-1}$.

Magnetic field measurements were made around power lines running at 275kV, 132kV and 33kV. Fields above $250\text{mA}\cdot\text{m}^{-1}$ were found as far away as 60m from a 275kV line and 15m from a 132kV power line. Fields near a 33kV power line were below $250\text{mA}\cdot\text{m}^{-1}$.

The maximum magnetic field near an electric blanket was $1\text{A}\cdot\text{m}^{-1}$ and a maximum field of $3.9\text{A}\cdot\text{m}^{-1}$ was measured in an electric train.

Introduction

The work of Savitz (1988), Wertheimer and Leeper (1979) and others has drawn attention to an increase in the incidence of leukaemia amongst children living in close proximity to sources of extra-low-frequency (ELF) magnetic fields. Contradictory work has been published by Fulton et al (1980) in which no increase in leukaemia was found in children living in elevated fields. By comparing the various studies and reworking the data it was concluded that, on balance, it was likely that an increased risk did exist for children living in such fields. It was concluded that the lower limit of the magnetic field strength for such an effect was approximately $250\text{mA}\cdot\text{m}^{-1}$ although it could possibly be lower. The $250\text{mA}\cdot\text{m}^{-1}$ level was used as a threshold to determine whether there was a group of the population potentially at risk in the urban environment of Aberdeen.

One advantage that Scotland has over other parts of the world when considering the effect of ELF magnetic fields, is that there are no power transmission lines greater than 275kV. The main power line into the Aberdeen area runs at 275kV but at the outskirts of Aberdeen drops to 132kV and then to 33kV. Before dropping to 132kV, the power line passes through a suburban area and it was there that most of the measurements were made.

The work of Savitz (1990) has drawn attention to the fact that, within most homes, there are many sources of ELF magnetic fields in everyday use. One of particular interest in Aberdeen was electric blankets, particularly electric over blankets. These can be in use for upto 8 months of the year in Aberdeen and some people will, for some of the time, sleep with them switched on. Measurements were taken in the areas close to both types of blanket and around various electrical items found in the home.

Although it was felt that no problems really existed once the overhead power line kV had dropped to 33kV, one situation was identified as being of interest where the overhead line was only at 15kV; this was the field which was created inside electric trains. The magnetic fields were measured inside a train on the Aberdeen to London route. The line is not electrified until Edinburgh, about one third of the journey, thus allowing comparative measurements to be made.

Figure 1: Magnetic field at right angles to a 275kV power line.

Measurements around power lines

Measurements were made at right angles to the power lines in autumn and summer. The summer measurements are shown in Figure 1. These were taken under a 275kV line on a warm day (for Aberdeen) at 1500 hours. Even in this situation, the distance from the centre of the line to the 250mAm^{-1} field strength boundary was upto 36 metres. Similar measurements made in autumn showed that this boundary could extend as far as 60 metres on a cold autumn evening. The strength of the field obviously depends on the current flowing through the power lines, but it was not possible to obtain numerical figures for the current. Only a subjective assessment could be made that, as the ambient temperature fell, more current would flow. Figure 2 shows measurements taken at right angles to 275kV, 132kV and 33kV power lines. Measurements taken over a week, shown in Figure 3, were made directly beneath the power line each day and showed that the field strength could vary by a factor of two. It is thought that similar measurements made in the evening could well show a much bigger variation. Although insufficient measurements were made to establish where an average magnetic field strength of 250mAm^{-1} would be situated it would not be being too pessimistic to assume a distance of 45 metres from the line. Even on this suburban housing scheme where the houses are quite widely spread, there were many well within this 45 metre distance. The cables pass twenty metres from an area health clinic and over the local primary school playground.

In the U.K. no legislation currently exists to limit the distance power cables must be from the houses.

Measurements close to electric blankets

The measurements were made with the probe positioned between a person and the blanket and at 0.1, 0.2 and 0.3 metres from it. Care was taken that no other local source of ELF magnetic field was present. Several different types of blanket were tested and all had magnetic fields in excess

Figure 2: Magnetic fields at right angles to 275kV (x), 132kV (+) and 33kV (o) power lines.

of 250mAm^{-1} . Some rose to as high as 1Am^{-1} . The field value depended on the inter-wire spacing and the map of the wires in the blanket. In some areas the magnetic fields were found to cancel. No blankets were tested where a conscious effort had been made by the manufacturer to try to cancel the magnetic fields. The information supplied with the blankets was insufficient to easily determine which would have the higher fields and which would not.

Magnetic field levels in trains

The levels measured during the non-electrified part of the journey were low and subjectively appeared to vary with the speed of the train. The maximum field recorded at seat level was 40mAm^{-1} but this rose to 50mAm^{-1} at floor level. Once the line was electrified the magnetic field became, as one might expect, much more stable. The maximum field was recorded with the probe at right angles to the axis of the railway carriage. Measurements made on an occupied seat had a maximum of 3Am^{-1} and measurements on an empty seat a maximum of 3.9Am^{-1} . The field fell to approximately 2Am^{-1} at floor level and 1.4Am^{-1} in the central corridor 1.4 metres from the floor. Although these fields are high, one would have to travel on many train journeys to be exposed to an average field of over 250mAm^{-1} from this source. However many long distance commuters could spend 2 hours per day in these fields, and the drivers, of course, would spend much longer. The long exposures are limited to adults and little positive evidence has been established linking increases in leukaemia or other cancers in adults from exposure to fields of this order of magnitude.

Conclusion

More effort should be put into measuring ELF magnetic fields as they occur in a multitude of situations at, occasionally, surprisingly high levels. In the first instance those countries which

Figure 3: One week survey of the magnetic field directly beneath a 275kV power line.

do not have restrictions on the proximity of power lines to housing should seriously consider introducing them.

OCULAR EXPOSURE TO ULTRAVIOLET AND VISIBLE RADIATION FROM LIGHT SOURCES

Maila Hietanen

Institute of Occupational Health
Laboratory of Physics
Helsinki, Finland

ABSTRACT

Exposure of the eyes to UV radiation and blue light of artificial light sources and the sun was evaluated. A spectroradiometer was used to determine the spectral irradiance at 1 nm intervals from 250 to 800 nm. Various groups of workers are at risk of ocular over-exposure to optical radiation. Outdoor workers maintenance personnel of bright light source as and wear eye-protectors with effective filtering of UV radiation and blue light.

INTRODUCTION

Normally, the human eye is not subject to prolonged bright visible radiation, since it is protected by the blink reflex and head movement. However, in certain situations bright light sources are situated so that high irradiances fall directly upon the the face and the eyes. To be able to work under such uncasual conditions, people have to overcome the natural aversion response. In the present study, spectroradiometric and photometric measurements weighted by various biologic functions were used to estimate ocular exposure to ultraviolet and visible radiation from three types of artificial light sources and the environmental solar radiation.

MATERIALS AND METHODS

In addition to the sun, study material included low-power tungsten halogen spotlights, fluorescent tubes for photostimulation, and photofloods in television and theatres. The main criterion for selecting the objects was a high probability of directly looking at the light source.

A portable spectroradiometer (Optronics 742) was used to determine the spectral irradiance and radiance of UV and visible radiation (250 to 800 nm). The detector attached to the monochromator was a photomultiplier tube. A digitally controlled stepping motor provided automatic wavelength scanning at 1 nm intervals. The spectroradiometric instrumentation was controlled by a microcomputer (Toshiba 3200).

The threshold limit values (TLVs) of the American Conference of Governmental Industrial Hygienists (ACGIH) for occupational exposure of the eyes to UV-radiation and blue light were used to evaluate the exposure of the eyes. In addition to these well-known occupational

recommendations, a biological action spectrum proposed by the International Committee on Lighting (CIE) was applied to UV radiation measurements.

RESULTS

The biologically weighted irradiance and radiance of the lamps studied were highest for photofloods used in TV studios. The unweighted UV-A irradiances varied from 1 to 38 W m^{-2} and the biologically weighted effective irradiance E_{eff} from 0.01 to 6.9 $\mu\text{W cm}^{-2}$. Particularly high values were recorded for metal halide lamps emitting strongly in the UV region. Correspondingly, the blue-light radiances L_B ranged from 0.02 to 1.9 $\text{W cm}^{-2} \text{sr}^{-1}$. The recommended daily exposure times varied from a few minutes to several hours depending on the type of the photoflood. The stage lighting systems studied were equipped with relatively low-power halogen lamps, so that the emitted optical radiation was insignificant at the realistic exposure distances.

UV irradiance and blue-light radiance of a few tungsten halogen spotlights measured at a distance of 1 m are summarized in Table 1. The calculated safe direct viewing times are based on the ACGIH limits for blue-light radiance.

Table 1. Ultraviolet irradiance and blue-light radiance of six various tungsten halogen lamps with the corresponding safe direct viewing times.

Snow ^a	0.023	-	6.8
Ice ^a	0.025	-	9.7

^a reflected solar radiation

An example of the typical UV spectrum of the solar reflections from fresh snow is shown in Fig. 2.

Fig. 1. UV irradiance of the solar radiation reflected from the snow.

CONCLUSIONS

The group of people subjected to the highest exposure is the maintenance personnel working near lamp sources. Also, outdoor workers (fishermen, farmers, personnel of skiing centers) are at the risk of chronic ocular over-exposure. Effective eye-protectors are necessary in such situations, especially if strong after-images are frequently produced.

Ocular exposure of phototherapy light sources is equal to the maximal environmental load of the eyes. Hence, the benefits and risks should be thoroughly considered, until the chronic effects of bright light will be unquestionable known.

Also in future revisions to the occupational and environmental safety standards the risk of ocular damage involved in chronic exposure should be carefully estimated.

**THRESHOLD LIMIT VALUES FOR ULTRAVIOLET RADIATION
MEASURED FOR SOURCES USED IN RESEARCH EQUIPMENT
AND SOME CASES OF OVEREXPOSURE TO UV RADIATION**

A.G. RICHARDS
RADIATION PROTECTION SERVICE
UNIVERSITY OF LEEDS
UNITED KINGDOM

ABSTRACT

The standard for occupational exposure to ultraviolet radiation is based on the Threshold Limit Values (TLV) published by the American Conference of Governmental Industrial Hygienists. These TLV are relative to a monochromatic source of radiation at 270nm. The exposure at this wavelength in 8h is 30 Jm^{-2} and the effective irradiance which will produce this exposure in 1 milliwatt m^{-2} . TLV have been measured for a range of ultraviolet sources used widely in educational establishments. Some cases are given of over exposure resulting in 5 - 35 Threshold Limit Values being received to the face and eyes.

INTRODUCTION

The Occupational Exposure Standard for protection against ultraviolet radiation adopted in the United States of America and accepted by the United Kingdom Health and Safety Executive for protection against ultraviolet radiation was produced by the American Conference of Governmental Industrial Hygienists (ACGIH).

The standard¹ which applies both to the skin and eyes is based on the threshold limit value for the eyes, and whilst it overprotects the skin of most individuals it should protect the eyes satisfactorily.

ACGIH Recommendations for the actinic region 200 - 315 nm

The TLV vary with wavelength. TLV for the actinic ultraviolet region 200-315nm are shown in Table 1.

Maximum permissible exposure for 8 hours at 270 nm = 30 Jm^{-2} (Compare this with a threshold² for Infra Red exposure of the cornea of $6 \times 10^4 \text{ Jm}^{-2}$)

$\lambda \text{ nm}$	TLV Jm^{-2}	S_{λ}
200	1,000	0.03
220	250	0.12
240	100	0.30
260	46	0.65
270	30	1.00
280	34	0.88
290	47	0.64
300	100	0.30
310	2,000	0.015
315	10^4	0.003

The effective irradiance for the ultraviolet source is defined by the following equation

$$E_{\text{eff}} = \int E_{\lambda} S_{\lambda} d\lambda \text{ in } \text{Wm}^{-2}$$

E_{λ} = Irradiance at wavelength

S_{λ} = Relative spectral effectiveness (relative to 270nm)

$d\lambda$ = Wavelength interval of

E_{eff} = Effective irradiance relative to a monochromatic source at 270nm

The effective irradiance for a period of 8 hours in 1 milliwatt m^{-2} . The exposure time in an eight hour period for other values of effective irradiance is given by

$$t(\text{secs}) = \frac{30}{E_{\text{eff}}(\text{Wm}^{-2})}$$

The relative spectral effectiveness S_{λ} is the factor which allows for the differing biological sensitivity of the skin and eyes against λ . S_{λ} is based on data determined for primates, rabbits and human exposure of the eye near the threshold.

ACGIH Recommendation for UVA region 315-400nm

1989-90 proposals for the TLV for the UVA region are as follows

λ nm	TLV Jm^{-2}	S_{λ}
315	1×10^4	0.003
320	2.9×10^4	0.001
330	7.3×10^5	0.00041
340	1.1×10^5	0.00028
350	1.5×10^5	0.0002
360	2.3×10^5	0.00013
365	2.7×10^5	0.00011
370	3.2×10^5	0.000093
380	4.7×10^5	0.000064
390	6.8×10^5	0.000044
400	1×10^6	0.000030

Measurement of Effective Irradiance and Threshold Limit Values

The effective irradiance can be determined by two methods

- (i) Measuring the irradiance at Wavelength λ multiplying this by S_{λ} and integrating this product over the spectral output of the lamp:
- (ii) Measuring the effective irradiance directly using an instrument where response matches the relative spectral effectiveness curve defined by ACGIH.

The International Light Radiometer 1L730A³ is an instrument that will, using a suitable detector, measure the effective irradiance directly for the region 200-315nm.

The detector used to undertake the measurements below was a type PT171D which is essentially a vacuum photodiode with a filter assembly. The detector response ideally should match the relative spectral effectiveness curve (S_{λ}) of ACGIH.

Sources of ultraviolet radiation and their outputs.

The equipment has been grouped into categories.

Low output (1 - 100) x TLV

Hilger Atomic absorption spectrometer		2 x TLV
Hilger DC Spectrograph with carbon-graphite electrodes		40 x TLV
Hilger DC Spectrograph with carbon-graphite electrodes		17 x TLV
Amnisco Colorimeter Hg lamp F4T4 BL		6 x TLV
Desaga UVIS Chromatogram Viewer Sylvania F85T/BLB lamp(10cm)		80 x TLV

Medium Output 100 - 1000 TLV

Isco UV flow monitor		168 x TLV
Philips Hg Type MB/U 400W	(25cm)	800 x TLV
Philips Hg Type MLU 300W	(25cm)	600 x TLV
Pen-ray UV Mineralight Hg lamp	(20cm)	160 x TLV

High Output > 1,000 TLV

Hanovia Portable Chromatolite Hg lamp with filter in place at (4cm)		2,500 TLV
with filter removed at (4cm)		26,000 TLV
Hilger Spectrograph Fe electrodes		2,600 TLV
Camag Universal Lamp (Sylvania G8T5) with filter (4cm)		3,400 TLV
no filter (4cm)		15,000 TLV
Desaga UVIS Chromatogram Viewer G8T5 (Germicidal lamp) 254		1,400 TLV
Hanovia Alpine Sun Lamp	(50cm)	8,000 TLV
Parker Printing Plate Machina		3,500 TLV
Sterilising Cabinet Philips TUV 30w Germicidal lamp	(25cm)	6,000 TLV
Philips TUV 15w lamp	(25cm)	1,600 TLV
Sterilisation Cabinet Sylvania G15T8	(25cm)	3,300 TLV

UV Microscopes

The output from UV microscope depends on the lamp and its power. The lamps are enclosed but leakage of UV may take place from the lamp housing. The leakage is usually low in intensity or is inaccessible and hence the hazard is small.

Occupational Over Exposure of Ultraviolet Radiation

Case 1

This involved a worker using a high intensity Hg/Xenon lamp. The lamp was housed inside an apparatus at about 2 metres from the floor some leakage took place. No estimate of the worker exposure could be made he sustained a small erythema on his forehead.

Case 2

An electrician was asked to replace a fluorescent tube in a sterilisation cabinet. The cabinet contained a visible light fluorescent tube and a germicidal UV lamp TUV 30W. The electrician worked for a period of about 15 minutes unaware that the UV lamp was switched on. Later the same day he suffered severe photophobia and photokeratitis. Subsequently it was estimated that the effective irradiance was 1.2 W m^{-2} which corresponds to an exposure time of 25 seconds in an 8 hour period. The electrician thus received about 35 x TLV.

Case 3

A research technician was working with a clean air cabinet containing a UV germicidal lamp (TUV 30w). The technician worked for a period of about 20 minutes during which time her eyes were probably about 170 mm from the lamp and it was estimated that the effective irradiance was $1.4 \times 10^{-1} \text{ Wm}^{-2}$. The technician suffered slight erythema of the skin of the face and mild irritation of the eyes. It was estimated the worker received about 5 x TLV.

Conclusions

Some equipment measured doses have a potentially hazardous high level output of UV radiation. Control of such sources of radiation is needed. The cases of over exposure considered suggests that the threshold limit values given by ACGIH are set at a reasonable value.

RADIO FREQUENCY RADIATION (RFR) EXPOSURES FROM MOBILE PHONES

**K.H. Joyner, V. Lubinas, M.P. Wood, J. Saribalas
and J.A. Adams***

**Telecom Australia Research Laboratories
770 Blackburn Road, Clayton Victoria
*Department of Physics,
University of Canterbury, Christchurch, New Zealand.**

ABSTRACT

Measurements of the free space levels of radio frequency radiation (RFR) around a hand-held mobile phone and the specific absorption rate (SAR) induced in the ocular region of a phantom head exposed to RFR from a mobile phone are presented. The level of RFR measured 5 cm from the antenna of a mobile phone transmitting 600 mW was 0.27 mW/cm². The average SAR level measured in the nearside eye of the phantom head containing tissue equivalent jellies was 0.7 W/kg for a 600 mW transmit power which is very much less than the spatial peak limit of 8 W/kg underlying the Australian and other national and international RFR exposure standards.

INTRODUCTION

In Australia the Telecom cellular mobile phone network is expanding rapidly with the total number of customers exceeding 300,000. The hand-held mobile phone transmits on frequencies between 825 and 845 MHz and has an output power of 600 mW. Questions associated with RFR exposure have been raised in the media and, in one report, the use of a mobile phone was likened to placing one's head in a microwave oven. Clearly such a claim is ludicrous as the hand held mobile phone has a transmit power of 600 mW and radiates into all space, whereas a microwave oven operates at around 600 W and radiates into a confined space.

Australian and IRPA Standards for Mobile Phones

Both the Australian [1] and IRPA [2] Standards contain exclusions for devices with output powers of less than 7W and transmission frequencies of less than 1000 MHz. The exclusions, although not explicitly stated in the Standards, are based upon a spatial peak limit for the specific absorption rate (SAR) of 8 W/kg averaged over any 1 gram of tissue. As stated earlier, the hand-held mobile phones in use in Australia have maximum radiated power of 600 mW and transmission frequencies of between 825 and 845 MHz and as such are excluded from compliance with both the Standards. If these exclusions did not appear in the Standards then for members of the general public, the appropriate limits of RFR exposure to be observed at 835 MHz would be 0.2 mW/cm² for the Australian Standard and 0.42 mW/cm² for the IRPA Standard.

EXPERIMENTAL MEASUREMENTS

Measurements were made of the free space levels of RFR in the vicinity of the antenna of a mobile phone. These measurements were conducted in a semi anechoic chamber with the mobile phone mounted in a vertical position on a wooden support 1.75 m above the ground. The mobile phone was configured to transmit a full 600 mW of continuous power. A Narda 8616 broadband monitor and Narda 8621C isotropic broadband probe (0.3 to 26 GHz), mounted on a wooden support 1.75 m above the ground, were used to measure the levels of RFR at various distances from the antenna. The following levels were recorded:

Distance From Antenna (cm)	Power Density (mW/cm ²)
0	0.39
1.0	0.33
2.5	0.32
5.0	0.27
7.5	0.21
15.0	0.10

Within distances of 7.5 cm from the antenna, the level of 0.2 mW/cm² recommended in the Australian Standard [1] for members of the general public is exceeded. However, in the normal mode of operation the antenna is unlikely to be closer than 7.5 cm to the eye. In any case exposures within 7.5 cm would only be of concern if there was no exclusion clause. The free space levels of RFR are not of concern for the IRPA Standard because they are below the limit values irrespective of the exclusion clause.

Energy Absorption in Eye of Phantom Head

In the Australian context it is possible for confusion to exist between the exclusion clause in the Standard [1] and the observation that the free space levels of RFR close to the antenna of a mobile phone exceed the recommended limit for members of the general public. Therefore, it was decided to conduct a series of measurements on a phantom head and actually measure the SAR in the ocular area. The ocular area was chosen as the primary site of investigation because of the limited ability of the eye to dissipate heat relative to the brain, and the possibility of local field enhancement in the orbit due to resonance.

The phantom head was fabricated to simulate as closely as possible the electrical characteristics of a real head. Consequently, artificial tissues for eye, muscle, brain, skin and fat were developed having the same conductivity and relative permittivity as their real counterparts. The tissues were applied to a plastic replica skull which, was found to have electrical properties closer to living bone than a dried human skull. The following electrical properties

corresponding to the various tissue types were used in the experiment.

Tissue	Relative Permittivity	Conductivity (mS/m)
eye [3]	70	1900
muscle [4]	59	1190
brain [5]	44	940
skin [6]	35	590
fat [7]	5.7	60

In order to measure the electrical properties of these mixtures at 835 MHz a technique has been adapted which relies on measuring the input admittance of a monopole antenna inserted into the medium under test. The complex permittivity and hence relative permittivity and conductivity are obtained from the measured admittance as they are functionally related according to the antenna modelling theorem [8].

Both an electric (E) field probe and a temperature probe were used in the experiment. The E-field probe was manufactured specifically for the task. It consisted of an 11 mm (tip-to-tip) dipole and an HP 2207 diode mounted across the centre gap. The dipole was angled at 54.7° to the probe handle such that when the probe handle was rotated through each of three 120° sectors an isotropic response was achieved. The dipole elements of the E-field probe were encased in a 4 mm coating of epoxy. This was to physically protect the dipole and to reduce any artificial enhancement of the probe output when inserted in tissue due to increased capacitive coupling between the dipole elements. The probe was then calibrated in air. The temperature probe used was a Luxtron Fluoroptic probe model 1000A which has a 0.1°C resolution.

During the experiment the mobile phone was placed along side the head in a normal manner and measurements made in the nearside eye. The SAR was calculated from the measured E-field level using the relationship $SAR = \sigma E^2 / \rho$ where σ is the conductivity and ρ the density of wet tissue (1000 kg/m³).

A number of measurements of the SAR were made and the average value obtained was 0.7 W/kg for a transmit power of 600 mW. If we scale up from 600 mW to the figure of 7 W which is used in the exclusion clause [1, 2] we find the scaled SAR corresponds to 8.2 W/kg which is in very good agreement with the spatial peak limit of 8 W/kg underlying the exclusion clause.

No temperature increases could be measured in the phantom with the Fluoroptic probe which indicates that any rise in a real head must be less than 0.1° C. An interesting point is that a 3mm sheet of polystyrene foam had to be used as a thermal barrier in order to shield the phantom head from heat generated by the electronic circuitry of the phone.

Temperature rises in the eye corresponding to the induced SAR were numerically calculated by applying the well known

bioheat equation to a finite element model of the eyeball. The model was axisymmetric about the optic axis and consisted of 64 triangular and 166 quadrilateral elements. The thermal conductivities used for the major structures of the eyeball were 0.58 W/m/°C for the cornea, sclera, aqueous humour, iris and ciliary body 0.40 W/m/°C for the lens and 0.603 W/m/°C for the vitreous humour [7]. The external heat loads to the anterior surface of the eyeball exposed to air were evaporation at 60 W/m² and convection and radiation to an ambient temperature of 20°C at a combined heat transfer coefficient of 16 W/m/°C. Convective heat transfer from the posterior surface of the eyeball to the blood flow of the choroid was set at a heat transfer coefficient of 67 W/m²/°C to a blood temperature of 37°C. Internally the respective blood flow in the iris and ciliary body was characterised as transferring 270 X 10³ and 416 X 10³ W/m³ per degree C difference from the blood temperature of 37°C, as per the heat sink term in the bioheat equation.

Steady state analyses were conducted on the model when the eyeball was uniformly loaded at 0.75 W/kg SAR and on the normal unirradiated eye. The maximum temperature difference between the two conditions was 0.07°C in the vitreous humour. The maximum temperature rise in the lens was 0.05°C around the posterior pole.

CONCLUSIONS

The level of RFR measured 5 cm from the antenna of a mobile phone transmitting 600 mW was 0.27 mW/cm². This level of RFR has been shown to produce an average SAR of 0.7 W/kg in the ocular region of a fabricated skull. The subsequent maximum temperature rise in the eye has been calculated to be 0.07° C. On the basis of these results the general exclusion for devices operating at less than 7 W and with transmission frequencies of less than 1000 MHz is justified. It can also be concluded that the use of hand-held mobile phone does not present a health risk.

