Frequency of accidental whole-body overexposures is low even though they may result in lethal effects. For that reason, present knowledge for diagnosis and treatment of such overexposures is scanty and it is necessary to extrapolate qualitative and quantitative data from animal models used to reproduce accidental overexposure conditions. To extrapolate with confidence, an adequate animal model should have a close phylogenetical relationship and show radiosensitivity similar to that of man.

Among New World Monkeys, *Cebus apella paraguayanus* (Fisher, 1829) is one of the most widely spread species in South America and frequently used in biomedical research. This species has shown a successful breeding and reproduction rate in captivity. Its karyotype has been standardized (1) and the amounts and variations of constitutive heterochromatin have been characterized (2). Among Platyrrhini, this species is the least distant to man, with about thirty five rearrangements separating both karyotypes (3). However, previous studies have shown that phylogenetical proximity does not necessarily imply a similar radiosensitivity because even the higher primates such as gorilla and chimpanzee (4) don't represent good models, at least for quantitative estimation of cytogenetical hazards, because chromosomal radiosensitivity is not related to chromosome number, chromosome arm number or similarities in the karyotypes (5) even if only first mitoses are considered.

Unstable chromosome aberrations frequency in short-term lymphocytes cultures is a useful tool to make direct analysis of the effects of ionizing radiation on human and other species genetic material using in-vitro irradiations or samples from in-vivo overexposures.

In order to establish if *Cebus apella paraguayanus* has a chromosomal radiosensitivity similar to that of man we have estimated the frequency of unstable chromosomal aberrations (dicentric+rings/cell) in 48 hours lymphocytes cultures of

both species, using simultaneously in-vitro irradiated human and primate blood samples with different doses of ^{60}Co gamma-radiation, from 0.5 Gy to dosimeter saturation point. Distribution of the breakpoints among the chromosomes involved in the production of dicentrics and rings has been scored in G-banded metaphases.

MATERIAL AND METHODS

Three human and three *Cebus apella paraguayanus* whole blood samples have been irradiated by gamma-rays at high dose-rate from a ^{60}Co source, pairing a human and a monkey sample in each irradiation at 0.5, 1, 2, 3, 5 and 6 Gy doses. Whole-blood cultures have been immediately set-up using RPMI 1640 medium with 1-2 % PHA and supplemented with FCS (15 %). Cells have been harvested after 48 hours. At this time practically 99 % and more than 95 % of human and monkey (own data) lymphocytes respectively are in first division. Irradiations at 7 Gy in both species indicate dosimeter saturation ($y:2\text{ dic}+r/\text{cell}$). For that reason the higher dose considered in data analysis has been 6 Gy. A blood sample of *Cebus apella* has been irradiated at 2 Gy and 300 well spread metaphases from 48 hours cultures were used to localize breakpoints on G-banded chromosomes following the procedure of Seabright, 1971 (6).

RESULTS

Human results have been fitted to a linear quadratic dose-effect model, using least squares weighted method (weight: $1/y$) obtaining values of $2.613\text{ E-}02 \pm 0.01$ and $5.074\text{ E-}02 \pm 0.004$ for α and β coefficients respectively (χ^2 : $2.35\text{ E-}02$; DF:4). (TABLE I)

Cebus apella results have been fitted to a quadratic dose-effect model with β coefficient: $5.575\text{ E-}02 \pm 0.01$ (χ^2 : $2.25\text{ E-}02$; DF:5) (Fig. I). Background levels have been discounted from y values in each dose and in both species. The two way analysis of variance indicates that there is no significant difference between species or for interaction dose-species ($p > 0.05$).

A total of 100 two-breaks chromosome aberrations (dicentrics + rings) were scored in 300 G-banded karyotypes prepared from gamma irradiated at 2 Gy cells of 48 hs culture. The distribution of the observed number of breakpoints per chromosome and comparison with the expected numbers is presented in Table II. The expected numbers has been calculated assuming that break distribution is proportional to chromosome corrected length in 54,XY cells, taking into account C-bands heteromorphisms for 11 and 19 chromosome pairs. This specimen shows the following heterochromatic variations: Pair 11: one chromosome (11L) with a large-size terminal block (85% of the chromosome length) and the other (11M) with a medium-size block (75% of the chromosome length). Pair 19: one chromosome (19H) with an intercalary heterochromatic block (40% of the chromosome length) and the other without it.

The differences between the observed and expected number of breakpoints per chromosome, determined by χ^2 analysis,

are shown in Fig. II. As can be seen, chromosomes 1, 12 and 16 show significant excess of breakpoints ($p < 0.01$). A trend toward a deficiency of breaks has been observed in chromosome 4 ($p < 0.1$) and to an excess of breaks in chromosome 11 L ($p < 0.1$) and 11 M ($p < 0.05$).

DISCUSSION

Even though each species fits to different models the results of analysis of variance indicate that differences are not significant. Under the light of this data this species could be considered a model in terms of cytogenetical evaluation, at least in the range from 0.5Gy to 6Gy. However, being ratio α/β approximately 0.5 Gy for man, the authors think this model deserves further studies under this low dose, to focalize the precise behavior of monkey chromosomes in the zone where it is postulated that dicentrics are produced principally by one track.

Respecting distribution of breakpoints, the results have indicated that chromosomes 1, 12 and 16 have been more frequently involved in radiation induced aberrations but they have shown random association with the second chromosome which takes part in each aberration. Interestingly, conspicuous terminal heterochromatic blocks in chromosomes 11 have shown more breaks than expected resembling chimpanzee terminal heterochromatin behavior (7), though this species seems to be more radiosensitive than man, contrary to *Cebus apella paraguayanus*. However, in the case of chromosome 19 H, clustered breaks in euchromatin but none in the intercalary heterochromatic block has been observed. If the amount and position of heterochromatin play some role and must be taken into account when chromosome radiosensitivity of a particular species is evaluated, requires more information.

The Effect of Dose Protraction on the Incidence of Lung Carcinomas in Beagle Dogs with Internally Deposited β -Emitting Radionuclides

W.C. Griffith, B.B. Boecker, F.F. Hahn, B.A. Muggenburg, and M.B. Snipes
Inhalation Toxicology Research Institute, PO Box 5890, Albuquerque NM 87185 USA

ABSTRACT: Studies using Beagle dogs were conducted to understand health effects when lung is the primary organ irradiated after inhaling insoluble radioactive particles containing one of four β -emitting radionuclides, ^{90}Y , ^{91}Y , ^{144}Ce , or ^{90}Sr . The low-LET β irradiation was delivered over a wide range of total doses and dose rate patterns that protracted the dose to lung from about 1 wk to several years. The tumor incidence rates for lung carcinomas were estimated using a proportional hazard rate model. These studies suggest that dose protraction only affects production of lung carcinomas at doses above 50 Gy.

INTRODUCTION: Studies using Beagle dogs were conducted to understand the health effects of inhaling radioactive particles when lung is the primary organ irradiated. Our studies were designed to complement the limited information available from human epidemiological studies. In this report, we present our analysis of four, β -emitting radionuclides, ^{90}Y , ^{91}Y , ^{144}Ce , or ^{90}Sr , acutely inhaled as relatively insoluble particles by young-adult dogs^(1,2). This aerosol form resulted in the radiation dose being delivered primarily to lung and adjacent tissues. These studies examined the health effects of exposure to low-LET β irradiation over a wide range of total doses and dose rates. The dose-rate patterns are characterized by a decreasing dose rates due to radioactive decay and clearance of particles from the lung. These patterns protracted the dose from a single inhalation exposure from about 1 wk to several years and are more similar to occupational and environmental exposures than are exposures that were received by the subjects of human epidemiology studies exposed to low-LET radiation from which regulatory limits for exposure have been developed. The exposures in the latter category were either a single, high-dose-rate exposure for the Japanese atomic bomb survivors or a series of high-dose-rate exposures for medically exposed patients, such as ankylosing spondylitis patients.

The importance of dose rate for low-LET exposures is difficult to resolve. Because of the lack of data, the effect of dose protraction has usually been summarized into a simple dose-rate-effectiveness factor that divides the cancer risk factors for low-LET radiation exposures at high dose rates. The BEIR V committee⁽³⁾ did not specifically recommend a number for this factor, because of the scarcity of data, but thought that it must be at least 2. These studies are the first to study the effect of dose-rate protraction for low-LET radiation exposure in lifespan studies, using a long-lived laboratory animal species.

METHODS: Predicting cancer risks for people by extrapolating from carcinogenesis studies using animals as subjects is a largely empirical process, because the present knowledge of the mechanisms of carcinogenesis is inadequate. This report is a summary of our studies of incidence rates of β -irradiation-induced lung carcinomas by means of a relative risk function. The relative risk function relates tumor incidence rate to both total dose and dose pattern. Similar methods are used to summarize carcinogenesis information from studies of human populations exposed to low-LET external radiation⁽³⁾.

We applied proportional hazard rate models to describe how tumor incidence rates change with radiation dose⁽⁴⁾. To describe these models, suppose that $X(t)$ is a time-dependent covariate vector where the tumor incidence rate is proportional to the baseline tumor incidence rate at $X(t) = 0$; that is

$$\lambda(t, X(t)) = \lambda(t, 0)\Theta(X(t)),$$

where $\Theta(X(t))$ is the relative risk function at $X(t)$. In this model, the estimated lung tumor incidence at 0 dose $\lambda(t, 0)$, is multiplied by the relative risk function $\Theta(X(t))$. All animals in these four studies were used to estimate both $\lambda(t, 0)$ and $\Theta(X(t))$. The multiplicative factor $\Theta(X(t))$ is the relative risk (i.e., relative to values of the covariates where $\Theta(\cdot) = 1$) and is only related to time through the covariates. No assumption about the function $\lambda(t, 0)$ is made, and thus, inference does not depend upon a particular shape or form of a mathematical relationship being satisfied. Estimation of the relative risk function $\Theta(X(t))$ is of main interest, because it summarizes the effect of the radiation dose. In this report we used an additive form of the relative risk $\Theta(X(t)) = 1 + \beta X(t)$ where β is a vector of coefficients to be estimated. Estimates of β were found by maximizing the partial likelihood with a Newton-Raphson technique, and the covariance matrix for these estimates was found by inverting the observed information matrix⁽⁵⁾.

Lung carcinomas were the primary biological endpoint of interest for this paper. Lung carcinomas were diagnosed on the basis of radiographic, autopsy, and histopathologic information. Time to lung carcinoma was taken as the time to the first positive radiograph, or to death, if there were no positive radiographs. Animals without detected lung tumors were treated as being censored at their death time.

RESULTS: A common baseline incidence rate function $\lambda(t, 0)$ for lung carcinomas was used for the four studies so that the relative risk function would be comparable for the four radionuclides. This was a reasonable assumption because all the dogs were produced in the Institute's animal colony using a randomized breeding program. Radiation doses to the lung were calculated as average absorbed β doses in Gy using the coefficients shown in Table 1 and estimating the lung weight including blood, to be 1.1% of the total body weight at time of exposure. The shifts in time to appearance of lung tumors make it possible to model these studies. If the time to appearance of the tumors were not considered, the numbers of animals and tumors would be too small to model in the same detail as has been possible using this information.

Table 1
Basic Dosimetric Parameters for Radionuclides Inhaled in
Fused Aluminosilicate Particles by Beagle Dogs.

	⁹⁰ Y	⁹¹ Y	¹⁴⁴ Ce	⁹⁰ Sr
Average β energy (MeV)	0.93	0.60	1.29	1.13
Radionuclide half-life (days)	2.7	59	284	10,600
Lung retention half-life (days)	2.5	50	175	154 (39.5%) 990 (60.5%)
Time to accumulate 95% of total committed dose (days)	11	220	760	3600

The parametric form of the relative risk $\Theta(\cdot)$ found to describe these studies best was a linear function of dose added to a power function of dose having the following form :

$$1 + \sum_{i \in A} [\exp(\alpha) d_i(t) + \exp(\beta_i) d_i^{\gamma_i}(t)],$$

where $A = \{^{90}\text{Y}, ^{91}\text{Y}, ^{144}\text{Ce}, ^{90}\text{Sr}\}$, $d_i(t)$ are time-dependent doses in Gy, and $\alpha, \beta_i, \gamma_i$ are estimated coefficients. The time-dependent dose functions $d_i(t)$ are non-zero only for animals exposed to radionuclide i . The maximum partial likelihood estimates for the coefficients are shown in Table 2 and the excess relative risk (1 subtracted from the relative risk) in Figure 1. By the likelihood ratio test, this model was a statistically significant improvement ($p < 0.01$) over models with just a linear function of dose or just a power function of dose (analysis not shown), but there was no statistically significant improvement ($p > 0.2$) to estimate separate linear coefficients, α_i , for each radionuclide.

Table 2
Estimates of Coefficients and Their Standard Errors for the Relative Risk Model Outlined in the Text with the Linear Coefficient $\alpha = -2.9(0.6)$ for All Four Radionuclides.

Coefficient	^{90}Y	^{91}Y	^{144}Ce	^{90}Sr
β	-39.7 (11.9)	-36.3 (6.3)	-25.0 (6.7)	-10.3 (3.6)
γ	10.2 (2.8)	8.3 (1.2)	5.3 (1.1)	2.8 (0.6)

Figure 1: Excess relative risk (1 subtracted from the relative risk) for development of lung carcinoma in Beagle dogs as a function of radiation dose to the lung.

DISCUSSION: The models used in this report relate the lung carcinoma incidence rates to two factors: 1) the cumulative radiation dose in Gy as a time-dependent quantity and 2) the pattern of accumulation of the radiation dose, by estimating separate

coefficients for each of the four radionuclides used in the studies. Because the physical half-lives of the radionuclides differed, the patterns of dose delivery differed greatly. The estimated coefficients for the four radionuclides also differ from each other, indicating that the characteristics of the exposure pattern, in addition to the time-dependent dose, are important to estimate the risks of developing lung carcinomas. In the case of dose protraction, the radionuclide dose is delivered at a constantly changing dose rate. Thus, a dog with a high initial dose rate will experience a constantly decreasing dose rate until death. This means that the pattern of dose protraction used in these studies does not have a simple relationship to any single dose rate.

The results of this analysis indicate that the effect of dose protraction on the incidence of lung carcinomas is similar at the lower range of doses used in this study but differs markedly at high doses (Figure 1). At high doses, it is much more effective to deliver the dose over a short time period. Within the power of this study, it was not possible to discern a difference between the four radionuclides below about 50 Gy. This suggests that there may not be an effect of dose rate on the production of lung carcinomas below doses in this range.

THE EFFECT OF ISOTOPE ON THE DOSIMETRY OF INHALED PLUTONIUM OXIDE

Raymond A. Guilmette¹, Albert W. Hickman² and William C. Griffith¹

1. Inhalation Toxicology Research Institute, P. O. Box 5890, Albuquerque, NM 87185

ABSTRACT: Results of experimental studies in which animals inhaled $^{238}\text{PuO}_2$ or $^{239}\text{PuO}_2$ aerosols have shown that the biokinetics and associated radiation dose patterns for these two isotopes differ significantly due to differences in *in-vivo* solubility caused by the 260-fold difference in specific activity between $^{238}\text{PuO}_2$ and $^{239}\text{PuO}_2$. We have adapted a biokinetics and dosimetry model derived from results of the ITRI dog studies to humans and have calculated dose commitments and annual limits on intake (ALI) for both Pu isotopes. Our results show that the ALI calculated in this study is one-third that for class Y ^{238}Pu from ICRP 30, and one-half or equal to that for class Y ^{239}Pu , depending on how activity in the thoracic lymph nodes is treated dosimetrically.

INTRODUCTION: Inhalation has been shown to be the most likely route of occupational exposure to plutonium. Nonoccupational inhalation exposures to Pu aerosols have also occurred as a result of atmospheric nuclear weapons testing. Despite these exposures, information from studies of people have not been adequate to define the dosimetry of inhaled Pu aerosols. Consequently, data from experiments with animals are used to augment our knowledge of Pu biokinetics and dosimetry and to identify important dose- and effect-modifying factors. This report summarizes results obtained from studies at ITRI in which adult dogs inhaled monodisperse aerosols of either $^{238}\text{PuO}_2$ or $^{239}\text{PuO}_2$ having similar aerodynamic sizes, produced in the same way, and having the same chemical form. Therefore, the two exposure materials differed only in specific activity.

MATERIALS AND METHODS: The materials and methods used in these studies have been reported in detail (1,2). Briefly, adult male and female beagle dogs (15 - 41 mo of age) received a single brief pernasal inhalation exposure to a monodisperse aerosol of $^{238}\text{PuO}_2$ (1.7 or 2.7 μm AMAD) or $^{239}\text{PuO}_2$ (1.4 or 2.9 μm AMAD). Each aerosol was produced by heat-treating droplets of a nebulized suspension of $\text{Pu}(\text{OH})_4$ at 1150°C, thus forming PuO_2 . After exposure, each animal was maintained in a metabolism cage for excreta collection and in a kennel run until the dog was either sacrificed, euthanized or died. Sacrifice times ranged from 4 hr to 4 y after exposure. Additional data from dogs that inhaled $^{239}\text{PuO}_2$ as part of a dose-response study were also included in this analysis (3). Radiochemical analysis of Pu in tissue and excreta samples provided the data for determination of the biokinetics of ^{238}Pu and ^{239}Pu following inhalation deposition of Pu in oxide form.

Fifty-year dose commitments for lung, liver and bone surfaces of humans were obtained from different models for ^{238}Pu and ^{239}Pu . In the former case, the doses were calculated using the canine-based model of Mewhinney and Diel (1) that was modified for application to man. Four changes in metabolic parameters from those of the canine model were made: 1) The partitioning of Pu that reached the blood from solubilization of the deposited Pu particles was 45% liver, 45% bone, 4% muscle and 0.4% kidney, values which were derived from the analyses of McInroy *et al.* (4),

and are similar to those suggested in ICRP 30 (5). 2) A ratio of Pu in urine to Pu in feces of 1 was used based on the systemic model of Leggett (6). 3) Biological retention half times of 40 y for liver and 100 y for skeleton, as proposed in ICRP 30 (5) and supported by analyses of exposed humans (7) were used. 4) The particle size of the inhaled aerosol was assumed to be 1.0 μm diameter.

The calculation of human dose commitments for ^{239}Pu was based on retention equations obtained from the ITRI dog studies modified to include the 40-y biological half time for liver and 100-y half time for skeleton. These equations are:

$$R_{lung}(t) = 0.18e^{-0.024t} + 0.82e^{-0.00045t}$$

$$R_{liv}(t) = 0.010e^{-4.7 \times 10^{-5}t}(1 - e^{-0.12t})$$

$$R_{skel}(t) = 0.0017e^{-1.9 \times 10^{-5}t}(1 - e^{-0.12t})$$

$$R_{thor}(t) = 0.17e^{-0.027t} + 0.83e^{-0.00016t}$$

where $R_i(t)$ is the retention in organ i (where i = lung, liver, skeleton and thoracic = lung + lung-associated lymph nodes, LALN, respectively) expressed as fraction of the initial lung burden, and time t is in days after exposure. For all dose calculations, the organ masses used were those specified in ICRP 30 (5), i.e. lung = 1000 g, liver = 1800 g, and bone surfaces = 120 g.

RESULTS AND DISCUSSION: Model curves describing the retention of ^{238}Pu and ^{239}Pu in dogs exposed to PuO_2 aerosols are shown in Figure 1 for lung and skeleton. The retention of Pu in liver (not shown) was similar to that in skeleton. The biokinetics of the two Pu isotopes were significantly different. Whereas ^{239}Pu was retained in lung and LALN for very long times, ^{238}Pu translocated from the lung mainly to liver and bone at an accelerated rate beginning at about 100 days after exposure. The accumulation of ^{238}Pu in liver and bone was about 200 times larger than that seen with ^{239}Pu .

The observed difference in biokinetics of inhaled ^{238}Pu and ^{239}Pu aerosols has been explained based on the 260-fold difference in specific activity of equivalently sized aerosol particles. The much higher specific-activity $^{238}\text{PuO}_2$ particles incur a proportionately higher amount of energy deposition within the particle itself, particularly from the recoil nuclei. This energy deposition results in damage to the crystalline structure of the PuO_2 , presumably lattice defects that accumulate with time, and that ultimately are expressed in an aqueous environment as fragmentation and accelerated dissolution (8). This theory is supported by autoradiographic observation of particle breakup (8). The dissolved ^{238}Pu was then available for translocation to blood and redistribution to the major deposition sites for systemic Pu, i.e., liver and bone. In contrast, the much lower decay rate of ^{239}Pu has yet to provide concrete evidence that fragmentation of these particles occurs to any significant extent, at least through 3 y after exposure.

The consequences of the different radiation dose patterns found for the two Pu isotopes are shown in Table 1 with respect to the 50-y dose commitments predicted for man, as calculated using the ITRI models and using ICRP 30 methods (5). It can be seen for ^{238}Pu that the highest dose commitments were to the bone surfaces for both methods of calculation, the difference being in the threefold higher dose

Figure 1: Model curves for the uptake and retention of ^{238}Pu and ^{239}Pu in lung and skeleton of dogs that inhaled Pu dioxide aerosols (data points for individual dogs not shown). Retention of Pu in liver was similar to those shown for skeleton.

Table 1
Dose Commitments for Inhaled ^{238}Pu and ^{239}Pu in Man (mSv/Bq inhaled)

Organ	^{238}Pu		^{239}Pu	
	This Report	ICRP 30	This Report	ICRP 30
Lung	0.079	---	0.65	---
Thoracic*	0.085	0.32	1.75	0.32
Liver	0.50	0.18	0.024	0.21
Bone Surface	2.4	0.83	0.019	0.95

* Includes Pu contained in lung and LALN, since ICRP 30 does not differentiate between activity in these two organs

derived from the ITRI model. This is due to the uptake of a larger fraction of inhaled ^{239}Pu that translocates to bone. For ^{239}Pu , there are several significant differences in the calculated dose commitments: 1) The dose to lung calculated with the ITRI model is either twofold or fivefold higher than that calculated using ICRP 30, depending on whether the activities translocated to the LALN are included in the dose calculation for the former. Although the rationale for including LALN activity with that of the lung as seen in the dog studies is speculative, there is evidence in human exposure cases that there is very long-term retention of insoluble Pu in the thoracic region (~6000 days based on thoracic photon measurement (9)), and the ratio of concentration of Pu in lung to that in lymph nodes is significantly larger in man than in dogs (10).

From Table 2, it is evident that the higher dose to bone surfaces for ^{238}Pu based on the ITRI model has resulted in a limiting ALI that is one third that of ICRP 30, i.e. 200 Bq vs. 600 Bq. For ^{239}Pu , the ITRI-derived ALI is either one half or equivalent to that of ICRP 30, depending on the manner in which the dose to lung is calculated. In either case, however, the limiting ALI for the ITRI model is determined by the stochastic ALI, of which most of the dose contribution comes from the dose to lung. This is more consistent with current data on the biokinetics and dosimetry of inhaled $^{239}\text{PuO}_2$ than is the ALI based on the nonstochastic dose to bone

Table 2
Annual Limits on Intake (Bq)

	Stochastic	Nonstochastic		
		Lung	Liver	Bone Surfaces
^{238}Pu				
This Study	450	6300	1000	200
ICRP 30	600	1600	2800	600
^{239}Pu				
This Study	240(630)*	290(770)*	14000	22000
ICRP 30	600	1600	2500	500

* ALIs in boldtype use dose commitments for lung and LANL; those in parentheses use lung only

surfaces. Whether reductions in the ALIs for Pu isotopes are warranted based on the available experimental data is a matter for discussion.

**GAMMA IRRADIATION EFFECTS ON MESENCEPHALIC AND STRIATAL
NERVE CELLS IN CULTURE**

ABSTRACT

Isolated rat mesencephalic and striatal nerve cells were gamma irradiated and cultured during 3 days. Significant increase mortality and neurite length reduction were observed with as little as 0.5 and 0.25 Gy respectively. The dopamine up-take in mesencephalic cells and the GABA up-take in cells of both structures were significantly decreased with 0.25 Gy and more deeply with higher doses. This study gave a threshold value with functions of living cells as target and established dose-effect relationships.

INTRODUCTION

Des embryons et des fœtus humains âgés de 8 à 15 semaines exposés aux radiations émises lors des explosions d'Hiroshima et de Nagasaki présentaient une microcéphalie et des retards mentaux dans l'enfance et leur nombre augmentait avec les doses croissantes reçues (Otake and schull, 1984). Pour les faibles doses (inférieures à 0,5 Gy), le problème de l'existence d'un seuil est posé.

Pour aborder ce point, nous avons utilisé un modèle de cellules nerveuses de rat en culture. plus particulièrement, nous avons étudié les effets de l'irradiation sur les cellules mésencéphaliques, principalement les cellules de la substance noire, ainsi que sur les cellules du striatum (Coffigny and al., 1990). Ces deux structures sont en relation étroite sur le plan fonctionnel.

Trois paramètres sont étudiés sur ces cellules en culture:

- la mort des cellules nerveuses
- la croissance des neurites
- la capture de dopamine (DA) et d'acide gamma-amino-butyrique (GABA).

MATERIEL ET METHODES

La substance noire et le striatum sont prélevés sur des fœtus de rat à 14 jours de gestation. Les cellules nerveuses sont isolées mécaniquement par passages répétés dans une pipette Pasteur à bout rodé à la flamme. Dans une étude préparatoire, nous avons déterminé la concentration cellulaire à ensemercer. Elle est de $4 \cdot 10^4$ cellules/cm² pour mesurer la létalité cellulaire et la croissance des neurites et de $2 \cdot 10^5$ cellules/cm²

pour mesurer la capture de neurotransmetteurs.

Juste après la séparation, les cellules sont soit pseudo-irradiées soit irradiées avec une source de ^{60}Co aux doses de 0,25; 0,50; 0,75; 1,5 et 3 Gy. Elles sont alors mise en culture dans un milieu sans serum pendant trois jours. A ce stade, la survie des cellules nerveuses est estimée par l'exclusion du bleu trypan; le plus long prolongement "axonal" est mesuré sur des microphotographies des cultures cellulaires de striatum; la capture de DA est déterminée sur des cellules mésencéphaliques et celle du GABA sur les deux types cellulaires.

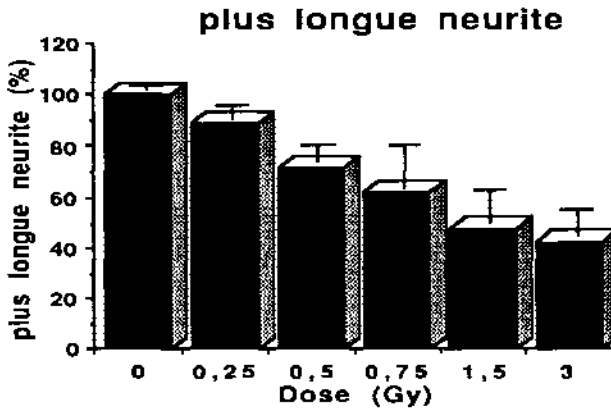

Tous les résultats sont exprimés en pourcentage de la valeur témoin.