Observed occupational radiofrequency and microwave radiation exposures during surveys around a few scientific, industrial and medical sources

Abstract

This paper summarizes the results of a few near electric field safety surveys conducted around radiofrequency and microwave radiation (RFMR) generating equipment. Field levels observed under actual working conditions have been graded into three categories. In the first category are the diathermy units. In the second, are inductively coupled plasma atomic emission spectrometers, crystal growing furnaces and feeder lines of the broadcasting transmitters. In the third category are surveillance radars and TV transmitters. Fields around plastic sealing machines vary widely.

Introduction

During the last few years there has been growing realization that occupational exposure to RF radiation in the lower frequency range, from health consideration, is of the same importance as that from MW. In this paper the observed electric field strengths in the vicinity of equipment have been graded and interpreted in the light of existing exposure limits¹. The instrument used for measurement of electric field in RF and MW region is model B611 radiation monitor of Narda make working in conjunction with probes B662B and B621C.

Main observations and Discussion

Salient observations on the electric field strengths observed around the equipment along with the frequency, power and distance of measurement are given in Table 1. Bathymetric representation of the field generated by operation of two furnaces in a single hall has been plotted as given in figure 1.

Below operating frequencies of 10 MHz electric and magnetic fields are required to be measured separately¹. In this study, however, measurements were confined to electric field strengths alone in all the cases². The fields observed in case of diathermy-unit surveys³ have been listed according to the part of the body being treated. It is seen that field as high as 776 V/m has been observed at a distance of 10 cm from the applicator plates. The farthest spot with appreciable field of 168 V/m is at 30 cm in the case of knee treatment. Occupational exposure limit for the 10-400 MHz slab which is relevant for the units operating at 27.12 MHz is 61 V/m. The observed fields are high when compared with a value of 17

mW/cm² at a distance of 15 cm reported elsewhere⁴.

It is clear from the bathymetric representation of the field around two crystal growing furnaces in a single working area that fields created by individual operation fall rather sharply and do not superimpose each other. In spite of the fact that power dissipated in one of the units is 2.5 times that in the other, the highest observed electric field strength is of the same level.

Concluding Remarks

It is concluded from the above study that high fields in most cases are confined to distances close to heating electrodes, radiating element or applicator plates. Awareness about high fields in close proximity and the knowledge that unnecessary exposures are to be avoided would go a long way in reducing exposure. When an instrument is under repair, inadequately shielded and inappropriately terminated, it can be a source of high leakage⁵. It is imperative that a programme of safety studies and survey around equipment generating RFMR be kept alive.

A STUDY ON THE RELATIONSHIP BETWEEN INCOMING SOLAR UV RADIATION AND CLOUD COVER

V.J. Daoo

Health Physics Division
Bhabha Atomic Research Centre
Bombay-400085 (INDIA)

ABSTRACT

In this study an empirical relationship between the incoming solar UV radiation and concurrently measured cloud cover at Bombay ($19^{\circ}01'N$, $72^{\circ}55'E$), based on data pertaining to two year (1986-1987) period is established. It is compared with a similar relationship used elsewhere and found to differ in its form as well as in the regression coefficients. Possible reasons for this discrepancy are discussed. Conditions under which the two relationships agree are also examined.

INTRODUCTION

Observed data on solar UV radiation reaching the earth's surface are sparse and particularly so in tropics. In tropical region, recent studies by Chacko et al. (1983), Ilyas (1987) and Daoo et al. (1991) deal with such observations. In the absence of direct measurements, the solar UV radiation is generally estimated from its extra-terrestrial value and assuming certain average atmospheric conditions. It has been established that the UV radiation is significantly attenuated by cloud cover and the atmospheric ozone content before reaching the surface. Among these, variation in ozone content is known to be somewhat regular but not so the cloud cover variation. Hence estimates are generally made for clear sky conditions and effect of cloud cover is accounted for by using an empirical relationship between clear sky UV radiation and cloud cover observations. In this study one such attempt is described. Based on measured data on UV radiation during 1986-87 and concurrently observed cloud data at Bombay ($19^{\circ}01'N$, $72^{\circ}55'E$) an empirical relationship is established. This can be used to predict UV radiation if cloud data is available and clear sky radiation is known. Such relationship is particularly useful because cloud cover data are routinely available at National Weather Service stations in the country and can be conveniently used to predict incoming UV radiation under actual conditions.

MEASUREMENT AND SITE DETAILS

The measuring instrument was an Eppley UV radiometer (model TOVR) having a spectral response over the region 295-390 nm wavelengths. Measurement accuracy is within 5%. Data on cloud cover were obtained from weather reports routinely published by India Meteorological Department. The measurement site was within the campus of Bhabha Atomic Research Centre at

Bombay. The site is located in a region subject to industrial air pollution. Further the site experiences regular monsoon rains during June to September. During this period the sky is generally overcast with cumulus types of clouds. Even during non-monsoon periods the sky is rarely clear except for few occasions during winter months.

RESULTS AND DISCUSSION

Plot of ratio of monthly mean daily total of UV radiation (UV) to mean daily total under clear sky conditions (UV_0) and concurrent daytime average cloud observations in fractions of cloud cover (n) is shown in Fig 1. Average daytime cloud cover is obtained from the visual observations made after every three hours. Clear sky UV radiation is obtained from the computed clear sky global solar radiation for Bombay (Mani and Kangarajan, 1982) and using observed ratio of the UV radiation to the global solar radiation, during clear weather (Dado et al., 1991). Thus UV_0 represents the radiation received at the earth surface under cloudfree atmosphere for average atmospheric conditions with respect to other relevant constituents like ozone and dust content.

Visual inspection of the scatter plot suggests a non-linear relationship. Regression analysis of the data set gives following relationship :

$$UV/UV_0 = 0.80 + 0.45 n - 0.64 n^2 \quad (1)$$

with correlation coefficient (r) = 0.785

The only other equivalent relationship widely quoted in literature (Johnson et al., 1976; Ilyas, 1987), after converting it as per our notations is -

$$UV/UV_0 = (1 - 0.56 n) \quad (2)$$

Comparison of Eq (1) and (2) reveals that -

(1) Eq (1) is quadratic while Eq (2) is linear. For higher cloud cover amount ($n > 0.3$), Eq (1) also tends to show a monotonic decrease as expected from Eq (2). The quadratic relationship shows a major departure from the linear form for low cloud cover amounts. Low cloud cover amounts are generally associated with broken or passing clouds (usually of cirrus type in the present case). These type of clouds lead to significantly increased diffuse radiation compared to that under higher cloud cover conditions. As a result the incoming UV radiation initially (when the cloud cover is less) does not decrease as expected but shows a slight increase and afterwards (for higher cloud cover) it decreases monotonically. Higher cloud cover conditions are usually associated with uniform and continuous sheet type of cloud (generally of cumulus type in the present case) obstructing the sun directly and hence the monotonic decrease. Thus the quadratic expression given here could give more realistic estimates under low cloud cover conditions.

(2) Intercept of Eq (1) is 0.80 and not unity like Eq (2). Relatively larger atmospheric dust content in the region can be one of the responsible factors in determining this.

(3) In low cloud cover range ($n < 0.3$), Eq (1) when compared with Eq (2), underestimates the ratio UV/UV_0 (upto a maximum of about 25 %) while in the higher cloud cover range it generally overestimates the ratio (upto a maximum of about 12 %). Hence while using any such relationship for estimating the incoming solar UV radiation levels, consideration must be given to the higher and lower ranges of cloud cover amounts. Otherwise the results can be misleading. This is particularly true for tropical regions where low cloud cover conditions occur with significant frequency.

CONCLUSIONS

The relationship established in this study is quadratic in form in contrast to linear relationship used in earlier studies. The difference has been attributed to the type and nature of cloud cover and dust content prevailing in the atmosphere. The relationship used in the earlier studies is generally suited for high cloud cover conditions (cloud cover > 0.3) whereas the present relationship is applicable to whole range of cloud cover.

ABSTRACT

Polysulphone film badges have been used to quantify the solar UVR exposure received by different subjects and these measured results are compared to those calculated from personal diaries and measured ambient solar UVB. In general, when UVR exposure activities took place under close supervision, good correlations were obtained between the polysulphone badges and the ambient/diaries approach. UVR exposures for indoor workers and a number of outdoor activities are presented.

INTRODUCTION

Recent evidence confirming the presence of global ozone depletion and of Antarctic ozone 'holes' has increased the concern over possible adverse human health effects as a result of increased levels of solar UVR. The scarcity of accurate long-term ambient UVR measurements and the lack of knowledge of personal solar UVR exposure has also become apparent.

Previous measurements of the anatomical distribution of solar UVR using polysulphone (PS) film as a dosimeter have been made with both mannikins and headforms as well as volunteers in a variety of outdoor activities^{1,2}. Personal histories of UVR exposures have been determined from retrospective questionnaires and the results used in epidemiological studies into factors affecting skin cancer incidence. Careful design of the questionnaire or diary of UVR exposure is crucial, as is the choice of sites at which the badges are worn.

EXPERIMENTAL MEASUREMENTS

The ARL radiometer/datalogger network³, which collects data continuously during daylight hours, provided ambient UVB levels for both the Sydney and Hobart studies. The dose response of PS film to solar UVR, which relates the change of absorbance (dA) to the erythemally effective dose (EED) in $J.m^{-2}$, can be determined from simultaneous exposure of the PS film and measurement of the incident solar UVR spectral power distributions^{4,5}. As the change in absorbance dA increases (ie for larger UVR exposures) the estimation of EED becomes less accurate. Any study to monitor UVR should try to limit the UVR dose to PS badges to the linear or near linear region of the dose response curve (dA less than 0.5).

Two studies using polysulphone dosimeters and volunteers were undertaken. The month-long Sydney study, in February and early March 1990 was undertaken in collaboration with the Sydney Melanoma Unit. The group of 40 indoor workers each wore a single PS badge attached at the shoulder. A new badge was used each day, some subjects recording the time periods spent outdoors on a time line in a diary at the end of each day, while others were asked to record the information only at the end of the study. In this way it was hoped to detect whether there was any variation in recall between the two groups of subjects. Following initial discussions at the beginning of the study, the subjects were given their PS badges and no further direct supervision took place.

The Hobart study, in collaboration with the Menzies Centre, took place primarily on two days in February 1991, with two small groups participating in a trial the previous day. Subjects each wore eight PS badges at different anatomical sites, while participating in one of the following activities, pool swimming (SM), sailing (SL), bushwalking (BW), gardening (GN), playing tennis (TN) or golf (GF). The subjects then filled in a comprehensive questionnaire covering the duration of solar UVR exposure, type of clothing or sunscreen worn, ground surface cover, and many other details. As well as determining the anatomical distributions of UVR, the calculated ambient/diary UVB exposure could be compared with the PS badge measurement to determine whether the subjects' diaries gave an accurate reflection of their UVR exposures.

RESULTS

As the Sydney study volunteers were indoor workers, the measured PS badge EEDs were generally low, the mean value for the group of subjects was $82 \pm 51 \text{ J.m}^{-2}$. In most cases exposure to solar UVR was in the morning and evenings on the way to and from work, with some contribution to the UVB exposure during lunch hour.

Figure 1. A comparison of the total measured PS badge exposures EED (J.m^{-2}) for the group of subjects for each day with the daily total UVB (radiometer counts).

Correlation between the EED from the PS badges and the calculated ambient/diary exposure for the Sydney study was poor. The variation between individuals was large. The diary provided no opportunity to indicate the quality of the UVR exposure, which is affected by shade and buildings in the immediate vicinity. If the subjects were analysed as a group, a pattern did emerge. Figure 1 shows the sum of the exposures in $J.m^{-2}$ for the entire group of subjects for each day, while also showing the daily total of ambient UVB (to a different scale). The weekend days stand out as days of high UVR exposures, the mean week day exposure being $65 \pm 26 J.m^{-2}$ while that for the weekend days was twice this at $123 \pm 54 J.m^{-2}$. The maximum measured daily total EED for any subject was 2060 $J.m^{-2}$, which occurred on a weekend. Monthly UVR exposure totals for each subject ranged from 500 to 6865 $J.m^{-2}$ (mean of $2294 \pm 1430 J.m^{-2}$).

Supervision of subjects and PS badge placement was more tightly controlled in the Hobart study. Figure 2 shows a comparison of the PS badge exposures EED in $J.m^{-2}$ with the UVB/diary calculations. The activities in the Hobart study can be considered to fall into two broad categories, the first where the subjects would have spent a fair proportion of their time out of the direct sun (in amongst trees etc for the BW, GF and GN), the second where the activities took place predominately in the open. Comparison of the PS badge readings with the UVB/diary calculations for the TN, SL and SM subjects in Figure 2(A) shows a series of points scattered about the expected straight line (ie good correlation). However, the comparison for the BW, GF, and GN in Figure 2(B) shows considerable scatter, with the points all in the region of the graph where the PS badge readings are less than the corresponding UVB/diary entries. These lower measured EEDs and the scatter in the results (BW,GF,GN) are almost certainly due to subjects spending different amounts of time in the shade. The effective exposure rates I in $W.m^{-2}$ (Table 1) are generally less than for the other activities (TN, SL, SM).

Figure 2. A comparison of the measured PS surface badge exposures EED ($J.m^{-2}$) for the different activities with the UVB exposures calculated from the diary entries and the measurement of ambient UVB (radiometer counts).

TABLE 1

The variation of UVR exposure with anatomical site as a fraction of ambient for different outdoor activities for the Hobart study (* denotes Day 1).

ACTIVITY Tennis* Tennis Sailing Swimming Walking Golf Gardening*

SITE	Tennis*	Tennis	Sailing	Swimming	Walking	Golf	Gardening*
Cheek	0.20	0.36	0.25	0.43	0.08	0.21	0.24
Hand	0.43	0.54	0.54	0.94	0.30	0.51	0.19
Shoulder	0.52	0.79	0.70	1.39	0.22	0.76	0.30
Back	0.40	0.57	0.57	0.98	0.39	0.66	0.31
Chest	0.32	0.41	0.28	0.61	0.17	0.36	0.14

Calf	0.40	0.51	0.25	0.62	0.19	0.41	0.16
Surface	1.00	1.00	1.00	1.00	0.39	0.74	0.30
EED(J.m ⁻²)	814	928	1712	289	834	1355	766
I#(mW.m ⁻²)	158	122	125	77	47	91	31

I is the effective irradiance calculated from the PS badges

The Hobart UVR exposures EEDs (Table 1) are higher than the average daily EED for the Sydney study, although they are comparable with many of the weekend exposures. Table 1 shows that the shoulder badges have the highest exposures, the reason this site was used for the Sydney study. The UVB exposure rates given by I in Table 1 show that activities (TN, SL, SM) which occur in the open have the highest UVB exposure, although (GF) can also have quite large UVB exposure rates.

CONCLUSIONS

Preliminary analysis of both studies indicate that good correlation between measured and calculated UVR exposures can be achieved if sufficient information is recorded in the diaries and if exposures occur under close supervision. In Australia the highest exposures to solar UVR (apart from outdoor workers) are due to outdoor recreational activities and any effort to reduce the general population's UVR exposures needs to concentrate on these.

UV radiation: sources, effects and risks of human and environmental exposure

G.J. Eggink, H. Slaper
Laboratory for Radiation Research,
National Institute of Public Health and Environmental Protection
P.O.Box 1, 3720 BA BILTHOVEN, The Netherlands

ABSTRACT

This paper summarizes the principal results of a review study on UV-exposure and UV related risks in the Netherlands. Both the present state of affairs and future developments are discussed, the latter partly based on model calculations.

The sun is the main UV source to which the whole population is exposed. Solar exposure is estimated to amount to at least 90% of the annual UV burden for the Dutch population. For certain groups in the population man made sources are estimated to contribute considerably to the yearly UV dose. Ozone depletion as a result of human activities, growing use of tungsten halogen lamps and increasing application of UV-sources in industry and medicine all tend to increase UV exposure.

UV exposure can lead to a wide variety of health effects, among which the induction of skin cancer, skin aging, cataract formation and suppression of immune responses. Risk estimates of these health effects are available for skin cancer and to a lesser extend for cataracts. The estimated UV related skin cancer incidence rate in the Netherlands is 10^{-3} per year (15 000 cases), and the associated mortality rate amounts to $6-25 \cdot 10^{-6}$ per year (90-400 deaths). The ozone depletion presently observed over the past decade (5% in the Netherlands), is expected to lead to an increased annual mortality rate due to skin cancer of $1,3 \cdot 10^{-6}$ per year.

Environmental exposure can influence plant physiology and lead to a decrease of biomass in aquatic as well as terrestrial ecosystems. This may result in adverse effects on the foodweb and biodiversity of ecosystems. Quantitative risk estimates for these effects are very uncertain or lacking.

INTRODUCTION

UV-exposure of man and the environment is caused by emissions from a number of sources. The UV-burden for man as well as for ecosystems is expected to increase due to:

- the depletion of the ozone layer (the main UV absorbing layer in the earth's atmosphere)
- the increasing use of UV-emitting light sources (e.g. tungsten halogen lamps)
- the use of tanning equipment
- the use of UV sources in industry and laboratories (lasers, welding, lamps for paintdrying, copiers, etc.)
- the use of UV-sources in medical therapies (PUVA, UVB-therapy, lasers)

Based on the recent knowledge of exposure and effects, an estimation is made of the related risks of (over)exposure.

Based on the 'source-distribution-exposure-effect-risk chain' this UV issue will be presented.

SOURCES, DISTRIBUTION AND EXPOSURE

The sun is the main and only natural UV source on earth. The spectral distribution peaks in the visible part of the spectrum with a relative large fraction in the UV. Due to the absorbing and scattering properties of the atmospheric layers (esp. the ozone layer) the radiation reaching the earth surface contains less UV.

The effectiveness of UV radiation is strongly dependent upon the wavelength. The MED is used as a unit for effective UV-doses and corresponds to a UV-dose which is just sufficient to elicit erythema (in unadapted white skin). One MED is equivalent to a dose of 200 J/m^2 of monochromatic 297 nm radiation.

In the Netherlands the total amount of solar (erythema-effective) UV radiation is estimated to be 2200 MED/a (Schothorst, 1987; Slaper, 1987). Over 75% is available in the period May-August; less than 7.5% from November-February. Based on measurements with personal dosimeters indoor workers are estimated to be exposed to about 70 MED/a and outdoorworkers receive about 150 MED/a (Slaper, 1987). The dose acquired during holidays must be added to this and is estimated to be 2-50 MED for a three weeks period in the Netherlands and 60-150 MED for three weeks in the Mediterranean (Health Council, 1986).

Based on recent measurements by NASA satellites the ozone layer decreased with an average of 5% in the last 10 years in North West Europe (Stolarski et al, 1991). Model calculations of the UV-transfer in the atmosphere indicate that this reduction leads to an increase in erythema-effective UV on the earth surface of about 6.5%. This in turn corresponds to an additional 6.5 MED/a for the average exposed person in the Netherlands and an

additional 13 MED/a for the group with highest sun exposure (5% of population).

Artificial UV-sources are found in various applications: regular lighting systems, tanning equipment, medical phototherapies, industrial lightsources, lasers etc. In the indoor environment exposure can be divided in intentional and unintentional exposure. Intentional exposure takes place during tanning and medical UV therapies.

Depending on the characteristics of the lightsources (e.g. temperature of tungsten lamps, quality of the glass envelope, pressure and gas used in gas discharge lamps etc.) the UV emission can vary by several orders of magnitude.

Assuming an exposure time of 500 h/a (= 1.5 h/d) a potential exposure of 10-500 MED/a for tungsten halogen lights and about 2 MED/a for fluorescent lamps is estimated (McKinlay et al, 1989). Personal dosimetry is lacking. It appears that tungsten halogen lamps are the most important UV emitting artificial lightsources for the general public.

The use of special UV emitting fluorescent lamps for tanning is widely spread in the Netherlands. About 7% of the population (= 1 million) uses tanning equipment. The average yearly dose received as a result of the use of these artificial sources is estimated to be 74 MED/a (Berghahn & Bruggers, 1986).

Since 1900 ultraviolet radiation is used in medical therapies, for treating tuberculosis, rachitis, and later on for treating several skin diseases. Nowadays UV is mainly used in treating psoriasis (ca 200 000 patients in the Netherlands). Two types of therapy are common: PUVA and UVB-therapy. In PUVA the skin is sensitized by means of psoralens and treated with UVA ("black-light"). In UVB-therapy the skin is directly exposed to UVB. The average yearly dose is 250 MED/a, but doses of more than 500 MED/a are not unusual. For PUVA-therapy the UV dose depends greatly on the amount and type of psoralens. An average value can not be given. Figure 1 gives the estimated yearly doses for the general public and for some selected groups of the population. In this figure outdoors workers are farmers, fishermen, roadworkers etc. Halogenlamp users are assumed to be exposed to bare halogen lamps for 500 h/a at a distance of 30 cm.

Figure 1. Estimated yearly effective UV dose for the general public and some selected groups in the Netherlands.

EFFECTS AND RISKS

UV exposure can lead to several deleterious effects in man, some shortly after acute exposure (sunburn, snowblindness) and some after prolonged exposure (skin cancer, skin aging, damage to the immune system and cataract formation).

For skin carcinoma (basal cell carcinoma and squamous cell carcinoma) UV exposure is assumed to be the main cause. For melanoma and cataract it is believed that UV contributes to the incidences although the extend is uncertain. The incidence and mortality rate for skincarcinoma, melanoma and cataract operations in the Netherlands is given in figure 2a. Figure 2b provides estimates of the additional effects of a 1% increase in effective exposure (1 MED additional for average exposed group).

A 1% increase of the effective UV exposure is expected to lead to an increase in cataract incidence of 0.5%, corresponding to an increased incidence rate of 10^{-5} per year in the Netherlands. This implies an additional 100-150 cataract operations per year in the Netherlands.

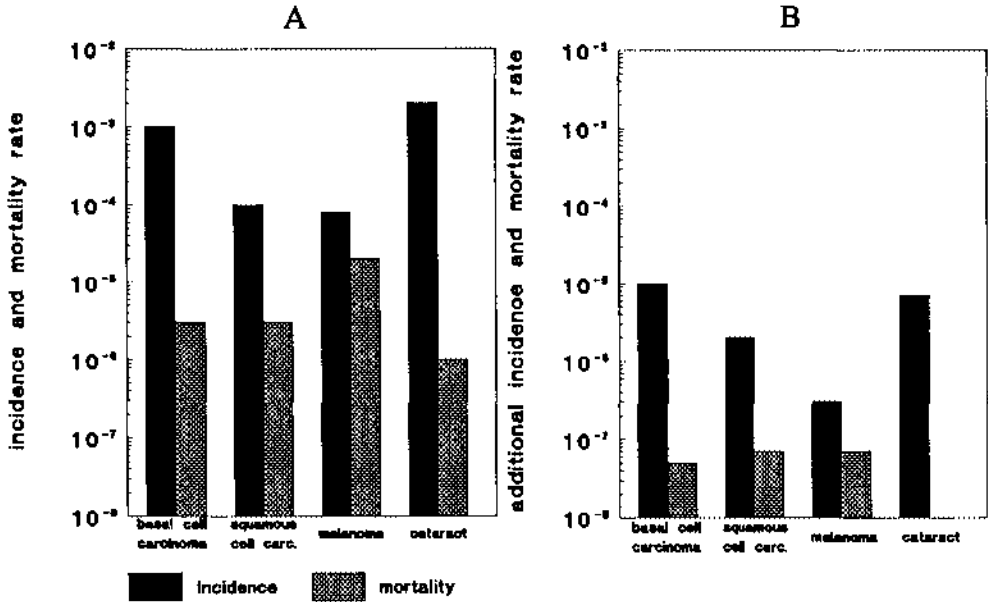

Figure 2. A. Incidence and mortality rate of carcinoma, melanoma and cataract (operations).
B. Additional incidence and mortality rate caused by an additional 1% effective UV.

Death rates due to skin cancer in the Netherlands are: 80-90 deaths per year due to skin carcinoma, 300 deaths per year due to melanoma. The estimated yearly mortality rate in the Netherlands associated with average UV exposure is $6.25 \cdot 10^{-6}$ per year. For 'highly-exposed' persons (200 MED/a) this is $25.55 \cdot 10^{-6}$. Based on models, the additional mortality rate for the 'average-exposed' group is calculated to be $2 \cdot 10^{-7}$ per MED. For the 'high-exposed' group this is estimated to be $4 \cdot 10^{-7}$. For persons with an extra sensitive skin the risks are $4 \cdot 10^{-7}$ and $7 \cdot 10^{-7}$ per MED respectively. Table 1 gives an overview of the estimated risks and mortality rates for various exposure situations.