RESULTATS

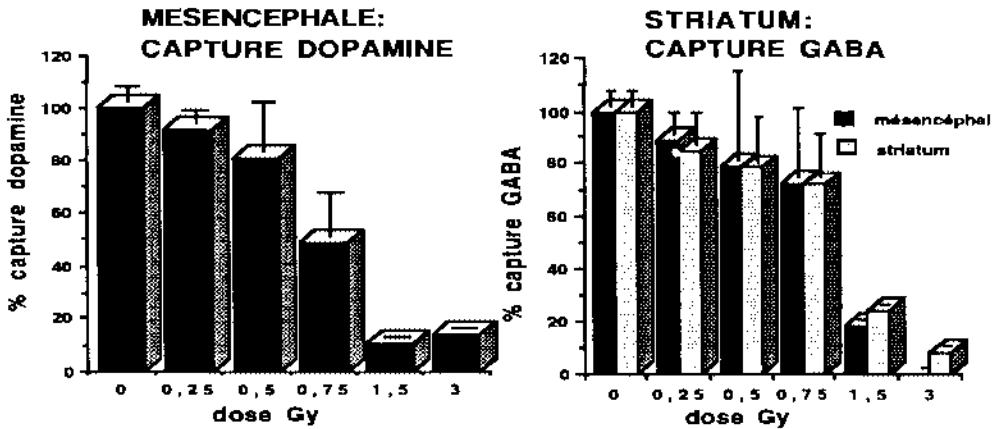

Le pourcentage de cellules vivantes décroît significativement après une exposition de 0,5 Gy et au-delà (figure 1).

Le plus long prolongement des cellules nerveuses est réduit dès la dose de 0,25 Gy (figure 2).

La capture de dopamine par les cellules mésencéphaliques et la capture de GABA par les cellules des 2 structures décroissent significativement avec 0,25 Gy et plus (figure 3 et 3').

Pour tous les paramètres, l'effet est dépendant de la dose.

DISCUSSION

Chez les fœtus de souris, dès 0,1 Gy des perturbations de la migration neuronale (Kamayema, 1986) et des modifications de l'alignement des dendrites dans le cortex (Koner mann, 1986) sont observés chez l'animal devenu adulte. Cependant, ces effets ne sont bien établis qu'avec 0,2 Gy. Nos résultats semblent donc confirmer qu'il y a un seuil aux environs de 0,2 Gy pour provoquer un effet mesurable après irradiation.

Dans l'étude de la survie cellulaire, les cellules striatales sont un peu plus radio-résistantes que les cellules mésencéphaliques. Par contre, lorsque la capture de GABA est le paramètre étudié, les cellules des deux structures ont la même radiosensibilité.

Cette étude associant le test classique de la survie cellulaire à des phénomènes de croissance et de fonction des cellules nerveuses permet d'apprécier la radiosensibilité cellulaire sur différents aspects. Ce type de travail est également développé par l'équipe suédoise de Walinder (Int. J. Radiat. Biol. sous presse) avec des cellules nerveuses cultivées sous forme de sphéroïdes. Cependant, aucun travail sur les effets de l'irradiation sur des cellules nerveuses en culture n'a encore été publié.

Conclusion

La mise au point de ce modèle d'étude in vitro des cellules nerveuses a permis de déterminer un seuil d'effet de l'irradiation gamma à moins de 0,25 Gy. Ce seuil est déterminé à l'aide de paramètres morphologiques et fonctionnels complétant ainsi les études histologiques classiques des autres auteurs. Pour des doses d'irradiation plus fortes l'effet sur ces paramètres est dépendant de la dose reçue.

Cette étude se prolongera par la mesure de la survie

cellulaire et de la croissance des neurites des cellules dopaminergiques et gabaergiques identifiées par immunohistochimie. Ceci permettra de définir si ces deux populations cellulaires sont plus ou moins sensibles à l'irradiation que l'ensemble des cellules nerveuses et donc de savoir si la réduction de la capture est liée à une réduction du nombre des cellules spécifiques ou à une modification de l'affinité des récepteurs et/ou de leur nombre.

TOXICOKINETIC OF 95M TECHNETIUM FOR NEWBORN AND PREGNANT RATS

ABSTRACT

In the future, technetium, a part of nuclear wastes, may increase dose equivalent delivered to members of the public. Technetium toxicokinetic was studied on newborn and pregnant rats. Results indicated concentration of technetium in the skin (95%), the kidney (3,5%) and the thyroid (1%).

INTRODUCTION

Le technétium 99 (^{99}Tc), émetteur bêta, est un produit de fission de l'uranium 235, de l'uranium 238 et du plutonium 239 présent dans les déchets nucléaires. En cas de dispersion dans l'environnement, le pertechnétate de Tc (forme probable de retour à l'homme), pourrait contribuer à l'augmentation des équivalents de dose potentiellement délivrés aux générations futures(2)(7), en raison de sa longue période radioactive (213000 ans). Rappelons que la CIPR fixe une limite annuelle d'incorporation par ingestion à 10^8 Bq pour le Tc, en retenant un coefficient d'absorption intestinal (f1) de 0,8, les organes de rétention étant la thyroïde, le foie et le tractus gastro-intestinal(5). Les références utilisées pour l'élaboration des recommandations de la CIPR(1)(9) laissent apparaître un manque de données expérimentales sur le comportement du Tc dans les divers états physiologiques. Le but de ces expérimentations réalisées à l'aide de ^{95m}Tc , émetteur gamma de période radioactive égale à 61 jours a été de préciser la toxicocinétique de l'élément après ingestion chez le rat nouveau-né, adulte et chez la ratte pendant la gestation et la lactation.

MATERIELS ET METHODES

L'étude toxicocinétique a été réalisée sur des rats Sprague Dawley (OFA, IFFA - CREDO). Une solution saline de pertechnétate de technétium, obtenue au cyclotron de Louvain la Neuve par irradiation de molybdène naturel par des protons de 50 Mev, a été administrée par sonde intragastrique à 8 rats nouveaux-nés (âgés de 6 heures lot1), à 12 mâles (âgés de 3 mois lot2) et à

8 femelles au 2ème jour de gestation (lot3). L'activité des animaux a été déterminée périodiquement par spectrométrie gamma pendant toute la durée des expérimentations (2 mois lot1; 14 jours lot2; 2 mois lot3). Les rats ont été sacrifiés 1, 2 mois (lot1), 1,3,7,14 jours (lot2) et à la fin de la période de lactation (2mois-lot3). Les animaux du lot 2 ont été placés dans des cages à métabolisme. Les reins, le foie, la thyroïde, le tractus gastro-intestinal (débarrassé de son contenu par lavage avec une solution de NaCl à 9%), le pancréas, le coeur, les poumons, le thymus, la rate, la parotide les testicules et les ovaires ont été prélevés et pesés. Des échantillons de peau, de muscle, d'os et de sang ont été effectués. L'activité des échantillons a été déterminée par une sonde à scintillation constituée d'un cristal à iodure de sodium 3"x3", placée au fond d'un puit. Les résultats sont exprimés en pourcentage de l'activité initiale.

RESULTATS

La valeur du coefficient d'absorption gastro-intestinal du Tc95m sous forme de pertechnétate chez le rat adulte après administration intragastrique, a été calculée d'après la formule suivante : (activité rétention + activité urinaire) / (activité totale). Le coefficient d'absorption apparent (le cycle entero-hépatique non pris en compte) est égal à 0,77 le 1er jour. (Tableau II)

La distribution et la rétention du Tc en fonction du temps chez les rats nouveaux-nés et les femelles gestantes sont présentées dans le tableau I. Les activités du sang, de la rate, du coeur, des poumons, des surrénales et de la parotide sont inférieures au seuil de détection. Les organes de rétention au 60ème jour sont selon un ordre décroissant : la peau, les reins, la thyroïde. La rétention globale du Tc suit une loi bi-exponentielle (figure 1). Les activités dans l'urine et dans les fèces chez les adultes sont inférieures à 1% de l'activité initiale 3 jours après administration du Tc. Le rapport entre l'excrétion urinaire et fécale est égale 0.85 après administration intragastrique. (tableau II)

DISCUSSION

La valeur du coefficient d'absorption apparent observés chez les rats adultes valide le choix de 0,8 par la CIPR pour le f1. La rétention globale du Tc chez les nouveaux-nés est inférieure d'un facteur 4 à celle des rattes au 60ème jour : la demi-vie du compartiment long terme est plus courte chez les nouveaux-nés que chez les femelles gestantes. La distribution du ^{95m}Tc est identique chez les nouveaux-nés et les femelles gestantes. L'organe de rétention prédominant est la peau (95% de l'activité totale) dont l'activité élevée peut s'expliquer par une contamination externe par léchage; cependant cette activité persiste dans le temps et s'avère élevée dans la région lombaire, dans une zone où la contamination externe est improbable. Rappelons que Sullivan et al.(9) observent une affinité du Tc pour des protéines du tissu cutané.

TABLEAU I : Distribution du ^{95m}Tc en % de l'activité initiale chez le rat nouveau-né et la femelle gestante suite à une instillation intragastrique.

Jour	NOUVEAU-NE	NOUVEAU-NE	FEMELLE GESTANTE
	30	60	60
Rein	0,416±0,054	0,038±0,008	0,169±0,035
Foie	0,040±0,009	ND	ND
TGI	0,054±0,021	ND	ND
Thyroïde	0,016±0,005	0,003±0,001	0,059±0,016
Peau	8,470±0,650	1,050±0,240	4,553±1,139
Animal	8,995±0,739	1,091±0,249	4,781±1,190

(moyenne ± écart-type de 4 animaux) ND = Non détectable

TABLEAU II Excrétions urinaire et fécale et rétention du ^{95m}Tc chez le rat suite à une instillation intragastrique.

Période de recueil (jours)	% Tc ^{95m} injecté (moyenne ± écart-type)			JOUR	RETENTION
	URINE	FECES			
0-1	31,3 ± 7,4	23,0 ± 7,5		1	45,70 ± 6,12
1-2	4,9 ± 0,3	17,1 ± 1,3			
2-3	1,6 ± 0,2	4,0 ± 0,3		3	18,05 ± 3,58
3-7	0,9 ± 0,2	0,9 ± 0,2		7	16,28 ± 3,44
7-14	0,4 ± 0,1	0,4 ± 0,1		14	15,52 ± 3,01
Total 0-14	39,2 ± 7,7	45,4 ± 5,9			

Figure 1: Rétention du Technétium ^{95m} chez le rat

Les autres organes de rétention sont les reins et la thyroïde. Les résultats pour les organes de rétention concordent avec les données de la littérature(3)(4)(6)(8). Rappelons cependant que l'ICRP ne mentionne pas la peau (5).

CONCLUSION

L'étude de toxicocinétique du ^{95m}Tc sous forme de pertechnétate chez le rat à différents stades physiologiques met en évidence une rétention de Tc variable suivant l'âge, toujours élevée au niveau de la peau, du rein et de la thyroïde ainsi qu'une excrétion rapide et intense. Ces données permettent de recalculer la dose efficace délivrée aux nouveaux-nés. L'évaluation de la dose engagée dans la peau devrait être prise en compte sur le plan sanitaire. Dans cette perspective, des études complémentaires sont à envisager pour localiser les sites de rétention cellulaire et intracellulaire du Tc dans le tissu cutané.

INFLUENCE DU DEBIT DE DOSE ET DE L'AGE A L'IRRADIATION SUR LES EFFETS
CANCEROGENES DU RAYONNEMENT GAMMA CHEZ LE RAT SPRAGUE-DAWLEY.

M. Morin

CEA-CENFAR, DSV-DPTE-STCE
BP n°6, 92265, Fontenay aux Roses Cedex.

EFFECT OF DOSE-RATE AND AGE AT IRRADIATION ON CANCER DEVELOPMENT
IN SPRAGUE-DAWLEY RATS EXPOSED TO GAMMA RAYS.

The probability that rats develop tumors following a 3 Gy exposure to gamma rays from cobalt 60 was observed to depend on age at exposure and on dose rate. Dose rate reduction by a factor of 60 decreased the carcinogenic incidence (mainly carcinomas) by a factor of about 5. Lifetime excess of malignant neoplasia decreased by a factor of about 10 in 9 month-old rats as compared to animals irradiated in utero. The 3 month age group developed slightly fewer cancers than the group irradiated in utero, and tumor location was different. The higher incidence of tumors following in utero exposure was dependent to the high sensitivity of brain and gonads during organogenesis.

INTRODUCTION

L'étude de groupes humains exposés à diverses sources de rayonnement ionisant, accidentelles ou thérapeutiques, a permis d'évaluer un risque d'excès de cancers en relation avec le niveau d'exposition. Les enquêtes épidémiologiques n'ont pas mis en évidence une augmentation du taux de cancers dans les groupes exposés à de faibles doses d'irradiation délivrées de façon chronique à faible débit de dose. L'évaluation du risque pour les faibles débits de dose, résultant d'extrapolations provenant d'observations faites à fortes doses et forts débits, reste incertaine. L'expérimentation animale apparaît indispensable pour vérifier si la diminution du débit de dose entraîne une diminution du risque cancérigène. Les expositions pouvant porter sur des périodes très longues représentant une fraction importante de la durée de vie, il est nécessaire de prendre en compte dans l'estimation du risque l'influence du vieillissement, et donc de l'âge au moment de l'irradiation.

METHODE

Les animaux utilisés sont des rats de souche Sprague-Dawley SPF qui ont été irradiés globalement par le rayonnement gamma d'une source de cobalt 60 à une dose cumulée totale de 2.5 à 3 Gy. Cette dose a été délivrée sur une durée variant de 38 heures à 14 semaines. Les animaux ont été irradiés à des âges différents, depuis le stade fœtal jusqu'à l'âge de 9 mois.

- Une première série, de mâles et femelles, a été irradiée du huitième jour après l'accouplement jusqu'au jour de la naissance (2.66 Gy - 53 mGy/h).

- Une deuxième série, de mâles, a été irradiée à l'âge de 3 mois (3 Gy - 78 cGy/h délivrés en 38 heures).

- Une troisième série, de mâles et femelles, a été irradiée à l'âge de 9 mois (3 Gy - 39 cGy/h pendant 5 jours).

- Enfin, pour étudier le rôle du débit, une quatrième série, de mâles, a été irradiée à l'âge de 3 mois à faible débit de dose (2.83 Gy - 1.34 mGy/h pendant 14 semaines).

Ces animaux ont été comparés à des animaux témoins mâles et femelles.

Les rats ont été surveillés quotidiennement jusqu'à leur mort, et les prélèvements effectués ont été fixés dans du Bouin-Hollande. A l'autopsie, toutes les lésions et tumeurs ont été prélevées ainsi qu'un certain nombre d'organes (poumons, cerveau, rein, foie, rate, thyroïde, hypophyse). L'examen anatomopathologique a été effectué sur des coupes de 5 microns après coloration à l'hémalum-éosine-safran.

RESULTATS

- Effets sur la durée de vie (tableau 1):

	sexe	nombre	dose (Gy)	débit (mGy/h)	âge (jours) début irradiation	durée de vie (jours)
témoins	M	785				833 ± 126
	F	120				750 ± 130
série 1	M	66	2.66	53	- 15	737 ± 151
	F	65	2.66	53	- 15	765 ± 131
série 2	M	120	3	78	90	738 ± 160
série 3	M	120	3	39	280	755 ± 138
	F	60	3	39	280	698 ± 126
série 4	M	304	2.83	1.34	90	726 ± 160

La durée de vie des rats a été diminuée par l'irradiation, mais ni l'âge au début de l'exposition ni le débit de dose n'ont eu d'influence sur la longévité des animaux.

- Effets sur l'incidence tumorale (Fig. 1 et 2) et tableau 2:

	Cancers en excès par rapport aux témoins (%)					
	Fœtus		3 mois	3 mois faible débit	9 mois	
	M	F	M	M	M	F
Total	46.6	82.2	43.7	20.6	5.2	- 1.4
Carcinomes sans THS*	18.8	60.3	18.9	3.3	3.9	- 1.6
Sarcomes sans cerveau	7.4	0.5	14.9	15.4	8.9	6.0
THS*	8.4	9.1	9.9	- 3.3	- 7.7	+ 5.8
Cerveau	12.0	12.3	-	5.2	0.1	0

*THS : Thyroïde, Hypophyse, Surrénales

1) Les carcinomes

Les tumeurs de la thyroïde, de l'hypophyse et des surrénales, organes endocrines dont l'évolution dépend plus du mode de vie que de l'exposition aux rayonnements et pour lesquels aucune relation dose-effet n'est

évidente, ont été considérées séparément. On a observé de la même façon dans la population humaine que le taux de cancers de la thyroïde était une variable non contrôlable.

La diminution du débit de dose a réduit l'incidence des carcinomes, et en particulier des poumons (d'un facteur 3), de la peau et des reins (d'un facteur 8).

C'est chez les rats irradiés à l'âge le plus avancé que l'excès de carcinomes par rapport aux témoins s'est avéré le plus faible.

Un excès significatif de cancers des organes reproducteurs a été observé chez les rats irradiés à l'état fœtal, en particulier chez les femelles dont les ovaires ont été particulièrement radiosensibles pendant l'organogenèse. L'excès de cancers des organes reproducteurs était de: 51.2% pour les femelles et de 5.6% pour les mâles dans la série des fœtus irradiés; aucun excès de cancers des gonades n'a été vu chez les animaux irradiés à 3 mois ou à 9 mois.

2) Les sarcomes

Le cerveau s'est révélé être très radiosensible pendant la période fœtale, alors qu'aucun excès de tumeurs cérébrales n'était observé chez les animaux irradiés à 9 mois. Le cerveau ayant été analysé de façon non systématique dans une des séries (3 Gy - 78 mGy/h), nous avons exclu la donnée pour cette série.

Les sarcomes, autres que cérébraux, ont été peu sensibles à l'influence de l'âge et du débit de dose.

DISCUSSION

- Rôle relatif de l'âge et du débit de dose.

L'action de ces deux facteurs est différente selon que l'on considère les carcinomes ou les sarcomes. L'augmentation de l'âge et la diminution du débit de dose ont agi, dans le même sens, en diminuant l'incidence des carcinomes, l'influence du débit semblant prépondérante.

En ce qui concerne les sarcomes, les variations de débit ont peu modifié l'incidence des tumeurs alors que l'augmentation de l'âge diminuait l'induction tumorale.

Une diminution du débit de dose d'un facteur 60 a réduit l'excès de carcinomes d'un facteur supérieur à 5.

Pour une même dose absorbée et un débit de dose équivalent, l'excès de cancers chez les mâles a été diminué d'un facteur 9 chez les rats irradiés à 9 mois par rapport aux rats irradiés en période fœtale; chez les femelles, le facteur de diminution entre ces deux séries apparaissait plus important en raison de l'incidence de cancers ovariens, élevée chez les fœtus et nulle chez les rates de 9 mois.

Dans la série irradiée à l'état fœtal, l'excès de cancers est dû essentiellement à la grande radiosensibilité du système nerveux central et des organes reproducteurs au moment de leur organogenèse.

CONCLUSION

Ces expériences ont montré que l'âge et le débit de dose avaient, selon les tissus et les types histologiques concernés, une influence complexe sur la cancérogenèse après irradiation. Le choix d'utiliser un seul facteur d'atténuation, pour passer des résultats des expositions à fort débit de dose à l'estimation du risque des expositions chroniques à faible dose et faible débit, ne peut conduire qu'à des approximations dont la justification est discutable.

COMPARISON OF THE EFFECTS OF INHALED $^{239}\text{PuO}_2$ AND β -EMITTING
RADIONUCLIDES ON THE INCIDENCE OF LUNG CARCINOMAS IN
LABORATORY ANIMALS

ABSTRACT: The health effects of inhaling radioactive particles when the lung is the primary organ irradiated were studied in rats and dogs. The animals were exposed to aerosols of $^{239}\text{PuO}_2$ or fission-product radionuclides in insoluble forms and observed for their life span. Lung carcinomas were the primary late-occurring effect. The incidence rate for lung carcinomas was modeled using a proportional hazard rate model. Linear functions predominated below 5 Gy to the lung. The life-time risk for lung carcinomas per 10^4 Gy for beta emitters was 60 for rats and 65 for dogs, and for $^{239}\text{PuO}_2$ it was 1500 for rats and 2300 for dogs.

INTRODUCTION: Irradiation of the lung in sufficiently high doses is known to result in lung carcinomas. This result has been demonstrated in populations of patients with ankylosing spondylosis treated with thoracic irradiation, in survivors of atomic bomb explosions in Japan, and underground miners exposed to radon and radon daughter products. None of these situations, however, directly applies to chronic alpha or beta irradiation of the deep, or alveolar, portions of the lung. Such can occur if individuals inhale radioactive particles such as might be released in reactor accidents or waste transportation accidents. No human populations are available for study that have inhaled particles of alpha- or beta-emitting radionuclides which deposit deep in the lung. To address this situation, studies were initiated at the Inhalation Toxicology Research Institute to establish the dose-response relationships resulting from the inhalation of plutonium dioxide or beta-emitting radionuclides with different radioactive half-lives. This paper briefly summarizes the dose-response for lung carcinomas induced by these types of lung irradiation.

METHODS: Details of the experimental design, animal exposure, dosimetry, and husbandry techniques have been reported.¹⁻³ Beagle dogs were exposed briefly, per nasum, to aerosols of $^{239}\text{PuO}_2$ of different monodisperse particle size or ^{90}Y , ^{91}Y , ^{144}Ce or ^{90}Sr in relatively insoluble forms. F344 rats were similarly exposed but only to $^{239}\text{PuO}_2$ or $^{144}\text{CeO}_2$. The animals were observed for their life spans for resulting biologic effects. At present, all animals have died, except for some of the dogs exposed to $^{239}\text{PuO}_2$. The incidence rate for lung carcinomas was modeled as the observed time course for the appearance of carcinomas using a proportional hazard rate model. The proportional hazards calculation of relative and absolute risks was made using the following relationships:

$$\text{Proportional hazards: } \lambda(t) = \lambda_0(t)(1 + \beta D(t)).$$

In this relationship, $\lambda(t)$ is the age-specific lung tumor incidence rate at dose $D(t)$, $\lambda_0(t)$ is the background lung tumor incidence rate, β is the relative risk coefficient, and $D(t)$ is the

time-dependent, cumulative absorbed dose to the lung. The relative and lifetime absolute risks are:

$$\text{Relative risk per Gy} = \beta$$

$$\text{Lifetime risk per Gy} = \frac{1}{D(t)} \int_0^t S(\tau) (\lambda(\tau) - \lambda_0(\tau)) d\tau,$$

where $S(\tau)$ is the fractional survival at time τ . This method is similar to the techniques used in the BEIR IV and BEIR V models of risk analysis.

RESULTS: The biological effects of these exposures have been documented elsewhere.³⁻⁶ Briefly, at the highest doses, animals died within months to 3 years with pulmonary injury. Those living longer (rats > 1 yr, dogs > 2 yr) developed a high incidence of lung tumors. Table 1 gives the total number of lung tumors seen, the relative distribution of tumor types for each species and the types of radiation.

TABLE 1

Distribution (%) of Lung Tumor Types in Animals that Inhaled Radionuclides and Were Observed for Life Span

LUNG TUMOR TYPE	RATS		DOGS	
	α -emitters	β -emitters	α -emitters	β -emitters
(# of Tumors)	(172)	(24)	(108)	(110)
Adenoma	9	13	1	2
Adenocarcinoma	70	62	96	59
Squamous Cell Carcinoma	19	21	1	9
Hemangiosarcoma	1	4	0	25
Other Sarcomas	1	0	2	5

The predominant tumor types were adenocarcinomas and squamous cell carcinomas for rats and for dogs, adenocarcinomas and hemangiosarcomas. The hemangiosarcomas and other sarcomas are unusual tumors and occurred at higher doses. The dose-response analyses are based on the carcinoma incidences.

For dogs, the relative risk was estimated by summing a linear function of dose and a power function of dose. The power function applies to the higher doses and the linear function of dose predominates over the power function at doses below 5 Gy for beta irradiation and 0.5 Gy for alpha irradiation (Fig. 1).

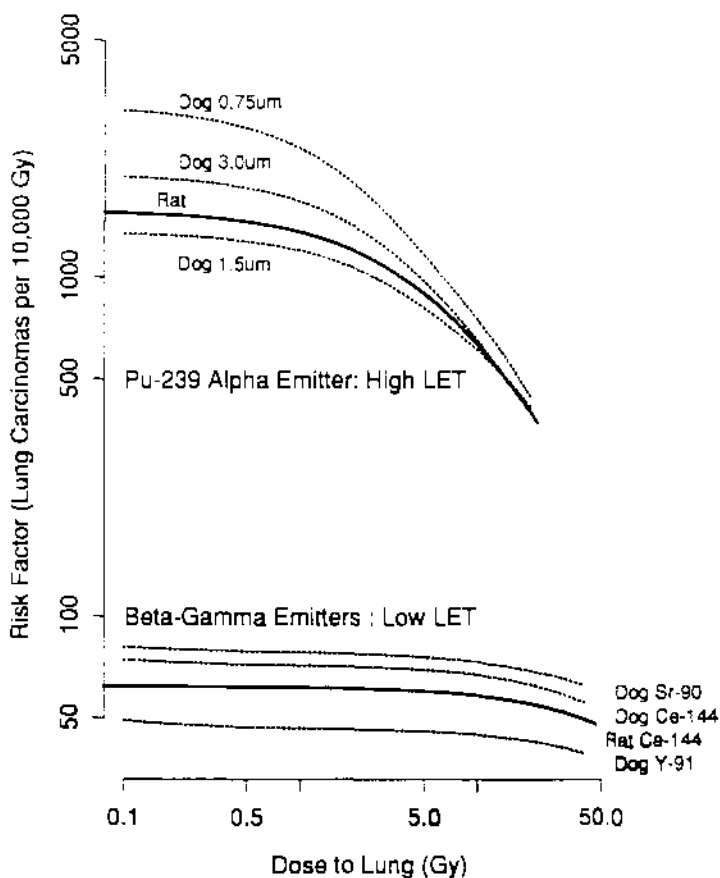

FIGURE 1 - Risk factors for lung carcinomas in dogs and rats that inhaled $^{239}\text{PuO}_2$ or beta-emitting radionuclides.

These analysis show a reasonable agreement between the life-time risks for lung carcinomas for rats and dogs for both alpha- and beta-emitting radionuclides.

Lifetime risks of lung carcinomas were calculated by integrating, over the life-time, the sum of the estimated lung carcinoma incidence rate at 1 Gy from the proportional hazard rate model and the mortality rate for competing causes of death in the control animals. The dose of 1 Gy was used because it did not cause an increase in competing causes of death. The lifetime risks of lung carcinomas per 10^4 Gy for beta-emitting radionuclides were 60 for rats and 65 for dogs. For $^{239}\text{PuO}_2$ the lifetime risk was 1520 for rats and 2300 for dogs. The ratio of $^{239}\text{PuO}_2$ risk to beta-emitter risk is 25 for rats and 36 for dogs. Although those ratios are higher than the presently accepted quality factor of 20 for alpha and x-irradiation, the uncertainties in this analysis would not exclude a value of 20. On the other hand, the results may indicate that the quality factor of 20 is too low for comparing radiation-induced lung carcinoma incidence of alpha irradiation with that of beta irradiation.

IMPROVEMENTS IN LUNG LAVAGE TO INCREASE ITS EFFECTIVENESS IN REMOVING INHALED RADIONUCLIDES

B.A. Muggenburg, R.A. Guilmette, L.M. Romero,
and J.A. Mewhinney

Inhalation Toxicology Research Institute
Albuquerque, New Mexico, USA

ABSTRACT: Lung lavage has been shown to be an effective method to remove insoluble radionuclides deposited and retained in the lung, but the treatment has been limited to the effective removal of only about 50% of the retained material. Reported here is a change in lavage technique that slightly increases the effectiveness and the addition of high-frequency chest wall oscillation. The latter increased the effectiveness of the lavage procedure but also caused significant physiological complications.

INTRODUCTION: Radioactive particles in relatively insoluble forms inhaled and deposited in the lung will be retained for long periods of time¹. For radionuclides with long physical half-lives, such as plutonium, this will result in the chronic irradiation of the lung (and lung associated lymph nodes) and the potential development of health effects. Decorporation of insoluble particles from the lung is limited at this time to lung lavage². Lung lavage has been shown to be effective in removing a variety of radioactive particles, but its efficiency, even with multiple procedures is approximately 50%². Improvements in the lung lavage procedure are needed to increase its efficacy. This study evaluated two changes in the procedure, the use of a single lumen endotracheal tube³ in place of the double lumen tube previously reported⁴, and the use of high-frequency chest wall oscillation (HFCWO). Both of these techniques improved the efficacy of the lavage treatment, but the use of the HFCWO induced some serious physiological complications.

METHODS: These studies were conducted in adult male and female beagles. The aerosol in the first study was ²³⁹PuO₂ heat-treated at 850° C, obtained as a powder from a commercial V-blending process. The dogs briefly inhaled the aerosol per nasi. The tissue content at death and the amount of ²³⁹Pu excreted and in the recovered lung lavage fluid was determined by radiochemical methods⁵. These values were used to reconstruct the initial pulmonary burden of ²³⁹Pu and the amount of ²³⁹Pu removed by lavage. In the second study, with the HFCWO, the aerosol was ⁸⁵Sr fused in aluminosilicate particles. The IPB of ⁸⁵Sr was determined by whole-body counting. The excreta and recovered lung lavage fluids were also assayed for ⁸⁵Sr activity.

In both studies, the lung lavage procedure employed the use of a single-lumen endotracheal tube as previously described³. Briefly, the dogs were anesthetized with halothane, an endotracheal tube placed in the trachea, and a T-tube connected to the end of the endotracheal tube. One end of the T-tube was connected to the anesthetic circuit to maintain anesthesia and for manual ventilation of the dog. The other end of the T-tube was connected by latex tubing to the lavage apparatus, which was simply a container of normal saline at room temperature suspended approximately 60 to 80 cm above the dog. A second T-tube was used in the lavage tubing to extend a latex tube to the floor to drain the recovered lavage fluid into a vessel. Clamps on the tubing were used to direct the flow of fluid or to permit

only the anesthetic/oxygen gas to reach the dog. Once the lavage apparatus was connected, the dog was manually ventilated for approximately 3 minutes to induce apnea, then placed on the table with the side to be lavaged in the down position, and a volume of saline equal to 40% of the estimated residual functional capacity was instilled in the lung. This fluid was then drained out of the lung into the vessel on the floor. Apnea, induced by several minutes of manual ventilation was repeated and then another wash was done. This procedure was repeated until 4 to 5 L of saline was used.

In the first experiment with $^{239}\text{PuO}_2$, the dogs were lavaged, alternating the right and left lung in each procedure on days 2 (both lungs were done), 7, 10, 14, 21, 28,35, 42, and 49 after inhalation exposure. There were two groups of dogs, a control group (2 dogs) and a lung lavage treated group (3 dogs). The dogs were euthanized 64 days after exposure by the intravenous injection of sodium pentobarbital to deep surgical anesthesia followed by exsanguination.

In the second experiment, a single lavage procedure was done on day 7 in which both lungs were lavaged. There were 4 groups of 2 dogs each in this study; 1) controls, 2) lung lavage only, 3) HFCWO simultaneous with lavage, and 4) HFCWO before lavage. The device used to perform HFCWO has been described⁶. It was operated at 13 Hz with a symmetric sine-wave input. The transducer was coupled to the dependant chest wall such that the middle of the device was at the midpoint of the rib cage. Two regimens of HFCWO therapy were followed. For group 3, HFCWO was administered during the time the lavage fluid was present in the lung but not during drainage or instillation of the fluid. Treatment time was approximately 30 minutes. Group 4 was treated for a 30 minute period just before the lung lavage was done. The dogs were euthanized 10 days after inhalation exposure.

RESULTS AND DISCUSSION: The distribution of $^{239}\text{PuO}_2$ in the excreta, lavage fluid, and tissues of the dogs that inhaled plutonium in the first experiment are shown in Table 1. The untreated controls had 70% of the initial lung burden in the lung at 64 days after exposure compared to 13% in the treated dogs. In the control dogs, most of the other plutonium was excreted in the feces with only about 5% being in other tissues. In the treated dogs, 66% of the IPB was removed in the lavage fluid, and, like the controls, the remainder was in the feces with about 5% in other tissues.

Table 1
Plutonium Activity in Excreta, Lavage Fluid, and Tissues of Dogs 64 Days
after Inhalation of $^{239}\text{PuO}_2$ with or without Lung Lavage

Group	No. of Dogs	Percent Initial Pulmonary Burden					
		Feces	Urine	Lavage Fluid	Lung	Liver	Skeleton
Control	2	24	0.1	-	70	0.01	ND
Treated	3	15	0.3	66	13	0.04	0.4

ND=not detected

In a previous study in dogs (n = 12) that inhaled $^{239}\text{PuO}_2$ in which a double lumen endotracheal tube method of lavage was used, the amount of plutonium removed by lung

lavage was approximately 44% of the IPB, with about 30% of the IPB remaining in the lung, 22% in the feces, and about 4% in other tissues at 64 days after inhalation of the plutonium aerosols⁷. A comparison of these similar studies suggests that the single lumen endotracheal tube method for lung lavage may be more effective than the double lumen tube method in removing radioactive particles from the lung. A possible increase in efficacy of nearly 20% is a significant improvement in the method; however, we must interpret this information cautiously because of the few numbers of animals involved and because the studies were not designed for direct comparison.

In the second study in which HFCWO was used, 85% of the IPB was in the lung of the control dogs at 10 days after inhalation of ⁸⁵Sr in fused aluminosilicate particles (Table 2). For the dogs that were treated only by lung lavage, the lung burden was 51% of the IPB and 44% was removed in the lavage fluid. The amount removed by lavage from these 2 dogs was higher than would be expected with only a single lavage procedure. Based on the study cited above, in which dogs inhaled ²³⁹PuO₂ and were treated with lavage, about 32% of the IPB would be expected to be removed in the first lavage of both lungs⁷. The third group, which also received HFCWO during the lavage procedure, had 34% of the IPB in the lung and 61% of the ⁸⁵Sr was removed by lavage. The last group, in which HFCWO was given before the lavage procedure, had 62% of the IPB in the lung and 32% removed in the lavage fluid. These results suggest that HFCWO during lavage, that is while the fluid is in the lung, does improve the effectiveness of the procedure. HFCWO performed before fluid was in the lung did not change the amount of radioactivity removed and appeared to be ineffective.

Table 2
⁸⁵Sr Activity in Excreta, Lavage Fluid, and Tissues for Dogs 10 Days after Inhalation of ⁸⁵Sr in Fused Aluminosilicate Particles and Treated with Lung Lavage and High Frequency Chest Wall Oscillation (HFCWO)

Group	No. of Dogs	Percent Initial Pulmonary Burden					
		Feces	Urine	Lavage Fluid	Lung	Liver	Skeleton
Control	2	9.8	2.2	-	84	ND	1
Lavage only	2	2.6	0.5	44	51	ND	0.5
Lavage with HFCWO	2	2.4	0.8	61	34	ND	0.7
HFCWO before lavage	2	2.2	1.2	32	62	ND	0.5

ND=not detected

The results from the lavage with HFCWO would have been very encouraging except for the accompanying pathophysiological sequelae. One dog from the group treated with lavage and HFCWO and one dog from the group that was treated with HFCWO before lavage died within 48 hours of the procedure from acute traumatic pneumonitis and pulmonary edema. The other 4 dogs from the groups treated with HFCWO and lavage had lung lesions at sacrifice, 72 hours after treatment, of inflammatory cell infiltrate and thickened alveolar septae with fibrin strands. Few indications of pulmonary edema remained.

These pathological effects were not expected because previous studies in dogs that employed either of the techniques did not result in significant damage to the lung. It appears, however, that the combination of treatments occurring close together in time produces very significant lung injury and therefore cannot be recommended at this time.

In summary, the lung lavage procedure using a single lumen endotracheal tube appears to remove radioactive particles from the lung more effectively than does the technique using a double-lumen tube. The increase in effectiveness may be as much as 50%. The HFCWO during lavage did improve the removal of radioactive materials from the lung, but serious lung injury occurred. Lung injury was not expected because previous studies with both of these techniques separately in dogs did not result in significant lung injury. The results from the studies with lavage and HFCWO were encouraging, but it is obvious that considerable work is needed to determine if a useful method can be developed.

EFFECTS OF A WHOLE BODY GAMMA IRRADIATION ON GABA REPARTITION IN INFANT RATS CEREBELLUM AND HIPPOCAMPAL FORMATION.

Thirteen-day-old rats were exposed to a single dose of 4 or 0,5 Gy of gamma at a dose rate of 0,25 Gy/min and were killed about 5h after. Fixation was achieved in situ using glutaraldehyde. For GABA immunocytochemistry transversal sections were incubated with antiserum against GABA, then with PAP and revealed with diaminobenzidine.

Proliferative layers are still observed in the infant rat cerebellum (external granular layer) and hippocampal formation (subgranular layer of the dentate gyrus). When irradiation occurs a high percent of these two layers cells are pycnotic.

In the normal cerebellum, no immunostaining is observed in external granular layer cell bodies. The only labelled structures are few cytoplasmic expansions coming from subjacent layers. When irradiated, a strong GABA staining appears around pycnotic cells as a network with labelled meshes. GABA staining and pycnotic cells were more especially important when the irradiation increases. Further studies are needed to specify the nature of labelled meshes.

In the normal hippocampal formation, subgranular cells are not GABA stained. Staining occurs in cells which are not granule cells. They are scattered throughout cell layers of the dentate gyrus with predominance in the hilus. After irradiation, GABA repartition is not modified.

After a 4 Gy whole body gamma irradiation, the inhibitory GABA system is not injured. Other amino-acid neurotransmitters such as Glutamate could be modified.

GUIDELINES FOR EXPOSURE TO SUB-RADIOFREQUENCY ELECTRIC AND MAGNETIC FIELDS

David H. Sliney¹ and Robert M. Patterson²

¹Laser Microwave Division, US Army Environmental Hygiene Agency, Aberdeen Proving Ground, MD 21010-5422, USA ²College of Engineering, Temple University, Philadelphia, PA 19122, USA

Introduction

The International Non-Ionizing Radiation Committee (INIRC) of IRPA and the American Conference of Governmental Industrial Hygienists (ACGIH) have recommended guidelines for exposure limits (ELs) for sub-radiofrequency (sub-RF, defined as 30 kHz and less) electric and magnetic fields. The ACGIH refers to ELs as "Threshold Limit Values," or TLVs, and limits its guidance to the workplace.

Separate ELs are established for the electric and magnetic components of sub-RF electromagnetic fields because exposures of practical interest occur in the "near zone," where the two components behave independently.

Background

The SI unit for the electric field strength, E , is the volt per meter, V/m, while the magnetic flux density, B , is described by the tesla (T). The background static electric field is about 130 V/m, while oscillating fields range up to about 1000 V/m (20 kV/m during thunderstorms) with frequencies up to about 1000 Hz. Amplitudes generally decrease with increasing frequency. The typical atmospheric field at 50-60 Hz is only about 10^{-4} V/m.⁽¹⁾ Man produces sub-RF fields primarily from electric power generation, transmission, and use. Fields are typically about 10 kV/m directly under the conducting wires of transmission lines and 1 or 2 kV/m at the edge of the line right-of-way. By contrast, electric fields from building wiring and electrical appliances typically range only up to 100 V/m. Visual display terminals (VDTs) can produce fields of about 10 V/m or less at 10-15 kHz, due to the high-voltage circuit flyback transformer.⁽⁵⁾

The earth's static magnetic field is about 50 μ T. Power-frequency flux densities of about 10 μ T can occur very near electrical appliances. The home has levels of about 0.1 μ T. Some occupational environments, such as those where induction heaters are in use, may have flux densities of 10-100 mT.

Dosimetry and Measurement

Guidance on measuring power-frequency fields has been developed.⁽⁷⁾ Portable monitors, from simple spot measuring devices to dosimetric devices with on-board computers, are finding increasing use in epidemiologic studies.

Field Effects in Man

Sub-RF electric fields can induce fields and currents within the body. Hair vibration or other sensory stimuli may occur in fields greater than 10 kV/m. Currents induced in metal structures may produce shocks when humans contact the structure and permit a path to ground.

A grounded person in an electric field experiences a short-circuit current of approximately $I = 15 \times 10^{-8} f W^{2/3} E_0$, where I is in μA , f is the frequency in Hz, W is the weight in grams, and E_0 is the electric field strength in V/m.⁽⁶⁾ Thus, a 70 kg person would have a total short-circuit current of about 153 μA in a 10 kV/m, 60-Hz field. Studies of models indicate that current densities induced in a grounded, erect person exposed to a 10 kV/m, 60-Hz vertical electric field are 0.55 $\mu\text{A}/\text{cm}^2$ through the neck and 2 $\mu\text{A}/\text{cm}^2$ through the ankles.

Time-varying magnetic fields induce electric currents directly as the magnetic flux density and the frequency of oscillation, and inversely as the radius of the current loop. The current density at the perimeter of an adult torso can be approximated by $J = 0.24 f B_0$, where J is in A/m^2 , f is in Hz, and B_0 is in T. The maximum current density induced by normal residential field levels is thus of the order of 1 $\mu\text{A}/\text{m}^2$.

Biological Effects

Biological effects from sub-RF electric and magnetic fields have been demonstrated by in vitro and in vivo laboratory studies. However, no convincing studies have demonstrated adverse health effects. Moreover, a great many studies have led to findings of no effects. The many excellent reviews⁽¹⁻⁴⁾ offer a comprehensive discussion.

Human Studies

Occupational health effects of electric fields have been studied mainly in electric utility workers. Again, the references⁽¹⁻⁴⁾ contain excellent summaries of these.

A number of epidemiologic studies have identified an increased risk of cancer among those employed in "electrical occupations," such as electricians, engineers, or radio repairmen. The associations were not consistent among the studies, which often involved small numbers of cases.⁽¹⁾ Other deficiencies of these studies are stated in the report.

A more recent review⁽⁹⁾ considered eleven separate studies of electrical workers. The most consistent finding was a small increase in the risk of leukemia. The authors warned that the results are equivocal with respect to cause, because electrical workers are also exposed to agents besides fields, some of which may be leukemogenic. In contrast, a case-control study of deaths due to primary brain cancer or leukemia found an increased risk of brain cancer but no

increased risk of leukemia among electrical workers.⁽¹⁰⁾

Occupational studies are underway now (1992) in the U.S., Canada, and other countries. Results will become available over the next few years.

The Basis for Exposure Guidelines

Although there is little hard evidence for adverse effects from sub-RF fields, the growing concerns of workers and the public have prompted both INIRC and ACGIH to set guidelines.

Both groups developed guidance by limiting induced current densities in the body to levels that occur normally, i.e., up to about 10 mA/m² (higher levels can also occur naturally in the heart). Certain biological effects have been demonstrated in laboratory studies at field strengths below those permitted by the exposure guidelines; however, there is no convincing evidence now that occupational exposure to these field levels leads to adverse health effects.⁽²⁾

The INIRC Guideline ELs

The INIRC recommended electric field exposure limits of 10 kV/m for a whole working day with a short-term limit of 30 kV/m.⁽⁸⁾ Interim times and field strengths are related by the formula, $t = 80/E$, where t is in hours and E is in kV/m. The limits for magnetic flux density for occupational exposure were set at 0.5 mT for the entire workday, 5 mT for exposures of two hours or less, and 25 mT for exposure to limbs.

The ACGIH TLVs

The ACGIH TLV⁽¹¹⁾ for occupational exposure to sub-RF electric fields limits exposure to 25 kV/m for frequencies from 0 Hz to 100 Hz. For frequencies of 100 Hz to 4 KHz, the TLV is given by

$$E_{TLV} = 2.5 \times 10^6 / f \quad (\text{V/m, r.m.s.})$$

where f is in Hz. A limit of 625 V/m applies to frequencies from 4 kHz to 30 kHz. Because electromagnetic interference may occur in some models of heart pacemaker in power-frequency electric fields as low as 2 kV/m, exposures of workers with pacemakers are limited to 1 kV/m.

The TLV for sub-RF magnetic fields was revised in 1992 to be in consonance with the American National Standards Institute at frequencies above 300 Hz. For fields from 1 to 300 Hz, routine occupational exposure is limited to

$$B_{TLV} = 60 / f \quad (\text{mT, r.m.s.})$$

where f is the frequency in Hz. The TLV at 60 Hz is thus 1 mT. For frequencies from 300 Hz to 30 kHz, the TLV is 0.2 mT, which corresponds to a magnetic field strength of 163 A/m.

Below 1 Hz, the TLV is 60 mT.

GUIDELINES FOR EXPOSURE TO SUB-RADIOFREQUENCY ELECTRIC AND MAGNETIC FIELDS

David H. Sliney¹ and Robert M. Patterson²

¹Laser Microwave Division, US Army Environmental Hygiene Agency, Aberdeen Proving Ground, MD 21010-5422, USA ²College of Engineering, Temple University, Philadelphia, PA 19122, USA

Introduction

The International Non-Ionizing Radiation Committee (INIRC) of IRPA and the American Conference of Governmental Industrial Hygienists (ACGIH) have recommended guidelines for exposure limits (ELs) for sub-radiofrequency (sub-RF, defined as 30 kHz and less) electric and magnetic fields. The ACGIH refers to ELs as "Threshold Limit Values," or TLVs, and limits its guidance to the workplace.

Separate ELs are established for the electric and magnetic components of sub-RF electromagnetic fields because exposures of practical interest occur in the "near zone," where the two components behave independently.

Background

The SI unit for the electric field strength, E , is the volt per meter, V/m, while the magnetic flux density, B , is described by the tesla (T). The background static electric field is about 130 V/m, while oscillating fields range up to about 1000 V/m (20 kV/m during thunderstorms) with frequencies up to about 1000 Hz. Amplitudes generally decrease with increasing frequency. The typical atmospheric field at 50-60 Hz is only about 10^{-4} V/m.⁽¹⁾ Man produces sub-RF fields primarily from electric power generation, transmission, and use. Fields are typically about 10 kV/m directly under the conducting wires of transmission lines and 1 or 2 kV/m at the edge of the line right-of-way. By contrast, electric fields from building wiring and electrical appliances typically range only up to 100 V/m. Visual display terminals (VDTs) can produce fields of about 10 V/m or less at 10-15 kHz, due to the high-voltage circuit flyback transformer.⁽⁵⁾

The earth's static magnetic field is about 50 μ T. Power-frequency flux densities of about 10 μ T can occur very near electrical appliances. The home has levels of about 0.1 μ T. Some occupational environments, such as those where induction heaters are in use, may have flux densities of 10-100 mT.

Dosimetry and Measurement

Guidance on measuring power-frequency fields has been developed.⁽⁷⁾ Portable monitors, from simple spot measuring devices to dosimetric devices with on-board computers, are finding increasing use in epidemiologic studies.

Field Effects in Man

Sub-RF electric fields can induce fields and currents within the body. Hair vibration or other sensory stimuli may occur in fields greater than 10 kV/m. Currents induced in metal structures may produce shocks when humans contact the structure and permit a path to ground.

A grounded person in an electric field experiences a short-circuit current of approximately $I = 15 \times 10^{-8} f W^{2/3} E_0$, where I is in μA , f is the frequency in Hz, W is the weight in grams, and E_0 is the electric field strength in V/m.⁽⁶⁾ Thus, a 70 kg person would have a total short-circuit current of about 153 μA in a 10 kV/m, 60-Hz field. Studies of models indicate that current densities induced in a grounded, erect person exposed to a 10 kV/m, 60-Hz vertical electric field are 0.55 $\mu\text{A}/\text{cm}^2$ through the neck and 2 $\mu\text{A}/\text{cm}^2$ through the ankles.

Time-varying magnetic fields induce electric currents directly as the magnetic flux density and the frequency of oscillation, and inversely as the radius of the current loop. The current density at the perimeter of an adult torso can be approximated by $J = 0.24 f B_0$, where J is in A/m^2 , f is in Hz, and B_0 is in T. The maximum current density induced by normal residential field levels is thus of the order of 1 $\mu\text{A}/\text{m}^2$.

Biological Effects

Biological effects from sub-RF electric and magnetic fields have been demonstrated by in vitro and in vivo laboratory studies. However, no convincing studies have demonstrated adverse health effects. Moreover, a great many studies have led to findings of no effects. The many excellent reviews⁽¹⁻⁴⁾ offer a comprehensive discussion.

Human Studies

Occupational health effects of electric fields have been studied mainly in electric utility workers. Again, the references⁽¹⁻⁴⁾ contain excellent summaries of these.

A number of epidemiologic studies have identified an increased risk of cancer among those employed in "electrical occupations," such as electricians, engineers, or radio repairmen. The associations were not consistent among the studies, which often involved small numbers of cases.⁽¹⁾ Other deficiencies of these studies are stated in the report.

A more recent review⁽⁹⁾ considered eleven separate studies of electrical workers. The most consistent finding was a small increase in the risk of leukemia. The authors warned that the results are equivocal with respect to cause, because electrical workers are also exposed to agents besides fields, some of which may be leukemogenic. In contrast, a case-control study of deaths due to primary brain cancer or leukemia found an increased risk of brain cancer but no

increased risk of leukemia among electrical workers.⁽¹⁰⁾

Occupational studies are underway now (1992) in the U.S., Canada, and other countries. Results will become available over the next few years.

The Basis for Exposure Guidelines

Although there is little hard evidence for adverse effects from sub-RF fields, the growing concerns of workers and the public have prompted both INIRC and ACGIH to set guidelines.

Both groups developed guidance by limiting induced current densities in the body to levels that occur normally, i.e., up to about 10 mA/m² (higher levels can also occur naturally in the heart). Certain biological effects have been demonstrated in laboratory studies at field strengths below those permitted by the exposure guidelines; however, there is no convincing evidence now that occupational exposure to these field levels leads to adverse health effects.⁽²⁾

The INIRC Guideline ELs

The INIRC recommended electric field exposure limits of 10 kV/m for a whole working day with a short-term limit of 30 kV/m.⁽⁸⁾ Interim times and field strengths are related by the formula, $t = 80/E$, where t is in hours and E is in kV/m. The limits for magnetic flux density for occupational exposure were set at 0.5 mT for the entire workday, 5 mT for exposures of two hours or less, and 25 mT for exposure to limbs.

The ACGIH TLVs

The ACGIH TLV⁽¹¹⁾ for occupational exposure to sub-RF electric fields limits exposure to 25 kV/m for frequencies from 0 Hz to 100 Hz. For frequencies of 100 Hz to 4 KHz, the TLV is given by

$$E_{TLV} = 2.5 \times 10^6 / f \quad (\text{V/m, r.m.s.})$$

where f is in Hz. A limit of 625 V/m applies to frequencies from 4 kHz to 30 kHz. Because electromagnetic interference may occur in some models of heart pacemaker in power-frequency electric fields as low as 2 kV/m, exposures of workers with pacemakers are limited to 1 kV/m.

The TLV for sub-RF magnetic fields was revised in 1992 to be in consonance with the American National Standards Institute at frequencies above 300 Hz. For fields from 1 to 300 Hz, routine occupational exposure is limited to

$$B_{TLV} = 60 / f \quad (\text{mT, r.m.s.})$$

where f is the frequency in Hz. The TLV at 60 Hz is thus 1 mT. For frequencies from 300 Hz to 30 kHz, the TLV is 0.2 mT, which corresponds to a magnetic field strength of 163 A/m.

Below 1 Hz, the TLV is 60 mT.

ON THE BOUNDARY BETWEEN IONIZING AND NON-IONIZING RADIATION

Lars Persson

Swedish Radiation Protection Institute
Box 60204, S-10401 Stockholm, Sweden

ABSTRACT

The recent Radiation Protection Act of Sweden applies for the protection of people, animals and environment against the harmful effects of both non-ionizing and ionizing radiation. There are, however, a few differences in the obligations etc. in the Act for the two types of radiation. Some detailed physical and biological arguments are given here for use of the wavelength 100 nm as the practical boundary between the two types of radiation in the legislation.

INTRODUCTION

The recent Radiation Protection Act of Sweden (1) applies for the protection of people, animals and environment against the harmful effects of both non-ionizing and ionizing radiation. There are, however, a few differences in the obligations etc. in the Act for the two types of radiation. Thus in the preparatory work for the legislation it was necessary to define the boundary between the non-ionizing and the ionizing radiation. The Swedish Government's consultative commission for the preparation of the Act argued for a 100 nm photon wavelength corresponding to 12.4 eV as the boundary between the two types of radiation. The Swedish Government and the consulted authorities had no objections to this proposal and since the Act has now been passed by the Swedish Parliament the 100 nm boundary has been established in Sweden. Below some physical, chemical and biological arguments will be given for the use of 100 nm as the boundary between the two types of radiation in radiation protection legislation.

DEFINITION OF IONIZING RADIATION

The International Commission on Radiation Units and Measurement (ICRU) has given the following definition of the term ionizing radiation (2): "Ionizing radiation consists of charged particles or uncharged particles (e.g. photons) capable of causing ionization by primary or secondary processes". It is also noted by ICRU that a radiation, such as low energy photons, may be ionizing in one medium but not in another. Hence, the choice of a suitable energy cutoff, below which a radiation is considered as non-ionizing, will depend on the circumstances. In this work the author will discuss the cutoff energy for the human body.

PREVIOUS WORKS

Irradiation of living human cells with photons e.g. from a synchrotron light source in the relevant region of 100 nm has, according to the present author's knowledge, not yet

been performed. However, Hutchinson (3) found in an experiment for the inactivation of bovine serum albumin using a slow-electron beam of the appropriate energies that at some electron energy in the range 10-13 eV, with increasing energy, a process occurs which is much more likely to cause inactivation than that caused by ultraviolet ionization of lower energies. From the amount of energy involved he argues that it seems natural to identify this second process with ionization.