Evidence has been gathered in experiments with animals and humans that UV exposure of the skin causes damage to the immune system. An assessment of the risks can not yet be made, due to a lack of information about the mechanism, the dose-reponse relation and the action spectra.

In terrestrial plants UV exposure can influence several processes that have a negative effect on the growth and development of plants, like smaller leaf size, less flowering, and a lower photosynthetic activity. These effects can be reinforced by certain deficiencies and waterstress (UNEP, 1989). Although this is very species-specific (even great intraspecific (cultivar) differences have been observed) many of the observed effects lead to a decrease of biomass by influencing the primary production. Further study is needed to get more information on the mechanisms of UVB-effects and the possible effects of ozone depletion on food plants.

Research indicates that also phytoplankton and zooplankton in aquatic ecosystems can be affected. This includes orientation, motility, photosynthesis and enzymatic reactions and the survival of small marine organisms during their first stadia of life (fish eggs and -young, shrimp larvae and crab larvae). These changes can lead to disturbance of stable ecosystems, and can have negative effects on the foodweb, the biodiversity of ecosystems, and finally on the human food supply. Based on the assumption of a 5% decrease in primary production (estimated for a 16% ozone depletion) Häder calculated that fish yield would reduce by approximately 6-9% (a 7% reduction in fish yield, if it is on a global basis, would then represent a loss of about 6 million tons of fish per year) (Häder et al, 1989). However, uncertainties regarding the magnitude of these effects remain large, because of problems of extrapolating laboratory findings to the open sea and the nearly absence of data on long-term effects and ecosystem responses.

Further research on the ecosystem effects is necessary to get a proper view of their possible ecological impact.

HEALTH EFFECTS OF EXTREMELY LOW FREQUENCY (ELF) FIELDS:
A PUBLIC HEALTH PERSPECTIVE FROM QUÉBEC:

This communication summarizes the report presented to the Quebec government by an expert-committee. The main health effects of ELF fields are reviewed and a discussion of the public health impact for Quebec is presented. Recommendations include the need of further research as well as a public information program and major efforts to improve risk assessment.

INTRODUCTION

En 1987, le gouvernement du Québec autorisa la construction d'une ligne à haute tension sur son territoire à la condition qu'un comité interministériel, coordonné par le ministère de la Santé et des Services sociaux du Québec, assure un suivi des études sur les effets des lignes à haute tension sur la santé. La présente communication résume l'état de situation sur les connaissances scientifiques qui a été déposé et accepté par ce comité¹.

RÉSULTATS

Plusieurs effets potentiels chez l'humain, associés à l'exposition chronique aux champs électromagnétiques de très basses fréquences ont été inventoriés. Le risque de cancer est le mieux documenté. D'une part, plusieurs chercheurs ont observé des associations entre l'exposition à ces champs (mesurée ou estimée) et l'incidence de certains cancers chez l'enfant: leucémies, tumeurs du système nerveux, lymphomes. D'autre part, plusieurs études réalisées en milieu de travail ont montré, de façon répétée, une association entre l'inci-

dence de leucémies et de tumeurs du cerveau et l'exercice d'une profession dans laquelle il y a exposition aux champs électromagnétiques de basses fréquences: électriciens, monteurs de ligne, soudeurs, etc.. Bien que plusieurs lacunes empêchent de porter un jugement définitif sur le risque de cancer (principalement à cause des difficultés de mesure de l'exposition), on doit considérer ce risque comme possible. D'une part, les études les plus perfectionnées tendent à confirmer les résultats des premières études, d'autre part, la plausibilité biologique de telles associations s'est renforcée ces dernières années. Même si le risque relatif de cancer est probablement faible pour les personnes anormalement exposées (RR <2), le risque pour la santé publique peut être important. Ceci est dû à l'omniprésence des champs et au nombre important de personnes exposées à ces champs. Ainsi, si 20 % de la population à risque était exposée de façon anormale et si le RR était de 1,8, 14 % des cancers incidents pourraient être attribuables à cette exposition.

D'autres problèmes de santé ont été moins investigués. Il s'agit principalement des troubles de la reproduction (infertilité, avortements, malformations congénitales) et des troubles neuropsychiques (en particulier les états dépressifs). Il est cependant encore trop tôt pour porter un jugement sur la possibilité de tels effets. Cependant, à cause de leur plausibilité biologique, ils ne devraient pas être négligés dans les recherches futures.

CONCLUSION

Le Québec, particulièrement par l'intermédiaire de la société d'État Hydro-Québec, participe à l'effort mondial de recherches pour élucider l'impact potentiel des champs électromagnétiques sur la santé humaine. Il faut poursuivre ces efforts mais ne pas s'y limiter. Dès maintenant des mesures devraient être prises pour mieux connaître l'exposition des populations québécoises à ces champs. Il y a lieu aussi de mettre sur pied un programme d'information publique sur le sujet. Le Québec devra aussi participer activement à l'effort international visant à mieux évaluer et gérer un tel risque environnemental.

CHROMOSOMAL ABERRATION ANALYSES OF BYELORUSSIAN CHILDREN
EXPOSED TO CHERNOBYL FALLOUT

S. Salomaa, A. Koivistoinen, W. Paile, T. Rahola, and T. Rytömaa

Finnish Centre for Radiation and Nuclear Safety
P.O.Box 268, 00101 Helsinki, Finland.

ABSTRACT

The radiation exposure of 26 Byelorussian children visiting Finland in summer 1990 was estimated by chromosomal aberration analyses and whole body counting. For comparison, twelve children from southern Finland were studied similarly. In general, the children were healthy and blood pictures and thyroid function tests were within the normal range. In the whole body measurements, the only nuclides detected were cesium-137 and cesium-134. The cesium body contents of the Byelorussian children were low (mean 6.3 Bq/kg of ^{137}Cs and 0.4 Bq/kg of ^{134}Cs), similar to those of the Finnish children. However, the Byelorussian children had significantly higher frequencies of radiation-related chromosome-type aberrations in their lymphocytes than the Finnish children.

INTRODUCTION

After the Chernobyl accident, many controversial reports have appeared of the radiation exposure and the possible health impact of the population living in the most affected areas. Also in the field of biological dosimetry the data are either inadequate or puzzling. Without any actual figures published, local studies have been described where no differences in the chromosomal aberration frequencies have been observed between the subjects living in contaminated or control areas. On the other hand, scientific papers report unexpectedly high aberration frequencies after exposures to minimal radiation doses from cesium in Central Europe.

We have estimated the radiation exposure of 26 Byelorussian children visiting Finland in summer 1990, four years after the Chernobyl accident, by whole body counting and chromosomal aberration analyses, and compared the results to Finnish children of the same age. Also the health status of the visitors was investigated.

MATERIAL AND METHODS

There were 15 girls and 11 boys in the Byelorussian group and their mean age was 14 years. The children originated from the Minsk, Mogil'ov and Gomel areas. Of these, the Gomel area is the most polluted by Chernobyl fallout, and the Minsk area the least. The surface contamination of cesium-137 in the Gomel area typically ranges from 37 to more than 1480 kBq/m², in the Mogil'ov area from less than 37 to 555 kBq/m², and is less than 37 kBq/m² in the Minsk district. In the Gomel region, there are also minor areas contaminated by strontium-90 with surface activities from 37 to 111 kBq/m².

The health status of the children was clarified by interviews and clinical investigations. Information was obtained on

diagnoses given to the children in Byelorussia. In Finland, every child went through a physical examination made by a general practitioner, and a few were referred for a specialist consultation. All the children were investigated for complete blood picture including differential count of leukocytes; free thyroxine, and thyroid-stimulating hormone. Other tests were made if indicated.

The activity in the body was measured using two whole-body counters. The IRMA 1 whole-body counter, installed in an iron room, uses a multidetector scanning technique, with four NaI(Tl)-crystals. The scanning time is 30 minutes and the minimum detectable activity (MDA) for cesium-134 and cesium-137 is 30 Bq. The mobile IRMA 2 whole body counter has a measuring geometry of chair type and a high purity germanium detector with 27 percent efficiency. The measurement time is 1,000 seconds and the corresponding MDA for cesium-134 and cesium-137 about 50 Bq.

Routine 48-hour lymphocyte cultures were established and 200 cells from each subject were analysed for chromosomal aberrations. The chromosomal aberrations scored included both chromatid aberrations (breaks, gaps) and chromosome-type aberrations (breaks, gaps, dicentric, rings, translocations and inversions). The results of chromosome aberration analyses were tested by Fisher's exact probability test.

For the results of whole body measurements and chromosomal analyses, the Byelorussian children were compared to twelve children from the southern Finland, matched by age, sex, and X-ray examinations. The control children originated from an area where the surface activity of cesium-137 was less than 6 kBq/m².

RESULTS

Generally, the children were in good health, and no major health problems were noticed. A clear discrepancy was noticed between diagnoses given them in Byelorussia and the scarcity of findings during their stay in Finland. Diagnoses like gastritis, arthritis, and neurocirculatory dystonia were frequent but, as a rule, could not be confirmed. Six of the children were reported to have an enlarged thyroid, which is not surprising, as they come from an area in which goiter is endemic. Four of these cases could be confirmed at the time of the examination in Finland. All of the children were, however, clinically euthyroid. The thyroid function tests were all in the normal range. The blood pictures were all normal except two cases of eosinophilia and two cases of slight anemia of iron deficiency type.

The results of the whole body measurements are shown in Table 1. The only Chernobyl fallout nuclides found were cesium-137 and cesium-134, with mean activities of 6.3 Bq/kg and 0.4 Bq/kg, respectively, in the Byelorussian group. The children from the Mogil'ov and Gomel districts tended to have higher values than those from the Minsk district, as could be expected by the distribution of surface ground contamination. As a whole, however, the cesium body contents of the Byelorussian children were low, similar to those of the Finnish children living in much less contaminated areas.

The internal mean effective dose equivalent delivered in 1990 from radiocesium to Finnish children was less than 0.05 mSv. The total internal dose delivered to the Finnish children studied from

1986 to 1990 was about 0.2 mSv. The external dose equivalent during the same time period was higher and the total mean effective dose equivalent 1986-1990 was estimated at 0.6 mSv. For the Byelorussian children studied, no information on temporal behaviour of radiation doses after the Chernobyl accident was available.

Table 1 The whole body contents of Chernobyl fallout nuclides in the Byelorussian children and the controls

Region	No. of subj.	Cesium-137 Bq/kg, mean (range)	Cesium-134 Bq/kg, mean (range)
Minsk	10	4.0 (3.2-5.2)	0.3 (0-0.8)
Mogil'ov	15	7.6 (3.1-14)	0.4 (0-2.0)
Gomel	1	9.2	1.5
Total	26	6.3 (3.1-14)	0.4 (0-2.0)
Control (Finland)	12	7.5 (1.1-14.4)	1.2 (0.5-2.7)

The frequency of the radiation-related chromosome-type aberrations was significantly ($P=0.046$) higher among the Byelorussian children than among the Finnish children, whereas there was no difference in the frequency of chromatid aberrations, that are not typically induced by ionizing radiation in resting lymphocytes (Table 2). The children from the more heavily contaminated areas of Gomel and Mogil'ov had more chromosome-type aberrations in their lymphocytes than those from Minsk, and the control children from the least polluted area also had the lowest number of aberrations.

The frequency of dicentric chromosomes was almost four-fold (1.5×10^{-3}) in the Byelorussian group as compared to the Finnish children (0.4×10^{-3}); this difference was not, however, statistically significant ($P = 0.167$). An absorbed dose of 100 mGy of ^{60}Co gamma radiation raises the number of dicentric chromosomes to about 4 or 5 per thousand lymphocytes from the control value of less than 1/1000. Assuming a dicentric half-time of 3 years, and that the majority of the radiation dose was delivered shortly after the accident, the average exposure of the children in this group could be as high as 100 mGy. However, this estimate is complicated by an uneven distribution of dicentrics between the cells analysed. As the cesium body contents of the Byelorussian children were similar to that of the Finnish children, most of their radiation exposure must have come from other sources, eg. external radiation.

Table 2 The frequency of chromosomal aberrations among the Byelorussian children and the Finnish controls

Region	No. of subj.	Aberrations per 1000 cells		
		Ct	Cs	Dic, r
Minsk	10	2.0	3.6	1.0
Mogil'ov	15	1.7	4.3	2.0
Gomel	1	5.0	20.0	0
Total	26	1.9	4.6*	1.5
Control	12	1.3	2.1	0.4

* P=0.046, Fisher's exact probability test

Ct, chromatid aberrations; Cs, chromosome-type aberrations; Dic, dicentric chromosomes; r, rings

CONCLUSIONS

Comparison of Byelorussian children to Finnish children showed that their cesium body contents are similar. It thus appears that the Soviet authorities have applied strict dietary restrictions within the areas studied, at least recently. However, the Byelorussian children had significantly higher frequencies of radiation-related chromosome-type aberrations in their lymphocytes.

ABSTRACT

This paper is concerned with an accident occurred in an industrial gammagraphy unit located in São Paulo, Brazil, on 2nd of July, 1988. A work team, composed of three workers, was engaged on a routine operation with a ^{192}Ir source of 3,299 TBq, when the flexible cable of the holder broke, giving rise to an accidental exposure. The evaluation of the dose received by the three workers was carried out by three different methods: the film badge measurement, the biological dosimetry and the reconstitution of the accident taking into account the exposition time and the distance between the source and the workers. In the film badge evaluation the dose obtained was around 300 mSv, whereas for the biological dosimetry doses of 370 mSv, 290 mSv and 110 mSv was achieved. In the accident reconstitution the doses obtained were: 200 mSv (whole body), 131.000 mSv (left hand) for the first worker; 232 mSv (whole body), 25.000 mSv (left hand), 99.000 mSv (right hand), for the second one and finally 232 mSv (whole body) for the last one. It was concluded, by the evaluation of the doses, that the irradiation was not uniform, being the hand the more severely irradiated organ. From 18th of July, 1988, the victims were treated by the medical staff, together with the radiological protection group, both from the IPEN. In this paper the clinical and laboratorial exams carried out for the evaluation of the extension of the deleterious effects are described. By that time, the victims presented already radiodermatitis in their hands, and the clinical treatment pursued is also described.

MEDICAL AND HEALTH FOLLOW-UP OF
VICTIMS OF THE TCHERNOBYL ACCIDENT :
A FRANCO-UKRAINIAN STUDY

SUMMARY

A Franco-Ukrainian center, devoted to medical follow-up and epidemiological study of 7 000 children who were living in PRIPYAT during the CHERNOBYL accident, was established at the beginning of 1991. After such an accident large numbers of patients and long follow-up are necessary to draw any epidemiological conclusions. However there are important lessons to be drawn from operating experience of the Center. For example it might be felt useful to open others centers. This paper describes the experience acquired during the first 6 months.

INTRODUCTION

Cinq ans après l'accident de TCHERNOBYL, de grandes incertitudes, voire une certaine confusion, règnent dans l'appréciation de ses conséquences médicales. Cette confusion rend difficile la tâche des autorités, mais crée aussi de nombreuses inquiétudes chez les victimes, à la recherche d'informations crédibles sur leur état de santé et sur les risques qu'ils encourent. On décrit ici le bilan du fonctionnement d'un centre médical franco-ukrainien mis en place en 1991.

HISTORIQUE ET OBJECTIFS

Sous l'égide du Ministère de la Santé d'Ukraine et du Secrétariat d'Etat Français à l'Action Humanitaire, une opération axée sur une population particulière a été mise sur pied en 1990.

Elle visait à la fois à fournir une assistance directe aux victimes et à recueillir des informations sur les effets possibles de l'accident et a abouti, en Février 1991 à la mise en place du Centre Médical Franco-Ukrainien de KIEV. Ce Centre, implanté en milieu hospitalier, fonctionne comme un dispensaire, il résulte de l'action de l'Association "Les Enfants de TCHERNOBYL" qui en a été l'initiatrice et qui le gère, de l'Institut de Protection et la Santé Nucléaire (IPSN) du Commissariat à l'Energie Atomique et de l'Institut Gustave ROUSSY (I.G.R.).

L'objectif principal de ce Centre consiste en la surveillance médicale et épidémiologique d'une population bien précise, celle des personnes évacuées de PRIPYAT et des environs relogées à KIEV. Sur 30 000 personnes environ, la priorité pour le suivi est donnée aux 7 000 enfants susceptibles d'avoir été irradiés et/ou contaminés pendant l'accident de TCHERNOBYL. Les personnes suivies subissent un examen complet, avec notamment une recherche des pathologies thyroïdiennes et immuno-hématologiques. Le suivi repose principalement sur le système de santé Ukrainien. Une des originalités du projet réside dans l'alliance de l'action humanitaire et de la coopération médicale et scientifique avec un transfert de compétences. Une autre originalité est le parti pris de s'appuyer autant que faire se peut sur les responsables et les initiatives locales, démarche dictée par le souci de créer un climat de confiance chez des populations méfiantes vis-à-vis des initiatives trop liées aux autorités centrales.

MISE EN PLACE ET RETOUR D'EXPERIENCE ACTUEL

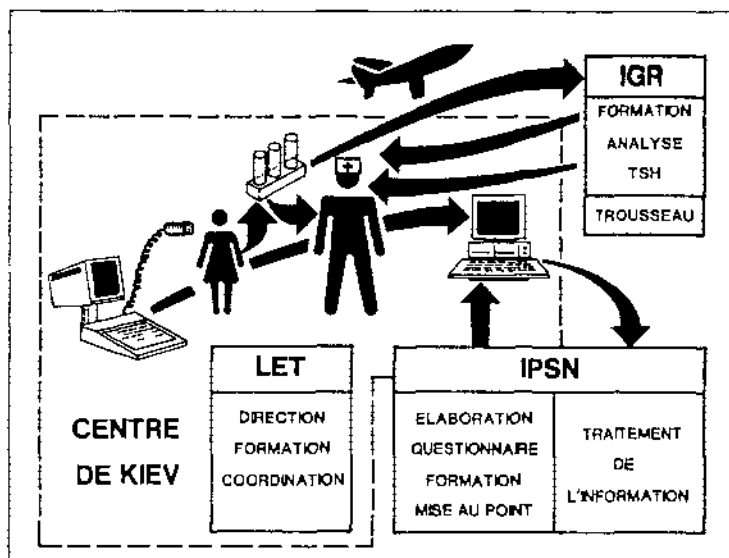

Inauguré le 19 Février 1991, le Centre a atteint son régime de croisière au début du printemps 1991.

Sur place, à plein temps, 3 pédiatres et 2 infirmières ukrainiens, un médecin de l'Association "Les Enfants de Tchernobyl" et une infirmière française bénévole, constituent l'équipe du Centre. En 1991, un premier travail a constitué à mettre l'équipe Ukrainienne en place et à la former à des approches diagnostiques et à des techniques médicales de type occidental. Dans le même temps, le Centre a été équipé, une partie du matériel (analyseur de sang, échographe, ordinateur) étant importé de France. Un stock de médicaments a aussi été fourni au titre de l'aide humanitaire. Parmi les outils spécifiques développés pour cette étude, il faut mentionner le questionnaire à visée médicale et épidémiologique qui comporte trois volets :

- . Une partie signalétique, permettant de repérer l'individu et d'organiser un suivi à long terme.
- . Une partie médicale, réalisée dans l'optique d'un dossier médical, l'accent étant mis sur les pathologies thyroïdiennes et certains paramètres biologiques (numération-formule sanguine et dosage de la TSH).
- . Une partie à visée dosimétrique, visant à reconstituer les localisations successives de l'individu de façon très fine (par tranche de 3 h pendant les premières 48 h, et jour par jour pendant les 8 jours suivants).

Un système de saisie a été conçu pour permettre l'enregistrement direct du questionnaire sur l'ordinateur du Centre.

A la date de ce bilan, 4 mois après l'ouverture, le mode de fonctionnement du Centre peut être considéré comme à peu près définitif. L'équipe de KIEV est secondée par du personnel français envoyé en mission (responsable de l'Association "Les Enfants de TCHERNOBYL", médecin spécialiste, médecin épidémiologiste, informaticien, etc...). La circulation de l'information est décrite par la figure ci-dessous.

Circulation de l'information

Avant Juillet 1991 (le Centre ferme en été), 953 personnes avaient été examinées ; parmi elles, 808 avaient moins de 18 ans au moment de l'accident et 31 ont été exposées in utero.

Ces premiers résultats permettent de valider le mode de recrutement : les personnes suivies sont convoquées par l'intermédiaire des médecins de quartier et suivies ensuite par le Centre. Les personnes convoquées ont toutes répondu et un climat de confiance paraît s'établir avec le Centre, ce qui justifie le choix initial de s'appuyer sur des relais locaux. Le questionnaire a aussi pu être validé. Quelques modifications mineures sont à envisager dans la partie médicale, et un contrôle de saisie devra sans doute être mis en place localement. La structure générale s'est montrée satisfaisante, et surtout, la partie à visée dosimétrique, a priori très délicate, a très bien été remplie. Les victimes de l'accident ont en effet gardé un souvenir précis de ce qu'elles ont fait pendant les heures et les jours qui ont suivi l'accident.

Les examens systématiques (écographies et dosages de TSH) sur 900 personnes mettent en évidence certaines anomalies, qui ne

s'accompagnent pas pour autant d'une traduction classique ; ces diagnostics nécessitent des confirmations, cas par cas. A cause de ceci, du fait du nombre limité de personnes déjà examinées et à cause de la possibilité d'existence de biais de recrutement qui restent à vérifier, il n'est pas permis d'effectuer pour le moment une interprétation épidémiologique des résultats. Tout au plus peut-on noter qu'une hypothyroïdie a été recensée, dont l'étiologie reste à établir, et qu'aucun cancer ou aucune leucémie n'a été observé sur cet échantillon.

PERSPECTIVES

Au début de 1993, la cohorte des 7000 enfants aura probablement pu être constituée. Même à cette date, les calculs que l'on peut faire à partir de nos connaissances sur les effets des rayonnements et sur les expositions des personnes suivies indiquent qu'il est improbable d'observer des résultats significatifs à cause de la faiblesse du nombre de personnes-années associées au suivi. Ainsi, pour les leucémies, compte-tenu des évaluations dosimétriques publiées par l'AIEA et des facteurs de risque retenus par l'UNSCEAR et le BEIR V, la taille de l'échantillon, plus que le délai écoulé depuis 1986, constituerait le principal handicap pour mettre en évidence un excès statistiquement significatif. Pour les tumeurs thyroïdiennes et les cancers en général la question se pose en des termes un peu différents à cause des longs délais d'apparition (5 à 15 ans après l'irradiation). La cohorte des 7000 enfants serait peut-être assez puissante, mais les difficultés inhérentes à un suivi prolongé, avec ses "perdus de vue" et ses "intrus", risquent d'affaiblir l'étude. En 1993, il est prévu de faire le point sur les "perdus de vue", afin de définir les conditions d'un suivi à long terme de cette cohorte.

En revanche, le simple fait de posséder un bilan descriptif en 1993 présentera un intérêt considérable, car, dans le cas de TCHERNOBYL, les inconnues sont très grandes et des hypothèses bien plus inquiétantes que celles mentionnées ci-avant (sur le plan de l'exposition et de l'effet de l'irradiation) circulent ; les données qui auront été recueillies permettront probablement d'éliminer les plus extrêmes. A titre d'exemple, sur 10 ans, un doublement des taux de leucémies ne serait sans doute pas significatif statistiquement, mais un quadruplement le serait.

Ce projet nécessite encore quelques développements. Les différentes méthodes de reconstitution des doses doivent être examinées (dosimétrie individuelle, reconstitution à partir du terme-source de l'accident, de modèles de diffusion et du comportement des évacués, données initiales soviétiques). L'objectif est évidemment de constituer des groupes d'exposition ; selon la qualité des données disponibles il sera plus ou moins facile à réaliser. Dans une hypothèse défavorable, il faudra créer des groupes en fonction des durées et modalités d'exposition.

Enfin, la mise en place d'autres Centres doit être examinée dans cette optique (groupes à faible exposition ou groupe témoin).

Over-exposure Cases on the Extremities in Radiological Accidents

The University of Tokyo, Tokyo, JAPAN

ABSTRACT

In a decade, we have treated from medical and radiological viewpoints five males who were over-exposed to direct beam of X-ray on their extremities when they had handled X-ray analysis machine during research or maintenance. All workers except one had worn personal dosimeters on the chest, but not on fingers or wrists. The estimated absorbed dose of the epidermis of the skin performed by a reconstruction of events ranged from 15 to 300 Gy. The causes of accidents in all cases were mishandling of safety system of machine. Clinical syndrome of radiation burn of the skin appeared in all cases and these clinical signs were very useful indicators to estimate dose of each individual.

INTRODUCTION

One of the most important purposes of radiological protection is preventing the deterministic effects of radiation. However, there were some cases of radiation injuries, particularly the radiation burn on hands and faces, quite recently. In a decade, we have treated five male workers over-exposed to X-rays on their hands with radiological and medical cares (1,2,3). Detailed analysis of these accidental subjects from viewpoints of radiological protection is important to prevent further accidental cases in future.

SUMMARY OF INDIVIDUAL CASES INCLUDED IN THIS PAPER

The exposure conditions of each subject are shown in Table 1. Physical properties of irradiated radiation are shown in Table 2. All individuals are male engineers or students. Causes of over-exposure were misuse of safety system of X-ray analytical machine and shortage of sufficient knowledge and perception on radiation safety in workers themselves.

Table 1 Summary of over-exposure by X-ray analytical equipment

Subject	Occupation (age)	Time	Distance	Area	Dose
A	engineer (30)	5 sec	3 cm	50 cm ²	200 Gy
B	engineer (20)	2 sec	0	4 cm ² x 2	300
C	student (22)	20-30 sec	6	4 cm ² x 2	8
D	student (23)	100-150 sec	5	2 cm ² x 3	30-300
E	engineer (20)	4-5 sec	10	20 cm ²	300

Table 2 Physical properties of exposed radiation from X-ray analytical equipment

Subject	Voltage	Current	Additional filter	Effective energy
A	50kV	20mA	-	10 keV
B	50	30	-	10
C	30	20	-	9
D	50	50	-	9
E	40	200	-	10

ESTIMATION OF ACCIDENTAL EXPOSED DOSE

Four cases were wearing personal dosimeters on the trunk when they were clearly exposed, but as irradiated areas were limited to only a part of the body, the dosimeters did not include exposed direct beam of X-rays. Therefore, their dosimeter recorded zero. One case, a college student, did not wear personal dosimeter because he was not registered as a radiation worker. In all cases, personal dosimeters on the wrist or finger were not worn; thus, in all cases, the doses to the exposed parts of the hands were not given by personal dosimetry. So we estimated dose by reconstruction of events after each accident. The detailed information of exposed time, distance, shielding and source strength were taken from interview of both subject and radiation safety officer immediately after exposure. Exposure doses were measured with the following equipment in the experiment of the reconstruction;

Ionizing chamber : CAPINTEC Model 192 (probe volume;6cc)
 Thermoluminescence dosimeter : CaSO₄, BeO

The estimated absorbed dose of epidermis of each case by reconstruction are shown in Table 1. Each estimated dose had uncertainty factor 2 to 3, because exposed times at the accident were equivocal. We considered that the clinical manifestations on the skin after accidents were the most valuable indicators for dose estimation. We did not perform biological estimation of dose, that is analysis of chromosome aberrations and hematological examination of circulating blood; because irradiated area was a very restricted volume, we considered that dose could not be detected by these biological analyses.

CLINICAL SIGNS AND TREATMENT

Acute and chronic syndromes of the radiation burns appeared in all subjects with some period of latency. Typical acute syndromes that appeared in each case were erythema, dry and wet desquamation, dermal oedema, blister and erosion. These acute syndromes disappeared in two or three months after exposure and chronic syndrome appeared after 9 or 18 months after events. In one case, chronic syndromes appeared without a break from acute syndromes. Typical chronic syndromes in all cases were ulcer, necrosis, hyperplasia, telangiectasis, pigmentation, dis-pigmentation and atrophy. The points of medical care of subjects were cleaning of the exposed area and giving it a good rest. Four cases were treated with non-surgical conservative therapies and one case was treated with surgical skin graft therapy.

Clinical manifestations, particularly the length of latencies of acute syndromes, were very useful information for dose estimation in individuals not wearing personal dosimeter. The times of appearance of each acute syndrome in individuals are shown in Fig.1.

ADMINISTRATION ACTION

(1) Improvement of safety equipment

All equipment was provided with safety lock system. However, many workers frequently ignored these safety systems while operating the machine. At the time of accident, the functions of safety systems were not effective in any of the cases reported in this paper. Then deep defense systems of safety were introduced.

(2) Creation of a formal management structure and operational guidance

New effective organizations for radiation protection and manuals of good practice expressed in clear terms were prepared in all institute after the accidents.

(3) Training and skill for radiation workers

Special training and skill were performed to establish a safety-based attitude in everyone concerned with operations of X-ray analytical machines in each institute. There were many types of machine and various techniques of utilization of X-ray analytical machine; thus, details of training concerning safety and protection depended on the type and technique of operating machine and degree of worker's skill.

(4) Lay-off from radiation work

All cases were permitted the subsequent employment in the same duties of radiation work from clinical and radiological consideration; however, the duties of all cases were modified from radiation work to non-radiation work as required by each individual.

DISCUSSION

(1) Biological dosimetry of very small part of the skin

Analysis of chromosome aberration in peripheral lymphocytes has usually been performed in accidental cases, but, in the cases where the irradiated area or volume is very small, chromosome analysis does not detect irradiation dose. Then, other biological dosimetric system must be investigated; particularly useful indicators under the dose range are the appearance of clinical manifestation, that is erythema and epilation. Now we research growth retardation of hair after over-exposure of skin as a biological indicator (4).

(2) Dose estimation of very low energy of X-ray

In cases of irradiation by X-ray analytical machine, the energies of radiation were very low, under 10 keV. The response of present dosimetric equipment, TLD, depends on energy of exposed radiation. The equipment is over-responsive in these energy ranges. Then, we employed a method of two kinds of TLDs, which are different in effective atomic number, to correct X-ray energy response.

(3) Shortage of knowledge of radiation safety and protection of workers

Our previous studies made it clear that the understandings of managers and workers for radiation protection were lacking. The most important aspect of radiation safety and protection is the close links between managers and workers. All persons concerned with radiation work must have appropriate knowledge of safety of radiation.

CONCLUSION

We have treated five male workers who were over-exposed to X-rays on their hands with doses from 8 to 300 Gy. The experience of detailed analysis of these subjects suggested that it is important to practice appropriate pre-operational and periodical education and training for workers on radiological safety and protection.

RADIOTOXICOLOGICAL ASSESSMENT OF BURNS CONTAMINATED BY NITRIC
SOLUTION OF PLUTONIUM

Skin burn by nitric solutions of plutonium is a possible way of contamination during fuel reprocessing. Two well documented cases have been analyzed. They show that the initial transfer of Pu through the skin is very important. Conversely, there is practically no long-term release of Pu from the burn. Consequently, DTPA therapy can be considered as a medical emergency whereas there is no urgency for an eventual surgical operation.

In fuel reprocessing plants, the Occupational Physician may occasionally come across cases of burns contaminated with plutonium in nitric acid solutions. A long-term follow-up of excretion is necessary in order to assess the systemic burden correctly.

Initial urinary excretion, over about the first ten days following the incident, is essentially attributable to the activity that has passed rapidly into the blood. Measurements performed during this period represent the sum of the excretion relative to systemic burden and of the activity released from the burn, washed away by the circulating DTPA. Excretion over medium and long periods is more difficult to interpret. Measurements performed beyond the first month allow a theoretical determination of the activity transferred very slowly to the blood.

Two examples are presented. The theoretical function of urinary excretion relative to the activity that is rapidly transferred to the systemic target tissues (1, 2) allows us to find the systemic burden by applying a factor of 50 for the action of DTPA. The margin of uncertainty, taking into account the variability of DTPA action (25 at least, 100 at most), is shown by a hatched band. It is obvious that an interpretation with a view to determine a long-term released activity could have been envisaged only if several points had been situated clearly above this band beyond one month. As this is not the case, it can be considered that the long-term release of activity from the burn is virtually non-existent.

In the examples treated, only the rapid transfer component participates in the systemic burden. Internal exposure thus results from the activity which passes in the blood through at the time of the incident or in a few hours thereafter. Emergency medical therapy, i.e. the administration

of DTPA as soon as possible, washes away the plutonium released from the burn.

The local activity which persists for long periods seems above all to be "inert", not at all or very little metabolizable. It is not possible to show a component of slow transfer to the blood. This suggests that, contrary to the medical action which should be very rapid, possible surgical action can be calmly prepared for reducing to a minimum any anatomical and functional risks.

The argument of local dose may be raised, but it should be tempered in view of the very small distance travelled by the radiation and of the very low probability of alpha particles hitting critical target cells. If an excision is performed, it actually removes the irradiated tissues, thereby eliminating the associated risk of a high local dose.

ACKNOWLEDGEMENTS

We would like to thank Dr. J. JEANPIERRE for providing the data of the case B and Mrs B. MENOUX for elaborating the excretion curves software.

COMMENTARY ON THE FIGURES

Case A : Burn of about 4 cm² located on the left forearm, plutonium was in nitric acid solution N 13; initial local activity 600 Bq; excision on day 20; assessment of systemic burden: 2 to 6 Bq.

Case B : Burn of about 48 cm² located on the right thigh; plutonium in nitric acid solution N 6 to 8; initial local activity: 50 kBq; no excision; assessment of systemic burden: 1 to 4 Bq.

The hatched bands give an estimate of the activity excreted relative to the systemic burden. The margin of uncertainty takes into account the variability of DTPA action (25 at least, 100 at most).

(a): the initial values above the hatched band represent the activity released from the burn, immediately trapped by DTPA and eliminated in urine.

(b): the measurement results located in these areas correspond to urinary excretion without DTPA; the points between square brackets represent results below the limit of detection.

(c): no value does appear above the hatched band; it means that there is no long-term release from the burn.

**COMPUTER AID IN RESCUE ORGANISATION ON SITE
IN CASE OF CATASTROPHIC SITUATION ON NUCLEAR PLANT**

The rescue organisation in case of catastrophic situation is based on known principles : creation of medical buffer structures between hazard spot where injured people are being collected and rear hospitals, triage of victims as urgent casualties.

We will propose computer aid in order to value the time used to prepare and evacuate all the victims from the site, knowing inventory of available means, waiting periods and lengths of intervention, types and number of victims. Thus, it is possible to optimize the former organisation, qualitatively and quantitatively to improve efficiency in rescuing operations.

INTRODUCTION

L'accident survenu à la centrale nucléaire soviétique de Tchernobyl le 26 avril 1986 a rappelé la nécessité d'une préparation optimale des plans de secours.

Si l'essentiel de cette préparation en ce qui concerne la population est à la charge des pouvoirs publics ("Plan Particulier d'Intervention"), le médecin du travail se doit de participer à la mise en place et à l'organisation des secours pour les travailleurs dont il a la responsabilité ("Plan d'Urgence Interne").

1 POSITION DU PROBLEME

Il importe tout d'abord de limiter notre champ d'action à la fois dans l'espace : secours aux personnes présentes sur le site (travailleurs, sauveteurs, visiteurs éventuels) et dans le temps : phase précoce de l'accident que l'on considèrera comme achevée lorsque toutes les victimes du site auront, après avoir reçu les soins immédiats nécessaires, été évacuées.

Notre objectif sera alors la prise en charge la plus efficace et dans les délais les plus courts possibles de chaque victime prise isolément et ce à chaque étape de la chaîne des secours qui comprend un relevage des premiers soins et une évacuation ; chaque étape étant dans la mesure du possible médicalisée.

1.1 Victimes en petit nombre (< 3)

Les moyens à mettre en oeuvre tant en matériel qu'en personnel sont en général faciles à créer ou à mobiliser car déjà disponibles à l'extérieur, les procédures d'alerte et de premiers secours assez faciles à organiser.

Par sa spécificité la pathologie nucléaire impose néanmoins, soit de s'adresser à des secours extérieurs compétents en ce domaine (Hôpitaux universitaires, armée), soit de former le personnel interne pour servir de spécialiste accompagnant au personnel habituellement confronté aux urgences dans le secteur concerné.

1.2 Victimes en nombre important (>3)

Les sites nucléaires français comportent souvent quatre unités dont l'effectif en personnel dépasse 1 000 personnes. Il peut exister un nombre important d'impliqués : personnes indemnes qu'il importe néanmoins de contrôler sur le plan radiologique.

Nous nous trouvons alors en inadéquation temporaire entre les moyens mis à disposition pour les secours et les besoins : c'est un contexte de médecine dite de catastrophe. Les grands principes en sont connus et deux sont essentiels : trier les victimes et créer un centre tampon précédant les structures habituelles de soins à l'extérieur. C'est le rôle du centre de tri et de soins (CTS) qui peut se dédoubler en poste médical avancé (PMA) et centre médical d'évacuation (CME).

Il faut établir l'inventaire des moyens à notre disposition tant en personnel qu'en matériel (interne au site, Services médicaux d'urgence, sapeurs pompiers, ...), en discuter l'opportunité et agir en conséquence.

Il faut optimiser leur répartition et leur mise en oeuvre de façon à éviter le problème majeur de ce type de situation : l'attente tant du côté de la victime que du sauveteur : attente des victimes ayant pour conséquence une augmentation de la morbidité et de la mortalité globale, attente des sauveteurs ayant au minimum une conséquence sur le plan économique ne serait-ce que par une surestimation a priori des moyens.

2 CHOIX D'UNE SOLUTION

2.1 Approche habituelle

C'est une approche pragmatique fondée sur le retour d'expérience. Il en est résulté des solutions types adaptées à quelques cas-types ne faisant pas toujours l'unanimité parmi les intervenants concernés. L'adaptation de la montée en puissance se fait au vu de l'évolution de la situation. Dans le secteur nucléaire, les accidents de ce type ont été fort heureusement rares et nos confrères soviétiques sont restés relativement discrets sur cette phase précoce et localisée au site de l'accident.

Cette approche est néanmoins une source indispensable de renseignements quantitatifs issus des statistiques disponibles en ce qui concerne les délais d'intervention, les durées moyennes de conditionnement des blessés...

2.2 Approche de type ordonnancement

Nous avons tenté une modélisation du déroulement des secours à l'aide de la méthode des graphes qui consiste à découper l'ensemble des actions à effectuer en tâches élémentaires de durée déterminée, puis à mailler par des chemins logiques l'ensemble de ces tâches.

Certaines tâches peuvent être effectuées simultanément : un blessé pourra être évacué pendant le conditionnement d'une autre victime si les moyens sont suffisants.

Certaines tâches doivent être effectuées successivement : tous les blessés seront d'abord conditionnés puis ils seront évacués l'un après l'autre au moyen d'une noria si une seule équipe médicale munie d'un véhicule d'évacuation est disponible.

L'ensemble des opérations de secours se passent par ailleurs sous contrainte de durée : une urgence absolue doit arriver en moins de 6 heures en milieu chirurgical, une urgence relative en moins de 18 heures (durées proposées par les médecins militaires que nous avons volontairement de beaucoup réduites). Dans ces problèmes très combinatoires dès qu'un grand nombre de variables apparaissent, l'informatique permet d'optimiser plus facilement les moyens pour les objectifs que l'on s'est préalablement fixés.

2.3 Présentation du programme

Le programme permet de simuler le déroulement des secours dans le cadre de l'organisation que nous lui avons fixée a priori : une chaîne de secours traumatologique avec ou sans caractère radiologique, une chaîne de secours radiologique isolée s'occupant essentiellement du contrôle de personnes.

Les données d'entrée comprennent :

. Des variables (10) concernant le nombre et la nature des victimes ; nous avons créé à ce propos une typologie adaptée à la prise en compte de la durée et de la qualification nécessaires des intervenants en ce qui concerne les classes de victimes. Ces valeurs sont fonction de l'accident envisagé.

. Des paramètres (21) propres à la configuration du site (déterminés par des exercices) et aux moyens disponibles en ce qui concerne les délais et durées d'intervention et les effectifs de ces moyens.

Pour un type d'accident donné l'essai de différents paramètres en ce qui concerne les moyens, fournit en temps réel la durée totale de l'intervention telle qu'on l'a définie précédemment et les durées partielles sur lesquelles il est judicieux de porter son effort (c'est la recherche du chemin critique).

3 APPLICATION PRATIQUE ET PRECAUTIONS D'UTILISATION

L'aide informatisée ne supprime pas la réflexion, elle ne prend pas par elle même de décision !

Il y a tout d'abord à s'interroger sur les incertitudes liées aux paramètres d'entrée : la durée du conditionnement du blessé peut être éminemment variable. On peut dire que plus il y a de victimes, plus la durée moyenne se stabilise, mais la distribution de ces durées est à prendre en compte dans une file d'attente.

Il y a aussi à s'interroger sur la robustesse aux nécessaires simplifications introduites dans notre modèle figé dans son organisation : la montée en puissance des contre-mesures à la fois progressive et cahotique est difficile à introduire mais ceci peut s'améliorer.

Nous estimons mal enfin le facteur de viscosité introduit par le climat psychologique inhérent à ce type de situation.

Actuellement ce programme nous a servi à l'aide de scénarios plausibles d'accidents que nous avons analysés, à déterminer des ordres de grandeur d'effectifs et des choix quant à la nature des moyens de secours, ceci nous permet de créer des exercices qui nous servent eux même à valider le modèle.

Nous espérons ne pas le voir utilisé en temps réel, mais il pourrait sans doute y apporter une aide.

EFFECTS OF POWDERED OYSETER SHELL ON DECORPORATION OF PLUTONIUM

S. Fukuda and H. Iida

Division of Comparative Radiotoxicology, National Institute of Radiological Sciences, Chiba, Japan

ABSTRACT

Active amino acid calcium (AAACa), a natural product which oyster shell electrolysate and seven amino acids were mixed, has strong bioavailabilities that can raise the serum level of calcium and affects on bone metabolism, by the action of high calcium intestinal absorption. This compound may be expectable as a abetting agent to reduce the risk of plutonium or other bone seeking radionuclides-induced cancers because it has beneficial effects to decorporate plutonium from bone and liver.

INTRODUCTION

Chelation agents such as DTPA (Diethylenetriaminepentaacetic acid) can decorporate effectively plutonium and other actinides, however the practical use for human is limited by the many unavoidable toxic side effects and the time of use.

AAACa is one of natural foods that the main component, CaO, of oyster shell electrolysate which is easily ionizing and the seven kinds of amino acids such as valine containing in seaweeds that has an action of active calcium transport [1,2] are mixed. Recently it was demonstrated that AAACa has beneficial effects to prevent and treat especially osteoporosis [3] and hypertension without side effects, indication it has a strong bioavailability against calcium and bone metabolism.

The present study was performed to examine the effects of AAACa to decorporation of plutonium particularly from bone in rats.

MATERIALS AND METHODS

Twenty five rats, 3 months-old, were divided into the following five groups: group A was give a control standard diet (1 % CaCO₃). group B was given a 1 % AAACa diet immediately after plutonium injection. group C was given a 1 % AAACa diet 1 week before plutonium injection. group D was given a 1 % AAACa diet and injected intra-peritoneally once a day a daily dose of 150 μ mol/kg body weight Ca-DTPA. group E was given a control diet and injected the same schedule of Ca-DTPA as that of group D.

Rats were injected intravenously plutonium under anesthesia and sacrificed 14 days later. The femur and liver were removed. The excreta, separated and feces urine, were collected at 24-hr intervals. Plutonium activity of these samples was measured by an alpha liquid scintillation counter after wet ashing.

RESULTS

The plutonium contents of skeleton were reduced to 63.6 % in the group B, 58.9 % in the group C, 10.4 % in the group D and 19.0 % in the group E, whereas the control was 69.3 %. Those of liver were 6.93 %, 6.43 %, 0.22 %, and 0.35 % in each B, C, D, E group, whereas the control was 7.74% (Fig 1).

DISCUSSION

The data obtained showed that AAACa can remove plutonium from not only bone but also liver, and a combination of it and Ca-DTPA can promote the reduction of plutonium contents in these organs. The possible mechanisms are considered that rapid absorbed and increased ionic calcium in serum covered the osteoid surface of trabecula bone, followed the inhibition of plutonium deposition in bone, and affected on some changes to the functions of osteoclasts and liver cells bone cells. The results indicated that particularly a long term dietary AAACa supplement has beneficial effects to reduce the risk of radionuclides-induced cancers and is expectable as one of agents to use practically and immediately to prevent and treat for human exposure without toxic side effects.

ABSTRACT

Radiological protection began with particle accelerators. Many of the concerns in the health physics profession today were discovered at accelerator laboratories. Since the mid-1940s, our understanding has progressed through seven stages: observation of high radiation levels; shielding; development of dosimetric techniques; studies of induced activity and environmental impact; legislative and regulatory concerns; and disposal. The technical and scientific aspects of accelerator radiation safety are well in hand. In the U.S., there is an urgent need to move away from a "best available technology" philosophy to risk-based health protection standards. The newer accelerators will present interesting radiological protection issues, including copious muon production and high LET (neutron) environments.

INTRODUCTION

The elegant work of Cockcroft and Walton at Cambridge and Lawrence at Berkeley was reported in that *annus mirabilis* of nuclear physics, 1932; as a result, this is regarded as the year in which particle accelerators were invented. However, accelerators are 35 years or more older. Since the time of J. J. Thomson's cathode-ray tube (1894) and the discovery of Roentgen rays (1895), particle accelerators have been associated not only with major discoveries in atomic, nuclear, and fundamental particle physics but also with radiological protection.

Accelerators were first developed as research instruments, and thus, many of the concerns that now occupy health physics were first identified at accelerator laboratories. Accelerators were the first to produce the symptoms of the acute radiation syndrome; induced radioactivity; radiopharmaceuticals; transuranic elements; and by an accelerator-derived instrument, the calutron, fissile and fissionable materials. It was at an accelerator laboratory that the first studies of the radiotoxicity of the alpha-emitting transuranic elements were made. Nevertheless, accelerator radiological protection is largely perceived as something of an academic backwater aside from the mainstream; many of the subdisciplines that began at accelerators are now so large in scope that they have become separate fields of endeavor.

HISTORICAL OVERVIEW

After the Second World War, studies of the radiological environments of accelerators began in earnest, following the work started during the Manhattan Project. Our understanding of the development has been reviewed by Perry et al. (1991), who suggested that it occurred in seven stages:

1. Observation of high radiation levels.
2. Shielding studies.
3. Radiation dosimetry.

4. Studies of induced activity and radiation damage.
5. Environmental impact.
6. Legislation and regulation.
7. Disposal.

Each of these aspects will be briefly discussed.

HIGH-RADIATION LEVELS AND SHIELDING STUDIES

Many years before nuclear reactors operated, the early accelerators were powerful neutron sources. In the late 1940s and early 1950s, many accelerators of various types were constructed in several different countries. Performance often exceeded expectations, and high beam intensities led to the production of high, unwanted, ambient radiation levels. Two immediate necessities resulted: (1) to shield and (2) to quantify radiation fields.

Incentives were greatest at laboratories, like Berkeley, where new accelerators had been built aboveground and with very little shielding. At the early synchro-cyclotrons buried in the ground, radiation problems were avoided, but at the cost of no improvement in understanding. The progress of shielding studies has been extensively documented in several texts to which the interested reader is referred. Suffice it to say that nowadays, accelerator shields may be defined with considerable confidence and efficiency (Patterson and Thomas, 1973; Swanson, 1979; Thomas, 1988; and Fassò, 1990).

RADIATION DOSIMETRY

Swanson and Thomas (1990) assert it is at accelerators that "the science and technology of radiation dosimetry are at their most sophisticated. In only one other class of radiation environments—those met in extraterrestrial exploration—do such novel and diverse dosimetric challenges need to be faced. Even here the dosimetrist does not encounter the range of particle intensities, variety of radiation environments, or pulsed characteristic of radiation fields."

These authors give detailed descriptions of the dosimetric systems that have proved useful in accelerator environments where measurements are made for many purposes, above and beyond the need to determine personnel exposure. Techniques that determine the physical characteristics of the radiation environment are preferred to attempts avoid the complex problem by expressing measurements in terms of a single scalar quantity, such as equivalent dose.

Philosophers might reflect on the vicissitudes of the dose-equivalent system over the past decade: the system is now so complex when applied to mixed radiation fields that it has lost its original intended virtue of simplicity.

INDUCED RADIOACTIVITY

The largest contribution to collective dose equivalent resulting from accelerator operation arises during repair, maintenance, and modification. While these doses mainly result from photons, the detailed inventory of radionuclides in accelerator environments differs from that found at nuclear reactors. High-energy hadron reactions tend to produce radionuclides that are neutron deficient and many decay by positron emission or electron capture (e.g., ^7Be , ^{54}Mn , ^{51}Cr).

In the decade from 1975 to 1985, there has been a general tendency for the annual collective dose equivalent at accelerators to fall by about a factor of 3. Typical collective dose equivalents at large accelerator facilities range from a few tens to a few thousand millisievert (Perry et al., 1991).