Setlow (4) has studied the effects of different wavelengths of ultraviolet light on nucleic acids and proteins. He observes at 121.5 nm with decreasing wavelength that the inactivation cross section of chymotrypsin increases much more rapidly than the absorption cross section. He noted in his paper that it is tempting to ascribe this large increase in quantum yield to the onset of ionization.

CALCULATIONS

The reference man with a weight of 70 kg consists of 15 elements with a quantity of 1.0 g or more (5). The ionization energies of these 15 elements vary from 4.3 eV for K to 17.4 eV for F (6). A mean value of the ionization energy, weighted according to the amount of these 15 elements in the reference man, is 12.9 eV corresponding to a photon wavelength of 96 nm.

DISCUSSION

As already mentioned there exist atoms in the human body with ionization energies much lower than 12.4 eV. For example the ionization energy 4.3 eV of K corresponds to a photon wavelength of 288 nm. However, the ionizing energy of K⁺ that you expect to find in biological systems is 31.8 eV corresponding to 45 nm.

The ionization potential of the isolated water molecule is 12.6 eV corresponding to a photon wavelength of 98 nm (7). However, there is also experimental evidence that at a quantum energy of only 6.8 eV corresponding to 185 nm some solvated electrons are formed (7). The reactive species of the irradiated water molecule may attack molecules in the cell leading to the production of biological damage yielding a highly reactive site on DNA in the form of a DNA radical (8). This is known as the indirect effect.

The DNA consists of atoms of H, C, N, O and P. The P atoms (approximately 10 weight percent of DNA) have an ionization energy of only 11.0 eV corresponding to a photon wavelength of 113 nm. Thus there exist some arguments for a wavelength longer than 100 nm as the boundary between ionizing and non-ionizing radiation.

The Swedish legal boundary between ionizing and non-ionizing radiation was established as 100 nm (or 12.4 eV) with the argument that it corresponds approximately to the upper wavelength limit for the production by photons of ionization in biologically important elements in the human body. This is by

the so-called direct effect (8). The World Health Organization has in its survey of protection against non-ionizing radiation (9) chosen a similar boundary between ionizing and non-ionizing radiation.

CONCLUSIONS

The 100 nm electromagnetic wavelength boundary established in connection with the adoption of the Swedish radiation protection Act may well in the field of radiation protection serve as a practical boundary between ionizing and non-ionizing radiation. However, there also exist some scientific arguments for a somewhat higher value. The data also indicate that there may be no sharp transition between ionizing and non-ionizing radiation.

An experimental investigation of the effects of photons on living, preferably human, cells in the boundary region approximately 10-400 nm, for example using synchrotron light should be valuable in the investigation of the problem.

BASIC CRITERIA FOR ELF-STANDARDS

J.H. Bernhardt

Institute for Radiation Hygiene,
Federal Office for Radiation Protection
D 8042 Munich - Neuherberg

ABSTRACT

Since possible late effects resulting from ELF-field exposure have not definitely been proven standards are based on acute effects. The established basic limits (i.e. induced current densities) and derived limits (i.e. electric and magnetic field strengths) are summarized. Additionally, contact currents, interferences with medical implants and field perception must be considered for establishing intervention levels, especially, with regard to the aspects of preventive public health care.

INTRODUCTION

Though several epidemiological studies suggest, that a weak association exists between the exposure to ELF-fields and an increase of various kinds of cancer, a final risk assessment of long-term continuous exposure to ELF-fields is so far not possible. It has not definitely been proven, that the electric and magnetic ELF-fields occurring at working places or in every-day life are mutagenic or cancerogenic. The main critical points are concerning statistical evaluation, the insufficient determination of the field strength during the exposure and dose-effect relationships, furthermore, the inadequacy in the demarcation of concomitant factors and the absence of known interaction mechanisms. The final clarification of the question of possible late effects requires further elucidation. Therefore, for deriving standards, the non-stochastic ELF-field effects are well in the foreground ^{1,2}.

ACUTE FIELD EFFECTS

Electric and magnetic ELF-fields can generate - due to different interaction mechanisms - electric field strengths (in V/m) and electric current densities (in mA/m²) within the body. These tissue field strengths and current densities can produce - dependent on their intensity - biological effects. Although the electric tissue field strength is the basic quantity responsible for the biological effects, in most cases dose-effects-relationships are given in terms of the current density. Both of these quantities are connected via the electric conductivity.

No biological effects are scientifically confirmed so far below about 1 mA/m². Current densities between 1 and 10 mA/m² are corresponding to the endogenous background level of current densities in most organs and tissues of the body ^{2,3}. On the surface of electrically active nerve or muscle cells current densities of up to 1000 mA/m² can occur for short times.

From in-vitro laboratory studies using current densities between about 1 and 10 mA/m² some minor biological effects have

been reported. Some of these effects were observed only at distinct frequencies and field strengths ("windows"). Examples include changes in the calcium-efflux from preparations of brain-tissue following exposure of 16 Hz-electric or magnetic fields, modified calcium - uptake of lymphocytes following magnetic field exposure, and inhibition of melatonin synthesis by the pineal gland following exposure to weak static magnetic fields. The significance of these findings with human beings is not clear.

ELF-fields of relatively high intensity, producing internal body current densities exceeding about 10 mA/m², can cause some biological effects which cannot be ignored. Examples are enhancement of DNA synthesis, alteration of the molecular weight distribution during protein synthesis, delay of the mitotic cell cycle, blocking of the action of parathyroid hormone at the site of its plasma membrane receptor, and inhibition of the cytotoxicity of T-lymphocytes.

A systematic evaluation of the actually induced currents and field strengths at the tissue and cellular level of these findings is complicated by the following facts:

- large variations of the exposure conditions and,
- lack of details on the geometry of the biological samples.

Furthermore, the lack of reproducible results between different laboratories limit the interpretation. Since dose-response relationships have not yet been identified, systematic determinations of threshold values for tissue field strengths are urgently needed.

Controlled laboratory studies on volunteers exposed for short periods to electric field strengths up to 20 kV/m or magnetic flux densities up to 5 mT revealed no adverse clinical or significant physiological changes. These data do not exclude that health effects may occur by long term exposure. The thresholds for stimulation of excitable cells are above 100 mA/m²; for frequencies above about 300 Hz these thresholds increase proportionally with the frequency¹.

In addition to effects caused by induced tissue field strengths, there exist surface effects due to electric field exposure resulting in sensory perception and, furthermore, perception of transient or steady electric currents occurring from touching charged objects in electric fields. At 50/60 Hz a field strength of 20 kV/m is the perception threshold of 50% of people for sensations from their head hair or of tingling between body and clothes. A small percentage of people can perceive a field strength of 2 to 3 kV/m. The effects of steady or transient ("spark discharges") contact currents are depending on many factors, e.g., the size and geometry of the object, the electric field strength, the body impedance, the size of the contact area and the strength and duration of the contact current¹. Typical electric field strength levels leading to spark discharges which are felt as an annoyance in our daily environment are between 2 and 7 kV/m. A small percentage of people can perceive a field strength of .5 kV/m via spark discharges.

A further group of indirect effects result from possible effects of ELF-fields on electric or electronic implanted medical devices. Typical example is the implanted pacemaker.

BASIC AND DERIVED EXPOSURE LIMITS

For establishing exposure limits and safety factors, duration of exposure, presence of controlled or uncontrolled environments, existence of risk groups (e.g. with medical implants) should be considered. The evaluation of the acute effects have lead to recommendations of exposure limits which are different for occupationally exposed persons and the general public.

The International Non-Ionizing Radiation Committee (INIRC) of IRPA recommends that the ELF field induced current density should not exceed 10 mA/m^2 in the body². Since most evidence is based on short term observations and, since there is a limited knowledge of the possible effects of long term exposure, the INIR Committee recommends to limit of induced current density to 4 mA/m^2 for the continuous occupational exposure and 2 mA/m^2 for the general public (a factor of 5 below 10 mA/m^2). The current densities should be averaged over a period of 1 s and a cross-section of 1 cm^2 perpendicular to the current direction. This averaging seems to be sufficient for picking up spatial and temporal peak values, in view of the fact that the effects of current densities are occurring at the cellular levels, that a plurality of cellular effects are resulting in an action on the whole organisation and, furthermore, the safety zone from stimulating effects are sufficiently large.

From these basic restrictions for the current density the dosimetric quantities, which are necessary for practical purposes, must be derived. The derived secondary exposure limits, i.e., the external electric and magnetic field strengths must be deducted in such a way, that the protective aim is guaranteed also under worst case conditions. For the derivation of field strength exposure limits from the basic restriction there exist numerical and measuring methods. For both methods considerable simplifications were used up to now not taking into account, i.e., the inhomogeneous distribution and anisotropy of the electric conductivity. Due to such simplifications possible spatial increased values of the basic restriction remain disregarded.

CONCLUSIONS

The table summarizes the results of measurements and calculations. The table reflects partially the heterogeneous distribution of the current density within the human body produced by external electric or magnetic fields. For example, an electric field strength of 5 kV/m (the IRPA/IRNIC recommendation for the limit of continuous exposure of the general public to 50/60 Hz electric fields) produces in trunk, head, neck and ankles current density of up to 1.7, 0.5, 2.5 and 10 mA/m^2 , respectively. A magnetic flux density of 0.1 mT induces in trunk, head and wrists/ankles current densities of up to 1.7, 0.4 and 0.15 mA/m^2 , respectively. A refinement of such model estimations, however, is urgently needed.

Table: Derived values for the electric field strength and magnetic flux density approximately producing a current density of 1 mA/m² in different body parts at 50 or 60 Hz.

Left: Values of the electric field strength;

Right: Values of the magnetic flux density (peripheral regions; R: Radius of current loop; a homogeneous conductivity of 0.2 S/m is assumed).

Electric field strength in kV/m				Magnetic flux density in mT		
Trunk (average)	Head	Neck	Ankles (both feet grounded)	Trunk (R=0.3m)	Head (R=0.075m)	Wrist/ Ankles (R=0.03m)
3	10	2	0.5	0.06	0.25	0.6

Generally, for the establishment of standards, the simultaneous occurrence of other physical agents, noxious chemicals or biologicals factors is not being considered. The exposure limit of 5 kV/m provides substantial protection for the public from annoyance caused by contact currents or transient discharges, which is considered acceptable for occupational exposed persons. For occupationally exposure, hazardous body currents and contact voltages must be avoided by special measures. An electric field strength of 5 kV/m, however, cannot completely eliminate perception of electric field effects. Additionally, there is a small probability that a malfunction of some sensitive unipolar cardiac pacemakers will occur under worst-case conditions at electric field strength values between 2.5 and 5 kV/m and magnetic flux densities between 0.02 and 0.1 mT. Furthermore, in view of this and some other unknowns and uncertainties concerning the complete understanding of the interacting mechanisms and the final clarification of possible long term effects it may be prudent not to exhaust the exposure limits. Such aspects of preventive public health care should be taken into consideration especially on developing new technologies by using electric energy or building transmission lines near public dwellings.

PROPOSAL FOR CHANGING THE LASER EXPOSURE LIMITS
FOR EXTENDED SOURCE VIEWING

D. Courant¹, D.H. Sliney², W. Marshall² and I. Court^{1,3}

¹ Commissariat à l'Energie Atomique, DSV-DPTE, Bp6, 92265 Fontenay aux
Roses France. ² Laser Microwave Division, US Army Environmental Hygiene

ABSTRACT

The current laser safety standards have two sets of ocular exposure limits. One set concerns the intrabeam or point source viewing condition, the other a diffuse reflection or an extended laser source. Recent studies of retinal injury thresholds for large retinal image sizes at microsecond exposure times have shown that no safety factor exists in current laser standards for this exposure regime. From a complete review of known biological data, it was possible to develop a set of new exposure criteria that much more closely follow actual injury thresholds. The new proposal makes use of the fact that retinal injury thresholds vary inversely as image size, and limits can be expressed as an angular correction factor to the intrabeam "point-source" exposure limits.

INTRODUCTION

The IRPA and IEC laser safety recommendations have two sets of ocular exposure limits. One set relates to the intrabeam or point source viewing condition, the other to a diffuse reflection or an extended laser source. The latter, although seldom used is nevertheless important. The increasing power of lasers can induce hazardous reflections. New laser products, especially in recent investigative techniques of the retina and in retinal imagery, are ever more using extended sources or optics producing large retinal images.

Many biological data exist on damage thresholds for minimal retinal image sizes. No controversy concerning the threshold values has been reported. The experimental results are in good agreement with present exposure limits. At the opposite, for non-minimal images few experiments were performed to know the influence of the retinal image size and specify the corresponding laser injury thresholds. Problems appear when comparing the limit values and the biological data base for large image sizes.

PROBLEMS RAISED BY THE EXPOSURE LIMITS FOR EXTENDED SOURCE VIEWING.

The present exposure limits for viewing extended sources or diffuse reflections of laser radiation are a function of the exposure duration. For extended sources, the exposure limits are usually expressed in $W.cm^{-2}.sr^{-1}$ (radiance) and in $J.cm^{-2}.sr^{-1}$ (integrated radiance). For a given exposure duration, the integrated radiance limit specified at the cornea determines a corresponding retinal radiant exposure limit expressed in

$\text{J}\cdot\text{cm}^{-2}$. This limit value does not vary with the size of the retinal image. Thus, the corneal exposure limit determines the same invariable radiant exposure limit for every retinal spot size. By example, the retinal radiant exposure corresponding to the exposure limit (EL), is $10 \text{ mJ}\cdot\text{cm}^{-2}$ for viewing angles as different as 0.004 and 0.033 radian. However, the biological data have shown a dependence of the retinal lesion threshold on image size. What is the maximal image size taken into account by the standard? This is not specified for the present EL.

The use, in the most recent studies, of an investigative technique such as fluorescein angiography, has shown that the retinal damage thresholds are lower than those reported in the early experiments using a direct ophthalmoscopic method [1,2]. The results demonstrated that at the relevant limit value, there is a risk of lesion which can be detected by angiography for retinal spot sizes greater than $250 \mu\text{m}$. The risk or probability of detecting a damage is increasing with the retinal image diameter.

THE NEW PROPOSAL

From a complete review of known biological data, it was possible to develop a set of new exposure criteria that much more closely follow actual injury thresholds. The good agreement of the experimental data with the exposure limits for point source or intrabeam viewing can be used to specify in a better way the limits for extended source viewing. The regression lines, fitting the biological data obtained with different image sizes, are divided in two groups which depend on the exposure duration in the same way as the intrabeam viewing exposure limits. The relationship established between the retinal lesion threshold level (ED_{50}) and the retinal image diameter can be described by the relevant equation:

$$Hr = b \cdot r^m$$

where Hr is the retinal radiant exposure expressed in $\text{J}\cdot\text{cm}^{-2}$, r the retinal image diameter expressed in μm , m the slope of the line and b is a constant. The similarity of the slopes of the curves allows one to consider very roughly the spot size dependence as a function that is inversely proportional to the image diameter. The best fit to the data is obtained with slopes m of -0.8 to -1.2 . This is corroborated for exposure durations ranging from 10^{-9} s to 10 s [2].

The new proposal makes use of the fact that retinal injury thresholds vary inversely as image size, and limits can be expressed as an angular correction factor to the intrabeam "point-source" ELs. Using this relationship, the retinal radiant exposure corresponding to the limit EL for extended source viewing (H ELs) could be expressed as the corresponding radiant exposure for the point source limit value (H ELps) multiplied by a correction factor CF that includes an image size dependent term:

$$\text{New H ELs (for extended source)} = \text{H ELps (for point source)} \times \text{CF}$$

Figure 1. The relationship between the retinal damage threshold (ED_{50}) and the retinal spot-size.

The multiplicative correction factor CF can be expressed as follows:

$$CF = (\alpha / \alpha_{min})^m$$

where α is the angular subtense or visual angle of the extended source and α_{min} the limiting angle which determines extended source versus point source viewing condition. The value of the slope m is chosen 1.0. In the standard, α_{min} varies with the exposure duration, whereas in our

proposal α_{inj} is a fixed value in the thermal injury domain. It may be convenient to consider a value of α_{inj} equal to the lowest effective retinal image size formed on the retina but it may be too possible to choose a larger value of α_{inj} , at which the experimental data still warrant the exposure limits.

For exposure durations larger than 10 s, the effects of eye movements become dominant on the retinal spot-size. A good value for α_{inj} , based upon eye movements recordings for fixating a point seems 11 milliradians. A transition value of α_{inj} should be defined for exposure ranging from 1-3 s, when the eye movements begin to influence the retinal image diameter, to 10 s.

The recent thermal model calculations show that the 1/r spot-size dependance ends at about 1-2 mm retinal image diameter. Hence, a single radiance limit is possible for visual angle subtending the source corresponding to retinal image diameters larger than 1-2 mm. The visual angle specifying the use of a radiance limit could be defined by the new term α_{rad} .

This formulation allows one to specify safety margins for large image diameters equivalent to those existing for intrabeam viewing conditions. This revision effort also has implications for exposure limits applied to non-coherent light sources.

**CURRENT AND PLANNED ACTIVITIES OF THE
IRPA - INTERNATIONAL NON-IONIZING RADIATION COMMITTEE**

A.S. Duchêne, INIRC Scientific Secretary,
32 rue Gambetta, 92260 Fontenay-aux-Roses, France

ABSTRACT

In its fifteen years existence, IRPA - INIRC has worked hard to achieve the objective that IRPA assigned to the Committee when creating it in 1977. The IRPA-INIRC Guidelines on limits of exposure now cover a large part of the electromagnetic spectrum as well as ultrasound and some of them have been updated in recent years. INIRC's activities since the last IRPA Congress in 1988, its work in progress and future programme are detailed below.

INTRODUCTION

As compared to ionizing radiation, non-ionizing radiation protection is a rather young matter of concern and IRPA-INIRC, the first international body specifically set up to this purpose, was created 50 years later than ICRP. For a long time health protection interests were mainly focussed on the nuclear industry. In recent years, however, the public has become increasingly aware of other factors of nuisance in its living and working environment, and NIR which is omnipresent in our everyday life is one of these. Public contests against planned or even existing NIR-emitting installations are developing and workers' concern about possible hazards from NIR has manifested itself in various industries. There is an increasing request for regulatory protection measures and guidance in this respect and the IRPA guidelines are being recommended or adopted in an increasing number of countries.

Non-ionizing radiation (NIR) refers to a wide range of radiations and fields with different physical characteristics and different processes of interaction with living matter. This requires that the composition of INIRC reflects appropriate expertise with respect to the different NIR and recognized competence within various disciplines. When considering the work achieved by INIRC since its creation, it must be borne in mind that its membership was limited to 12 members plus a Chairman and a Scientific Secretary, and for a long time was even less than that. For the last 4-year period, INIRC's membership included the following :

M.H. Repacholi, Chairman (Australia),
H.P. Jammet, Chairman Emeritus (France), J.H. Bernhardt (F.R.Germany),
B.F.M. Bosnjakovic (The Netherlands), L.A. Court (France), P.A. Czerski (U.S.A.), M. Grandolfo (Italy), B.G. Knave (Sweden), A.F. McKinlay (U.K.),
M.G. Shandala (U.S.S.R.), D.H. Sliney (U.S.A.), J.A.J. Stolwijk (U.S.A.),
M.A. Stuchly (Canada), L.D. Szabo (Hungary), A.S. Duchêne, Scientific Secretary (France).

Professor P. Czerski, charter member of INIRC, died in April 1990. He was a pioneer investigator in the effects of non-ionizing radiation on biosystems and a fervent promoter of international cooperation. With him, INIRC lost one of its most active members.

ACTIVITIES OF IRPA-INIRC.

INIRC's work up to 1988 has been reported in detail at the 7th International Congress of IRPA. Since then, INIRC carried on its activities in three directions, namely: the preparation of new guidelines for other parts of the NIR spectrum and of statements on questions of the moment; the analysis of background data relating to NIR in cooperation with the World Health Organization (WHO); and the development of practical guidance for protection against NIR at the workplace in cooperation with the International Labour Office (ILO).

In addition, INIRC contributed to the promotion of NIR protection through the organization or cosponsoring of Workshops (Melbourne, Australia, 1988; Vancouver, Canada, 1992) or International Courses on NIR (Erice, Italy, 1989).

IRPA-INIRC guidelines

New data on the biological effects and the relative spectral effectiveness in the UV-A region lead INIRC to revise its 1985 Guidelines on limits of exposure to ultraviolet radiation. The table of relative effectiveness values has been completed for the different wavelengths between 315 and 400 nm. Furthermore, it was felt that the former irradiance limit of 10 W m^{-2} for periods greater than 1000 s included an insufficient safety factor for longer periods. The revised exposure limits for the near UV spectral region, expressed in terms of radiant exposure (J m^{-2}), were published in Health Physics, vol. 56, June 1989.

Many specialists in the field of ultraviolet radiation have called attention to the long term health risks of excessive UV exposure. Following some concern about the potential hazard associated with fluorescent lighting, INIRC's conclusions that UVR exposure from indoor fluorescent lighting should not be considered a malignant melanoma risk were published in a statement on "*Fluorescent lighting and malignant melanoma*", Health Physics, vol. 58, January 1990. Despite many warnings, the populations living in temperate climates are still keen about suntanning. While voluntary exposure to the natural sun cannot be controlled, there is a real need to minimize the risks due to the use of artificial sunbeds and a statement to this purpose "*Health issues of ultraviolet 'A' sunbeds used for cosmetic purposes*" was published in Health Physics, vol. 61, August 1991.

INIRC's "*Interim guidelines on limits of exposure to 50/60 Hz electric and magnetic fields*" were published in Health Physics, vol. 58, January 1990. These guidelines deal with one of the presently most controversial issues in the field of NIR. The question in debate is whether extremely low levels of 50/60 Hz electric or magnetic fields (about $0.25 \mu\text{T}$) could induce an increased risk of occurrence of cancer or leukemia, although there is no proof of such a risk at high levels. INIRC's position in this respect, as stated in the guidelines, is: "The exposure limits are based on established or predicted effects of exposure to 50/60 Hz fields. Although some epidemiological studies suggest an association between exposure to 50/60 Hz fields and cancer, others do not. Not only is this association not proven, but present data do not provide any basis for health risk assessment useful for the development of exposure limits".

Magnetic resonance imaging and spectroscopy have become useful tools in clinical diagnostic. These techniques involve exposure of the patient to radiofrequency electromagnetic fields and to static and time-varying magnetic fields. A report dealing with "Protection of the patient undergoing a magnetic resonance examination" has been published in the December 1991 issue of Health Physics, vol. 61.

A few months ago, draft guidelines on limits of exposure to static magnetic fields have been distributed to IRPA Associate Societies for review. Depending on the comments received, these will be either finalized and approved or discussed again during the INIRC meeting in May 1992.

Finally, it is important to note that, for easier consultation, the INIRC guidelines and statements published in Health Physics up to end 1990 have been collected together in a single book issued by Pergamon Press in May 1991. The book is available to IRPA members at a special rate.

Environmental health criteria

Important advances in biological radiofrequency radiation research made it necessary to revise E.H.C.16 for Radiofrequency and Microwaves (1981). Therefore, a new E.H.C. document for Electromagnetic fields in the frequency range from 300 Hz to 300 GHz was prepared in cooperation with WHO and with funding from UNEP. The Environmental Health Directorate of the Health and Welfare of Canada kindly hosted and provided financial support for the international task group that met in Ottawa to review and complete the draft. The new UNEP/WHO/IRPA document is expected to be issued in 1992 in the WHO Environmental Health Criteria series.

Guidance for safe occupational practice

IRPA-INIRC collaborates with the ILO to provide guidance on working conditions and procedures that will lead to higher standards of safety in the workplace. After a report on protection against radiofrequency and microwave radiation published in 1986, ILO has asked INIRC to deal with further topics about which workers were concerned. At ILO's request the three following practical guides have been prepared :

- Practical guide on the protection of workers from power frequency electric and magnetic fields ;
- Visual Display Units - radiation protection guidance ;
- Practical guide on the use of lasers in the workplace.

These joint ILO/IRPA-INIRC publications will be published in the ILO Occupational Safety and Health Series.

Future programme of work

Environmental Health criteria documents. INIRC has submitted to WHO proposals for the revision of EHC 14 for Ultraviolet Radiation (1979) in priority, to be followed by the updating of EHC 22 for ultrasound (1982) and EHC 23 for lasers (1982).

Guidelines on limits of exposure. As a general rule, INIRC's guidelines are periodically revised to be kept in line with significant progress in scientific knowledge.

In the field of optical radiation, INIRC intends to develop guidelines on limits of exposure for visible and infrared radiation, and to amend the guidelines for lasers with respect to the exposure limits for extended sources.

Concerning electromagnetic fields, the guidelines should be completed over the frequency range between 0 and 10^5 Hz.

- *Guidance for safe operational practice.* INIRC feels that several topics should be dealt with, such as UV and infrared radiation for indoor workers, UV radiation for outdoor workers, and radiofrequency heating devices.

- *Joint project.* Considering the expanding use of NIR in medical technologies, it was found desirable that a Manual for the protection of health care workers against NIR be developed under the joint sponsorship of ILO, INIRC and WHO.

CONCLUSION

IRPA-INIRC has now gained international recognition in the field of protection against NIR and the IRPA-INIRC guidelines are known in all parts of the world. This would not have been achieved without the continuous and active support of the IRPA Executive Council and the IRPA members. INIRC is also grateful for the encouragement and support of national institutes and of international organizations and, in particular, of the World Health Organization, the United Nations Environment Programme, the International Labour Office and the Commission of the European Communities. INIRC has grown up and, to consolidate its international status, IRPA intends to give it a charter as a more independent body. If set up during the present Congress, the future International Commission on Non-Ionizing Radiation Protection (ICNIRP) will continue INIRC's work and still retain a special relationship with IRPA.

**DEVELOPMENT OF A PORTABLE DIRECT READING INSTRUMENT FOR
THE TRIAXIAL EVALUATION OF ELECTRIC AND MAGNETIC FIELDS
AT EXTREMELY LOW FREQUENCIES**

Concerned by the growing studies linking low frequency exposure and certain types of cancer and by the lack of a suitable direct reading instrument capable of analyzing specific frequencies, IRSSTQ has developed a portable direct reading microprocessor based instrument capable of measuring triaxially both electric and magnetic fields at any frequency in the 50 to 720 Hz range with a dynamic range of at least 70 db. The sensitivity of the instrument is 0.5 V/m and 10 nT. Accuracy is within $\pm 5\%$ and the bandwidth at 60 Hz is ± 2 Hz at - 60 db. At 720 Hz it is ± 41 Hz at - 60 db. In addition, the instrument has the capability of producing a printout of selected parameters via an RS-232 fibre optics port.

L'exposition à des champs électriques et magnétiques de basses fréquences préoccupe de plus en plus les spécialistes de la santé. Les ressources énergétiques du Québec sont abondantes et ont permis l'installation des industries qui consomment de grandes quantités d'énergie électrique. Les travailleurs qui oeuvrent dans ces industries et ceux qui voient à l'entretien des lignes de transport et de distribution d'électricité sont possiblement exposés à de forts champs électriques et magnétiques. Des études [1] laissent entrevoir la possibilité que ces champs soient des initiateurs ou des promoteurs de certains types de cancer ou du moins, qu'ils puissent interférer avec les mécanismes internes du corps [2], d'où l'intérêt grandissant pour l'évaluation de l'intensité de ces champs.