ENVIRONMENTAL IMPACT AND DISPOSAL

Accelerator operation may expose the general public by four pathways. In order of importance they are

- Prompt radiation;
- Production of radionuclides and noxious chemicals, and release to the environment;
- Production of radionuclides in soil and groundwater near the accelerator and possible migration to water supplies;
- Radioactivity produced in materials of accelerator components that may be subsequently recycled or released to the general environment.

Measurements of the transport of neutrons to large distances (on the order of km) from the roof-less synchrotrons began at Brookhaven and Berkeley in the 1950s. These studies have been refined over the past 30 years, and this source of environmental impact is now well understood (Thomas and Stevenson, 1988; Stapleton et al., 1991; Stevenson and Thomas, 1984).

No significant population dose is expected from the latter two pathways and the second pathway is of less consequence than the first by an order of magnitude (Thomas and Rindi, 1979; Goebel, 1987).

LEGISLATION AND REGULATION

In the United States, perceptions of increasing concern for health by the general public have led legislators to reduce allowed radiation exposures to the general public using legislative and regulatory means regardless of cost. Such regulation often takes the form of control by the "best available technology"—and this often translates into merely what minimum level may be measured—rather than any assessment of risks to public health.

Such a process has resulted in a set of protection standards promulgated by the U.S. Environmental Protection Agency that is disparate and illogical. For example, under the Clean Air Act, radioactive emissions are limited to produce an annual dose equivalent of no more than 100 μ Sv. However, if these radionuclides were waterborne, the committed dose-equivalent limit would be 40 μ Sv. The annual limit for all radiation exposure from both external and internal sources is 1000 μ Sv. One wonders how the particular biological structure being irradiated discerns the specific origin of its own radiation exposure!

RADIOLOGICAL PROTECTION AT PARTICLE ACCELERATORS

In most respects, the operational requirements of radiological protection at particle accelerator laboratories do not substantially differ from those at other radiological facilities that have been well documented; for example, in Report 59 of the National Council on Radiological Protection and Measurements (NCRP). Nevertheless, there are aspects unique to particle accelerators that are of concern:

- Facility design,
- Personnel access control,
- Control of radioactive materials,
- Control of contamination, and
- Radioactive-waste management.

These special topics will be discussed in the new version of NCRP Report 51, which is now under revision.

THE FUTURE

Accelerators have entered into the very fabric of our life: they are applied in medicine, materials science and solid-state physics (e.g., ion-implantation);

micro-lithography; food preservation; sterilization of toxic wastes; polymerization of plastics; and radiopharmaceutical production. The applications are many and will increase in the future. Heavy ion accelerators may be used in fusion devices; accelerators will be used to incinerate radioactive waste to produce fissionable material and in plasma heating.

Research instruments now planned or under construction, such as the SSC near Dallas, are of enormous proportions—large enough to encircle a large metropolitan region—and will bring with them other, unanticipated technological spin-offs. In adopting these new technologies, it is to be hoped that society will move to develop cost-effective health standards based upon an assessment of all risks to human health and a proper placing of them in context with radiation risks. This could be a welcome change from our present obsession with the "best available technology" approach, which is not necessarily related to health risks.

These newer high-energy accelerators present two radiological issues of interest: first, the generation of muons (because of their copious production at higher energies), presenting an environmental impact; and second, the production of neutrons and other high-LET radiation. Perhaps, in the last analysis, it will be only high-LET radiations that are of concern at low doses. In the future, accelerators will provide a continuous source of high-LET radiation to which workers and nearby members of the public will be exposed. We will need to understand the radiobiological implications of such exposures and improve on our techniques of measurement to meet this important challenge.

RADIATION PROTECTION AT THE CERN LARGE ELECTRON POSITRON
COLLIDER(LEP)

M. Höfert, A. Fassò, K. Goebel, G.R. Stevenson
CERN, Geneva, Switzerland

P. Schmidt
Technical University, Dresden, Germany

ABSTRACT

Results of recent investigations into two particular aspects of radiation protection at LEP are presented: penetration of radiation as a result of beam losses through the main shield and attenuation of low energy photons from synchrotron radiation in ducts and labyrinths.

INTRODUCTION

The Large Electron Positron collider (LEP) is an accelerator where counter rotating beams of electrons and positrons are stored for periods of several hours and collide in four experimental areas. LEP is housed in a circular tunnel with a circumference of approximately 27 km. The collider came into operation in July 1989 and has worked since then at beam energies of 45 GeV. Following the installation of superconducting RF cavities in the near future with the consequent possibility of transferring more power to the beam, the energy will be increased over the next few years to its design value of 100 GeV.

Studies of radiation protection issues in this unique high-energy installation started in 1980. In this paper attention will be primarily concentrated on only two aspects: shielding against beam losses and shielding against the intense synchrotron radiation emitted from the bending sections of the collider.

SHIELDING AGAINST BEAM LOSSES

The amount of shielding necessary around LEP is determined by beam losses either during the filling operation of the storage rings at an injection energy of 20 GeV or by the possibility of a full loss of the stored beams at their maximum energy (100 GeV). CERN's radiation protection philosophy already stipulated in 1981 that annual personal exposures should stay within a reference dose of 15 mSv i.e. below the new dose limits only recently recommended by ICRP^{1,2}. It was decided to design the shielding for LEP such that annual doses in occupied areas would never exceed 10 mSv. Occupancy time would then provide an additional safety factor.

The classical way to treat shielding assessment for electron accelerators is to consider the three main radiation components of the electron-induced shower that develops in the shield separately, i.e. the electromagnetic, the fast neutron and the high-energy particle components. In most materials, due to the short radiation lengths which govern electron-gamma shower development, the effective source for shielding against beam losses can be regarded as point-like so that a $1/r^2$ dependence for the overall attenuation of the radiation will hold.

Furthermore the intensity of stray radiation produced in the interaction of a several GeV electron beam is considered to be proportional to the beam energy. Lateral shielding requirements for each component can then be characterized by two parameters, a source term per interacting electron given in $\text{Sv m}^2 \text{GeV}^{-1}$ and an attenuation length for the shielding material (concrete or earth) in g/cm^2 . These parameters are presented in the following table as they were used in the shielding estimations for the LEP collider³.

Source terms for electron beam losses and radiation lengths in concrete or earth perpendicular to the beam line for the three radiation components as used in the shielding estimations for the LEP collider.

Radiation component	Source term in $\text{Sv m}^2 \text{GeV}^{-1}$ per electron	Attenuation lengths in g/cm^2
Electromagnetic	$2.2 \cdot 10^{-15}$	48
Giant resonance neutrons	$1.0 \cdot 10^{-15}$	42
High energy particles	$1.5 \cdot 10^{-17}$	115

Since LEP was designed, three changes have occurred which will modify the parameters in the table. ICRP has recommended that the radiation weighting factor for fast neutrons should be changed from 10 to 20 in the energy range from 0.1 to 2 MeV^2 . It would therefore be prudent to multiply the source term for the giant resonance neutron component by a factor of two. Recent work has shown that the source term for the high energy component is higher than previously assumed ($4.2 \cdot 10^{-17} \text{Sv m}^2 \text{GeV}^{-1}$) and the attenuation length somewhat lower (100g/cm^2 compared to 115g/cm^2)⁴. These new values are used in figure 1 where the dose equivalent in Sv per electron for the different radiation components is plotted as a function of the lateral thickness of concrete (density 2.4g/cm^2).

Fig. 1: Curves showing the lateral attenuation of the three main radiation components in the case of electron accelerators.

- 1) Electromagnetic component,
- 2) Giant resonance (fast) neutrons and
- 3) High energy particles.

The functions for three components are purely exponential when the geometrical $1/r^2$ dependence for a point source is removed. The parameters that were used in the LEP design give similar answers to those obtained using the more recent parameters since it is only beyond a shielding thickness of about 1.5 metre that the high energy particle component will determine the overall shielding requirements of a GeV electron accelerator. At LEP the required shield thicknesses are in the 1 to 2 metre range and here the effect of the higher source term for the high-energy particle component is compensated by the shorter attenuation length. Hence, for LEP the change of parameters had no effect but since the knowledge of source terms and attenuation lengths is particularly important for a future generation of high intensity machines like CEBAF or CLIC it is essential that extrapolations of earlier measurements and recent calculations be supported by benchmark experiments.

SHIELDING AGAINST SYNCHROTRON RADIATION

Photon energies for synchrotron radiation resulting from the operation of the LEP collider extend from below 1 keV to several 100 keV even reaching energies greater than 1 MeV when the machine will have attained its design energy of 100 GeV. The high photon intensities mean that particular care has been taken in the design of lead shielding around the LEP vacuum chamber in order to protect sensitive equipment in the accelerator tunnel against damage caused by radiation. Correct design of the ducts for cables and access labyrinths for personnel through the main shield in order to limit doses in occupied areas is also essential. The construction of these passage-ways was based on so-called "universal attenuation curves" that had been confirmed by measurements in the case of neutrons⁵.

Fig.2: Universal attenuation curve (solid line) for the second and higher legs in access labyrinths as a function of their cross-section A and their depth d . The dotted lines give the range of uncertainty⁵. The rectangles present results for photon transmission by Morse-calculations and their uncertainties⁶, \diamond the results of measurements in a second leg, Δ the results for a third leg⁷.

For photons Monte-Carlo simulations suggested that the attenuation of photons in labyrinths would be more important than for neutrons, but these simulations were poorly supported by very few measurements⁶. Hence the labyrinths of LEP were built with a considerable safety factor.

Reliable experimental information for the penetration of synchrotron radiation through ducts and labyrinths in the shielding of LEP became available only recently⁷. The results of the experiment are shown in figure 2 together with results of Monte-Carlo calculations and the universal attenuation curves for the second and higher legs of a labyrinth. For photon radiation the attenuation with depth follows the relation on the lower bound of uncertainty and confirms the earlier results from calculations with the MORSE transport code.

CONCLUSIONS

Up to now radiation protection experience with the operation of LEP has revealed no surprises. Radiation levels in occupied areas are barely measurable in the present mode of operation. It is however expected that radiation levels will increase as beam energies and intensities are increased to their design value. Future developments of the radiation situation will be closely followed in order to compare the predictions made in the design studies (summarized in reference 3) with the results of actual measurements.

PHOTONEUTRON LEAKAGE FROM MEDICAL ACCELERATORS: A COMPREHENSIVE
APPROACH TO PATIENT AND PERSONNEL DOSE MEASUREMENT

F. d'Errico and G. Curzio

Dipartimento di Costruzioni Meccaniche e Nucleari
Università degli Studi di Pisa
Pisa, ITALY

ABSTRACT

Simple and reliable techniques, based on the use of superheated drop neutron detectors (SDD's*), are presented for both medical accelerator personnel exposure monitoring, and the direct measurement of non therapeutic dose equivalent received by patients undergoing high-energy x-ray and electron treatment.

INTRODUCTION

Radiotherapy by means of high energy bremsstrahlung allows for a well established advantage over Cobalt-60 therapy: the treatment of a target volume with minimum dose deposition in surrounding healthy tissues.¹ Unfortunately, nuclear interactions between such radiation and the medium- to high- atomic number constituents of the accelerator head, treatment room and patients themselves, yield fast neutrons causing further undue exposure.

The assessment of dose equivalent from these photoneutrons is among the most complex tasks in mixed field dosimetry: the x-ray field is extremely intense, photons exceed the neutron fluence by factors of 1000-4000 inside the collimated beam, and 10-100 outside; neutron energies are mostly in the 100 keV to 2 MeV range, over which the dose equivalent per unit fluence varies by a factor of three; finally, the pulsed nature of the radiation field overwhelms the counting electronics of any active detector.²

Passive neutron rem-meters provide the simplest way to measure ambient dose equivalent, the regulatory quantity of interest, which should be monitored periodically, since neutron leakage appears to vary with machine age and state of adjustment.³ The main advantage of rem-meters is that they are insensitive to the neutron spectral shape, restrictions on their applicability derive from their large dimensions and directional response. In an attempt to overcome the above mentioned shortcomings, a new approach based on SDD's has been developed.^{4,5}

MATERIALS AND METHODS

The SDD is a suspension of superheated halocarbon drops dispersed in a nearly tissue equivalent gel. High LET neutron recoils trigger the boiling of these drops, nucleating visible bubbles. The total volume of vapor or the pressure pulses

* SDD is a trademark of Apfel Enterprises, Inc., New Haven, CT.

accompanying each nucleation event may be registered and give a measure of neutron irradiation.

While virtually insensitive to photons up to 15-18 MeV, the SDD detects neutrons with a free-in-air energy response that, above 50 keV, resembles fluence-to-ambient-dose-equivalent as well as kcrma-equivalent (ideal response for an in phantom rem-meter) conversion factors.⁶ The agreement between albedo response and individual dose equivalent (penetrating) per unit fluence is even closer.⁷

Based upon these considerations, we devised the application of SDD's in personal, ambient and depth- dosimetry around medical accelerators. In particular, a passive, integrating rem-meter of 2 cm³ active volume and isotropic response was realised by simply screwing a graduated pipette onto the detector vial. Vapor bubbles displace an equivalent volume of gel into the pipette (Figure 1), providing an immediate reading of the neutron dose equivalent field inside and outside x-ray treatment beams.

Figure 1. Passive, integrating, instant read-out neutron detector.

Furthermore, these devices are tissue equivalent (Table 1), and can be placed inside phantoms without affecting neutron spectrum and charged particle equilibrium.

Table 1. Physical properties of TE composition recommended by ICRU Rep. 33, our phantom, and superheated drop detector.

Material	Per cent elemental weight					Density (g cm ⁻³)
	H	C	O	N	Other	
ICRU 33 TE	10.1	11.1	76.2	2.6	-	1
TE liquid	10.2	11.1	76.1	2.6	-	1.07
SDD	8.8	28.2	62.5	-	0.18 F, 0.32 Cl	1.25

Employing sets of previously calibrated detectors, we acquired free-in-air and entrance dose equivalent profiles for various 18 MV x-ray beam sizes of a Saturne 20 accelerator. Entrance dose was measured at an average depth of 1 cm inside a 20x30x80 cm³ TE phantom (Figure 2).

RESULTS

The results of our measurements are summarized in Figure 3. For each beam size, dose values are normalized to x-ray dose at maximum build-up at the isocenter. The error bars overestimate optical misreading of the graduated pipettes.

Figure 2. In-phantom irradiation scheme.

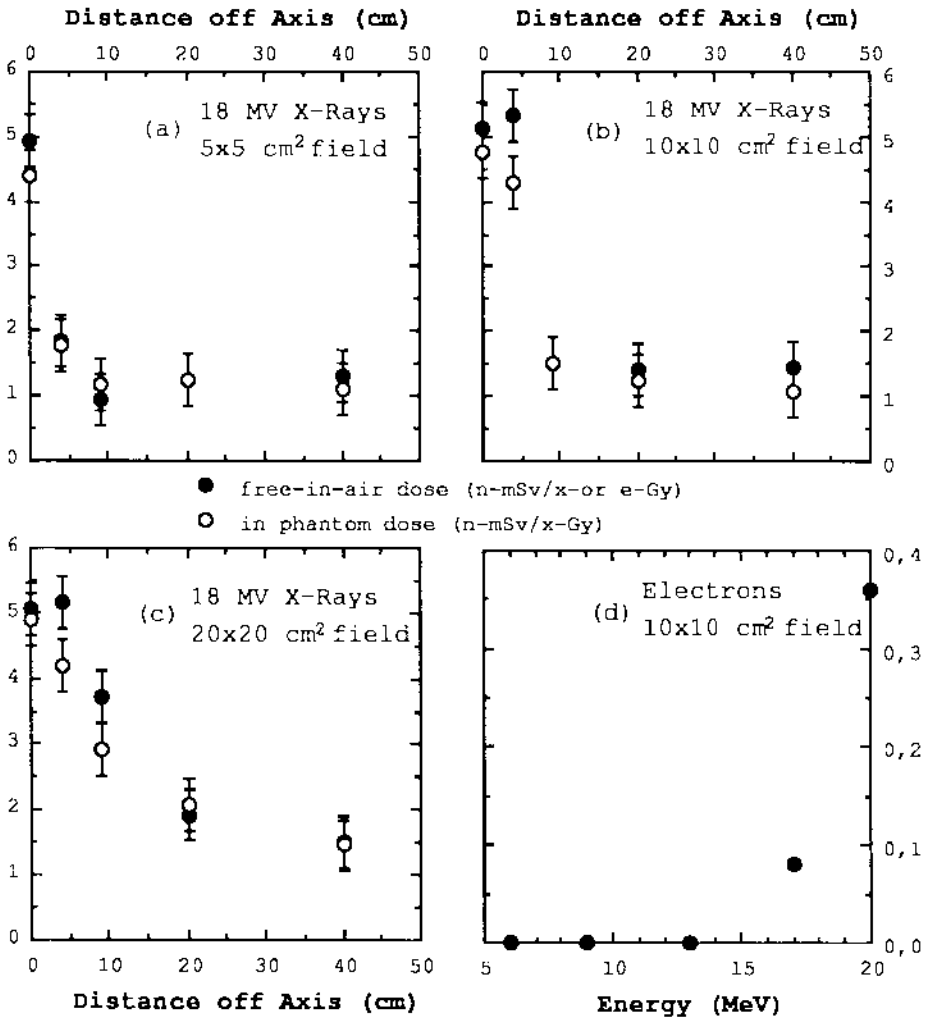

Figure 3. (a, b, c) Neutron dose equivalent profiles for some x-ray fields. (d) Neutron dose equivalent at the isocenter of 6-20 MeV electron beams.

Our measurements show that free-in-air dose is slightly higher than entrance dose, and confirm that the contribution from photo-neutrons generated inside the patient is negligible, as asserted by several authors. Also, the neutron source strength at the x-ray beam isocenter appears to be substantially independent of beam size. These results are in good agreement with the preliminary indications of an on-going intercomparison with CR-39 detectors.

CONCLUSIONS

The mixed field dosimetry method presented here allows for an immediate evaluation of photoneutron leakage from medical accelerators, without any detector post-processing subject to operator error. The integral dose delivered to the patient outside the treatment volume may be easily assessed from the dose equivalent profiles.

EMPLOYEE DOSE REDUCTION AT BRITISH NUCLEAR FUELS plc

A.H. Fishwick, J.L. Finlayson and R.D. James

British Nuclear Fuels plc
Risley, Warrington, Cheshire, U.K.

ABSTRACT

Average workforce doses in uranium fuel fabrication plants are a small percentage (about 6% or 3 mSv pa) of UK regulatory limits. In uranium metal casting, and uranium oxide production plants, doses are somewhat higher than the average. Dose reduction methods have, however, resulted in these being reduced to 20%, or less, of the same limit. Major future investment should reduce doses in oxide production plants to about the current average level.

INTRODUCTION

British Nuclear Fuels plc (BNFL) sets stringent Company targets for employee dose uptake and, in addition, has always vigorously employed the principle of ALARP. Thus, the current design targets for new plant are 5 mSv per calendar year (average) and 15 mSv per calendar year (maximum individual). For existing operational plants, the relevant targets are 20 mSv per calendar year (maximum individual) and 75 mSv maximum individual over any five consecutive years. All targets are the sum of effective dose equivalent and committed effective dose equivalent. These targets are the outcome of a response to a growing emphasis on the application of ALARP since 1975 and, more recently to the added impetus provided by the "Gardner Report" (Ref 1) and ICRP 60.

Employee dose reduction at the Sellafield reprocessing plant has been the subject of previous papers (Refs 2 and 3). This paper describes trends in dose reduction, and methods of achieving that, at the Springfields nuclear fuel fabrication plant, from 1986 to 1991.

DOSE REDUCTION TRENDS

By comparison with the above targets, average doses at Springfields have always been low (Table 1).

TABLE 1

Average Whole Body, and Collective Doses
(all Classified Workers)

<u>Year</u>	<u>Average Dose</u> <u>(mSv)</u>	<u>Collective Dose</u> <u>(manSv)</u>
1986	4.0	12.6
1987	3.8	11.9
1988	2.4	7.0
1989	2.6	7.0
1990	3.1	7.4
1991 (projected)	2.5	6.0

The slight increase in 1990 was a result of some increase in programme with a workforce strength at about 75% of the 1986 figure. Further emphasis on ALARP has since reversed this trend.

Against this background, dose reduction policies and practices have been focused primarily on reducing dose in areas of the plant where these have been highest by comparison with the above averages. The two areas receiving the greatest attention have been the Uranium Casting Plant and the Oxide Powder and Pelleting Plants. Springfields is a multi-purpose Site, providing a wide range of finished fuels and intermediate products. It incorporates major production lines for the fabrication of metal fuel for Magnox reactors and Oxide fuel for AGR and PWR reactors. The Casting Plant is one of the stages in the production of Magnox fuel.

Recognising the eventual termination of the UK Magnox programme, major capital investment in new plant to service this programme could not be justified. Therefore, the casting, and other, stages of the fuel fabrication process have undergone extensive refurbishment of which dose reduction has been a significant, but not the only, feature. The cost of the casting renovation project was £2.5M (1981 MV) ie £4.5M (1991 MV). New, and modified, equipment and procedures were installed to bring about reduction in both internal and external doses.

For Oxide fuel production, the situation is different. In the UO_2 Powder Production plant, extensive modifications to existing cubicalised plant items had been carried out progressively from the mid 1970s to the mid 1980s (total cost in 1991 MV, £0.9M). Improved ventilation of, and operator access to, the cubicles, together with other engineered features, had resulted in significant reduction in airborne contamination levels in the working areas. Following this, nothing further by way of major renovation of existing facilities was practicable. Similar, though less extensive, work was carried out in the UO_2 Pellet

Plant. However, future potential Oxide fuel business, in both UK and worldwide, has justified investment (£145M, 1991 MV) in a major new plant, the New Oxide Fuel Complex (NOFC) to completely replace all existing Oxide production facilities and allow continuation, and expansion, of this side of the business into the 21st century. NOFC is currently under construction and will come on line, in phases, from 1994. Again, dose reduction is a prominent design feature. In the meantime, existing plants have continued to operate at high proportions of capacity but, by attention to good housekeeping and making modifications to reduce dose wherever reasonably practicable, doses have been steadily driven down (Table 2).

TABLE 2

Whole Body Doses, Casting and Oxide Plants

<u>Year</u>	<u>Casting</u>		<u>Oxide Powder</u>		<u>Oxide Pelleting</u>	
	<u>Ave Dose (mSv)</u>	<u>No. > than 15 mSv</u>	<u>Ave Dose (mSv)</u>	<u>No. > than 15 mSv</u>	<u>Ave Dose (mSv)</u>	<u>No. > than 15 mSv</u>
1986	18.8	35	13.9	33	11.3	12
1987	17.2	32	9.6	NIL	7.9	NIL
1988	13.4	10	8.8	NIL	5.6	NIL
1989	8.5	1	8.2	NIL	6.3	NIL
1990	6.6	NIL	10.6	NIL	7.9	NIL
1991 (projected)	3.3	NIL	8.0	NIL	6.3	NIL

In addition to average dose, the other important indicator of the dose uptake position is the number of workers whose dose exceeds the UK Ionising Radiations Regulations investigational level of 15 mSv per calendar year. This number, also, has been reduced from the mid 1980s figure to a position in which there are now no such cases.

THE FUTURE

NOFC has, of course, been designed to meet Company dose targets. In practice, it is assessed that actual doses will be well below target (about 3 mSv pa or less as an average) due, mainly, to sophisticated methods of containment of any airborne UO₂ powder, internal dose uptake being the dominant potential factor in Oxide plants. In other areas, the now well established Joint (Management/Workforce) Dose Reduction Working Parties will continue to identify dose reduction methods for implementation wherever they can be justified on ALARP grounds. These Working Parties now operate throughout the Works including areas where dose has always been very low, with the objective of reducing doses still further wherever reasonably practicable.

CONCLUSION

Average, and maximum, doses at Springfields Works are well within Company targets which, themselves, are well within regulatory requirements. Future developments will continue to drive doses down to levels that are significantly below ICRP 60 recommendations.

DOSE AND DOSE RATE MEASUREMENTS AROUND THE SIS

J. G. Festag

Gesellschaft fuer Schwerionenforschung mbH, Darmstadt,
Federal Republic of Germany

ABSTRACT

Dose equivalent measurements with a TEPC and a modified rem counter around a heavy ion accelerator are reported. These measurements give some informations about the composition of the radiation field.

INTRODUCTION

A heavy ion synchrotron (SIS) is operated by the GSI at Darmstadt, Germany. The highest attainable specific energy of 2 GeV/n for carbon descends to about 1 GeV/n for uranium. Till now ions from neon to bismuth have been accelerated with up to 10^9 particles per spill. The length of the interval between two successive spills depends on the extraction mode, but this time is usually longer than 1 second at the moment.

EXPERIMENTAL MEASUREMENTS

Dose and dose rate measurements were made by a TEPC, type HANDE (1), and a high pressure ionization chamber (7 bar, Ne/Ar mixture), type FAG FHT 191 N, in regions with thin and thick shielding. The dose equivalent is calculated from the energy dose by using the ICRP 21.

Behind thick shielding (more than 400 g/cm² concrete) the TEPC gives a quality factor near to 4 (3,94). Such a value is known from other high energy accelerators (2). Distributions of the lineal energy are shown in figure 1a. The contribution of the neutrons to the dose equivalent appears in the higher lineal energies.

Measurements with ⁶LiF TLD's in a 12 inch polyethylene moderator give also a quality factor of 4. Here the calibration was made with neutrons coming out of an Am-Be source.

In regions with a thin or almost no shielding the quality factor varies depending on the degradation of the primary beam. The figures 1b and 1c show two examples. ¹⁹⁷Au ions of 814 MeV/n are stopped in carbon surrounded by concrete (less than 300 g/cm²); the secondary high energy particles deposit only a little energy in the detector (figure 1b); the Q - value is 2.1. Figure 1c shows the frequency distribution of the lineal energy registered by the TEPC during stopping and focussing of an ¹⁹⁷Au ion beam with a specific energy of 1 GeV/n. This distribution is very similar to that measured behind thick shielding (figure 1a) and indeed here the quality factor is also near to 4 (3.99).

For comparison a frequency distribution of the lineal energy of a background measurement with $Q = 2.2$ is shown in figure 1d.

The energy doses (Gy) registered by the TEPC and by the ionization chamber are very similar.

The measurements were made for times of several hours during the normal course of nuclear physics experiments, therefore relations between the dose rate and the ion current of the beam cannot be given because the intensity of the beam was not held constant.

Activation techniques for the evaluation of the neutron energy spectrum could not be applied on behalf of too low intensities.

Birattari et al. (3) have described an extended range neutron rem counter, which shall be able to measure neutrons with energies up to about 400 MeV with an adequate sensitivity.

An unmodified rem counter and a rem counter surrounded by a layer of 2 cm lead were used to look for neutrons with energies above 20 MeV. The measurements were taken behind thick shielding. The results are given in the following table.

accelerated ions	ion energy	measured dose equivalent by the unmodified rem counter	(dose equivalent measured by the rem counter with lead) divided by (dose equivalent of the unmodified rem counter)
	MeV/n	μSv	
^{20}Ne	310 - 400	6.7	1.71 ± 0.03
^{20}Ne	400	0.3	1.84 ± 0.61
^{209}Bi	800	1.1	1.65 ± 0.08

The given uncertainties of the result take only into account the standard deviation of the registered counts.

CONCLUSIONS

The results are preliminary, but at this stage they point out that a not negligible share of the dose equivalent is caused by neutrons with energies of more than 10 Mev.

CONTAMINATION BY TRITIUM OF WATERS AND CONCRETE
IN A RESEARCH REACTOR CONTAINMENT DUE TO LEAKAGE OF HEAVY WATER

Masami Fukui

Radiation Control Division,
Research Reactor Institute, Kyoto University,
Kumatori-cho, Sennan-gun, Osaka(590-04), Japan

ABSTRACT

Approximately heavy water of ca. 28.2 L (ca. 0.34 TBq of tritium) leaked from the D₂O facility of the Kyoto University Reactor (KUR) during the period of about one and half year. As a result of the incident, HTO concentrations in pool waters had increased extensively as well as in the containment building air during the period before the leak detection. The soaking effect of HTO vapor by the building concrete was also confirmed by air monitoring. Although the leak was of little radiological consequence, it served as a useful lesson of our emergency response.

INTRODUCTION

Radiation protection both on and off the site is deeply dependent upon the availability of appropriate monitoring data both in nuclear facilities and in natural environs.

The KUR near Osaka, Japan commenced operation in 1964 at 1 MW_{th} but the power was raised to 5 MW_{th} in 1968. Ventilation system in the containment building works so as to cover the duration of the reactor operation cycle of 70-80 h/wk. By the routine monitoring the concentrations of radionuclides in the exhaust air from the KUR, operating at 5 MW_{th} have been confirmed to be in the order of 10⁻² Bq/cm³ for ⁴¹Ar, 10⁻⁶ Bq/cm³ for HTO, 10⁻⁸ Bq/cm³ for ¹³³I and 10⁻⁹ Bq/cm³ for ¹³¹I. Because of the low detection limits, as measured by a 22-L ionization chamber set for the exhaust streams, the presence of most radionuclides in the stream is usually masked by the reading of ⁴¹Ar for such minor releases during normal operation of the reactor; this is especially true for HTO vapor. For this reason, monitoring of HTO vapor in the exhaust is carried out during the operation of the KUR on twice a year basis using liquid scintillation counting of water samples collected by condensation from the exhaust air.

BACKGROUND TO THE INCIDENT

During such a routine check in fall 1987, a relatively high concentration of HTO vapor was detected in the condensate. This result, however, was attributed to probable contamination of experimental devices because the same staff of the Radiation Control Division was involved in the research of tritium metabolism and routine monitoring of HTO from the KUR stack. A water sample was not taken from the exhaust during the next monitoring period (Spring 1988) because the operation of KUR was suspended over a 3 month period beginning in April because of fixation for secondary

coolant system. Although passing over data from the exhaust air monitoring had delayed the confirmation of HTO leakage, there was another indicator of leakage. The source monitoring data obtained by the Research Reactor Division had showed gradual increases in the HTO concentration in pool water in the containment building. This was especially the case in the sub-pool (ca. $1.0 \text{ m}^2 \times 1.7 \text{ m}$ deep), located on the top of biological shield, where the HTO concentration in water had increased 60-fold during the period of 1 y (May 1987-April 1988). Investigations into the source of this increase in the HTO concentration in water were focused mainly on the presence of irradiated materials such as lithium and boron which could be a source of HTO production by a neutron activation process. A smear test carried out on August 1988 revealed significant contamination on the front surface of a heavy water tank, and a high HTO concentration was detected in the atmosphere near the D_2O tank using a 1.5-L portable ionization chamber. These findings led to the conclusion that HTO increases in water were the result of leakage of the heavy water. Nevertheless, the mechanisms by which HTO concentrations of both the sub-pool and the primary coolant water (about 30 m^3 and 9-m deep) had extensively increased during 1 year since May 1987, were unknown.

SURVEY OF LEAK POINT AND RECOVERY OF HTO

Under normal conditions, the aluminium D_2O tank contains approximately 2.2 m^3 of heavy water with a purity of 99.7%. As is shown in Fig.1, one face of the D_2O tank, ca.1.8 m in dia., is adjacent to a graphite block layer (ca. 1.5 m^3), 48 cm thick, with a bismuth plug. The space in front of this layer is used as an irradiation room with dimensions ca. $2.4 \text{ m} \times 2.4 \text{ m} \times 2.4 \text{ m}$, covered with high density concrete identical to the biological shield of the reactor core. By 5 October 1988, the concentration of HTO in condensate in air near the tank was found to be as much as 2.2 MBq/ml . Then, using an air conditioner and a 20-L water bubbling trap, a 6-wk program was started to lower the moisture in the air in the irradiation room adjacent to graphite blocks. On 16-17 November, the heavy water in the D_2O tank was withdrawn into 200 L drums and replaced by light water to carry out a leak test. An estimated loss of 28.2 L of heavy water was made by comparing the weight of the water removed with that initially loaded into the D_2O tank. Inspection with a remote TV camera failed to locate the source of the leak in any of the suspected areas such as joints or flanges in the D_2O plumbing system. Then, the high density concrete shield of the irradiation room was dismantled on 21 November 1988. The graphite layer adjacent to the D_2O tank was removed and stored in a container ($2 \text{ m}^2 \times 2 \text{ m}$ in height) on 19 January 1989 so as to access more easily to the tank and to recover any HTO absorbed by the graphite blocks. In early February, air, heated to $90 \text{ }^\circ\text{C}$ was circulated through this container with electrical condensation loop system over a 2-mo period. By this procedure ca. $4.6 \times 10^1 \text{ GBq}$ (ca. 12.4 L of condensate) of HTO was recovered as shown in Fig.2.

On 25 January 1989, less than 100 mL of water was found in a guide tube in the D_2O tank used to hold a thermo-couple. The HTO

concentration of this water was 7.9 MBq/ml, which was close to that of the stagnant heavy water (8.1 MBq/ml) in the dead space of the D₂O plumbing system, and two thirds the concentration of the heavy water in the D₂O tank itself (1.2×10^1 MBq/ml). Therefore, the source of the HTO leak was located somewhere in the guide tube. This tube was cut on the upper part of the tank where it had been inserted, and the resulting hole was welded shut. This resulted in the isolation and sealing of the main sources of HTO in the reactor containment building by early April 1989.

Fig. 1 Cross section of KUR.

Fig. 2 Amount of HTO recovered.

CHANGE IN HTO CONCENTRATION IN AIR

After the ventilation was shut down, the concentration of HTO vapor in air increased and reached a steady state condition within a few days. Assuming a constant production rate of HTO vapor from sources such as building concrete and neglecting physical decay process of tritium, the growth of HTO concentration in containment building air is formulated as follows:

$$d(CV)/dt = P - \mu CV \quad \dots (1)$$

where

- C : HTO vapor concentration in air (Bq/cm³),
- V : volume of the containment building (cm³),
- P : production rate (Bq/h),
- μ : leak rate (1/h), and
- t : elapsed time after turning off of ventilation (h).

Setting C=0 at t=0, the HTO concentration is given by:

$$C/C_0 = 1 - \exp(-\mu t) \quad \dots (2)$$

where

- C₀ : HTO concentration in air (=P/μV) under steady state condition (Bq/cm³).

Fig. 3 Growth of HTO concentration in building air.

The growth curve, as expressed by eqn (2) for HTO concentrations in air during shut down of the ventilation allows for the estimation of the leak rate, which was approximately estimated to be 0.04 h^{-1} by the curve fitting as shown in Fig.3.

The production rate, P, could be approximated from eqn (1) as the product, $\mu C_0 V$, for large times ($t > 3 \text{ d}$). Therefore, long-term monitoring of HTO concentration in air (C_0) under steady state conditions allows for the estimation of the attenuation rate of the HTO production rate, which depends on the HTO content in the building concrete. The concentration, C_0 , in air monitored over nearly a 1-y period after venting shut down, shows attenuation rate of approximately $5.0 \times 10^{-3} \text{ d}^{-1}$ ($T_{1/2} = 20 \text{ wk}$) for the first 8-month starting on late November 1988 after transferring heavy water into drums and $3.0 \times 10^{-3} \text{ d}^{-1}$ ($T_{1/2} = 33 \text{ wk}$) since August 1989.

CHANGE IN HTO CONCENTRATION IN POOL WATERS

Laboratory experiments revealed that the fundamental mechanisms describing the HTO dynamics between water and air are exchange and evaporation. A model developed on the basis of this concept gave an average concentration of HTO vapor in air as soaking effect during the period for the HTO concentration in water to decrease from C_{w0} to C_w as expressed in eqn (3),

$$C_v = aH\varepsilon k_c^{-1} \{C_w - C_{w0} \exp(-at)\} / \{1 - \exp(-at)\} \quad (3)$$

where k_c : exchange rate constant between air and water (cm/h),
 k_e : evaporation rate constant (cm/h),
 H : water depth (cm),
 a : $(k_c + k_e)/H$ (1/h),
 ε : isotopic ratio in HTO vapor and water (-),
 C_{w0} : HTO concentration in water at time 0 (unit/ml),
 C_w : HTO concentration in water at time t (unit/ml), and
 C_v : average HTO vapor concentration in condensate in air (unit/ml).

A linear regression for the attenuation of HTO concentrations observed in sub-pool water after removing sources in containment building gave a half-life of approximately 15 wk. Using a value for ε of 0.92 in eqn (3), the average concentration, C_v , in the condensate in the containment building air was calculated to be 36 Bq/ml during 50 wk starting on 20 March 1989. The average value estimated for the air corresponds to only ca. 5×10^{-5} times of the Administrative Level for radiation workers ($7 \times 10^{-1} \text{ Bq/cm}^3$), though it was more than ca. one order larger in magnitude compared with that during normal operation.

CONCLUSIONS

Approximately 0.34 TBq of tritium had been leaked from the D_2O tank over a 19-mo period. More than 80% of HTO leaked was estimated to be released promptly as exhaust. Part of HTO leaked (ca. 2.5 GBq) moved into pool waters via air and increased the concentration as much as ca. 60-fold for sub-pool (1.7 m^3) and 5-fold for primary coolant (30 m^3), respectively. A significant amount of HTO vapor had been absorbed by the concrete material (4.2 GBq) and 46 GBq of HTO absorbed by graphite blocks was recovered.

REDUCTION OF EXPOSURES ARISING DURING THE
MANUFACTURE AND DISTRIBUTION OF RADIOACTIVE
PRODUCTS FOR HEALTHCARE, RESEARCH AND INDUSTRY

R W Davies

Amersham International plc
Amersham Place, Little Chalfont
Buckinghamshire, HP7 9NA
England.

ABSTRACT

Radiation dose uptake for workers in a company producing radioactive materials for use in medicine, research and industry is reviewed. The measures that were introduced to optimise protection are detailed and shown to lead to a 90% reduction in the numbers of workers receiving in excess of 15 mSv in the past four years.

INTRODUCTION

Amersham International specialises in the development, manufacture and distribution of radioactive products for use in healthcare, life sciences research, environmental safety and industrial quality assurance. The production and distribution of the radioactive materials give rise to a number of challenges in radiological protection. These include operation and maintenance of cyclotrons for the production of short lived diagnostic products (containing for example Tl-201, Ga-67, In-111) for nuclear medicine; the design and operation of shielded plant for high energy gamma emitting nuclides used in cancer therapy (eg. Co-60, Cs-137); the preparation for transport of more than $\frac{1}{2}$ million radioactive packages annually.

SAFETY POLICY

The company has had a continuing policy of working to reduce radiation exposure to staff and has set company whole body dose limits below those required by legislation as a means of promoting dose reduction. The success of this policy is evidenced by Figure 1. which shows the progressive reduction in the percentage of the UK workforce receiving doses in excess of 15 mSv over the past 15 years to 0.3% in 1990.

Amersham's focus on safety and dose reduction obtained further impetus with the Ionising Radiation Regulations 1985 (IRR) in the UK, and the introduction of formally recorded reviews of working practices and processes for staff who exceeded 15 mSv.

ANALYSIS OF DOSE REDUCTION

Figure 2 shows the collective dose (man-mSv) and number of staff over the period immediately before and after the introduction of the IRRs. Figure 3 shows the numbers of staff receiving more than 15 mSv over the same period. It is evident that the reduction in numbers of staff exceeding 15 mSv was a result of genuine dose reduction since it was accompanied by a reduction in the collective dose. Figure 4 gives a breakdown of the numbers of staff exceeding 15 mSv since 1986 by work activity.

RADIATION SOURCE PRODUCTION

The main reduction achieved in radiation source production areas followed reviews of working practices which developed increased operator awareness. Line management commitment to dose control encouraged the workers to improve techniques; reduce waste arisings, decrease occupancy times and improve general housekeeping. On older plant, use was made of improved local shielding at critical stages of the processes while new plant was designed and built. The majority of the staff receiving greater than 15 mSv in 1990 were working on old plant which is scheduled for replacement in the next 2 years.

CYCLOTRON OPERATIONS

The very nature of cyclotron operations presents unique radiological problems. Cyclotron produced isotopes typically have half lives of the order of 3 days and thus must be produced several days a week, every week to meet the needs of hospitals. Staff outside the heavily shielded machine vaults only receive background levels of radiation. Maintenance of the machine and any other in-vault work, however, give rise to the potential for high doses from highly activated components.

Machine reliability will always have an overriding effect on operator doses so at Amersham, machine components requiring regular, frequent changing, have been designed to facilitate quicker, simpler maintenance. Component failures have been analyzed to attempt to eliminate them. Changes to machine operating schedules, whilst remaining aligned with customer requirements, have maximised the decay of the shorter lived activation of the vault and the machine components. The combined effect of the actions has been to keep all cyclotron staff doses below 15 mSv in 1990.

TRANSPORT

Introduction of new plant to handle and package certain products (eg Technetium generators), along with major refurbishment of the despatch warehouse area has resulted in significant reductions in operator doses. The material flow pattern through the warehouse has been improved and items requiring manipulation or further work in the warehouse are stored in shielded interim storage facilities. The build up of packages on conveyor lines is prevented to reduce ambient dose rates and the conveyor lines themselves are run, where possible, at high level to increase distance between packages and staff. Increased staff awareness coupled with use of gamma integrating dosimeters has had a positive effect on dose reduction.

The numbers of staff exceeding 15 mSv in other work areas also decreased as a result of similar actions to those outlined above.

CONCLUSIONS

Line management commitment with Health Physics support led to a heightened awareness of dose control measures which encouraged individuals to review and improve their own work method. Investment in personal dosimeters, plant modification and new facilities provided the necessary resource to support the dose reduction initiatives.

VERY LOW ENERGY β MEASUREMENTS IN TRITIUM
CONTAMINATED PARTS

S. K. AL-ARBI, B. M. BAHAL, U. M. EL-GHAWI,
A. A. GULAK and H. H. ENBIA
T. N. R. C., P. O.Box 30878, Tripoli, LIBYA

ABSTRACT

Possibility of utilizing a gas proportional counter for routine beta activity contamination checkup in a Neutron Generator lab is explored. The sensitivity of the gas flow counter has been improved and suitable modifications made to record beta energy spectrum. Samples from all over the laboratory were collected to monitor accidental spread of tritium.

INTRODUCTION

There is a renewed interest in fast neutron generators for their use in studying radiation damage on structural materials as well as its medical application in radiation therapy of cancer cells. High flux generators usually use solid targets with Tr. adsorbed in a matrix. Intense deuterium beam desorbs the tritium, thereby, contaminating several parts of the generator. In spite of usual precautions it leaks to unexpected areas causing a possible health hazard if internally taken [1,2]. Since tritium is a very low energy pure β emitter, it escapes detection by conventional radiation detectors employed in a routine checkup. Therefore, windowless gas flow detectors are specially useful for the measurement of soft β . They have high efficiency, large solid angle and a convenient size. The counter can be successfully employed for low energy β emitters such as H^3 , Ni^{63} and C^{14} .

RESULTS AND DISCUSSION

For tritium detection a conventional 4" windowless gas counter has been developed and improved by us [1,3]. The lower limit on the electron energy was determined by sensitivity of associated amplifiers, stability of the high voltage power supply and the characteristic of the counter gas. Its sensitivity for low energy electron has been enhanced from 300 keV to less than 5 keV. The

upper limit on the electron energy producing a full spectrum due to the chamber size and gas pressure in our case was < 50 keV [4]. Other factors affecting are the absorption of electrons in the source backing and backscattering from foils. Fig.1 shows spectrum of pure H^3 and C^{14} sources measured from the modified counter. For C^{14} β only partial energy is spent in the anode chamber. The laboratory faced at several occasions contaminations of which the causes could not be ascertained. As a result more than 100 samples from all over the lab. and working rooms were collected on a Watman filter paper. Table I & II summarises the measurements of β activity of these samples. Fig.2 presents the spectrum measurement of an oil sample of ruffing pump . The pump was in operation for more than 8 years and required maintenance work. The oil was found highly active with tritium.

CONCLUSION

The use of D-T based sources exposes personnel to hazards of radiation of neutron induced activities as well as of the tritium in the targets [5]. Tritium contamination are found in unexpected areas due to the easy migration of specs which might fall down while changing of the target or during some maintenance of the beam line. Such a spread can be controlled by regular measurements of swap samples using the modified gas flow counter. Strict rules of safety should be followed during changing of tritium targets. Use of a face mask is strongly recommended. The used targets should be placed in an air tight container and stored in separate housing immediately.

EXPERIENCES LIEES A L'EVALUATION DU FACTEUR DE REMISE EN
SUSPENSION D'AEROSOLS DE PLUTONIUM

G.Pescayre, J.Moll

CEA/Service de Protection contre les Rayonnements

EXPERIMENTS TO ESTIMATE THE RESUSPENSION FACTOR OF PLUTONIUM
AEROSOLS

In the field of interventions in hardly contaminated areas (60 to 100 MBq.m⁻²), we have studied the resuspension factors of plutonium aerosols and the atmospheric contamination gradient between 20 and 150 cm, to estimate the risk incurred by a lying case, compared with a standing operator. K (m⁻¹) has been evaluated between 10⁻⁶ (m⁻¹) and 10⁻⁵ (m⁻¹) without any personnel in the area, and between 10⁻⁴ (m⁻¹) and 10⁻³ (m⁻¹) with personnel.

INTRODUCTION

Un groupe de travail constitué de médecins et de radioprotectionnistes s'est interrogé sur le risque encouru par un blessé couché au sol sans protection respiratoire dans une zone fortement contaminée (activité surfacique comprise entre 3,7 et 37 MBq.m⁻²). Le facteur de remise en suspension est généralement pris égal à 10⁻⁴ m⁻¹ pour un individu en station debout mais quel est-il à 20 cm du sol au niveau de la respiration du blessé ? C'est pour répondre à cette interrogation qu'ont été entreprises, dans une zone opérationnelle où l'on n'accède qu'en tenue ventilée, des expériences visant à évaluer le gradient du facteur de remise en suspension des aérosols de plutonium entre le sol et en hauteur standard de respiration d'un individu.

ZONE DES EXPERIENCES

La zone d'expérience n'est accessible qu'en tenue ventilée. Les contaminations surfaciques sont élevées (en moyenne entre 60 et 100 MBq.m⁻²) au niveau du sol et entre 1 et 2 MBq.m⁻² sur les surfaces verticales. Le sol est recouvert d'un vinyle, enlevé périodiquement pour faciliter l'assainissement de la zone. Les locaux sont ventilés (8 renouvellements par heure) et en dépression par rapport aux sas d'entrée et aux autres locaux de l'installation (- 20 mm CE).

MATERIELS UTILISES

Les contaminations atmosphériques ont été mesurées à l'aide d'appareils de prélèvement du type SIT dont le débit est de 5 l.mn-1. Ces appareils étaient placés sur un trépied à 20 cm et à 150 cm du sol. Après prélèvement, les filtres ont été minéralisés et l'activité mesurée en spectrométrie α .

La contamination surfacique a été mesurée par frottis à l'aide d'un contaminamètre de surface du type DSM 2. 3 frottis successifs ont été réalisés en chaque point pour bien connaître la part de la contamination détachable. Une calibration préalable a été réalisée entre la réponse du contaminamètre et l'activité réellement prélevée par frottis.

DEROULEMENT DES EXPERIENCES

3 expériences ont été réalisées :

- Expérience 1 : elle avait pour objectif de mesurer le facteur de remise en suspension sans présence de personnel dans la zone.

- Expériences 2 et 3 : elles ont été réalisées en présence de 3 agents opérant dans la zone.

L'introduction du matériel de prélèvement et de mesure a fait l'objet de précautions particulières pour éviter toute contamination parasite apportée par l'environnement très contaminé de cette zone.

RESULTATS DES MESURES

La valeur du facteur de remise en suspension K (m^{-1}) a été calculée en faisant le rapport de l'activité atmosphérique C ($Bq.m^{-3}$) sur l'activité surfacique A_s ($Bq.m^{-2}$) :

$$K \text{ (m}^{-1}\text{)} = \frac{C \text{ (Bq.m}^{-3}\text{)}}{A_s \text{ (Bq.m}^{-2}\text{)}}$$

Les activités surfaciques moyennes ont été obtenues à partir des points représentatifs de la zone de travail ; avec $A_{1s} = 64 \pm 15 \text{ MBq.m}^{-2}$ et $A_{2s} = 96 \pm 10 \text{ MBq.m}^{-2}$. Le premier frottis détache 60% de la contamination non fixée.

Les facteurs de remise en suspension obtenus sont donnés dans le tableau ci-joint.

Coefficient de remise en suspension	distance (cm)	expérience 1 sans opérateur	expérience 2 avec opérateurs	expérience 3 avec opérateurs
K1 (m ⁻¹)	20	6.10 ⁻⁶	2,4.10 ⁻³	5,8.10 ⁻⁴
	150	8,7.10 ⁻⁶	2,7.10 ⁻³	1,3.10 ⁻³
K2 (m ⁻¹)	20	4.10 ⁻⁶	1,6.10 ⁻³	3,8.10 ⁻⁴
	150	5,8.10 ⁻⁶	1,8.10 ⁻³	8,9.10 ⁻⁴

COMMENTAIRES ET CONCLUSIONS

On constate qu'entre 20 cm et 150 cm l'activité volumique prélevée sur le filtre a pratiquement la même valeur, on n'a donc pas relevé de gradient de contamination atmosphérique sur la durée totale des expériences réalisées.