Il existe présentement des instruments de mesure sur le marché, mais la majorité de ces instruments n'évalue les champs que selon un seul axe, ce qui exige de la part de l'utilisateur une recherche de la lecture maximale par la rotation de la sonde. Ceci a pour conséquence de rendre ardues les mesures répétitives telles que la cartographie des champs en plus d'augmenter les risques d'erreur. De plus, les mesures à distance ne sont pas possibles avec de tels instruments. D'autres encore ne peuvent qu'évaluer une seule fréquence, généralement à 50 ou 60 Hz, ignorant tout des harmoniques supérieures qui sont souvent très élevées. Certains évaluent les intensités des champs sur une large bande ce qui nous empêche d'évaluer correctement l'exposition. En effet, l'American Conference of Governmental Industrial Hygienist (ACGIH) a récemment émis des recommandations [3] sur les champs électriques et magnétiques couvrant la plage de 0 à 30 kHz. Ces recommandations sont proportionnelles à la fréquence. Auparavant, seul un analyseur de spectre ou un voltmètre sélectif permettaient de telles mesures.

L'IRSSTQ a développé un appareil de mesure portatif à microprocesseur qui effectue la mesure triaxiale et sélective de l'intensité rms des champs électriques et magnétiques pour n'importe quelle fréquence située entre 50 et 720 Hz avec une gamme dynamique d'au moins 70 db. La sensibilité de cet instrument est de 0,5 V/m et 10 nT. La largeur de bande à 60 Hz est de $\pm 0,7$ Hz à un niveau de - 6 db et ± 2 Hz à un niveau de - 60 db et à 720 Hz elle est de ± 7 Hz à un niveau de - 6 db et ± 41 Hz à un niveau de - 60 db. L'exactitude est de $\pm 5\%$ de la lecture. De plus, l'appareil est muni d'une sortie RS-232 à fibre optique.

La figure 1 illustre un exemple de rapport que l'utilisateur peut obtenir de l'appareil.

FIGURE 1

CONCLUSION

Les essais sur le terrain ont été très encourageants, l'appareil rencontre nos objectifs initiaux. Vu la nature extrêmement fluctuante de certains champs, il est apparu nécessaire d'ajouter une fonction de moyenne et d'écart type afin d'obtenir des valeurs plus représentatives du milieu. L'ajout de paramètres de direction et de phase des champs permettront de mieux identifier l'origine des champs.

ABSTRACT

The quantification of magnetic field exposure has been the subject of considerable debate. A number of surrogates have been used including, spot measurements, wire coding and 24 hour averages. The quantification of domestic magnetic fields including the identification of sources is important if any mitigation is required. The State Electricity Commission of Victoria has developed recording instrumentation and measurement protocols for the survey of domestic magnetic field strengths in the Melbourne area.

A range of domestic locations in the Melbourne metropolitan area is chosen to test the influence of external installations and the effect of appliance usage and energy consumption on the domestic magnetic field environment.

INTRODUCTION

The importance of residential magnetic fields has been the subject of considerable debate throughout the last decade. Several residential epidemiological studies of childhood cancer and magnetic fields suggested there may be an association, but the measures of exposure used were not entirely rigorous and criticised in several reviews.

The SECV has previously carried out a spot measurement survey of residential magnetic fields in the Melbourne metropolitan area and gained a good knowledge of the range of values involved. The magnetic fields debate has widened in its consideration of what it is that constitutes exposure. The equipment described below was designed to provide additional information regarding the variation, likely sources and level of residential fields.

SPOT MEASUREMENT SURVEY

This survey selected homes in the metropolitan area of Melbourne using a randomisation technique. The measurement protocol provided for measurements in each room and at common occupier locations. The measurements were taken under "high" load and "low" load conditions. These can be most simply described as the condition of the house during low activity of the occupants for low load and a typical evening meal time where lights are on and appliances operating for high load. Measurements were taken under the nearby street line and near the water meter.

The results of this survey showed that the energy consumption in the house had a significant effect on the magnetic field levels in the house. Histograms in Figures 1 and 2 show the distribution of magnetic field levels for each condition together with the average values for low and high load conditions.

Figure 1 Effect of house energy usage on magnetic fields at the front door

Figure 2 Effect of house energy usage on the magnetic fields in the kitchen

Australia uses the Multiple earthed neutral system (MEN) for residential distribution of electricity. With this system the possibility exists for a fraction of the neutral return current to flow via earth. The influence of this current on the magnetic fields in the house is determined by the path of the current. To a great extent this is determined by the location and the type of the domestic water supply system used in that location and whether the MEN earth is bonded to the water pipe or not.

From a study of earth return currents it has been found that the majority of earth return current flows through the water and gas pipes. The magnitude of this current has been investigated in another project and estimated to be an average value of 5% of the household current.

INSTRUMENTATION DEVELOPMENT

The spot measurement survey using different house load conditions highlighted the need for knowledge of the range of variation of fields during normal activity in the house. Instrumentation was developed for this purpose. The requirements for the instrumentation included the need to record magnetic fields in up to three locations simultaneously and also record up to four currents. At each measuring point there are three coils mounted orthogonally and data is collected from each coil prior to combining to find the resultant value. Individual directional data can be analysed if required.

With the datalogger selected it is possible to vary the sampling rate between 1.0 seconds and several hours. The memory capacity allows for a recording time of 1 day at a sampling rate of 60 seconds.

Provision was included for the instrument to be pole mounted in streets. For this application a single measuring point (three orthogonal coils) is attached to the pole 1 metre above the ground. Results are shown in Figures 3 and 4 where the instrument has been used in street locations for up to 5 days. The cyclic variation of the results is indicative of supply to a domestic area.

Figure 3 variation of magnetic fields over several days

Figure 4 variation of magnetic fields over one day

The rapid variation of the field level combined with the daily cyclic variation could have ramifications for studies relying on spot measurements to quantify exposure. The time of measurement may introduce significant misclassification errors both from the point of view of short term variation and daily cyclic loading.

MEASUREMENT PROTOCOLS

For the measurement of residential data the measuring units will be located in the main living area, the main bedroom and the near the front door. Simultaneously measurements are also taken of the active, neutral and earth return currents.

A calibrating load will be operated for short periods at a range of locations throughout the house to measure the sensitivity of the household measuring locations to household power consumption. This load draws 10 amp and will cycle on and off each 10 seconds. The cyclic pattern will be visible in the recorded results and will give a measure of the contribution of the power consumption to the the overall magnetic fields.

Data is collected using sampling rates of 2 seconds during use of the calibrating load, 1 minute and 10 minutes. The short sampling time will collect details of the peaks and allow evaluation of the contribution provided by the house wiring. The 1 minute time will show the variation over a day and the longer sampling rate will show the cyclic pattern over several days including a weekend.

Household data regarding the electrical energy usage is recorded and use and type of electrical appliances for the measurement period is logged by the resident for factoring into the analysis of the data.

Details of street lines are noted for each location to test surrogates of magnetic field levels. This data includes the electrical proximity to the supply transformer as measured by the number of houses served by the transformer beyond the house selected for measurement. Other factors included with this data are the distance of the house to the lines and the function of the distribution feeder at that point, if present.

CONCLUSION

From the spot measurement survey it was determined that the sources that contribute to the residential magnetic field levels include the local distribution circuits, both low voltage and distribution voltage, the use of electrical energy in the home and contributions from the earth return currents. The relative importance of these sources depends on their relative strengths at the measuring point. To investigate the importance of components datalogging instrumentation has been developed and used with measurement protocols to try to evaluate the relative strength of each source.

The magnetic fields being measured in this survey and the assessment of the residents exposure relate to the long term pattern of the fields. The assessment of peak exposures must relate to appliances, their usage pattern and the strength of the associated magnetic field.

ABSTRACT

We describe the development of a wire coding protocol based on a study of electrical installations in Melbourne. Because of very significant differences between our power distribution system and that used in Denver, a different approach from that used by Wertheimer and Leeper was required.

INTRODUCTION

The hypothesis that exposure to extremely low frequency (ELF) magnetic fields may be responsible for an increase in the incidence of cancer remains the subject of several epidemiological studies. Wire coding, that is the grouping of residences based on the type, number and distance of nearby visible electrical installations, has been repeatedly used for assessment of exposure¹⁻⁵. In some studies³⁻⁵ actual measurements of the magnetic fields were also carried out, but, where an association with cancer was found^{3,5}, it was stronger for classification based on wire coding than for that based on measured fields. This can be interpreted in two ways: i) wire coding is a better index of magnetic field exposure than measured magnetic fields, either because it is less affected by time variability or because it is correlated to a parameter of the magnetic field different from the one measured (usually the time weighted average) or ii) wire coding is also correlated to some unidentified confounder which is responsible for the association with cancer.

In either case, it is important that analysis of data classified by wire coding remain a part of current residential exposure studies, so that either the relevant magnetic field parameter or the confounding agent can be identified.

Wire coding was devised specifically for the Wertheimer and Leeper studies in Denver and Boulder, Colorado. Electric power distribution practices vary significantly from place to place and it can not be assumed that the Denver code may be used in a different locale.

We describe here a wire coding protocol that we have developed for Melbourne, Australia, as part of the preliminary work for an epidemiological study of residential exposure to ELF magnetic fields and childhood cancer.

METHOD

The main difficulty we encountered was due to the fact that, in Australia, pole mounted transformers have a typical power rating much larger than that common in the US. A single transformer may supply a secondary distribution line consisting of dozens of spans. The current drop along the secondary line is thus very gradual and the resulting variation in the strength of the magnetic field from point to point of the same line is less than random time variability. Moreover, the lines often branch into side streets and it is very difficult for a field worker to classify a house in relation to its distance from the transformer. The use of standard gauge wire contributes to make classification difficult.

Our objective is that of identifying two reasonably large groups of subjects that can be reliably regarded as 'high' and 'low' exposure and an intermediate category which will contain most of the subjects whose exposure is less easily determined. We anticipate that this approach will not allow a reliable estimate of a risk-exposure trend (because of the large misclassification of the intermediate group). However, it offers the advantage over simple dichotomous classification of comparing two smaller but reliably classified groups, rather than two groups both grossly affected by misclassification.

Using a random number generator, we identified 415 points in the Melbourne metropolitan area. At each of these points, measurements were taken directly under the power lines, if any existed or at an equivalent position on the sidewalk, if no electrical installations were visible.

RESULTS

The data obtained from the random measurements are summarized in Table 1. According to these data, in a sizable fraction of the metropolitan area there are no significant external sources of ELF magnetic fields. Thus, it should be possible to identify with a certain degree of confidence a sufficiently large reference group.

The approximate magnetic field profiles were calculated from the median values of the measured magnetic field. These are plotted in Figure 1 for the most important wire types, as a function of the horizontal distance in the direction perpendicular to the line.

Note that in several cases this profile is asymmetrical, due to the presence of an unbalanced current. This introduces an additional uncertainty, since in general we cannot determine the predominant direction of the unbalanced current. Thus at a distance of 10 m from a secondary line the field may be less than 20% or more than 40% of the field measured under the line.

Table 1
Summary of magnetic field measurements

Wire type	Number of occurrences	Magnetic field (μT) mean	Magnetic field (μT) median	Stand. dev.	Quartile lower	Quartile upper
1	71 (17.1%)	0.067	0.017	0.146	0.017	0.042
2	18 (4.3%)	0.077	0.029	0.105	0.017	0.095
3	48 (11.6%)	0.078	0.017	0.149	0.017	0.032
4	20 (4.8%)	0.350	0.276	0.330	0.074	0.517
5	73 (17.6%)	0.359	0.279	0.306	0.121	0.489
6	74 (17.8%)	0.439	0.312	0.371	0.152	0.669
7	9 (2.2%)	0.530	0.461	0.356	0.288	0.695

(Wire type code: 1 = no visible wires; 2 = end pole; 3 = primary; 4 = 2 phase secondary; 5 = secondary; 6 = primary + secondary; 7 = high voltage distribution line + primary + secondary).

The 'strength' of a power line as a source of residential magnetic fields was defined as a function of the wire type and distance from the house. We arbitrarily defined a strong source as a power line capable of generating a typical field of 0.16 μT or more at the point of a house closest to the line.

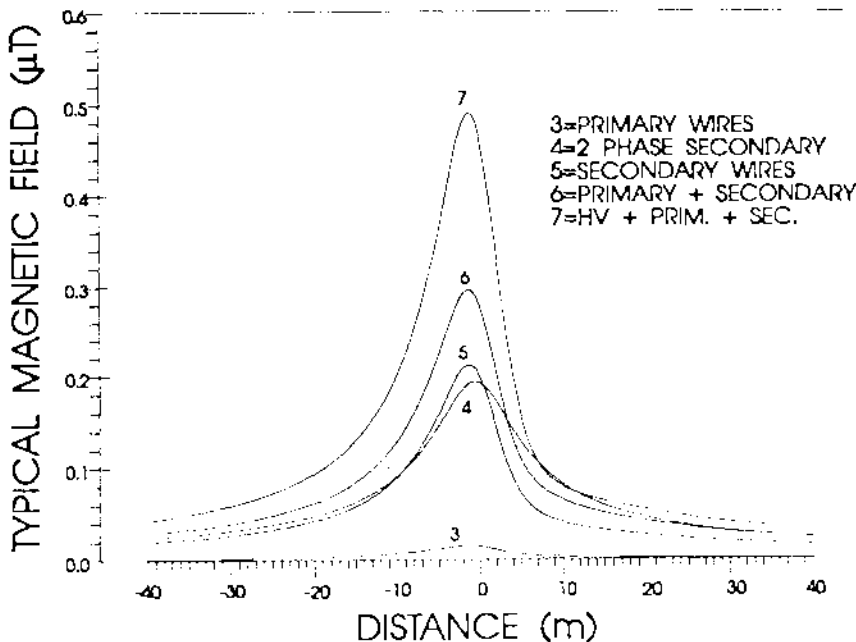

Figure 1. Typical magnetic field profile for several wire types.

Table 2
Exposure scores assigned to several wire types on the basis of their distance from a residence.

Wire type	Strong source (score = 4)	Moderate source (score = 2)	Weak source (score =1)
4	0 - 7.0 m	7.5 - 18 m	18.5 - 28 m
5	0 - 6.5 m	7.0 - 14 m	15.5 - 35 m
6 or 7	0 - 10.0 m	10.5 - 20 m	21.5 - 40 m

A line generating at that point a typical field of 0.08 to 0.16 μ T is regarded as moderate and one generating a typical field of 0.04 to 0.08 μ T is considered weak. From Table 1 and Figure 1 we determined, for each line type, the distances from the lines at which a median field of approximately 0.16, 0.08 and 0.04 μ T could be expected. Exposure scores were assigned to reflect the relative strength of the various sources (Table 2). Less common wire types were also similarly classified.

Houses with nearby sources totalling a score of 4 or more are classified as high exposure, while houses affected by no more than one weak source are regarded as low exposure. Houses with a total score of 2 or 3 are classified as medium exposure.

Validation of this exposure assessment protocol is, strictly speaking, not possible, since we do not know what the 'true' exposure metric is. We are investigating the long term correlation between this and other possible exposure indices.

L'ORGANISATION DES POUVOIRS PUBLICS ET DES SECOURS EN FRANCE
EN CAS D'ACCIDENT NUCLEAIRE

M. le Préfet C. GUIZARD,
Secrétaire Général du Comité Interministériel de la Sécurité Nucléaire

THE FRENCH GOVERNMENTAL ORGANISATION AND RELIEF IN FRANCE
PLANNING IN CASE OF A NUCLEAR ACCIDENT

Despite of the unlikeliness of a nuclear accident, emergency planning is a must. It has several aspects : Internal Emergency Plan, Specific Intervention Plan, Post Accident and Relief specialized Plan. As a whole, the organisation is similar to the one used for others industrial risks. In a "Department", the supervisor for overall emergency action is the "Prefet", a high civil servant appointed by the Cabinet and responsible for nuclear security ; all the other civil servants are under the Prefet's command and assist him. A national post-accident plan is being worked out ; it will cover all the fields of intervention: control, administration of stable iodine, sheltering or evacuation.

----*--*

Les 55 réacteurs nucléaires Français et toutes les installations nucléaires associées, en particulier celles du cycle du combustible, obligent les pouvoirs publics à être en mesure de protéger les personnes qui pourraient être affectées par un accident sur ces installations. En effet, même si l'exploitant fait la preuve qu'il est toujours capable de ramener son installation dans un état sûr, quoi qu'il arrive, l'autorité politique ne peut pas faire aujourd'hui l'économie de la préparation des mesures qui permettraient de faire face à un accident dans le but d'en réduire le plus possible les conséquences. Tant que la technique ne permet pas d'affirmer que la probabilité d'un accident grave est réellement nulle, les responsables gouvernementaux mettent donc en place des plans d'urgence ;

- plan d'urgence interne (PUI) pour le personnel des installations,
- plan particulier d'intervention (PPI) pour le public applicable dans les premières heures qui suivent l'accident,
- plan post-accidentel (PPA) qui intervient après le PPI lorsque l'accident a des conséquences de longue durée,
- plans de secours spécialisés tel par exemple ceux associés aux transports de déchets radioactifs.

Il est clair que la pérennité du choix nucléaire, alternative énergétique la plus économique lorsque les autres ressources énergétiques nationales sont réduites, est liée à cette capacité d'annihiler toute velléité d'accident ou dans le pire des cas à en supprimer toute conséquence. Le monde ne pourrait pas supporter un second Tchernobyl ; ceci étant, 5 ans après, les réflexions de nos collègues soviétiques sont pour nous très précieuses et nous les remercions de nous en faire part.

L'organisation en cas d'urgence nucléaire ne diffère qu'assez peu de celle adoptée pour d'autres risques industriels ou naturels. La décentralisation de 1982 ne concerne ni la police, ni l'armée dont fait partie la gendarmerie et l'un des points forts du système français vient encore de cette centralisation napoléonienne.

Les Préfets nommés par le gouvernement sont les premiers responsables sur leur département des mesures à prendre pour le public : protection des personnes, information, police, contrôle sanitaire, soins, évacuation, etc... Le plan ORSEC (organisation des secours) départemental recense les moyens à mettre en oeuvre et leurs conditions d'emploi pour toutes les catastrophes. Le passage du PUI au PPI a pour conséquence que le Préfet gère l'ensemble des moyens disponibles, y compris ceux qui avaient fait l'objet de conventions particulières au titre du PUI. Il use en tant que de besoin de son droit de réquisition.

Le Préfet prend l'avis des autorités centrales de l'état (Service de Protection contre les Rayonnements Ionisants - SCPRI, Direction de la Sûreté des Installations Nucléaires), qui délèguent sur place leurs représentants comme conseillers directs du Préfet, qui examinent la situation depuis les centres de Crise de Paris, qui renforcent en personnels et en moyens les équipes préfectorales (pompiers, équipes médicales, hélicoptères,...), qui donnent éventuellement des directives au Préfet. Le Secrétariat Général du CISN ⁽¹⁾ que je dirige, placé auprès du Premier Ministre, suit la situation depuis le centre de Crise de l'Hôtel Matignon, informe le Premier Ministre et décide si nécessaire d'informer les autorités étrangères et internationales vis à vis desquelles nous sommes le point de contact. Dans le cas où l'accident prend une ampleur géographique qui dépasse le département, un préfet coordonnateur est désigné pour assurer la cohérence des actions prises dans les autres départements.

Au niveau local les postes de commandement sont opérationnels dans l'heure qui suit l'alerte. Ce sont environ 40 ingénieurs et techniciens qui sont mobilisés. L'organisation nationale est opérationnelle en 1 à 2 heures avec mobilisation d'une vingtaine de spécialistes.

Ces temps sont tout à fait compatibles avec les scénarios d'accidents envisagés dans nos réacteurs à Eau pressurisée : la présence de l'enclume de confinement, la durée de sa montée en pression pour atteindre celle à laquelle il serait nécessaire de l'ouvrir sur l'extérieur par les filtres à sable font qu'un rejet à l'extérieur n'est pas envisageable avant un délai de plusieurs heures après le début de l'accident.

(1) CISN = comité interministériel de la sécurité nucléaire

Le contrôle de l'efficacité de ce système est assuré par chacun des niveaux d'action et de nombreux exercices sont effectués régulièrement dans les installations, dans les Préfectures au niveau local, au niveau national par la Direction de la Sûreté Nucléaire ou par le Secrétariat Général qui décide une fois tous les 2 ou 3 ans d'un exercice national avec tous les acteurs du temps de crise. Le dernier exercice a mis en évidence les difficultés de l'information du public et des élus locaux en temps de crise ; aussi, des formations adéquates vont être mises en place pour tous ceux qui seraient requis. Le fonctionnement des Etats-Majors nationaux est apparu satisfaisant tandis que les Etats-Majors locaux doivent encore s'entraîner à faire face à ces situations.

Une ébauche de plan post-accidentel type a été réalisée. Elle doit être revue et améliorée, notamment au niveau des moyens pour recevoir des cartes en couleur, pour mesurer l'activité présente dans l'environnement et pour rendre performantes les transmissions. Ce sont d'abord les Cellules Mobiles d'Intervention Radiologiques (CMIR) des pompiers qui interviennent pour effectuer ces mesures sur le terrain.

Si besoin est, les moyens du CEA sont ensuite mis en oeuvre; cela peut aller jusqu'à la réquisition de tout le personnel et de tous les moyens de laboratoire disponibles ; des mesures par hélicoptère aident à dresser rapidement une carte de la contamination existante et les moyens de calculs de l'Institut de Protection et de Sûreté Nucléaire, appui technique des décideurs, permettent d'effectuer des prévisions sur l'évolution de la situation. Les moyens du SCPRI sont aussi d'un grand secours dans ce cas, tant pour les mesures sur le terrain que pour le contrôle des populations. Ce sont une voiture rail spectrométrique, 2 semi-remorques, 18 Master-Géminis ; des engins télécommandés permettent d'intervenir en milieu contaminé : un télémanipulateur, un engin téléopéré (VERI), un robot pour l'intérieur des bâtiments (CENTAURE), des mini-engins OSCAR, des engins de génie civil.

La philosophie Française est celle des recommandations de la CIPR, et des règles de la CEE. Cependant compte tenu des risques liés à des évacuations trop vite décidées, ainsi que du caractère d'irréversibilité des conséquences de ces évacuations, la France, comme la Grande-Bretagne recherche plutôt le confinement que l'évacuation. Rappelons que le choix des sites est toujours effectué pour que le nombre de personnes à évacuer ne soit pas trop important ; par exemple, certaines communes qui passent de 2000 habitants à 20 000 ou 30 000 en période estivale ont été éliminées pour cause d'évacuation trop difficile.

La distribution d'iode stable peut être demandée par le SCPRI; cette administration destinée à suture la thyroïde est justifiée lorsque l'activité de l'air respiré atteint 800 Bq/m^3 avec une durée prévisible d'exposition ne dépassant pas 10 jours; dans le cas d'une durée plus courte, le niveau à prendre en compte pourrait être plus élevé (8000 Bq/m^3 pour moins de 24 h par exemple).

Des stocks de comprimés d'iode (50 mg sous forme d'iodure de potassium) ont été constitués au niveau national (SCPRI, Service Central de santé des Armées, Hopitaux centraux) et au niveau local (Centrales nucléaires, Hopitaux Régionaux notamment). Leur distribution préventive continue de faire l'objet de réflexions sur le meilleur moyen de la réaliser : pompiers, gendarmerie, associations, enseignants. Une notice explicative serait distribuée simultanément. Les enfants et les femmes enceintes qui présentent une plus grande sensibilité, seront servis en priorité ; ils constituent d'ailleurs aussi le premier groupe de population auquel on interdirait la consommation de lait frais (activité supérieure à 500 Bq/Kg et à 150 Bq/Kg pour les nourissons). Les normes imposées par la CEE, sont des normes de commercialisation pour l'exportation et pourraient être dépassées dès lors qu'il s'agirait de la survie des populations.

Une surveillance permanente du territoire est assurée par : le réseau Téléray du SCPRI : les 67 stations transmettent automatiquement leurs mesures dans les préfectures, au SCPRI et à tous ceux qui en font la demande ; ces mesures, disponibles en permanence sur le minitel, sont consultables par toute la population ; une interrogation s'effectue automatiquement toutes les heures. Une station vient d'être installée au sommet de l'aiguille du Midi (3840 m) dans les Alpes et d'autres seront encore installées. De plus, un important réseau de prélèvement sur les avions longs courriers permet de prévoir l'arrivée de nuages radioactifs ; cela avait permis au SCPRI de communiquer à l'AFP, 60 heures après l'accident de Tchernobyl, la composition exacte du nuage en provenance d'URSS.

Le SCPRI peut accueillir jusqu'à 25 personnes exposées au rayonnement ou contaminées et est en mesure, selon l'urgence, de répartir les accidentés dans les hopitaux spécialisés. Au niveau régional, le SCPRI dispose de 4 divisions (Bordeaux, Avignon, Angers, Nancy) qui assureraient l'intervention immédiate sur place. Localement, une attention toute particulière est apportée à la gestion prévisionnelle des soins aux irradiés, afin d'être certain qu'il n'y aura aucune difficulté.

La dizaine d'exercices qui sont déjà réalisés chaque année oblige tous les acteurs à réfléchir sur le rôle qu'ils auraient à jouer en cas d'accident et conduit à perfectionner constamment ce système, de telle sorte que les aléas certains d'une situation de crise soient aussi limités que possible. Des détails sur toutes ces mesures vont vous être présentés et vous pourrez convenir que la France apparaît aujourd'hui tout à fait à même de gérer une situation d'accident nucléaire au mieux des intérêts du public.

EMERGENCY PLANNING AND EXERCISING
WITHIN BRITISH NUCLEAR FUELS plc

N J W McPhail, N J Oakes,
BNFL, Health and Safety Directorate,
Risley, Warrington, Cheshire, England

Abstract

Emergency planning within BNFL covers arrangements to deal with the on and off-site effects of an incident. The on-site arrangements cover measures to recover the situation at the scene of the incident and protection of the workforce. The off-site arrangements include co-ordination of the off-site emergency response, implementation of counter-measures to protect the public and information flow to the public, media and government. Regular emergency exercises held to test the arrangements may involve some 12 agencies and many hundreds of persons over a 2-day period.

Introduction

The general principles of emergency arrangements are common to all British Nuclear Fuels Plc (BNFL) sites. Detailed local arrangements at each site reflect their specific hazard, their local management arrangements, and the arrangements for emergency response within their county. As an illustration the arrangements described within this paper are those specific to BNFL's Sellafield site, the UK's centre for the reprocessing of irradiated fuel and also the site of the world's first large-scale nuclear power station, Calder Hall.

Background

The possibility of an accident leading to the release of sufficient radioactive material to cause interference with the normal activities of the public or requiring special arrangements to be made to protect the workforce is remote. During design of plant, safety aspects are considered to be of great importance and all credible combinations of events which could lead to an accident are taken into account. The Site Licence, issued by the Health and Safety Executive (HSE), also requires BNFL to make arrangements for dealing with any accident or other emergency on the licensed site which affects, or might affect, the safety of any person or property whether on or off the site. The emergency arrangements for Sellafield are essentially split into two broad interrelated sections, the arrangements for within the site, and the arrangements for off the site.