Les facteurs de remise en suspension sont compris entre 10⁻⁶ (m⁻¹) et 10⁻⁵ (m⁻¹) sans présence de personnel et entre 10⁻⁴ (m⁻¹) et 10⁻³ (m⁻¹) en présence de personnel. Ces facteurs relativement élevés peuvent s'expliquer par la turbulence et le massage de l'air à l'intérieur du local (8 R/h).

Un blessé séjournant une ½ heure, sans protection dans une zone contaminée au niveau de 37 MBq.m⁻² pourrait engager un équivalent de dose efficace de 0,25 Sv et 1 Sv, ce qui nécessite, sur le lieu même de l'accident de prendre des mesures telles que protection des voies respiratoires, éloignement ou évacuation la plus rapide possible.

GAMMA RADIATION INDUCED ALTERATIONS IN THE ULTRASTRUCTURE OF PANCREATIC ISLET, METABOLISM AND ENZYMES IN WISTAR RAT

Jayashree V. Dao and S.A. Suryawanshi
Institute of Science

ABSTRACT

Effects of gamma irradiation (600 rads) on the ultrastructure of pancreatic islet, metabolism and some enzymes in wistar rat, are reported. Electron microscopic observations of endocrine pancreas revealed prominent changes in beta cells while alpha and delta cells were not much affected. Irradiation also inflicted hyperglycemia, increase in liver and muscle glycogen and decrease in insulin level. It has also increased the activity of enzymes but failed to produce significant changes in protein, lipid and mineral metabolism.

INTRODUCTION

Though large number of information is available on long term effects of radiation, studies on immediate effects are comparatively a few. This investigation deals with the immediate effects (observed after 24 hours) of gamma irradiation (600 rads) on the ultrastructure of pancreatic islet, carbohydrate, protein, lipid and mineral metabolism and some enzymes.

MATERIAL AND METHODS

Twenty acclimatized male rats were exposed to 600 rads of gamma rays (Co-60) with a dose rate of 39 rads/min. Equal number of animals served as a control group. The animals were sacrificed after 24 hours and blood samples were collected and were subject to biochemical analyses. For electron microscopic observations the pancreas was fixed in 3% glutaraldehyde and blocks were prepared in araldite. The ultrathin sections were stained with uranyl acetate and lead nitrate and observed under JEM-T-8 electron microscope.

RESULTS AND DISCUSSION

Ultrastructural changes included degenerative effects and vacuolization of the cytoplasm in alpha and beta cells (Plate I). The decrease in hormone granules was observed in beta cells while no noticeable changes were seen in alpha and delta cells. The presence of less number of hormone granules in the beta cells suggests reduction in insulin secretion which agrees well with observations in golden hamster (Tsubouchi and Sasumu, 1981).

Gamma irradiation inflicted changes in the carbohydrate metabolism and some enzymes but failed to produce significant changes in protein, lipid and mineral metabolism (Table I).

The changes in carbohydrate metabolism include pronounced hyperglycemia with a marked decline in serum insulin level. Liver and muscle glycogen showed significant increase after irradiation which can be attributed to the fact that the irradiation stimulates secretion of corticosteroids which enhances deposition of glycogen in the liver and muscle (Malatova et al., 1977).

The irradiation is known to cause an increase in gluconeogenesis from the amino acids (Kandysh and Moroz, 1979), and decrease in glucose utilisation by cells (Ahlersova, 1980). The hyperglycemia observed in the present study may be the result of release of amino acids from the destroyed tissues and less uptake of glucose by the cells.

Except for serum glutamate pyruvate transaminase, all other enzymes studied, showed significant increase in the concentrations after irradiation. This might be due to increased permeability consequent upon the disturbed metabolism. The enzymes diffuse abnormally from the cell to the plasma because of increased permeability which can be considered as an early non-specific reaction of every cell when its metabolism is disturbed.

CONCLUSIONS

Gamma irradiation reduced the synthesis of insulin as confirmed by the decrease in the hormone granules of the beta cells and decline in serum insulin level. The irradiation might have stimulated release of corticosteroids leading to hyperglycemia and deposition of glycogen in the liver and muscle. Proteins, lipids and minerals remained almost unchanged. Prominent increase in some enzymes concentration can be attributed to the diffusion of enzymes from the cell into the plasma due to change in the permeability.

LIFE-SPAN HEALTH EFFECTS OF RELATIVELY SOLUBLE FORMS OF INTERNALLY DEPOSITED BETA-EMITTING RADIONUCLIDES

B. B. Boecker, B. A. Muggenburg, F. F. Hahn,
K. J. Nikula, and W. C. Griffith

Inhalation Toxicology Research Institute, P.O. Box 5890, Albuquerque, NM 87185 USA

ABSTRACT: As part of a large research effort to study the lifetime health risks of inhaled radionuclides, Beagle dogs inhaled $^{90}\text{SrCl}_2$ or $^{144}\text{CeCl}_3$ or were injected intravenously with $^{137}\text{CsCl}$. Because these three compounds were soluble in body fluids, the resulting widely differing patterns of radionuclide distribution and dose reflected tissue affinities of the elements involved. Long-term health effects, predominantly cancers, were seen in the organs receiving the highest doses. Investigations are continuing on the extent to which other less irradiated organs may have also been affected.

INTRODUCTION: A major series of life-span studies on the effects of inhaled radionuclides is in progress at the Inhalation Toxicology Research Institute¹. Both fission product and transuranic radionuclides are being studied. The primary goals of these studies are to determine the life-span health risks of inhaled radionuclides, the influence of various dose- and effect-modifying factors, and to extrapolate these results to possible human exposures, particularly those for which no direct human data currently exist. One of the important areas addressed in the fission-product studies is the influence of *in vivo* solubility of the inhaled material on the doses received by, and effects seen in, different organs and tissues. This report presents and compares results from three studies in which young-adult Beagle dogs inhaled $^{90}\text{SrCl}_2$ or $^{144}\text{CeCl}_3$ or were injected with $^{137}\text{CsCl}$. This comparison was chosen because of known differences in the pattern of metabolism and dosimetry among these three radionuclides, ranging from concentration mainly in one organ (^{90}Sr), several organs (^{144}Ce), and the whole body (^{137}Cs). Of particular interest are the relative distributions of radiation dose and long-term biological effects among organs exposed by these three regimens.

MATERIALS AND METHODS: Young adult Beagle dogs (12-14 mo, equal number of both sexes) inhaled, on a single occasion, different activity levels of either $^{90}\text{SrCl}_2$, or $^{144}\text{CeCl}_3$, or were injected once, intravenously, with $^{137}\text{CsCl}$. The 224 dogs used in these studies were divided as follows: ^{90}Sr , 66; ^{144}Ce , 55; ^{137}Cs , 54; and combined controls, 49. The exposure aerosols, consisting of the radionuclide plus a CsCl or CeCl₃ vector, had polydisperse size distributions with activity median aerodynamic diameters ranging from 1.5 to 2.4 μm ($\sigma_g = 1.6$ to 2.1). Exposures were completed in less than one hour. Each dog was whole-body counted immediately after radionuclide exposure and at selected intervals thereafter to determine the initial body burden and its retention as a function of time after exposure. Each dog's health status was evaluated periodically and illnesses considered not to be associated with the radiation exposure were treated using standard veterinary practices. All dogs were maintained in the ITRI kennel facility until they died or were euthanized when moribund. Complete necropsies and histopathological examinations were performed. When all dogs in a study were dead, all clinical and histopathological results and materials were reviewed to ensure accuracy and consistency of the diagnoses. All diseases were coded for

a FOCUS database using the SNOMED system modified for dogs. Absorbed beta doses were computed for individual organs or the whole body as appropriate for the radionuclides and forms used. These dose calculations were based on the whole-body retention data from each radionuclide-exposed dog in the longevity study and tissue distribution and retention data obtained from serially sacrificed dogs in separate, but similar, dosimetry studies. The small photon contribution was ignored except for the whole-body dose from ^{137}Cs where the photon portion contributed about one-third of the total dose.

RESULTS AND DISCUSSION: Table 1 presents the experimental design features for the three studies compared in this report. In each of these studies, a range of long-term retained burdens was studied, the highest of which led to early deaths within the first two years after exposure. Most of these early deaths were from hematologic dyscrasias resulting from irradiation of the bone marrow. Several others were due to radiation pneumonitis, pulmonary fibrosis, or hepatic degeneration. The focus of this report is on the remaining ~80% of the dogs that survived more than two years after exposure and, therefore, were at risk for the development of cancer and other later-occurring diseases.

Table 1
Experimental Design Features for Life-Span Studies of Dogs Exposed to
Relatively Soluble Beta-Emitting Radionuclides

Study	LTRB ^a (MBq/kg)	Number of Dogs			
		Exposed		Controls	
		Total	> 2 y ^b	Total	> 2 y ^b
^{90}Sr	0.10 - 4.8	66	58	22	22
^{144}Ce	0.096 - 13	55	41	15	15
^{137}Cs	28 - 130	54	42	12	11

^aLTRB = long-term retained burdens for exposed dogs

^bSurvived more than 2 y after exposure

Cumulative absorbed dose factors for organs in animals exposed to these three different patterns of radionuclide distribution are given in Table 2. The organs and tissues listed for ^{144}Ce are the four that received the highest total beta doses. Of these four, only two, bone and nasal mucosa, received significant doses from ^{90}Sr . In contrast, the relatively uniform whole-body distribution of ^{137}Cs produced about the same total dose (beta plus gamma) in all four organs.

Table 2
Cumulative Absorbed Beta Doses to 5000 Days after Exposure of Beagle Dogs to Radionuclides in a Relatively Soluble Form²

Organ/Tissue	Gy per MBq/kg LTRB ^a		
	⁹⁰ SrCl ₂	¹⁴⁴ CeCl ₃	¹³⁷ CsCl ^b
Lung	--- ^c	24	0.15
Liver	---	60	0.21
Bone	220	18	0.13
Nasal Mucosa	270	92	0.18
Whole Body	N/A ^d	N/A	0.21

^aLTRB = long-term retained burden

^bDoses for ¹³⁷Cs include gamma contribution

^c--- = Dose < 0.1% of skeletal dose

^dNot applicable

Neoplasia was a prominent long-term finding in both the exposed and control dogs.^{3,4,5} Table 3 gives the number of dogs in which primary malignant or benign tumors were found. All tumors, whether they were the primary cause of death, a major contributing disease or an incidental finding, are included. For this report, the controls for the three individual studies have been combined. One can roughly compare the number of tumors across the three exposed groups and the combined controls because the number of two-year survivors was about the same in each group.

Table 3
Occurrence of Primary Tumors in Certain Organs of Dogs that were Exposed to ⁹⁰SrCl₂, ¹⁴⁴CeCl₃ or ¹³⁷CsCl and Lived > 2 y after Exposure or in Control Dogs

Organ/Tissue	Number of Tumors ^a			
	⁹⁰ Sr	¹⁴⁴ Ce	¹³⁷ Cs	Controls
Lung	2,1 ^b	3,1	3,0	5,0
Liver	0,1	10,11	5,5	0,2
Bone	45,1	1,0	--- ^c	---
Nasal Mucosa	3,0	5,0	4,0	---
Number of Dogs	58	41	42	48

^a Some dogs had more than one tumor. In addition to the tumors listed, a number of tumors were found in other organs of dogs in each of these groups; many were incidental findings at necropsy.

^b Number malignant, number benign

^c --- = No tumors

The number of lung tumors was similar in all three exposed groups and the control group. These tumors were mainly bronchioloalveolar carcinomas and adenocarcinomas in dogs that died from 10 to 16.5 y after exposure. The exceptions were two ^{144}Ce -exposed dogs that died at 4.5 and 7.6 y after exposure in which a bronchioloalveolar adenoma and adenocarcinoma, respectively, were found. In the liver, bone and nasal mucosa, pronounced differences were found between the exposed dogs and the controls. No tumors were found in these organs in the control dogs except for two bile duct adenomas in the liver. A large number of liver tumors, both malignant (hemangiosarcoma, hepatocellular carcinoma, cholangiocarcinoma and neurofibrosarcoma) and benign (biliary cystadenoma and bile duct adenoma) were found in dogs exposed to ^{144}Ce or ^{137}Cs but not to ^{90}Sr . In contrast, the tumorigenic response in the ^{90}Sr -exposed dogs was primarily the occurrence of bone tumors (osteosarcoma, hemangiosarcoma and fibrosarcoma). No bone tumors were seen in the other groups except one osteosarcoma that occurred in a ^{144}Ce -exposed dog at 2.2 y after exposure. Tumors in the nasal mucosa, mostly carcinomas, occurred in all three studies, but not in the controls. The relative distribution of tumors between the $^{144}\text{CeCl}_3$ and $^{90}\text{SrCl}_2$ studies is consistent with the dosimetry information in Table 2. The occurrence of tumors in the livers and nasal mucosa of $^{137}\text{CsCl}$ -exposed dogs indicates that these tissues are relatively responsive to this radiation insult.

These initial analyses have been directed to organs and tissues that have been clearly identified as targets of radiation from these and other internally deposited radionuclides. Investigations are continuing on the question of whether additional organs or tissues may also be at risk from these different patterns of chronic beta irradiation. These results are providing valuable *in vivo* information on the appropriateness of current radiation-protection practices for internally deposited radionuclides.

PRELIMINARY EARLY EVALUATION OF RADIATION ACUTE SYNDROME
SEVERITY IN AN ANIMAL MODEL.

SUMMARY

To improve the knowledge of Radiation Acute Syndrome radiopathological picture, whole body X-rays irradiation at 2Gy of a primate (*Cebus apella paraguayanus*) used as model has been performed.

Early evaluations of clinical symptoms and dose and damage biological indicators have shown that this primate has given out similar responses to those of man.

INTRODUCTION

All accidental overexposures, particularly Chernobyl and Goiânia, have made evident the need to evaluate even more precisely the severity of the Radiation Acute Syndrome during the first days in order to decide the specific treatment (1,2). A delay in applying a compensatory treatment may be as fatal as an early supplying of a substitutive one (3). The difficulty in evaluating the RAS severity in the shortest time is due to complex accidental circumstances, variability in clinical response and imprecise knowledge of the underlying radiopathological mechanisms.

In order to increase and to improve the information about these infrequent events it is necessary to obtain data from animal models which may reproduce accidental situations.

Cebus apella paraguayanus is a primate which has shown cytogenetical radiosensitivity similar to that of man and this fact makes this species an interesting potential model (4).

The variables chosen to define therapeutical behaviour were:

a) Dose biological indicators (5) which may predict how deep and severe overexposure has been.

b) Damage indicators which may predict clinical evolution through the insufficiency degree of affected organs.

The information obtained from both indicators is complementary.

Intensive care of the overexposed animal model necessarily implies some analysis of the mechanisms and stages of radiation induced damage.

According to overexposure dose and dose rate, there are different degrees of insufficiency in different tissues, some of which have high vital hierarchy such as the hemopoietic, gastrointestinal and neurovascular ones. Evolution to lethal condition is not frequent when multiparenchymatous insufficiencies are not evident (6).

It is not simple to distinguish deviations of the physiological state from insufficiencies or transitory stages

strictly physiologically generated by the lost of functional balance. It is necessary to develop a repeatable quantificator to diagnose insufficiency and its severity degree, particularly when RAS clinical and humoral expressions appear relatively late.

All above mentioned leads to a wide physiopathological approach such as that applied to Multiple Organ System Failure (7,8).

Radiation Acute Syndrome objective evaluation needs to take into account severity and chronometry of dose and damage biological indicators.

The aim of this work is to establish multiple correlations between dose and damage indicators observed during the first 2 or 3 days to in order to:

- Found therapeutic decisions.
- Interpret radiopathological mechanisms.
- Train medical staff to assist accidentally overexposed people.

MATERIAL AND METHODS

An adult female primate has been X-Rays whole- body irradiated with the following exposure conditions: 200 Kvp. 10 mA, 0,25 Gy/min.

Previous dosimetry with a phantom and TLD dosimeters have been performed. The entrance dose has been 2 Gy and outlet dose has been 1.8 Gy.

A LD50 of approximately 4 Gy is supposed.

RESULTS

1) Dose indicators

a) Cytogenetical Dosimetry: dicentric + rings/cell has been 0.38 dic.+rings/cell (human frequency: 0.34 dic + rings/cell).

b) Taurine quantification: in 24 hours taurine in plasma had not increased as expected, whereas a non identified compound, next in its position in the chromatography column, had.

c) α -amylase has doubled in 6 hours, while TGO, CPK and LDH have increased 24 hours post irradiation 4,20 and 10 times respectively.

2) Damage indicators

a) Blood parameters

-Peripheral blood: the kinetics of blood cells concentration related to time for equal dose, has been similar to that of man, though it has shown a more marked tendency to cell depletion, except for platelets. Neutrophiles increased 260%, 24 hours later. During this time lymphocytes have decreased 50%. From this moment neutrophiles have reached the lowest value (20%) in 20-22 days. Lymphocytes have reduced to minimal value (14%) 8 days post-irradiation.

Platelets have increased 175% in 24 hours for later fluctuations between 75% to 125% of control values. Reticulocytes have increased 4% in 48 hours; they have reduced to minimum (0.12%) the 6th. day post-irradiation and have fluctuated during follow-up between 0.5% and 1% .

-Bone marrow: Previous to irradiation, slides for mononuclear cells recognition, reccount and recovering have been performed (24 E6 cells/ml.).

A few hours after irradiation cell changes had not been observed yet. On the 14th. day post-irradiation an 370% lymphocyte increase and megakaryocytes disappearance has been observed.

Cultures from a withdrawal made some hours after irradiation have not developed colonies; only a fibroblastic type monolayer has been formed.

The cultures set-up on the 14th. day post-irradiation has developed CFU-GEMM colonies, whose size was similar or slightly inferior to that of man, particularly erythrocytes "burst" type, having few hemoglobinized cells.

Mors than 50% of granulocytes colonies have immature cells. The number of colonies has decreased in all lineages except for some very compact macrophagic colonies, whose number has increased.

The cell stroma was abundant till 14th. day; then its decreased till all cells disappeared one month later.

b) Metabolic parameters

The acid-base balance has moved towards metabolic acidosis. Chloride has significantly increased. Glucemia has doubled in 24 hours and at the same time uremia has decreased.

c) Endocrinological parameters

Premature luteinization of the growing follicule has been observed, with a later insufficient luteal phase.

Thyroid parameters have ranged within control values. T3 has had greatest fluctuations.

CONCLUSIONS

A preliminary assay of primate acute overexposure evaluation has given out similar responses to those of man, even though hemopoietic radiosensitivity (except for platelets) has been more marked than human.

Cell kinetics has been similar.

Deep changes in bone marrow cell stroma has been observed. However, in 50 days recovery has been complete.

The stable platelet concentration is associated with high megacaryocytes proliferation.

Metabolic parameters and acid-base state have been modified with the same trend as that of man but more highly marked.

There has been an outstanding premature luteinization of growing follicule.

Primate has not shown clinical manifestations during the period of observations. The handling of the animal model has been an adequate stage of operative training for medical personnel who treat overexposed people.

SUMMARY

Class I and II HLA antigenic expression was explored before and at various intervals after a 10 Gy total body irradiation delivered in 4 hours, before allogeneic bone marrow graft for various hematologic malignancies. A reliable class I HLA typing appears to be possible in almost all cases 6 to 8 hours after the start of irradiation, but is only possible in 5/12 patients after 24 hours. Preliminary results with class II antigens might suggest a still higher "fragility" of this antigen class. These results urge to take blood samples for HLA grouping as soon as possible after an accidental whole body irradiation.

INTRODUCTION

In a situation of accidental total body irradiation, allogeneic bone marrow transplantation from a HLA-compatible donor may represent the only therapeutic solution. In such a case, the class I and II HLA antigenic profile of the irradiated recipient must be precisely known, in order to be able to look for a HLA compatible donor among the relatives or in a donor "bank".

The total body irradiation (TBI), part of the conventional conditioning regimen before bone marrow transplantation for various hematologic malignant disorders (mostly leukemias), represents an interesting "model", since it mimicks an accidental high-dose whole body irradiation.

This model was used in a series of 14 patients to study the expression of class I and II antigens after a 10 Gy-4 hour therapeutic TBI, in order to try and answer the questions : is it possible to define a precise HLA typing after such an irradiation ? And, if yes, how long after TBI the identification of a precise HLA profile remain possible in those patients ?

METHODS AND MATERIALS

a) Irradiation technique

The series is comprised of 14 patients who were given a total body irradiation by 18 MV photons of a linear accelerator (SATURNE GE-CGR MeV), using two antero-posterior and postero-anterior beams at a SSD (Skin-Source Distance) of 4 meters, according to usual technique of the Institute Gustave Roussy.

The total dose, calculated at mid-depth of the abdomen, was 10 Gy. The lung dose was reduced to 8 Gy by an appropriate lead shielding.

The irradiation was delivered in an overall time period of 4 hours with several interruptions. The "instantaneous" dose rate was 12 cGy/min,

while the "mean" dose rate (taking into account the 4 hour setting) was about 4 cGy/min.

A double extemporaneous in vivo dosimetry (semiconductors and thermoluminescent dosimeters) precisely ensured the delivery of the prescribed dose.

An additional chemotherapy, usually using cyclophosphamide, was systematically given **AFTER** irradiation (more than 24 hours afterwards), therefore non interfering with this study of antigen expression in the first 24 hours after irradiation.

b) Patients

Fourteen patients were entered in the study. Sex, age and disease are reported in table 1.

TABLE 1 :

Patient	Sex	Years	Type of disease
1	F	26	Hodgkin's disease (HD)
2	F	21	Chronic Myelogeneous Leukemia (CML)
3	M	55	Myeloma
4	M	30	CML
5	M	4.5	Acute lymphoblastic Leukemia (ALL)
6	M	38	Acute Myeloid Leukemia
7	F	34	CML
8	M	24	Lymphoblastic Lymphoma (LL)
9	M	21	LL
10	F	21	LL
11	F	38	CML
12	M	21	ALL
13	M	22	CML
14	M	21	Low grade Non Hodgkin's Lymphoma

c) Class I and II HLA subtyping was performed using the conventional serologic technique (microlymphocytotoxicity). We considered, as widely accepted, that a minimum antigenic expression of 70 % was necessary for the typing to be reliable. Molecular biology procedures were not utilized in this study.

RESULTS

1) Class I HLA antigens.

The mean expression of class I HLA antigens **before** irradiation (HC), then 6, 8, 17 and 24 hours after the **initiation** of the 10 Gy- 4 hour irradiation, respectively, is given for each patient in table 2.

TABLE 2 :
Class I HLA antigen Mean expression.

Patient	H0	H6	H8	H17	H24
1	78.75 %	83.65 %	n.d	n.d	63.25 %
2	46.14 %	52.20 %	n.d	n.d	14.43 %
3	69.92 %	66.59 %	n.d	n.d	0%
4	95.57 %	89.38 %	n.d	n.d	0%
5	95.83 %	83.33 %	n.d	n.d	73.61 %
6	82.95 %	78.66 %	n.d	n.d	81.16 %
7	100.00 %	73.96 %	n.d	n.d	31.77 %
8	71.73 %	71.35 %	n.d	n.d	0%
9	97.97 %	n.d	88.07 %	n.d	74.48 %
10	77.86 %	n.d	69.53 %	n.d	61.20 %
11	81.94 %	n.d	72.22 %	65.63 %	62.50 %
12	82.50 %	n.d	63.13 %	n.d	n.d
13	100.00 %	n.d	100.00 %	87.78 %	87.78 %
14	97.92 %	n.d	96.35 %	91.88 %	83.54 %

(n.d : not done)

- **Before** irradiation, Class I HLA typing appears to be reliable in 13/14 patients.
- **Six hours** after the irradiation start, HLA typing remains possible for all the 7 tested patients for whom typing was initially possible.
- **Eight hours** after the beginning of irradiation, 4 out 6 tested patients exhibit a sufficient antigenic expression for a reliable typing.
- **At 17 hours**, the number of tested patients (3) is too small for any serious conclusion to be drawn.
- **Twenty-four hours** after the irradiation start, a class I HLA antigen typing could be reliably performed in only 5 out of 12 tested patients with initial reliable typing.

Table 2 emphasizes the large interindividual variations of the mean value of class I antigenic expression over time. Moreover, for a given patient, we were able to demonstrate different evolutions with time of the expression of the various class I antigen (data not shown), thus suggesting different "fragilities" of the various class I antigens after irradiation ; A1, B35 and B44 expression would seem more "resistant" after irradiation in this series.

2) Class II HLA antigens

This study was initiated later ; this explains why only 6 patients were explored.

Before irradiation, only 4 patients out of 6 could benefit from a precise class II HLA typing (possibly because of the type of previous chemotherapy in 2 patients (?)).

Three of the 4 patients with initial typing were tested at 8 hours ; class II antigen typing was still possible in 2 cases.

Twenty four hours after the irradiation, class II antigenic typing was only possible in one case out of the 4 initially reliably typed.

CONCLUSIONS

- For class I histocompatibility antigens, a precise typing seems to be possible in a majority of cases 6 to 8 hours after the start of a 10 Gy-4 hour total body irradiation, but is only possible in 5/12 patients at 24 hours.

- For class II HLA antigens, the small number of patients presently enrolled in our study precludes any valid conclusion. Our preliminary data could only suggest a "sensitivity" to irradiation -at least- equal to the one of class I antigens.

These results urge to take blood sample for HLA typing as soon as possible after an accidental irradiation, since a 20-24 hours delay would preclude the precise HLA typing of an irradiated individual in a significant proportion of cases.

In case of impossibility of HLA grouping by serologic techniques, one should be ready to resort to the new of molecular biology techniques.

CHRONIC IONIZING RADIATION EXPOSURE
AS A TUMOR PROMOTER IN MOUSE SKIN

R.E.J. Mitchel and A. Trivedi

AECL Research
Chalk River Laboratories
Chalk River, Ontario, Canada

ABSTRACT

We have tested a chronic exposure to ^{90}Y beta-radiation as a tumor promoter in mouse skin previously exposed to a chemical tumor initiator. Three different tests of radiation as a stage I tumor promoter, in skin subsequently given chemical stage II promotion, all indicated that the beta-radiation acted as a weak stage I skin tumor promoter. It showed no action as either a stage II or complete tumor promoter.

INTRODUCTION

Tests of ionizing radiation for its action at the promotion step in the multi-step process of carcinogenesis have usually indicated a lack of tumor promotion by single or multiple doses of radiation (1,2). One test of γ -radiation as a stage I promoter, given as two doses of 1.0 Gy each to DMBA initiated mouse skin, and followed by a chemical stage II promoter also failed to produce tumors (3). In spite of these negative results, exposure of cells to ionizing radiation results in expression of protein kinase C, *C-jun* and *C-fos* (4,5), molecular changes associated with tumor promotion. *In vivo* tumor promotion by ionizing radiation may therefore occur only at certain doses or dose rates. In this paper we present the results of our tests of chronic exposure to ^{90}Y beta-radiation as a stage I, stage II or complete tumor promoter in mouse skin.

EXPERIMENTAL MEASUREMENTS

Groups of female 7-8 week old SENCAR mice had their dorsal skins initiated by a single topical application of 10 nmol of the carcinogen 7,12, dimethylbenz(a)anthracene (DMBA, in acetone). Some groups subsequently received the complete chemical tumor promoter 12-O-tetradecanoylphorbol-13-acetate (TPA, 2 μg in acetone, twice/week) for 13-20 weeks, after which time multiple skin tumors appeared on the mice. For some groups chemical promotion was broken into two steps, stages I and II. Those groups received TPA stage I promotion, as above for 2 weeks only, followed by mezerein (4 μg) applied in the same protocol for an additional 13 weeks. Multiple skin tumors also appeared after this treatment. Some groups had their dorsal skins irradiated with a ^{90}Y source at a surface dose rate of 13.4 mGy/s, twice/week for varying periods (chronic exposure).

Table 1 shows the results of two tests of multiple 0.5 Gy β -radiation exposures as a complete promoter in DMBA initiated skin. Used alone this radiation exposure produced no tumors, and in conjunction with the complete chemical promoter significantly reduced ($p < 0.001$) the tumor

frequency. The reduction in tumor frequency may be attributable to radiation induced death of initiated cells.

Table 1: Chronic β -Radiation Exposure as a Complete Tumor Promoter.

Test No.	Treatment*	No. Animals	Tumors/Animal + SD
1	DMBA + No promotion	23	0
	DMBA + TPA (13 weeks)	25	9.72 \pm 0.45
	DMBA + 0.5 Gy (13 weeks)	100	0
2	DMBA + TPA (15 weeks)	25	14.21 \pm 0.30
	DMBA + TPA + 0.5 Gy (15 weeks)	22	9.88 \pm 0.54

* TPA treatment twice per week
0.5 Gy exposure twice per week.

Table 2 shows the tests of chronic exposure to β -radiation used as a stage II promoter in a two stage promotion protocol. DMBA initiated skin, stage I promoted with TPA (2 weeks) followed by 13 weeks of chemical stage II promotion by mezerein produced multiple tumors/animal. Substituting β -radiation exposure (0.5 Gy, twice/week, 13 weeks) for mezerein resulted in essentially no tumors indicating that this radiation exposure did not act as a stage II promoter. The reduced tumor frequency seen when chronic radiation exposure was given prior to or with the chemical stage II promoter, again may be attributable to radiation induced cell death.

Three protocols were used to test chronic radiation exposure as a stage I tumor promoter (Table 3). In the first, initiated skin was subsequently exposed to radiation alone as a stage I promoter followed by chemical stage II promotion. For the second protocol, initiated skin was subsequently treated with a combination of radiation and a chemical stage I promoter (TPA), followed by chemical stage II promotion. The third protocol gave the radiation exposure entirely preceding the initiation, which was then followed by chemical promotion. In all three cases the radiation significantly ($p < 0.05$) increased the tumor frequency, in spite of the concurrent, radiation induced loss of initiated cells shown in Tables 1 and 2.

At the doses and dose rates tested the action of β -radiation as a stage I tumor promoter was weak in comparison to the chemical promoters, consistent with its relatively weak action as a tumor initiator (6) or progressing agent (1). However, its promotion action was offset by its apparent lethal action on initiated cells. At lower dose rates, lethal effects may diminish and enhance the effectiveness of radiation as a promoter.

Table 2: Chronic β -Radiation Exposure as a Stage II Tumor Promoter.

TREATMENT*	NO. ANIMALS	TUMORS/ANIMALS \pm SD
DMBA \rightarrow TPA \rightarrow Mezerlein (2 wks) (13 wks)	24	6.05 \pm 0.29
DMBA \rightarrow TPA \rightarrow no treatment (2 wks) (13 wks)	25	0
DMBA \rightarrow TPA \rightarrow 0.5 Gy (2 wks)(13 wks)	25	0.14 \pm 0.03
DMBA \rightarrow TPA \rightarrow 0.5 Gy + Mezerlein (2 wks) (13 wks)	25	4.79 \pm 0.26
DMBA \rightarrow TPA \rightarrow 0.5 Gy \rightarrow Mezerlein (2 wks)(13 wks) (13 wks)	25	4.53 \pm 0.28

* TPA, Mezerlein and/or radiation (0.5 Gy) were all applied twice per week for the indicated time.

Since stage I promotion can occur prior to the DNA damaging initiating event in cells (7), it is likely to depend on an inducible biological process which subsequently acts on the initiated cell to produce the change necessary for this step in carcinogenesis. We have other (unpublished) evidence that tumor promotion is a process which occurs naturally, in the absence of stimulation by chemical or physical agents. We suggest that the chronic radiation exposure prior to or after tumor initiation stimulates this natural process, such that when an initiating event occurs, there is an increased probability that stage I promotion will also occur and tumor frequency will consequently rise.

Table 3: Chronic β -Radiation Exposure as a Stage I Tumor Promoter.

Test No.	Treatment*	No. Animals	Tumors/Animal \pm SD
1	DMBA \rightarrow No treatment \rightarrow Mezerlein (13 wks) (13 wks)	24	3.46 \pm 0.16
	DMBA \rightarrow 0.5 Gy \rightarrow Mezerlein (13 wks) (13 wks)	25	3.99 \pm 0.23
2	DMBA \rightarrow TPA + Mezerlein (2 wks) (13 wks)	24	6.05 \pm 0.29
	DMBA \rightarrow TPA + 0.5 Gy \rightarrow Mezerlein	25	6.95 \pm 0.43
3	MNNG \rightarrow TPA (20 wks)	25	4.73 \pm 0.23
	0.5 Gy \rightarrow MNNG \rightarrow TPA (4 wks) (20 wks)	23	5.47 \pm 0.37

* Chemical tumor promotion or radiation exposure (0.5 Gy) was twice per week.

CONCLUSIONS

Chronic exposure to ^{90}Y beta-radiation does not act as a complete tumor promoter or a stage II tumor promoter in mouse skin previously exposed to a tumor initiator. However, it does act as a stage I skin tumor promoter possibly by stimulating or inducing a naturally occurring stage I tumor promotion process in cells. This result suggests that chronic exposure to radiation may increase the risk of tumor formation in persons exposed to a previous or subsequent tumor initiating dose.

GENE CONVERSION IN YEAST AS A FUNCTION OF LINEAR ENERGY
TRANSFER (LET) FOR LOW-LET RADIATION

ABSTRACT

The relative biological effectiveness (RBE) for low linear energy transfer (LET) radiation is known to depend on such factors as LET and dose rate. Microdosimetric calculations indicate that the biological target size could also be an important parameter, and calculations predict that the RBE for effects produced by hits in target sizes below about 100 nm should be unity for all low-LET radiation. We have measured the RBE for gene conversion in yeast (a small target) for five different low-LET photon sources, and the results were consistent with an RBE of unity. This finding is consistent with microdosimetric predictions.

INTRODUCTION

Radiation quality is normally estimated using the linear energy transfer (LET). Radiation with LETs less than 10 keV μm^{-1} are called low-LET, and the quality-factor-versus-LET relationship predicts a range in radiation quality of about 0.5 to 2.⁽¹⁾ Similar values are predicted when the quantity of linear energy is used to define radiation quality.⁽²⁾ However, linear energy theory predicts that radiation quality is dependent on the size of the biological target, and the theory also predicts that the ratio of tritium beta rays (LET ≈ 6.5 keV μm^{-1}) to ^{60}Co gamma rays (LET < 1 keV μm^{-1}) has a maximum of about 3 for target sizes of 1 to 3 μm , and decreases to unity for smaller and larger target sizes.⁽³⁾

Gene conversion in irradiated yeast is generally thought to result from DNA damage in the immediate vicinity of the mutant gene. Such damage presents a small target that can be used to test microdosimetric predictions. The repair of this damage can result in the mutant gene's being converted to the "wild" type that will form colonies when plated onto growth medium. These colonies can be counted; thus, the conversion yield is considered a function of dose estimated.⁽⁴⁾

EXPERIMENTAL

Two mutant varieties of the yeast *Saccharomyces cerevisiae* were first irradiated with five different sources of low-LET radiations normally encountered in the workplace.

Fig. 1. Typical results obtained for gene conversion yield as a function of dose. The dose to cells from the 50 kVp x-rays is considerably less than the dose in air.

Fig. 2. Experimental arrangement to measure doses to cells. The ion chamber was at an equal dose position to the lucite test tubes containing yeast cells in suspension.

After each exposure, gene-conversion yields in the yeast were measured (see Fig. 1). The following radiations were used: 50 to 150 kVp x-rays from a thin window (2.5 mm Be) x-ray tube, 150 and 300 kVp x-rays from a thick window (0.4 mm Cu) x-ray tube, and ⁶⁰Co gamma rays. The x-rays emitted from the thin window tube have a much higher LET (50 kVp thin window $\approx 7.5 \text{ keV } \mu\text{m}^{-1}$, 150 kVp thin window $\approx 2.5 \text{ keV } \mu\text{m}^{-1}$) than those from the thick window tube (150 thick window = $1.5 \text{ keV } \mu\text{m}^{-1}$, 300 thick window = $1.0 \text{ keV } \mu\text{m}^{-1}$). The gamma rays from ⁶⁰Co have an even lower LET ($\approx 0.26 \text{ keV } \mu\text{m}^{-1}$). The dose rates used in all the experiments were about 100 rad/min, which, as shown by the authors' previous experience with this system, is well below that which produces dose rate effects.⁽⁴⁾

Cells were suspended in growth medium in lucite test tubes (see Fig. 2) and maintained at 0°C (ice bath) during irradiation. To give yields under both oxic and anoxic conditions, either air (O₂) or nitrogen (N₂) gas was bubbled through the medium.

Typical results are shown in Fig. 1. The slopes (b_1) of straight line fits to the data were estimated and their ratios and uncertainties obtained from the formula

$$R = \frac{b_x}{b_y} \pm \left[\frac{\Delta b_x^2}{b_y^2} + \frac{b_x^2 \Delta b_y^2}{b_y^2} \right]^{1/2}$$

These slopes are given in Table 1. Δb_i are the uncertainties returned by the fitting routine.

The much lower yield for the 50 kVp irradiation was because the average dose to cells for these low-energy x-rays is much smaller than that in air. (Absorption of radiation by the lucite tube and by the suspension caused this reduction in dose.) For all irradiations, the absorption was estimated using two methods. First, theoretical energy spectra of the x-rays were used to calculate the average dose to cells by using known absorption cross sections. These values were then checked by inserting the ion-chamber into a water-filled tube (Fig. 2) and measuring the average dose. The correction for absorption was applied to the ratio of slopes to obtain the RBEs in Table 2.

DISCUSSION AND CONCLUSION

The estimated RBEs (Table 2) for the TRP (N_2) mutant are all less than 1, and those for the HIS (O_2) are all greater than 1, indicating that there may be some unexplained bias in the results. However, the overall results are consistent with an RBE close to unity and serve as experimental support for the predictions of the microdosimetric theory that the RBE for low-LET irradiation of small biological targets is approximately one.

ABSTRACT

Taurina, which is the metabolic end-product of cysteine shows a dose dependent change in urinary excretion after radiation exposure. The results of whole body gamma irradiated rats with doses of CO-60 ranging from 100 cGy to 800 cGy are expressed as percent increase of taurine in urine in the first 48 hours postirradiation and confirm the existence of a linear relationship.

INTRODUCTION:

To predict the medical consequences of accidental irradiation, the absorbed dose has to be determined with a sufficient degree of accuracy and precision. It is also essential that the dose information can be produced within an acceptable time period, before clinical symptoms requiring important medical treatment are manifest. So, known dose effect relationship reproducibility of observations and early availability of results are some of the basic requirements for practical applicability of bio-indicators.

Biochemical analysis of the metabolic patterns in the body can provide information on cellular disturbances that may arise due to the radiation exposure.

There is a general increase in the levels of aminoacid in the urine of animals and humans during the first day after irradiation.

The relative enhancement depends on the absolute excreted amount and on the metabolism of the specific aminoacids. Accordingly, the excretion of aminoacids is not usually an appropriate indicator.

However, taurine, a metabolic end product of the aminoacid cysteine, shows a dose dependent change in urinary excretion after irradiation.

Raghavan et al. (1) showed a linear dose-response relationship in urinary taurine of rats measured at 24 Hs. postirradiation with dose ranging from 100 cGy to 800 cGy of X rays.

In this work we estimated taurine in urine collected during the first 48 hours postirradiation, and the results are expressed as percent increase respect to control value.

MATERIALS AND METHODS:

Normal male rats (Wistar) weighing 200-250 g, maintained on stock laboratory diet, were used in the experiments.

Whole body gamma irradiation was carried out with Co-60 Picker C4M60 unit at a rate of 29.3 cGy/min, total doses ranging 100 to 800 cGy.

The rats were housed in individual metabolic cages for urine collection. The urine was collected at intervals of 24h, in flasks containing a few drops of toluene.

It was ensured that there was no contamination of urine by water and faeces.

Taurine was analysed by reversed-phase HPLC after mixed-bed ion-exchange clean up and precolumn derivatization with Dansyl Chloride based on the method of Marquez et al. (2).

Briefly, 1 ml samples of urine were deproteinized adding 0.1 ml 3.2 M of perchloric acid and filtered through an ion-exchange clean up column to remove aminoacids that could interfere with taurine separation by HPLC. Columns were prepared according to Larsen et al. (3).

Separation of Dansyl derivatives was carried out on a 5 μ m Supelcosil LC-18 reversed phase column (150 x 4.6 mm I.D., Supelco, Bellefonte, PA, U.S.A.).

Two mobile phases were used: a) methanol 14%, b) 0.6% acetic acid with 0.008% triethylamine in water solution (30:70). It was delivered at a flow rate of 1.5 ml/min and constant room temperature. Detection at 250 nm of wavelength were performed.

RESULTS:

The excretion values of urinary taurine of rats at 24, 48 and 72 hours after exposure are shown in table 1.

TABLE 1

URINARY EXCRETION OF TAURINE (μ moles/24 hours)

Dose (cGY)	100	300	500	600	800
Control*	76.0	87.2	77.1	30.4	50.
S.D.	30.1	35.0	31.6	9.9	19.2
24 Hours	57.8	126.7	130.0	52.0	100.6
S.D.	20.2	53.2	49.0	16.6	27.2
48 Hours	24.2	32.2	67.3	36.5	57.7
S.D.	7.7	10.2	20.1	14.6	17.8
72 Hours	38.7	60.3	47.2	36.1	28.9
S.D.	16.6	20.7	13.2	10.1	6.6

* Before Irradiation

Taurina levels reach a peak at 24 hours and return to normal values at 48 hours. After 72 hours, taurina levels decrease below control values.

The increase during the first 48 hours postirradiation taken in percentage of controls were plotted against doses and a linear correlation was found (fig. 1).

Each point is the average of at least 4 rats.

DISCUSSION:

A number of studies have shown an enhancement in the urinary excretion of taurine after accidental exposures and in irradiated rats and mice.

The present results confirm that increase and the existence of a linear relationship up to a dose of 800 cGy. The lower limit of dose detection is restricted to 100 cGy.

However, the values obtained are not in agreement with the findings of Raghavan and Nadkarni showing a persistence of high taurine levels after 72 hours of high dose irradiation. We have found a decrease of the mean values in irradiated samples below of control ones, at that time.

It may be questioned the validity of this assay pointing out the relatively great fluctuation in the "normal" physiological taurine status in urine and plasma, but this level is restored after 48-72 hours postirradiation and can be estimated for each individual.

The technique used provides accurate and precise quantitation of taurine in biological materials within 70 minutes.

The level of urinary taurine may be useful for high dose ranges in the early evaluation of radiation injury.

Buenos Aires. Argentina

ABSTRACT

CB57 female mice whole body gamma irradiated were orally administered with acetato DL- α -tocopherol. It was observed a higher survival in α -tocopherol treated groups up to 14th and 10th days with doses of 8.5 and 10 Gy respectively and a greater bone marrow cellularity at day 10 in α -tocopherol treated group irradiated with 10 Gy.

INTRODUCTION

Radiation-induced damage to biological membranes is important because these cellular elements perform a decisive role in the functional organization of the cell. In view of the importance of α -tocopherol in membrane structure, we chose this drug to test its action not only in protecting against initial radiation damage but also in the recovery from radiation stress.

Rejholcová and als. (1) found an increase in lipid peroxidation from the 13th postirradiation day after doses of 6.8 Gy. They suggested this peroxidation was the result of metabolic disorganization caused by the radiation sickness.

In this work we used higher doses of radiation (8.5' and 10 Gy) and assuming that increase in lipid peroxidation could be observed earlier, the α -tocopherol was administered to mice immediately after exposure and 4 and 7 days later.

MATERIAL AND METHODS

CB57 female mice, 8 weeks old, weighing 18-20g were whole body gamma irradiated with doses of Co-60 (8.5-10 Gy, dose rate 0.25 Gy/min).

Acetato DL- α -tocopherol (50mg/kg body weight) using corn oil as carrier was orally administered to mice immediately after exposure and 4 and 7 days later. Animals treated with only corn oil served as control.

Damage was assessed using mortality as endpoint. Animals were observed daily from the first day following irradiation. A group was sacrificed at different times, and the other one when terminally moribund. Splenic weight and bone marrow and splenic cellularity were evaluated at different times (3-8-16-23 and 30 days). Body weight was daily monitored.

Data represent mean values obtained from 4 separate experiments and were analysed using Student t test.

RESULTS

Survival data are summarized in Table 1.

SURVIVAL

TABLE 1

day	DOSE = 8.5 Gy		DOSE = 10 Gy	
	α -tocopherol	control	α -tocopherol	control
0	100.0%	100.0%	100.0%	100.0%
7	97.6%	85.4%	100.0%	84.2%
10	84.6%	81.1%	100.0%	52.9%
14	81.1%	57.1%	11.8%	0.0%
30	21.2%	32.2%	0.0%	

The α -tocopherol and control groups irradiated with 8.5 Gy showed a significant mortality by the 30 day, but up to 14th day α -tocopherol treated group had greater survival than control one. Although a dose of 10 Gy resulted in 100% lethality of treated and control animals by day 15 after irradiation, treated group had a significantly higher survival than control one up to 10th day.

The body weight was decreased by about 20% on day 2 postirradiation in treated and control groups irradiated with 8.5 Gy. The growth recovered to the normal level by 30 days (fig. 1). Animals irradiated with 10 Gy did not reach normal weight until the end of the experience. Although the values are not significant, body weight in α -tocopherol treated group tended to be greater than control one (fig. 2).

Relative to normal (nonirradiated mice) the splenic weight of 8.5 Gy irradiated animals was reduced to \approx 30% at day 3 postirradiation and so on up to day 20, when it was observed an overshoot. Thirty days were needed for recovery to the control level (fig.3). A similar initial fall was observed in mice irradiated with 10 Gy. The splenic weight in α -tocopherol treated group tended to increase showing a

significant difference on day 12 ($p < 0.01$). The splenic hyperplasia and the recovery to normal level could not be observed because of the earlier death (fig. 4).

The bone marrow cellularity of both irradiated groups (8.5 Gy) reached minimal values (about 1.5% of the nonirradiated mice) on day 3, and tended to recover on day 12. The complete recovery was reached on day 30 (fig. 5). Bone marrow cellularity of both irradiated groups (10Gy) decreased significantly to 0.7% on day 4, and turned to increase thereafter, but finally the recovery failed. However, mice treated with α -tocopherol exhibited increased bone marrow cellularity at day 10 postirradiation relative to control group (fig. 6).

Qualitatively splenic cellularity was similar to bone marrow cell counts. However in groups irradiated with 8.5 Gy it was observed a very significant increase on day 20 postirradiation, reaching normal values on day 30, accordingly to splenic weight.

DISCUSSION

Although radiation lethality does not seem to be greatly affected by the oral intake of α -tocopherol after irradiation our results show a greater survival in α -tocopherol treated groups up to 14th day and up to 10th day with doses of 8.5 and 10 Gy respectively.

After total body irradiation at low doses death from hematopoietic depletion continues beyond 10 day, and is complete by 15 days, while death from gut failure occurs by day 10 at high doses.

Analysis of our data would suggest a probable radioprotector role of α -tocopherol on bone marrow syndrome. With doses of 8.5 Gy, the differences between bone marrow and splenic cellularity in α -tocopherol and control groups were not significant, but the survival of α -tocopherol treated group was higher than control one up to 14th day. In animals irradiated with doses of 10 Gy, it was observed not only a higher survival up to 10th day, but also bone marrow cellularity was greater in α -tocopherol treated group respect to control one. Alfa-tocopherol administered after irradiation would help animals exposed to recover from radiation damage, decreasing lipid peroxidation events. It is suggested these events are the result of a late metabolic disorganization caused by the radiation sickness.

Although our data are not concluding they show a trend to a radioprotector role. There would be different explanations for these not concluding results: 1) Alfa-tocopherol contained in corn oil (1mg/g corn oil, Rowe and Wills, (2)) could play certain radioprotective action, explaining why there were not significant differences in animal survival and bone marrow cellular counts with doses of 8.5 Gy. 2) The days chosen for the reinforcement doses of α -tocopherol probably were not accord to a 10 Gy dose of radiation, being the plasmatic levels of α -tocopherol not sufficient to prevent secondary lipid peroxidation events. 3) Alfa-tocopherol treated group irradiated with 10 Gy had higher survival and bone marrow cellularity at day 10. However, this dose resulted in 100% lethality by day 15. It could be suggested that this mortality is caused by gastrointestinal damage rather than bone marrow failure. It seems that α -tocopherol would prevent death from bone marrow depletion but not from gastrointestinal injury.

SUMMARY

The response of a New World monkey species (*Cebus apella paraguayanus*) lymphocytes to various doses of 60 Co gamma-rays has been studied using dicentric + rings frequency in first mitosis and compared to that of man. Results have shown that differences between both species are no significant. The distribution of 200 breakpoints in G-banded metaphases has been scored showing an excess of breaks in chromosomes 1, 11, 12 and 16. Terminal heterochromatic blocks differ from intercalary heterochromatin in the response to gamma radiation being the former more affected.