On Site Emergency Organisation

The principal aims of BNFL's site emergency management organisation are as follows:

- i recover the situation at the scene of the incident
- ii establish lines of communication to the incident plant, the remainder of the site and off-site
- iii alert people in the affected areas of the site, and handle any resultant local site evacuation and radiological monitoring
- iv keep people on site out of the affected areas by closing roads where necessary and providing adequate diversions
- v inform the site generally of the problem, including repre-

representatives of Staff Side and Trade Unions, and
vi notify external organisations where appropriate.

The emergency management functions outlined above would be discharged from a number of emergency centres established on declaration of a Site Emergency Standby. The principal centre, the Site Emergency Control Room (SECR) would act as the focus for the co-ordination of all post-accident management control functions. It would be manned on a continuous basis by designated senior staff until cessation of the emergency.

To provide a focus for the co-ordination and organisation of rescue and recovery operations on the incident plant, an Incident Control Centre (ICC) would be established. It would be located within or as near the affected plant as conditions permit. To control access to and from the incident area an Access Control Point (ACP) would be established. At this single point of entry to the incident location all necessary radiological advice and protection would be provided to personnel involved in rescue and recovery operations. A Health Physics (HP) Monitoring Station would be set up adjacent to the scene of the incident as a centre for the measurement of all HP samples obtained from the vicinity of the incident plant.

The focus for collection, collation and interpretation of HP data and for the management of HP resources would be the Health Physics Information Room (HPIR). Radiological data received from the scene of the incident, other areas on site, and from the district monitoring teams would be processed as appropriate. Additionally a continuous direct read out from a system of remote monitoring stations located at the site perimeter is also available in this room. This information would be passed to other centres such as the SECR and District Control Centre, (See below), for action as appropriate.

Other centres designated to receive and treat personnel affected by the emergency eg emergency reception centres, medical centres and decontamination centres would be activated depending on the severity of the incident. Control and communication with personnel on the remainder of the site would be achieved from the SECR via a communication network of manned Area and Building Control Points.

Off-Site Emergency Arrangements

Responsibilities for actions offsite to protect the general public rests with local and national organisations eg emergency services, health and environmental protection agencies according to their statutory responsibilities as for other types of emergencies. Each organisation has its own detailed arrangements and an overall composite plan is prepared. To ensure a coordinated response can be provided and the general public are appropriately advised, BNFL would establish a District Control Centre (DCC) and Media Briefing Centre (MBC) in a Company hostel some 13 Km from the site. The function of the DCC is to:

- i ensure the activities of the participating organisations in the District Emergency Scheme are effectively coordinated.
- ii provide a centre where definitive advice on the course of the

incident and the effect on the public and the environment can be given.

- iii provide a focus for information on the course of the incident for the media (via the MBC), and the general public (via the Public Information Centres).

The DCC would be staffed by representatives of all agencies with a responsibility in the emergency. The organisation of the centres although a matter for local and national agreement, is generally organised around a conference facility permitting close liaison between representatives of all organisations, together with adjacent facilities for each organisation.

In order to operate successfully, the key function of the DCC is to offer definitive advice on the course of the incident and the offsite consequences of the incident in terms of potential or actual radiation exposure. Emergency environmental monitoring resources are deployed and controlled from the site. The results of the surveys would be interpreted and fed to the DCC, where, initially, a BNFL team of Health Physicists would be available to advise the agencies on the actions which should be taken to protect the general public, ie sheltering, evacuation or the issue of iodate tablets. For any incident involving offsite action to protect the public, a government representative would be appointed by the Secretary of State for Energy to report to the scene as quickly as possible and to take over responsibility from BNFL for advising the police and local authorities on actions necessary to protect the public.

A Media Briefing Centre is provided with appropriate facilities for representatives of the media. This centre would be manned continuously by BNFL and Constabulary staff, supplemented, as necessary, by representatives of other organisations manning the DCC. Media briefings would be held at regular intervals.

In the event of evacuation of the general public being required, reception centres would be established at an appropriate location dependent on the prevailing weather conditions and following consultation with representatives of the voluntary services and appropriate county and district council officers. Public Information Centres would be established in County libraries to provide information and advice to residents within the district, whose fears may have been unnecessarily aroused. All 24 hour manned Police Stations would be activated to deal with enquiries from the public about the incident.

In addition to the above local centres, national emergency centres would be established as well as the control centres of the individual organisations.

Exercising the Plans

In order to test the effectiveness of the emergency procedures and to develop the necessary skills of staff involved in post-accident management, regular emergency exercises are held. The scale of these exercises ranges from building emergency exercises related to specific plants to full scale Site and District Emergency exercises. The frequency of these exercises are determined by Site

Licence Provisions and exercises are independently assessed by HMNII inspectors. In addition to exercises, regular training is given to all levels of staff involved in emergency duties.

Procedure for planning District Emergency exercises within BNFL

The planning of District Emergency exercises which can involve some 12 agencies and several hundreds of persons over a 2 day period, follows a now well established procedure at BNFL Sellafield.

- i Planning usually commences some six or more months in advance of the proposed date of the exercise.
- ii The representatives of all organisations involved in planning and taking part in the exercise are invited by the Company to form an exercise steering group of some 20 individuals chaired by a senior representative of BNFL. The group approves the overall objectives of the exercise, including the outline technical scenario and selects a working group of representatives to undertake detailed planning.
- iii The working group and it's sub-groups progress the detailed planning of the exercise, including technical scenario derivation, driving inputs, media simulation.
- iv Documentation describing the full exercise arrangements is ultimately referred back to the steering group for endorsement at a meeting usually held 1 month before the exercise. Key documentation is used as briefing material for exercise participants.
- v The exercise is conducted according to the agreed arrangements determined during planning. The exercise is independently assessed by a team lead by the Nuclear Installations Inspectorate (NII).
- vi Within 24 hours of the end of the exercise a 'hot' debriefing meeting is held for the principal participants and assessors, chaired by the Chief Assessor. A note of this meeting is prepared and circulated to agencies promptly to enable them to submit their detailed comments in writing, within 4 weeks of the exercise.
- vii A draft follow up report is produced by BNFL and circulated to the steering group for approval within 2 months of the exercise.
- viii The detailed follow-up of exercises is vested in a small working group of representatives of key agencies who report back to the steering group at appropriate intervals, nominally 6 months.

Conclusion

The safety precautions taken in the design and construction of a nuclear installation and the safety standards used in operating them, reduce the chance of accidents to an extremely low level. Emergency planning provides an additional assurance that even if an accidental release of radioactive material were to occur, arrangements exist for prompt action to protect both the workforce and the general public. Major exercises are held regularly to test these arrangements and train staff involved in implementing them. Experience gained leads to constant evolution and improvement in the plans.

A TABLE TOP EXERCISE AND WORKSHOP

J. R. A. Lakey

John Lakey Associates, Meopham, Gravesend, UK

ABSTRACT

Table top exercises are widely applied in training for emergency preparedness and have long been a feature of Courses on Planning for Nuclear Emergencies. Experience of a large number of table top exercises is used to provide a classification of the types of exercise indicating the application and the disadvantages. The use of workshops is considered to be complementary rather than an alternative to teaching methods available from table top exercises.

INTRODUCTION

The types of table top exercise which may be used to achieve emergency preparedness are reviewed on the basis of experience in running training and facility exercises (1). The method of conducting the exercise is also evaluated and where appropriate the disadvantages of the approach are given. In some cases a workshop may be more effective since the emergency planning problem can be approached by synthesis from existing components or an existing plan may be analyzed.

TYPES OF EXERCISE.

Linear. The scenario does not deviate from a predetermined sequence of events and the participants follow a route for which correct solutions have been specified. Unexperienced staff or students can perform directing staff duties. The exercises which have been applied in the Planning for Nuclear Emergencies courses at Harvard (2) since 1981 and at the Surrey University courses since 1987 are linear and are designed to stress the approach recommended by NRC (3). The exercise is developed based on a real incident and is run in real time (4). The method can be transferred internationally with few language difficulties.
Disadvantage: Lack of opportunity for initiative by the participants and not acceptable to those who have some experience in the field.

Open Play. The exercise is free running from the point of the initial scenario and the out-come is not known. It is preferred by students but demands considerable directing staff time. This method has been used in table top exercises at the RNC (5, 6) since 1976 and is useful for developing communication procedures between on-site and off-site facilities. A bank of messages, media questions and the injection of additional scenario items is required to keep up the momentum.
Disadvantage: The evaluation of success is difficult and the play may fail to cover some key areas.

Experimental. The exercise may be performed as an experiment to study a dubious feature of the plan and this may be approached from several different points of view by repetition of the exercise. An exercise of this type has been conducted by FEMA (7) to study post accident relocation decisions by using ten "mini-scenarios" each focused on one problem. The play was conducted in a "no fault" mode so that the participants concentrated on the identification of issues, problems and procedures arising during this post accident phase.

Disadvantage: Expensive in staff time and the number of scenarios which can be examined is limited.

CONDUCT OF THE EXERCISE

Rôle Playing. All of the above exercises may use rôle playing and it is an advantage if some individuals perform their normal task in the scheme. This is stimulating and can be used to enable a new member of a team to play themselves into their team position.

Disadvantage: The course of the exercise cannot be predicted and so it is difficult to ensure that a particular topic has been covered.

Functional Play. Functional play involving the players as groups or teams with a specific task. Typical tasks are, assessment of the event, media contact, rumour control and in this way exercise may focus on the desired topics. It is an advantage when functions are played by the group responsible for that aspect of the plan.

Disadvantage: Individuals may opt out of the play.

Committee Exercise. When broad issues are on the agenda and a large numbers of players must participate the exercise can be conducted like a committee meeting at which regulatory authorities, service organisations etc. are represented. The NRC conducted such an exercise (8) which ran for two days with 90 players. The first day was used to define rôles and review the accident through the plume phase. On the second day the play turned to re-entry, relocation and then to decontamination and recovery. The NRC found it to be difficult to adequately discuss all the issues attempted in the exercise but 12 important lessons were identified. A committee exercise encourages an exchange of views and a good chairman can ensure useful conclusions. The method can be entertaining and has been used in the UK as the format for a television documentary.

Disadvantage: Limited scenario with the temptation to seek too many aims especially with a large number of players.

Communication Exercise. In many exercises communications is the only part of the emergency scheme to be tested and the table top is ideal for this purpose. In some case a field exercise may be enhanced by using a table top team to provide communication responders. This avoids the use of dedicated networks and reduces the chance that exercise messages may be received outside the area of play. Communications are the weakest link in any scheme and

frequent table top testing is strongly recommended. Disadvantage: It is unrealistic to run communications exercises in the absence of the uncertainty and errors associated with a real event.

WORKSHOPS.

The exercises described above are run under pressure which can be avoided by using a workshop format to analyze or synthesize the plan.

Analysis. Participants analyze selected parts of the scheme critically reporting to a plenary session on their findings.

Synthesis. The teams are free to create a plan from elements provided by the directing staff but they have to defend their choice of plan in plenary session.

SURREY UNIVERSITY TABLE TOP EXERCISE AND WORKSHOP

Table Top Exercise.

The aim is to give participants an overview of planning and preparedness concentrating on the communications and management problems which arise in the first few hours of an incident. The technical aspects of the initiating conditions are considered and an assessment of dose due to the release of fission products is made. The players are assigned to one of four functions:-

Technical - plant conditions, assessment, recovery,

Radiation Protection - dose assessment, access, re-entry, protective action,

Communications - local authority, media and preparations for a press conference,

Management - actions, assistance, security and records.

This is a linear exercise but some mistakes similar to those made in the real incident are inserted in the scenario. A press conference is held and video taped for critical review at the plenary session. The scale of the event is then raised to produce a significant release of fission products which are evaluated.

Workshop.

The aim of the workshop (9) is to prepare a plan for the exercise site based on a list of tasks and a model plan. The actions required by the plan are analyzed to identify the responsible team, the authority under which they are acting and the support required. The plan is reviewed to find out if it is sufficiently robust to cope with an overload of the communication systems, with excessive doses to off-site workers and with an extended emergency.

CONCLUSIONS.

The table top exercise is recommended as a powerful training tool which is most successful when all participants are actively engaged throughout the exercise. The least effective being the committee type of exercise. Table top exercises also provide support for field exercises and may be used for research and for evaluation of plans and preparedness for nuclear emergencies. Workshops provide a complementary training technique in which the plan may be examined in depth.

COORDINATED PROTECTION OF THE POPULATION IN EMERGENCIES IN SWITZERLAND: THE NATIONAL EMERGENCY OPERATIONS CENTRE (NAZ) AND THE EMERGENCY ORGANISATION RADIOACTIVITY (EOR)

Hans H. BRUNNER

Secretary Fachverband für Strahlenschutz (FS)

c/o GSEDI/Nationale Alarmzentrale (NAZ), Postfach, CH-8044 Zurich, Switzerland

ABSTRACT

As a consequence of the nuclear weapons tests Switzerland has since 30 years expert commissions, concepts, monitoring networks, monitoring and emergency teams for the protection of the population following radiological accidents of all types inside or outside the country. Thus Chernobyl hit a prepared country - except information. The Radiological Emergency Organisation (EOR) and its National Emergency Operations Centre (NAZ) have up-to-date legal bases, concepts and operational means. Besides radiological events, NAZ deals also with chemical accidents, satellite crashes and dam breaks. Unique is the coordinated use of the combined means of civil authorities, civil defense and army in all strategic cases.

GENERAL ORGANIZATION, TASKS AND CONCEPTS

Nuclear tests caused Switzerland in 1964 to establish an emergency organisation for protection against any radiological incident inside or outside the country. Since 1979 the permanently operating contact point (Alarmstelle ARMA) and the National Emergency Operations Centre (NAZ, Nationale Alarmzentrale) are located in Zurich close to the Swiss Institute of Meteorology (SMA). In 1984 a fully protected underground installation was taken into use, the permanent team of the NAZ was enlarged (now 15 persons) and supplemented by a militarized staff.

The main purpose is to protect the population by early warning of authorities, timely alert and instruction of the population and initiation of protective and preventive actions.

The Radiological Emergency Organization (EOR) operated very successfully after the Chernobyl accident but was restructured to improve the cooperation at the government and political levels and the information of the public.

The head of the EOR is the Secretary General of the Federal Department of the Interior (GSEDI) who is supported by a Managing Committee (Leitender Ausschuss Radioaktivität LAR) consisting of the directors of the relevant federal authorities. This links the Emergency Organisation directly to the Government. The Information Centre of the Federal Chancellery is responsible for communications with the cantonal authorities and for information of the public. (Fig. 1)

The official concepts of Total Defense and of Coordinated Radiological and Chemical (AC) Protection provide for full cooperation of the resources of federal, cantonal and communal authorities and of emergency services, army and civil defense for preparations and actions. Cantons and communities dispose of most of the means for countermeasures and actions such as health services, food control, police, fire-brigades, civil defense or public transports and must assist EOR at the order of the Federal Government.

Legal bases for the organisation are the new radiation protection law, the revised radiation protection regulations (both fully adapted to ICRP-60) and regulations on the EOR and on the NAZ. EOR has the legal competence to request the cooperation of any public or private specialists or services needed in an emergency. The pre-Chernobyl action concept based on emergency reference levels has been replaced by a thoroughly revised dose-action concept (Table 1) which contains the general action criteria and upper and lower dose levels as action / non-action criteria both for immediate preventive actions and later countermeasures. This concept corresponding to international recommendations will be specified in detail for various types of events. Thanks to good shielding provided by massive houses and to the large number of shelters in Switzerland, the main preventive action is not horizontal but vertical evacuation, i.e. stay in the house -> basement -> shelter. Horizontal evacuation would only be a later, well planned action, if necessary.

A fundamental concept is to use normal means and structures as far as possible, and extraordinary ones only where necessary. Regrouping in the early phase of an event could only result in chaos. Governments, authorities, public services on all levels must have an emergency organisation allowing them at any time to cope with unusual events besides their normal operations. Special means needed for emergency purposes, such as computers and monitoring networks, are regularly used for normal purposes, too.

The Federal Commission for Radiological and Chemical Protection (KOMAC) with 25 members and an additional 70 scientists in its Working Groups supports the NAZ in the development of concepts, in the preparations and in the conduct of exercises.

NATIONAL EMERGENCY OPERATIONS CENTRE (NAZ)

The NAZ forms EOR's permanent nucleus and first-stage action team. A contact point operating 24 hrs/day (ARMA) at the meteorological computer center, a duty officer and automatic monitoring networks assure instant readiness, rapid warning and alarming of authorities, emergency teams and population, evaluation of monitoring data and quick initiation of protective and preventive actions. The main tasks of NAZ relate to radiological events, from transport or operational incidents over nuclear installation accidents to nuclear weapons events in peacetime and war, but also include satellite crashes, chemical incidents and dam breaks. Within a few hours the permanent team of the NAZ can be enlarged by a military staff (Armeeabteilung) of over a hundred scientists (mostly members of KOMAC working groups), specialists, and support personnel. Thanks to the militia system of the Swiss Army, they have been recruited among the best specialists and scientists in radiation protection, nuclear safety, chemistry, data processing, communications and other related fields. Their main tasks are the management of the monitoring and laboratory organisations, the collection and evaluation of all informations and data on the event and its consequences, the presentation of up-to-date informations on the situation, especially the radiological one, the evaluation and proposal of protective actions to be taken, the judgement of their effectiveness, and whatever consultative support may be required by the federal authorities and the Information Centre.

In action, the NAZ operates from an autonomous protected installation with modern data processing and communications systems and safe communications to national partners, neighbouring countries and IAEA.

The organisation in action is centred around the three overlapping sectors intelligence + information / monitoring / evaluation and consequences, which are supported by technical, computer and communications services.

MONITORING, DATA PROCESSING, COMMUNICATIONS

The monitoring organisation shall permit to detect, identify and verify radiological events and hazards, to forecast, follow and evaluate their development and extent, to estimate the doses to the population and to check the efficiency of countermeasures. It consists of automatic networks and of quickly activated monitoring posts, a laboratory organisation, and mobile monitoring and sampling teams with cars and helicopters.

The main monitoring networks is NADAM, an automatic radiation monitoring network coupled to the automatic meteorological monitoring network. It collects dose rate and weather data every ten minutes from 56 stations all over the country. Daily dose-rate averages from 16 stations are shown on text-TV together with basic informations on radiation and nuclear safety. Other automatic networks collect and measure aerosols (FWP/RADAIR) or monitor the environment of nuclear power plants (MADUK). 107 monitoring posts (AWP) at police stations, equipped with highly sensitive dose rate monitors, can be activated within 1-2 hours and transmit data at short intervals. Mobile monitoring teams comprise special teams of health physicists with all sorts of instruments and sampling devices, and teams of police, fire-brigade, army and civil defense radiation protection specialists, monitoring helicopters and an aeroradiometry helicopter. The core of the laboratory organisation for sampling and analysing all kinds of samples and especially food are 5 permanent special laboratories which also do routine radiological environmental monitoring. 20 cantonal chemistry laboratories have been equipped with radioanalytical instrumentation and can on short notice be supplemented by 30 total-defence radioanalytical laboratories with militarized staff in shielded underground locations. This suffices to collect and analyse the large number of daily samples required to control food quality all over the country, making use of established food control routines.

All the monitoring data (from routine monitoring and in emergencies) are transmitted to, stored and analysed in a large data processing system at NAZ (project PHOENIX) which is also the base for several applications and expert systems, for visual presentation of results and for the exchange of data and informations within the EOR and its partners.

Communications must be reliable and redundant in all situations and make use of all available technical means and public as well as special systems, including those of the army. Both for data processing and communications simple robust stand-by methods are available in case of failures of the main systems.

Monitoring is only part of the entire intelligence activities needed for verifying and evaluating an event, especially if it happens abroad. An extensive information network, with links to news agencies, military intelligence, private information networks such as NucNet, and close contacts to partner organisations in neighbouring

countries, institutions and scientists in other countries and to international organisations such as IAEA and ESA are indispensable for NAZ. IRPA and its associate societies, especially the Fachverband für Strahlenschutz, are of invaluable help in this task.

INFORMATION, PUBLIC RELATIONS

Information was the weak spot after Chernobyl, not on the scientific and specialist level but on the political and government one. As a consequence the Information Center (Infozen) of the Federal Chancellery was made fully responsible for this task and was accordingly reorganized and equipped. The facts will come from NAZ and EOR which will provide consultants to the Infozen.

But information of the public in an emergency is only credible and accepted, if NAZ and EOR are already familiar to the public and to local and regional authorities. This requires a well planned continuous public relations program which makes use of all publicity means and of all situations where the media and the public may be willing or interested to learn about emergency preparations. The Gulf war was such an occasion. The widespread radiophobia among media, politicians and public and their tendency to rather believe horror stories than facts do not simplify this difficult task.

In a multilingual country with three official languages, with 15% alien population and many tourists using several dozen languages the information is further complicated.

EXPERIENCES AND PROBLEMS

Chernobyl was not the first but the largest real operation of the EOR. Although no genuine emergency as far as exposure levels were concerned, it allowed a full scale run of the monitoring and laboratory organisation and data evaluation far beyond anything feasible in exercises. Political decision making and information were put to a severe test. Exercises of parts or the whole organisation are done every year. Their preparation, execution and evaluation puts a large additional load on the NAZ.

As everywhere in the nuclear and radiation protection field we also have an abnormal age-structure in our staffs and will have to replace more than half within the next 5-10 years. How to find sufficient new and well trained staff when radiophobia makes any nuclear or radiation job unattractive, is a yet unsolved problem as is the transfer of all the knowledge and experience accumulated by the first generation to the newcomers. How far artificial intelligence will be able to ease that problem remains to be seen; we are working on prototypes for decision support systems.

Although Chernobyl set free an unexpected amount of funds for emergency preparations, this effect may soon decay, so all new investments will need a thorough justification and optimisation.

European integration and cooperation will increase in the near future and our concepts as well as monitoring, data processing and communications systems must be or become internationally compatible.

THE NEW EMERGENCY ORGANIZATION IN FRENCH POWER PLANTS

B Houpin
Contrôleur général adjoint
Electricite de France

ABSTRACT

Initially, the emergency organization within french nuclear power plants was based on the practices used in conventional plants, extended to allow for the aggressions specific to nuclear activities. This approach tended to emphasize individual treatment needed, rather than taking due account of potential number of victims, which imposes a collective organization. After the Chernobyl accident a complete reorganization was undertaken with the exhaustive and rational approach used in nuclear safety, and based on the medical aid in catastrophes.

RESPONSABILITIES OF THE OPERATOR AND PUBLIC AUTHORITIES

French legislation aims to place responsibility on authority in best position to take action in a given area and at a given time. In general terms, the deciding factors are whether the activities are inside or outside the site and whether contamination has occurred or not.

As far as the preparation of emergency organization is concerned, the nuclear operator, who knows the risks involved, is consequently responsible of the resources committed ; these may be outside resources, in which case he is responsible for ensuring their availability and their suitability. This may do through agreements, or coordinated plans of action.

As soon as an accident occurs, the operator is responsible for starting emergency action, inside the site. Subsequently he transfers his responsibility to the public authorities, in particular by transferring victims to the hospitals capable of dealing with contamination.

A rational approach to these responsibilities implies :

- determining the characteristics of all potential accidents
- defining the required resources ,
- organizing the resources, which must be known by all participants

CHARACTERISTICS OF ACCIDENTS

An approach comparable to that used for nuclear accidents was applied. The internationally-reported accidents were supplemented following extensive enquiries held in all french power plants and amongst nuclear engineering companies. All incidents which led, or which in other circumstances, could have caused an accident which led to victims, were analysed and extrapolated into seven typical scenarios which, in terms of the emergency resources they require, encompass all real scenarios.

The table below indicates the typical scenarios from which the following conclusions were drawn:

- accidents to equipment or during maintenance represent a greater threat for nuclear plant staff than major nuclear accidents, which primarily represent a threat to the population.

- some scenarios may induce a risk of contamination to a great number of people working on the site. Even though possibly unaffected, some of them could consider they had been exposed and demand immediate checks and treatment, hampering the organization of real emergency work. In any case it is necessary to check a great number of personnel, this needing a special organization.
- finally the risk of multi-traumata and the complexity of the plant mean that not all victims will be discovered immediately, preventing accurate classification of the urgency.

scenarios	Injuries and or Burns		Asphyxia	contaminated		Exposed		
	serious	slight		to be checked	real	0 to 0,3 Sv	0,3 to 1 Sv	more than 1 Sv
1 Failure of a steam pipe	15							
2 Turbine burst on reactor shut-down	5	25						
3 Primary pump oil fire	10		10					
4 Primary pump motor dropped on the pool	5			5	5		5	
5 Gaz tank explosion	8			8	8	40		
6 Steam generator tube burst, valve open	5			5	5			
7 Entry into red zone				100	100			5
	1			2400				1

As an example, scenario N°4 illustrates one of the series of worst-case assumptions used. A sling breaks when a primary coolant pump is being handled ; the motor drops onto the cofferdam between the two half-pools in the reactor building. The cofferdam distorts, allowing water to flood the reactor-side pool and contaminate workers in the compartments. The internal structures placed in the other compartment become uncovered, exposing other workers on the pool floor, to a high dose rate while two teams of specialists are preparing other operations.

All the victims are irradiated, including 5 exposed to a total dose between 0,3 and 1 Sv, 13 of them are seriously injured and contaminated.

RESOURCES

LEVEL ONE The human resources available in the plant differ between working hours and non-working hours but the number of victims varies in the same way. The shift staff is the first to be informed of an accident by a special telephone reserved for this purpose, always available in each control-room. This staff provides the first team of 5, most of them trained

in emergency work : an assistant shift foreman and 4 members. This shift uses the fire-fighting installations and portable equipment.

LEVEL TWO The VICTIM RELIEF PLAN is part of the INTERNAL EMERGENCY PLAN (IEP), prepared by all nuclear plants to cover all types of accidents, particularly major nuclear accidents. A rotating on call system of the personnel at home, ensures the setting up of an emergency organization providing the following resources :

- a "Management Command Post" headed by one of the plant's managers, to coordinate emergency actions,
- a "Local Command Post", headed by an operation engineer to control the damaged unit and minimize the effects of the accident,
- a "Resources Command Post", headed by a maintenance engineer, responsible for providing any exceptional equipment required,
- at least one nurse on-call in permanent connection by phone with an industrial doctor specialized in nuclear accidents, who can reach the site, if necessary, within less than 3 hours.

LEVEL THREE The IEP of a nuclear plant is closely coordinated with the SPECIAL EMERGENCY PLAN (SEP) organized by authorities of the "DEPARTEMENT", who have two emergency organizations under their control :

- FIRE EMERGENCY UNITS, mainly specialized in "technical" work (fire-fighting, explosions, etc...) whose tasks include finding, rescuing and evacuating the injured and asphyxiated. These units are part of a national structure and can, therefore, increase their capacity by calling in regional or, if necessary, national resources.
- EMERGENCY MEDICAL SERVICE (known by its acronym, SAMU) which is part of hospital services in the Departement. The SAMU possesses a main control center and mobile medical units (doctors, reanimation specialists, fully-equipped ambulances) and, through mutual-aid agreements, can call in SAMU units from other Departement.

A member of the plant's staff, specialized in first-aid and decontamination, accompanies to the civil hospital any injured people who cannot be completely decontaminated on the site. He takes the responsibility for all decontamination problems during treatment, including responsibility for preventing the spread of contamination into the hospital. Each plant has an agreement with at least one hospital, specifying the responsibilities and procedures involved.

LEVEL FOUR To overcome any real or psychological difficulties involved in moving contaminated victims into a civil hospital, agreements are also made with regional military hospitals who are particularly well equipped for this type of work. In addition, three agreements have been reached, on a national scale, with :

- the "INSTITUT CURIE", to treat a limited number of highly irradiated victims,
- the "SERVICE CENTRAL DE SANTE DES ARMEES" (PERCY hospital), to treat a large number of burn or irradiation victims,
- the "INSTITUT DE PROTECTION ET DE SURETE NUCLEAIRE", to analyse hematological, cytogenetic neurophysiological balances and evaluate doses

Finally the SERVICE CENTRAL DE PROTECTION CONTRE LES RAYONNEMENTS IONISANTS possesses mobile (trucks, coaches, etc...) anthropogammametric equipment to carry out very large-scale checks.

EMERGENCY ORGANIZATION

The principles applied to the organization of internal and outside resources are those proposed by the "medical aid in catastrophes", a field which was highly developed in France. These principles aim at constantly coordinating and optimizing the use of all emergency resources by quickly setting up :

- a strong hierarchical structure including an "general emergency directorate", over an "emergency technical management " and an "emergency medical management",
- a SORTING AND TREATMENT CENTER (STC) close to the accident to group and quickly classify all the victims,
- an EVACUATION NORIA ie a "small noria" between the accident site and the "Sorting and Treatment Center", and several "major noria", between the STC and hospitals, the STC and the infirmary decontamination rooms, etc
- a CENTRAL EMERGENCY STATION where men and vehicles waiting to intervene are grouped,
- an INFORMATION ROOM to provide information to families and media.

The chronological sequence following a serious accident outside normal working hours could be as follows, (times are given in minutes) :

- 0 ALERT- Call from the control room to the first-aid shift staff

- 5 RECONNAISSANCE-First emergency operations
 - the assistant foreman automatically becomes "emergency manager" and has the control of the team of the 4 first-aid shift personnel
 - a member of the team fight against the fire, supported and protected by a second member,
 - the third member of the team becomes the first "medical manager". he lists the victims and gives first aid
 - the fourth member is available either for technical or medical aid

- 20 INTERNAL EMERGENCY PLAN IMPLEMENTED
 - the Management Command Post manager (i e the plant manager) takes over from the system shift foreman to manage emergency activities,
 - the team members are replaced by on-call first-aid workers,
 - a Sorting and Treatment Center is organized close to the accident,
 - the on-call nurse or on-call industrial doctor may take over as "medical manager" if their higher skill are not necessary to deal with extremely urgent victims,
 - the infirmary is open, particularly for decontamination,
 - the RCP manager sends staff to the plant entrance to guide outside emergency resources called in and then, set up one or several check stations at exits from controlled zones or outside the site.

- 30 SPECIAL EMERGENCY PLAN IMPLEMENTED
 - a medical team (SAMU) arrives. The doctor of this team may take over as medical manager. The first fire emergency unit arrives to help fire-fighting under the organization of the plant staff.

- 60 two SAMU teams and several other emergency units arrive.

- 120 the last two SAMU teams arrive at the site.

CONCLUSIONS

This new organization makes the best of the resources available and allows all victims to be dealt with in less than 3 1/2 hours. However, both internal and outside resources must regularly take part in full-scale exercises to ensure coherent, and efficient cooperation.

BASES TECHNIQUES DES PLANS PARTICULIERS D'INTERVENTION DES SITES NUCLEAIRES

J.P. MAIGNE - J. COLLINET

Département de Protection de l'Environnement et des Installations

B.P. n° 6 - 92265 FONTENAY-AUX-ROSES CEDEX - FRANCE

ABSTRACT

Off-site emergency planning for french nuclear sites

A method is suggested to elaborate, on realistic technical basis, an off-site emergency plan for a nuclear site. This method gives an homogeneous and exhaustive structure to guide :

- the identification of the representative accidents that have to be taken into account in the design of an off-site plan, according to the different installations, nuclear or not, likely to be set up on the site,
- the assessment of this representative accident consequences on the environment and the population,
- the forecast and the planning, in the off-site emergency plan, of adequate counter-measures implementation with regard to this environment and the population.

1 - INTRODUCTION

Malgré les dispositions préventives prises au cours de la conception et de l'exploitation des installations nucléaires, il n'est pas impossible que les exploitants et les pouvoirs publics aient un jour à faire face à une situation accidentelle grave.

Afin de gérer au mieux une telle situation, de remettre l'installation dans un état sûr, de limiter les conséquences éventuelles pour l'environnement et les populations, divers plans d'urgence précisément spécifiés en terme de responsabilités, d'organisation et de moyens ont été établis. Le Plan Particulier d'Intervention (PPI) d'un site nucléaire est l'un d'eux. Son objectif est de prévoir et de planifier la mise en oeuvre, sous l'autorité du préfet, de moyens appropriés de secours dans la phase accidentelle à court terme.

Les différents niveaux d'organisation et des moyens prévus en fonction de la gravité de la situation à gérer ainsi que les modalités de leur mise en oeuvre sont définis de la façon suivante :

- le niveau 1 du PPI correspondant aux situations accidentelles à caractère non radiologique et/ou non toxique qui peuvent résulter des risques classiques, inhérents à toute installation industrielle (incendie, explosion, émission de matières toxiques, ...). Ces situations ne devraient pas conduire à des conséquences importantes dans l'environnement. A ce niveau, le PPI a essentiellement pour objet l'information des populations et des autorités administratives d'une part, l'organisation de l'intervention éventuelle de moyens de secours extérieurs au site, à l'appel de l'exploitant, d'autre part ;

- le niveau 2 du PPI doit permettre de gérer des situations accidentelles à caractère radiologique et/ou toxique dont les conséquences restent d'ampleur limitée à l'extérieur du site, compte tenu des dispositions prises à la conception et dans l'exploitation des installations pour limiter les conséquences de ces accidents (ordre de grandeur des accidents de dimensionnement). A ce niveau, le PPI a le même objectif qu'au niveau 1 mais s'inscrit dans une organisation plus importante, à l'échelle régionale et nationale, et prévoit la possibilité de la mise en oeuvre de moyens plus importants, notamment de moyens spécialisés ;

- le niveau 3 du PPI concerne les accidents les plus graves envisageables qui pourraient conduire à des conséquences radiologiques et/ou toxiques importantes dans l'environnement, en l'absence de la mise en oeuvre des contre-mesures prévues à ce niveau.

La décision effective d'application des contre-mesures prévues dans le niveau 3 du PPI (confinement, évacuation des populations, ...), n'interviendrait, sur la base des niveaux d'intervention recommandés par la CIPR 40 en particulier, qu'en fonction de l'évaluation des conséquences et des délais prévisibles, effectuée par les équipes de crise au cours de l'accident même, à partir des données disponibles comprenant éventuellement des mesures dans l'environnement.

Sur le plan pratique, l'appréciation des dispositions et des moyens associés à prévoir dans le PPI nécessite la définition d'un ou plusieurs "termes sources", représentatifs des rejets maximaux auxquels peuvent conduire les différentes installations du site en cas d'accident. Cette définition repose sur l'évaluation réaliste de scénarios d'accidents et de la dispersion de produits dangereux qui en résulterait.

Les dispositions à prévoir sont déterminées à partir des effets éventuels sur la santé, qualifiés et quantifiés sur la base des données radiologiques et/ou toxicologiques.

II - IDENTIFICATION DES SITUATIONS ACCIDENTELLES A RETENIR DANS UN PPI (SCENARIOS)

II.1 - Initiateurs

On retient les initiateurs suivants :

- criticité,
- incendie d'origine interne ou externe à l'installation,
- explosion d'origine interne ou externe à l'installation,
- fuite de matières radioactives et/ou toxiques.

II.2 - Classement des installations du site

Les scénarios d'accidents envisageables étant de nature différente selon le type d'installation, on a retenu la classification suivante :

- réacteurs nucléaires électrogènes (REP, UNGG, rapides),
- réacteurs nucléaires expérimentaux,
- usines, ateliers, laboratoires, installations de stockage mettant en oeuvre des matières nucléaires (cycle du combustible, Centre d'Etudes Nucléaires),
- installations industrielles non nucléaires qui peuvent présenter en situation accidentelle un risque pour les populations et l'environnement, soit par elles-mêmes, soit par l'impact de cette situation accidentelle sur les autres installations du site, nucléaires en particulier (installations mettant en oeuvre de l'hydrogène, du propane, du fioul, du sodium, ...).

II.3 - Termes-sources

De manière générale, pour chacune des installations du site, selon son type (Cf. II.2) et en fonction des initiateurs possibles (Cf. II.1), on recherche les scénarios réalistes des accidents les plus graves envisageables qui pourraient conduire à des conséquences radiologiques et/ou toxiques à l'extérieur du site. Cette recherche conduit, pour l'installation considérée, à la définition de termes-sources caractérisés par les activités des différents produits radioactifs et/ou les quantités de produits dangereux rejetées et une cinétique associée au rejet.

II.3.1 - Réacteurs nucléaires

Pour les réacteurs nucléaires électrogènes, les scénarios accidentels consistent à étudier le comportement du confinement après une fusion du cœur de ces réacteurs, situation relevant du domaine "hors dimensionnement" considérée actuellement comme enveloppe par ses conséquences à l'extérieur du site des situations accidentelles justiciables de la mise en œuvre du PPI.

Pour les réacteurs nucléaires expérimentaux, les scénarios accidentels à retenir pour l'établissement du PPI du site concerné et les termes-sources en résultant, sont recherchés au cas par cas, compte tenu des caractéristiques de conception et de fonctionnement propres à chaque réacteur.

II.3.2 - Usines, ateliers, laboratoires et stockages nucléaires

Dans le cas des usines, ateliers, laboratoires et stockages nucléaires, la démarche de l'étude des accidents graves diffère selon la nature du confinement primaire des matières nucléaires pouvant être mises en jeu lors de l'accident considéré :

- si les matières radioactives contenues dans l'installation bénéficient d'un confinement primaire par conception, à l'intérieur d'un gainage, les scénarios accidentels à retenir éventuellement dans le PPI, sont ceux qui peuvent conduire à une perte importante de l'intégrité de ce gainage et à la dispersion des matières dans l'environnement.
- si les matières nucléaires contenues dans l'installation considérée ne bénéficient pas d'un tel confinement primaire, on évalue les quantités de matières radioactives disponibles à l'intérieur du confinement pour un rejet éventuel qui sont considérées comme enveloppes de ce qui est envisageable de manière réaliste.

Les termes-sources sont alors définis par un niveau d'activité et une cinétique associée.

II.3.3 - Installations non nucléaires

Dans le cadre du PPI, il convient d'examiner les situations accidentelles qui pourraient affecter des installations industrielles non nucléaires implantées sur le site ou au voisinage de celui-ci, en particulier les installations classées pour la protection de l'environnement (ICPE), et présenter un risque pour les populations, soit par leur impact sur les installations du site voisines, nucléaires notamment, soit par elles-mêmes lorsqu'elles affectent des installations situées sur le site.

La première étape de cet examen consiste à établir un recensement aussi précis et exhaustif que possible des installations concernées du site ; on s'appuie essentiellement à ce stade sur la nomenclature des installations classées. A partir de ce recensement, deux catégories d'installations sont distinguées.

- les installations du site susceptibles de rejeter en situation accidentelle les produits toxiques qu'elles utilisent (par exemple, stockage d'acide fluorhydrique, de sodium, ...),

- les installations du site ou extérieures au site mettant en oeuvre des produits inflammables qui pourraient par explosion sur place de ces produits ou de la nappe dérivante éventuellement formée à la suite d'une fuite, conduire à une situation accidentelle grave sur des installations voisines du site, nucléaires notamment.

Des scénarios accidentels réalistes pour chaque installation sont alors définis et les rejets dans l'environnement qui peuvent en résulter sont évalués : on s'appuie, d'une part sur des évaluations théoriques a priori (calcul du débit de fuite d'un stockage, masse pouvant exploser et surpression engendrée par l'explosion de cette masse sur une installation, ...), d'autre part sur des données expérimentales ou tirées du retour d'expérience (fuite d'UF₆, feux de sodium, ...).

III - EVALUATION DES CONSEQUENCES SUR L'ENVIRONNEMENT ET LES POPULATIONS DES REJETS RESULTANT DES SITUATIONS ACCIDENTELLES RETENUES POUR LE PPI

L'évaluation des transferts dans l'environnement des rejets résultant des situations accidentelles retenues (Cf. II), est effectuée à partir de modèles de dispersion de ces rejets dans l'air, l'eau et le sol.

Pour la détermination des contre-mesures de confinement ou d'évacuation des populations à prendre à court terme (objet du PPI), la voie de transfert par l'air est la plus critique : c'est à partir de l'évaluation des transferts des produits dangereux par cette voie que seront déterminées les zones pouvant nécessiter l'application de contre-mesures. L'évaluation des transferts en fonction de la distance au point de rejet est effectuée au moyen de codes de dispersion atmosphérique adaptés à chaque cas : rejet gazeux ou assimilable à un rejet gazeux, rejet de gaz lourd, rejet liquide, compte tenu de la géométrie de la source (ponctuelle, surfacique, volumique) et de la cinétique du rejet.

On retient pour cette évaluation des données météorologiques relatives au site réalistes, mais toutefois pessimistes au plan des coefficients de transfert atmosphérique.

Toujours par souci de réalisme, il est également tenu compte éventuellement de l'effet de bottement de la direction du vent ou cours du temps.

Les conséquences radiologiques et/ou toxiques des transferts sont ensuite calculées selon les méthodes classiques, les résultats étant généralement exprimés, pour les premières en équivalents de dose engagés durant l'accident par irradiation externe et/ou interne, pour les secondes, en concentrations des produits dans l'air associées aux durées d'exposition à ces concentrations.

IV - DEFINITION DES CONTRE-MESURES A PREVOIR DANS UN PPI

La définition des zones de confinement ou d'évacuation des populations repose sur l'examen des conséquences radiologiques et /ou toxiques, telles qu'elles sont évaluées en III, des situations accidentelles retenues selon les principes proposés en II, en regard, au plan radiologique, des niveaux d'intervention proposés par la publication n° 40 de la CIPR, et, au plan de la toxicité, des données françaises ou étrangères les plus récentes concernant les produits mis en cause.

Les données classiques en matière de toxicité sont constituées d'abaques qui représentent les seuils d'apparition sur l'homme d'effets toxiques croissants du produit considéré (en général : irritation, malaise, danger, décès) en fonction de sa concentration dans l'air et de la durée d'exposition à cette concentration.

Lorsque de telles données n'existent pas, on utilise les repères que constituent pour un produit donné les valeurs limites d'exposition à court terme (VLE) ou les valeurs limites de moyenne d'exposition (VME) pour les travailleurs, publiées en particulier par l'Institut National de Recherche en Sécurité (INRS).

Sur ces bases, on retient, pour l'ensemble des situations accidentelles examinées (Cf. II) celles qui nécessitent, selon les critères ci-dessus, la mise en oeuvre de contre-mesures.

Ces situations et leurs conséquences doivent être répertoriées dans le PPI ainsi que les zones concernées par les contre-mesures.

Les modalités et moyens pratiques de la mise en oeuvre des contre-mesures sont à définir par les autorités publiques compétentes. Compte tenu en particulier des courts délais d'intervention que requièrent certaines situations accidentelles à cinétique rapide, des contre-mesures particulières ponctuelles, spécifiques au site, peuvent être mises à la charge de l'exploitant au nom des pouvoirs publics avant l'intervention effective de ceux-ci.

V - CONCLUSION

La méthodologie proposée ci-dessus constitue un canevas structuré, homogène et exhaustif pour élaborer, sur des bases techniques fondées, le PPI d'un site nucléaire.

Elle a d'ores et déjà été appliquée à différents sites nucléaires français.

MAKING UP DECISION SUPPORT SYSTEM IN NUCLEAR EMERGENCY
———FRAMEWORK OF DECISIONS———

Y.Nakashima* , T.Suzuki** and A.Nagai**

ABSTRACT

In the case of nuclear emergency, decision will be made at various situations. Decisions are made to minimize detrimental effects to the population and environment of interest. Many materials and data are necessary. In the present study, the authors focus on making up the decision support system (DSS) in a nuclear emergency to help a decision-maker (a prefectural governor or a co-prefectural governor) in the headquarters of countermeasure against the emergency. As a first step to make up the system, the framework of the system is given in the following.

INTRODUCTION

There have been many natural disasters in our country and some experiences learnt from the disasters would be available to the situations in nuclear emergencies. One have experienced to some extent natural disasters everywhere in our country, accompanying recommendation of relocation due to landslide by heavy rain, for example. Since the naturally occurring phenomena could be felt by one's senses, one could apply his experiences activating his own script in natural disasters.

The decision-maker for the case recommending intervention measures in the headquarters of countermeasure against the emergency will be a prefectural governor or a co-prefectural one. It is important to prepare for nuclear emergency paying attention to the similarities and differences between natural disasters and the situations being supposed in the emergency. The authors discuss a framework of the decision in the emergency to support the decision-maker.

DECISION S IN NUCLEAR EMERGENCY OUTSIDE FACILITY

In the case of nuclear emergency, local authority set up the headquarters of countermeasure by the instruction of the central conference on countermeasure for disasters based on information from the nuclear facility, or by the judgement based on the indication of fixed environmental monitors above 10 μ Gy/h or dose predicted over 5 mSv.

A prefectural governor or a co-prefectural governor will be a head, and make decisions in various situations with assistance of the comments of senior advisers such as radiation protection and safety.

Stages of Decisions

With the declaration of nuclear emergency, environmental emergency monitoring will be made according to the procedure in advance. The decision-making in emergency have to be made based on information from the monitoring, economic and social factors. The decision-making will be done for (a)sheltering in the house, (b)sheltering in a PS concrete building, (c)evacuation, (d)restriction of area, food and water, (e)restriction of shipment for agricultural products, (f)cleanup of the environment ((d)-(f) are in the case of environmental contamination) and so on according to the situations. Based on justification and optimization procedure, decisions will be made after discussion on the alternatives and their feasibility. It is necessary to evaluate the cost of unit collective dose in the case of the emergency. As tentative value, the authors adopt the cost of ten times of D_0 -value for workers in normal practices⁴⁾.

Factors Specific to Local Site to Support Decisions

In the case of nuclear emergency, the local factors specific to the site have to be taken into account. The main factors include the followings; (a)populations (according to kinds of occupations and earnings), (b)distribution of populations, (c)agricultural products in each season, shipment and consumption of the products, (d)the data on the fishery products, shipment and consumption of the products, (e)network of roads, land and maritime transportation, (f)types of houses and building (including the characteristics of surfaces), (g)geological and geographical data (types of soil, agricultural field, plants, forest, and so on), (h)data on water resources, (i)equipments applicable to environmental cleanup, (j)data on societies, local culture and custom, and so on. On the introduction of intervention, economic and social data are important specially in comparison of predicted detriments. It is preferable for these basic factors to be incorporated into database. Some data in the database will be also applicable to decision-making in natural disasters. One could feel risk from natural disaster with his senses. Since the detriment could not clearly be felt in nuclear emergencies, it is important to make decisions referring the objective data.

CONSTITUTION OF DSS

In the case of the emergency, strategic and tactical decisions will be important. The former ones would be made to minimize (or to optimize) detriment from the view point

of the whole emergency, and the latter ones would be made to reduce hazard in the scene (to select routes of minimum exposure for refuge in the case of relocation or sheltering in a PS concrete building, for example).

DSS includes database management software, model-base management software and dialogue generation software²⁾. Major parts of DSS are classified into knowledge information system and modeling support system. These give information on the model necessary to the decisions after systematic referring knowledge on disasters in the database. The authors intend to introduce Fuzzy theory for judgement in the scene accompanying uncertain factors. Figure 1 give a conceptual framework of the present DSS.

CONCLUDING REMARK

In the present study, a decision support system in nuclear emergency was discussed. However, the system is just begun to start. The content of database and model-base necessary in nuclear emergency will be gradually revealing. Since the α -value in the emergency is the most important factor in comparison of the detriments, further discussion on the value will be needed.

ABSTRACT

Intervention Levels (ILs) and Derived Intervention Levels (DILs) for initiating countermeasures in public domain following a nuclear accident or radiation emergency are established in advance. Public regime is divided in Domain 1,2 and 3 incorporating space-time concept to meet ICRP-40 recommendations. ILs in dose ranges from 1 mSv to 500 mSv to whole-body and 50 mSv to 2500 mSv to thyroid are proposed. A correlation between gamma dose rate from ground contamination and whole-body dose and inhalation thyroid dose is established to workout DILs. Relationship to obtain period of persistence and completion of countermeasure is also proposed. DILs for important radionuclide concentration in major food items are suggested.

BASES FOR INTERVENTION LEVELS

Accident in a nuclear installation, giving rise to radiological consequences in public domain, may call for implementation of countermeasures (intervention) for protection of public. Thus, there is a need to establish ILs and DILs in advance so that appropriate countermeasures could be undertaken in a planned manner. System of radiological protection for intervention is based on : i) the proposed intervention should do more good than harm; ii) the form, scale and duration of intervention should be optimised. Dose limits used for normal operations do not apply in the case of intervention (1).

The Sets of lower and upper levels of ILs are based on : a) serious nonstochastic (deterministic) effects should be avoided by introduction of countermeasures to limit individual dose to levels below the thresholds for these effects, b) the risk from stochastic effects should be limited by introducing countermeasures which achieve a positive net benefit to the individuals involved and c) the overall incidence of stochastic effects should be limited, as far as reasonably practicable, by reducing the collective dose equivalent (2).

ILs should be so selected that the dose criteria prescribed for Design Basis Accidents (DBA) in nuclear power plants, which dictate the design of engineered safety features, if exceeded only, should pose radiological consequences requiring implementation of disruptive countermeasures such as evacuation. Averting exposure by sheltering, administration of stable iodine or control of food stuffs for a limited period may be acceptable for

SPACE			
	NEAR FIELD (A ₁)	INTERMEDIATE FIELD (A ₂)	FAR FIELD (A ₃)
TIME			
EARLY PHASE (B ₁)	A ₁ -B ₁	A ₂ -B ₁	A ₃ -B ₁
INTERMEDIATE PHASE (B ₂)	A ₁ -B ₂	A ₂ -B ₂	A ₃ -B ₂
LATE PHASE (B ₃)	A ₁ -B ₃	A ₂ -B ₃	A ₃ -B ₃

Figure 1: SPACE-TIME DOMAIN ILLUSTRATION FOR EMERGENCY PREPAREDNESS PLANS accidents enveloping DBA.

Three Space-Time domains are identified on the basis of these principles for establishing ILs. These are; Domain 1: Near Field - Early Phase (A₁- B₁); Domain 2 : Near Field - Intermediate Phase (A₁-B₂) ; Intermediate Field - Early Phase (A₂-B₁) ; and Intermediate Field - Intermediate Phase (A₂-B₂) and Domain 3: Near Field -Late Phase (A₁-B₃); Intermediate Field - Late Phase (A₂-B₃); Far Field - Early Phase (A₃-B₁); - Far Field - Intermediate Phase (A₃-B₂); and Far Field - Late Phase(A₃-B₃). These are illustrated in figure 1.

Physical boundaries of domains in space and time are dependent on a large number of variable parameters such as, source term; duration of release, atmospheric conditions, etc. Thus, identification of these boundaries in case of an accident leading to atmospheric release of radioactive material would require multiple measurements and evaluations.

INTERVENTION LEVELS

Administration of stable iodine, sheltering, evacuation and control of food stuffs are considered important countermeasures for averting dose in the short term. ILs, suggested for these countermeasures for the three domains are summarised in Table 1 and are given in a range - lower and upper. If assessed release and measurements confirm that lower levels of ILs are not likely to be exceeded, countermeasures need not be initiated. If lower levels are likely to be exceeded, countermeasures should be initiated and completed such that upper levels of ILs are not exceeded. Persons in Domain 1, whose estimated exposures are in excess of upper levels of ILs of dose, may need special attention including medical care. Bases for adopting ILs are : Domain 1: Domain 1 is a low population zone. It is physically nearest to plant. ILs are based on prevention of serious nonstochastic effects. Objective of countermeasures viz., administration of stable iodine, sheltering and/or evacuation is to limit individual doses so as to avoid serious nonstochastic effects. Inhalation route for thyroid exposure would be a major consideration. Domain 2: ILs are chosen to limit stochastic risk to individual member of public. Ingestion route is likely to be the important mode of exposure. Exposure from plume, inhalation and ground contamination are expected. Countermeasures envisaged are administration of stable iodine, sheltering and / or control of food stuffs. Domain 3: ILs are aimed to reduce collective dose. Ingestion route is the predominant mode of exposure. Countermeasure recommended is control

D O M A I N	Counter- measure	Intervention Level mSv			
		Whole Body		Thyroid	
		Lower	Upper	Lower	Upper
	Administration of stable I	-	-	500	2500
1	Sheltering	20	100	-	-
	Evacuation	100	500	-	-
	Administration of stable I	-	-	50	500
2	Sheltering	5	20	-	-
	Control on food stuffs	5	20	50	500
3	Control on food stuffs	1	5	not anticipated	

Table 1: INTERVENTION LEVELS FOR DOMAINS 1, 2 & 3.

of food stuffs.

DERIVED INTERVENTION LEVELS

ILs are translated into DILs in quantities which are easily, reliably and accurately measurable. The time required for these measurements is important for initiation of countermeasures in Domain 1 & 2. Measurement of radiation field at 1 m above ground is a simple, fast and accurate parameter. A relationship is, therefore, derived to correlate gamma dose rate at 1 m from ground contamination to projected dose received by individual member of public following an accident resulting in atmospheric release. Dose rate from ground contamination DR_g is given by :

$$DR_g = X \cdot V_d \cdot DCF_i \quad \text{-----} \quad (1)$$

Where, X is time integrated airborne concentration, V_d is deposition velocity (0.01 ms^{-1}) for iodines and DCF_i is dose conversion factor ($2.9 \times 10^{-12} \text{ Sv h}^{-1} / \text{Bq m}^{-3}$). Intake of $6.76 \times 10^5 \text{ Bq}$ of iodines gives thyroid dose of 0.5 Sv, hence for a breathing rate of $1.7 \times 10^{-4} \text{ m}^3 \text{ s}^{-1}$, X is $2 \times 10^9 \text{ Bq m}^{-3}$. Using these values, DR_g calculates to $5.8 \times 10^{-5} \text{ Sv h}^{-1}$ for inhalation dose of 0.5 Sv. Thus 0.1 mSv h^{-1} dose rate from ground contamination would be equivalent to $> 0.5 \text{ Sv}$ thyroid dose from inhalation.

DR_g should be reliably available before initiating sheltering and/or evacuation. Thus, there is need to confirm these measurements over a period of time, and, if, radiation field persists, appropriate countermeasures can be initiated and completed. Total dose D_t to the whole body consists of plume dose D_p , inhalation dose D_i and ground contamination dose D_g . D_g is a

Countermeasure	Sheltering		Evacuation		
	DR _g (mSv/h)	P _h (h)	P _c (h)	DR _g (mSv/h)	P _h (h)
0.1 - 0.5	4	56	2.0 - 2.5	10	50
0.5 - 1.0	4	26	2.5 - 3.0	10	40
1.0 - 1.5	4	16	3.0 - 3.5	10	32
1.5 - 2.0	4	11	3.5 - 4.0	10	27

Table: DILs IN DOMAIN 1 FOR SHELTERING & EVACUATION

fraction $f = .3$ (4). Hours of persistence P_h , hours of completion of countermeasures P_c , ILs and DILs are related as follows:

$$(P_h + P_c) = IL \times f / DIL \quad \text{---- (2)}$$

Thus, for given DILs in terms of DR_g, IL and P_h , P_c can be calculated.

Relationships (1) and (2) are used for arriving at DILs for Domains 1 and 2. Accordingly, administration of stable iodine should be completed as soon as DR_g is more than 0.1 mSv/h and 0.01 mSv/h in Domain 1 and 2 respectively. DILs for evacuation and sheltering are given in Table 2. DILs for control of food stuffs in concentration of radionuclides, are calculated based on reference (3)

CONCLUSIONS

The ICRP-40 concept of recommending ILs for phases has been extended to incorporate space dimension. DILs are established in terms of radiation field at 1 m above contaminated ground, which is easily, reliably and accurately measurable. Proposed relationship between IL, DIL, P_h and P_c helps to adjust P_h and P_c to suit typical site conditions. Also, selective implementation of sheltering and evacuation can be undertaken depending on radiological conditions.

THE BRAZILIAN RADIOLOGICAL ACCIDENTS ANALYSIS METHODOLOGY
IN INDUSTRIAL GAMMA RADIOGRAPHY

F. C. A. Da Silva and L. Tauhata

Instituto de Radioproteção e Dosimetria
Comissão Nacional de Energia Nuclear
Rio de Janeiro - Brasil

ABSTRACT :

A critical review of 34 severe radiological accidents in industrial gamma radiography, that happened in 15 countries, from 1960 to 1988, was performed. It was noted that there is a need for improvement of the analysis and dose estimations methods, in order to obtain real information and good dose estimations.

The present paper shows the Brazilian radiological accidents analysis methodology in industrial gamma radiography, based in the analytical tree techniques, recommended by International Atomic Energy Agency to perform radiation protection and nuclear safety programs.

INTRODUCTION:

Industrial gamma radiography is a non-destructive technique used as nuclear application in industry. In spite of the simplicity of the technical procedure, the industrial gamma radiography is responsible for the highest number of radiological accidents in most countries. In this type of accident people are injured due to high radiation exposure given by the high activity of the small size sealed radioactive source.

The worst situation as far as exposure to radiation is concerned occurs when the radioactive source is at the unshielded position and it disconnects from the control cable. The more dramatic situation is when the radioactive source is found by individuals of the public who take it home and show it to their friends or members of the family. Depending on the source handling, absorbed dose can reach high values which cause severe injuries and even deaths.

In order to analyze a radiological accident, circumstances need to be carefully reconstructed to obtain accurate information on the number of exposed people, time of radiation exposure, probable values of absorbed dose and most affected organs. Such information help the medical treatment to be used, since they allow an estimation of the extension and type of injury, prognosis of damages, corresponding risks for the victims, etc.

As it has had some difficulties to analyze and to attend the Brazilian cases due to the absence of important data, it was elaborated a methodology, based in the analytical tree techniques, recommended by IAEA.

The Brazilian radiological accidents analysis methodology has five major constituents: investigation, reconstitution, dosimetry, conclusion and recommendation.

CONCLUSION :

The analysis of the 34 selected radiological accidents (Table 1) showed that 118 persons were highly exposed to radiation where 28 (23.7%) were workers and 90 (76.3%) were individuals of the public. Fifty five injured persons had acute exposures in localized parts of the body, mainly extremities (hands, fingers and arms) since they held the source in their hands and put it in their pockets.

The causes analyzed of radiological accidents in industrial gamma radiography showed that workers need a more detailed and wide-range training including an updating in radiation protection procedures to avoid faults in source monitoring and inadequate routine procedure.

Dose assessment methods for whole body, organs or parts of the body need to be improved to obtain good estimation of dose to help the medical treatment of victims.

The suggested methodology, that was elaborated to analyze and to attend the Brazilian cases of radiological accidents and is showed in the Figures 1 to 6, is very adequate and promising because it gives a systematic analysis procedure. This methodology enables to determine the true causes of the event, to estimate the dose with less uncertainty and to obtain recommendations to avoid future accidents.

Decontamination Exercise at a General Hospital

B. Heaton

Department of Bio-medical Physics,
University of Aberdeen, Foresterhill,
Aberdeen AB9 2ZD, SCOTLAND.

Abstract

By using a luminescent material as a substitute for radioactive contamination a realistic assessment of the emergency plans for dealing with contaminated radiation casualties at a Regional General Hospital was made. The areas where problems arose in these plans are described and the changes now made to them given.

Introduction

Many hospitals have contingency plans to receive contaminated radiation casualties as part of the national arrangements for dealing with such events. Fortunately very few have to ever implement these plans and a real experience of how they would work is not available. Aberdeen Royal Infirmary is a receiving hospital for the North East of Scotland. Although we have no nuclear reactor or naval bases in our area we do have several research institutions and the University, all of which use quite large quantities of unsealed sources. A large air force base with strike aircraft based at it is also present. In addition to these long standing users we have had, in recent years, spent radioactive fuel occasionally passing through the area on its way to Dounreay for processing. The biggest recent influx of radioactive sources however is those introduced by various service companies to the oil industry. These are mainly large sealed sources but also include some unsealed sources. Our plans to deal with such casualties were written and prepared on very similar lines to those prepared for use in other hospitals and we had every confidence they would deal with the situation if it ever arose. As part of an on going evaluation of all emergency plans it was decided to test the plans in what would be perhaps the worst scenario.

Scenario

An accident was assumed to have taken place at one of the oil related companies resulting in the rupture of a sealed source. Casualties were restricted to two so that a realistic assessment of the plans could be made within a reasonable period of time. The clinical injuries were kept to a minimum as our decontamination procedures were being tested not the medical treatment. Sufficient clinical work had to be provided however to provide a realistic situation. One casualty was made up so as to indicate a broken tibia and facial lacerations from flying debris, the other broken ribs with a pneumothorax. Radiation contamination was simulated using a fluorescent powder. This had the very real advantage that in small quantities it was invisible to the eye but could be seen when viewed under a U.V. light. By using hand held

U.V. lights it was possible to simulate the contamination monitoring equipment that would be available. [Anthracene was used for this exercise, as this was commonly used in other areas for similar work. Tests were made to ensure that the two casualty volunteers were not sensitive to it by contaminating a small area of forearm skin a few days before the exercise. Recent recommendations on the use of anthracene for this purpose would suggest that an alternative powder should be considered]. The contamination of the casualties was restricted to quite a small area and was not visible to the naked eye. Likewise the floor around the casualties was contaminated but this again was not visible to the naked eye.

Senior management staff in all areas were aware of the exercise, mainly to stop events escalating rather than to ensure the exercise did not come to a complete stop. Most of the participants from telephone operators through to the emergency staff either did not know or were only vaguely aware that some sort of exercise was planned.

Description of Exercise

The hospital switch board was notified of the incident at 1.30p.m. and had successfully alerted all the emergency staff who had gathered with their equipment in the Accident and Emergency (A & E) department before the ambulance arrived with its casualties. If the incident had been out of normal working hours the physicists called in would have inevitably taken some time longer to appear. The first part of our plan involved covering the floor of part of our A & E department with polythene together with a "corridor" to this area from the designated entrance. It was very quickly realized this would not be possible to do in the time available before the casualties could arrive and the attempt was abandoned. Even with sheets of polythene cut to size it takes a surprising amount of time to lay and stick them down so that it is safe to walk on. Barriers were erected round the area to demarcate it. The personnel going into this controlled area put on protective clothing and other staff were positioned to service them as required.

Response of the Ambulance Crew

The crew were warned that the casualties were contaminated and they were entering (for the exercise) a radiation controlled area. They put on rubber gloves which subsequently split. If expert staff were present they would of course normally have advised them on what precautions to take. In this exercise no detailed advice was volunteered but would have been given if asked for. Likewise additional equipment held in the area would also have been provided if requested. No attempt was made by the crew to request contamination monitoring and none was undertaken. The clothes of both members of the crew became contaminated as well as the skin on their hands and knees. At the time of the exercise they were also expected to wear peaked hats at all times (this requirement has since been totally rescinded). As their hats fell over their faces and they pushed them back up, their faces and hair also became contaminated. Special 'impervious' coveralls were not normally carried on the ambulance although they were available at the ambulance depot. The ambulance became badly contaminated after they had put the casualties into it as, although they wrapped the casualties, their shoes and hands carried quite a large quantity of powder with them. During the crew's initial examination of the casualties and their treatment the contamination was spread over a much wider area. Without involving someone on site with a contamination monitor this spread of contamination

is impossible to control. Even if a monitor was available it is suspected that control would still be difficult.

Response of Accident and Emergency Department

The opportunity was taken to try out different types of protective clothing to see which was the most efficient and which the most convenient. This clothing varied from a simple white waxed paper suit with a theatre mask to a full PVC protective suit with a battery powered breathing hood. All staff wore normal disposable rubber gloves. Our plan stipulated that the ambulance men should hand over the patients at the entrance to the A & E department. Despite being aware of this they followed their normal practice and entered the area thus immediately contaminating the floor. One physicist had to be diverted from dealing with the casualties to monitor them and advise them what to do.

In the course of treating the injuries the doctor and nurses, even with "monitors" and advice available, spread the contamination to areas of the patient not previously contaminated. Our plans had laid down that staff in the controlled area should be kept to a minimum. This policy was felt to contribute to this spread as people moved from patient to patient and perhaps forgot the location of contamination on each patient. The other marked tendency was to use as little localised decontamination using swabs as possible and rely on the shower in the area to clean the rest. [The fact that the casualties were postgraduate male students and the nurses of similar age was not felt to have contributed to this].

At the end of the exercise anthracene powder was found all over the floor of the area and on the walls. The shower was generally contaminated. All individuals had some anthracene on their wrists and all but the person wearing the hood had some on their face. If it had been a real event a large part of the A & E department could have been taken out of use for several days while it was decontaminated. The consultant staff felt that even with the very small chance that a real incident would occur such a situation should not be contemplated.

Conclusions

For very little effort our procedures were tested under realistic conditions which highlighted many unsuspected inadequacies. The major one was that an alternative area required to be identified to receive contaminated patients if a large part of the A & E department was not to be under threat of being contaminated. This has now been found. A small room has been created at the very periphery of the A & E department which can, if necessary, be completely isolated without affecting the work of the A & E allowing decontamination to take place in a controlled manner. Medical equipment will have to be taken there if required but this is a minor problem. The room is completely tiled with a shower in one corner and can cope with two casualties. If more than two appeared they would have to stay outside in an Ambulance unless a life threatening situation existed. By being very prudent with the brief for this room the cost was kept to an acceptable level, even within the UK Health Service, for a room it is hoped never to use.

It was also apparent that although the hood provided complete protection it made communication with other staff and the casualties very difficult. It is now considered that the white wax suits used in conjunction with a high quality nasal mouth mask (i.e. rated for asbestos work) would suffice. It is accepted that some facial contamination may occur if loose powders

are present. Goggles should also be available. Long sterile gloves are absolutely essential, normal sterile gloves are inadequate. The stock of wellingtons also required changing - most of them were too big for the nurses.

Measuring pulse rates was difficult and a large clock with a sweep second hand would have been useful. Gauze swabs were found far more useful than disposable wipes and it was found that the stock of polythene bags for putting waste items into was soon finished. The idea of keeping the number of people involved to a minimum contributed to the spread of contamination and in future each casualty will have a "team" of people who will solely work on him/her. This will also allow much more of the contamination to be removed by local swabbing rather than using the shower.

Recommendation

All emergency plans for dealing with contaminated casualties should be tested using a real contaminant which can be spread in much the same way as a radioactive contaminant. Only by monitoring the spread of this material can a real assessment be made of the efficiency of the plans. Plans which are apparently quite adequate under routine trials can prove to have deficiencies when tested in this way.

AGRICULTURE, ENVIRONNEMENT ET NUCLEAIRE :

COMMENT REAGIR EN CAS D'ACCIDENT

AGRICULTURE, ENVIRONMENT AND NUCLEAR USES :

HOW TO REACT IN CASE OF ACCIDENT

Presentation of a reference handbook analyzing the consequences of a nuclear accident on agriculture and how to react in order to mitigate them.

Based on the right of citizens to be informed on civil security organization, on the protection of population, goods and environment : this book is a preliminary reflexion to post-accidental planification.

INTRODUCTION

Dans le monde actuel, la communication a pris une importance considérable. Le public demande à être informé car il veut comprendre et apprécier le bien-fondé des choix faits par les instances politiques.

C'est dans ce contexte qu'a été élaboré, conjointement par un organisme professionnel, la Fédération Nationale des Syndicats d'Exploitants Agricoles, et un organisme scientifique, l'Institut de Protection et de Sûreté Nucléaire, un document intitulé "Agriculture, Environnement et Nucléaire : comment réagir en cas d'accident".

MOTIVATION ET OBJECTIFS

La FNSEA, au nom de ses adhérents, les agriculteurs, se préoccupe depuis longtemps déjà des conséquences que le développement de la filière nucléaire peut avoir sur l'agriculture : il ne faut pas oublier, en effet, que ce développement ne se fait pas dans les villes, mais à la campagne.

Jusqu'à l'accident de Tchernobyl, cette cohabitation s'est bien passée : par la suite, il en a été différemment. En effet, les agriculteurs ont été frappés de plein fouet par cet accident, à travers un flot d'informations désordonnées, contradictoires et auxquelles ils ne comprenaient pas grand chose, si ce n'est qu'il en résultait des difficultés pour écouler certaines de leurs productions.

Très rapidement, les responsables de la FNSEA, persuadés que l'information doit permettre, en ce domaine comme en d'autres, d'éviter une attitude moyennageuse et d'aborder ouvertement les problèmes éventuels, ont décidé de se rapprocher des spécialistes du nucléaire, parmi lesquels se trouvent des agronomes et des vétérinaires.

Ensemble, ils ont produit le document cité, qui a reçu un accueil étonnamment favorable, prouvant qu'il y avait là un véritable besoin.

LES DESTINATAIRES

La préoccupation principale de la FNSEA étant tournée vers ses adhérents, c'est d'abord à leur intention que le document a été préparé. Les agriculteurs connaissent bien l'environnement, ses forces et ses faiblesses : de plus, ils sont réalistes et savent bien qu'il faut parfois composer avec les événements notamment les agressions naturelles auxquelles ils sont sans cesse confrontés. Et, il faut le rappeler, ils ont été les principales victimes de l'accident de Tchernobyl.

Mais l'audience peut être beaucoup plus large, dans le monde agricole (administration, organismes publics ou professionnels, industrie agro-alimentaire, ...), vis-à-vis des associations préoccupées par les problèmes d'environnement, les médias (notamment scientifiques), les enseignants, ... et puis tout citoyen soucieux de s'informer et conscient du fait que l'environnement est son cadre de vie et l'agriculture le support de sa subsistance.

LES OBJECTIFS

L'objectif essentiel du document apparaît dans son intitulé "Comment réagir en cas d'accident". Il s'agit de donner des informations qui permettraient, en cas de crise, de prendre très vite toute initiative susceptible d'en atténuer les conséquences, puis, lorsque des consignes seraient données par les autorités compétentes, de les appliquer intelligemment. Ces informations doivent également aider le milieu agricole à sauvegarder ses intérêts et à ne pas être dépassé par une situation que certains sont tentés d'exploiter à des fins qui ne sont pas altruistes.

Pour cela, il faut non seulement intégrer l'information, mais aussi bien la comprendre. Le document s'est donc voulu explicatif, en traitant notamment des processus de transfert des éléments radioactifs de l'atteinte des productions agricoles et des conséquences des utilisations ou des transformations de ces productions.

Il fallait aussi faire précéder ceci par une information plus générale sur la radioactivité, ses effets, les moyens de s'en protéger. Il fallait enfin aborder le domaine des accidents nucléaires "Risques accidentels associés aux diverses utilisations de la radioactivité, éléments radioactifs concernés, typologie des accidents, organisation de l'intervention, mesures protectives,".

CONCEPTION DU CONTENU

De ce qui précède, découle le plan adopté qui porte sur :

- les connaissances générales ;
- les aspects liés aux accidents nucléaires, y compris les bases et l'organisation de l'intervention ;
- la contamination des milieux (atmosphère, sol, eaux, milieu naturel) ;
- la contamination des productions (légumes, fruits, lait, viande, ...) ;
- des exemples concrets.

Pour faciliter la lecture d'un document assez volumineux, on a cherché :

- > à faciliter la compréhension, en évitant les termes peu communs, en définissant les termes spécifiques, en repérant dans un index les termes importants et en utilisant un système de renvois entre parties similaires ou complémentaires ;
- > à rendre chaque "fiche" auto-porteuse (le lecteur peut ne lire que ce qui l'intéresse) et en adoptant une présentation standardisée pour les fiches "milieux" et "productions", à savoir :
 - * comment se produit la contamination ?
 - * quels sont les risques résultants ?
 - * comment s'en protéger ?
- > à équilibrer les explications théoriques et les applications pratiques ;

-> à utiliser un style direct, concis et clair et une présentation aérée et abondamment illustrée.

Cette approche, pour autant qu'elle soit réussie, ne va pas sans certains pièges. Le principal est sans doute de faire cohabiter l'exactitude scientifique et la simplicité de présentation. Difficile aussi de présenter des aspects qui sont encore en évolution ou sur lesquels il n'y a pas consensus.

CONCLUSION

Il serait illusoire de croire que l'on peut atteindre parfaitement un objectif aussi délicat, dans un domaine encore bien neuf, où tout n'est pas toujours net et précis et où la passion l'emporte bien souvent sur la raison.

Rester objectif, éviter tout catastrophisme mais aussi toute tendance lénifiante, essayer d'être bien compris : tel a été le souci des rédacteurs. Il sera fort utile de savoir s'ils y sont parvenus.

DACFOOD
Un système d'aide à la décision en cas de contamination de la chaîne alimentaire

Alain DESPRES, Antoine DIAZ & Dominique SOULATGES
CEA/Institut de Protection et de Sécurité Nucléaire
Département de Protection de la santé de l'Homme et de Dosimétrie

BP n 6 - 92265 Fontenay-aux-Roses Cedex (France)

DACFOOD
A Decision aiding-system in case of contamination of the foodchain

DACFOOD is an interactive decision-aiding software allowing:

- to calculate the doses due to the consumption of contaminated foodstuffs;
- to propose countermeasures, taking into account the type of foodstuff and the concerned radionuclides;
- to estimate the dosimetric impact, the cost and feasibility of the available countermeasures;
- to suggest a classification for sets of combined countermeasures, ie. actions, on a cost/effectiveness basis.

Introduction.

L'objectif du programme DACFOOD (Decision Aiding for Contaminated FOODstuffs) est de fournir aux décideurs les éléments d'une gestion optimisée des produits alimentaires contaminés à la suite d'un accident nucléaire. Cette gestion repose sur l'évaluation coût/efficacité des contre-mesures susceptibles d'être mises en oeuvre et sur des jugements d'experts.

Les fonctionnalités du système

L'analyse coût-efficacité repose sur deux types de données :

- des données propres à l'accident : la nature et la quantité de produits contaminés, l'activité mesurée de chaque isotope et l'activité déposée au sol;
- des données archivées de façon permanente.

Ces dernières figurent dans les bases de données suivantes :

- une base de données relative aux radionucléides (périodes radioactives, facteurs de dose);
- la base de données EUROGRID /1/, qui donne les populations, l'utilisation des sols, les productions agricoles annuelles, l'effectif du cheptel et le nombre d'emplois par type d'activité sur un réseau maillé. Cette base peut être appelée à défaut de données plus spécifiques du moment de l'accident;
- une base de données relative aux contre-mesures (coût, efficacité, faisabilité);
- une base de données relative aux différents facteurs de transfert sol-plantes;
- une base de données relative aux facteurs techniques traduisant l'impact des transformations agro-alimentaires.

Ces différentes données sont utilisées pour évaluer les doses individuelles et collectives consécutives à l'ingestion des denrées alimentaires. A ce stade, le système compare les doses individuelles aux seuils d'intervention proposés par la CIPR et aux seuils de commercialisation des denrées adoptés par la Commission des Communautés Européennes. Il en déduit s'il convient ou non de mettre en oeuvre une contre-mesure. Dans l'affirmative, le système évalue et classe les contre-mesures envisageables par le coût de l'homme-Sievert évité.

Les doses dues à l'inhalation et à l'irradiation externe sont introduites en tant que données pour le calcul des doses individuelles.

L'analyse précédemment décrite ne suffit pas, à elle seule, pour décider de la mise en oeuvre d'une contre-mesure. Plusieurs éléments, plus difficilement quantifiables et rassemblés sous le terme générique de jugements d'experts, doivent être pris en compte. Ces experts, sociologues, politiciens, économistes ou agronomes, ont naturellement des préoccupations différentes. Par exemple, un économiste pourrait prendre en compte la surproduction européenne actuelle de produits laitiers pour rejeter a priori la transformation du lait sous forme de beurre ou de poudre.

Pour introduire ces différents aspects, un système de maintien de la cohérence a été développé, qui met en évidence les contradictions entre les points de vue et recherche un compromis.

La phase actuelle de développement concerne le recueil de cette expertise. C'est une tâche difficile, qui nécessite l'identification des experts, leur sensibilisation au problème, ainsi que le recueil et l'organisation de leurs jugements sous forme de règles. Deux voies sont suivies pour parvenir à ces objectifs : la participation à des exercices de crise et l'enquête par questionnaire.

La maquette, entièrement conversationnelle, a été développée sur le logiciel GOLDWORKS. Son utilisation sur micro-calculateur nécessite une mémoire RAM de 6 Mbytes.

Exemple d'application

L'application, brièvement décrite ci-après, est issue de l'exercice de crise qui s'est déroulé sur le site de Cadarache (Bouches du Rhône, France) du 15 au 17 Octobre 1991.

Six produits alimentaires ont été retenus (salade de plein champ, pomme, raisin de table, viande d'agneau, laits de chèvre et de vache). Les services régionaux du Ministère de l'Agriculture ont pu rapidement estimer les quantités contaminées dans trois régions définies à partir des courbes d'iso-dépôt (seuls ^{131}I et ^{137}Cs ont été pris en compte).

La connaissance des rations alimentaires et la formulation d'hypothèses relatives à l'origine des produits consommés permettent de calculer les doses reçues par deux groupes de population (proche et lointain): les habitants de la zone proche sont considérés comme un groupe critique (on admet que tous les produits qu'ils consomment proviennent de la zone proche), tandis que les habitants de la zone lointaine ont une alimentation qui provient à part égale des trois zones respectivement proche, intermédiaire et lointaine.

La dose efficace reçue par les habitants de la zone proche ainsi que les limites de commercialisation conduisent à entreprendre des actions

sur toutes les productions de la zone proche, ainsi que sur la viande d'agneau, le lait de chèvre et le lait de vache de la zone intermédiaire. Pour chacun des produits alimentaires considérés, les contre-mesures envisageables sont les suivantes :

- aalade : destruction (D);
- viande : destruction (D), abattage différé (Ad) ou stockage;
- lait : destruction (D), décontamination (d) ou transformation;
- fruits : destruction (D) ou éventuellement stockage (pommes).

L'impact de chaque contre-mesure sur chaque lot de produit et pour chaque classe de consommateurs (zone et classe d'âge), ainsi que le coût de ces contre-mesures (incluant la destruction, le stockage des déchets, le transport,...) est illustré à l'aide des figures 1 et 2.

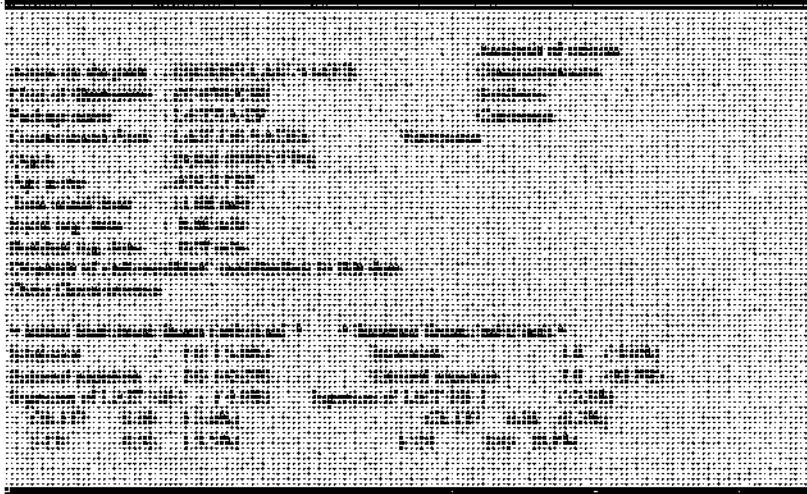

Figure 1 : Image d'écran montrant l'efficacité d'une contre-mesure

Figure 2 : Image d'écran montrant le coût d'une contre-mesure

Appliquées aux différents lots de produits, ces contre-mesures élémentaires permettent de définir des actions. Le choix d'une contre-mesure sur un lot peut être effectué, par l'opérateur ou par le système, en fonction d'un critère choisi (efficacité maximale pour une classe de consommateurs donnée, coût minimal, efficacité maximale sur la dose collective). Les actions évaluées dans le cadre de l'exercice étaient les suivantes :

Actions	Zone	Salades fruits	Lait chèvre	Lait vache	Viande
CM1	proche	D	D	D	D
	intermédiaire	-	D	D	D
CM2	proche	D	D	d	D
	intermédiaire	-	D	D	Ad
CM3	proche	D	d	d	Ad
	intermédiaire	-	D	D	Ad

Le coût et l'efficacité sur les doses individuelles sont donnés pour chaque action :

	Effic.	Coût (ECU)
CM1	90 %	6,7 E05
CM2	80 %	4,6 E05
CM3	90 %	3,7 E05

Figure 3 : Ecran de la synthèse des différentes actions envisagées.

Une telle analyse met en évidence le gain apporté par l'abattage différé, pour une perte d'efficacité relativement faible. Enfin, la décontamination du lait de la zone proche, parce qu'elle porte sur une faible quantité (5 tonnes en 10 jours), est tout à fait envisageable.

Conclusions

Au-delà de l'aide opérationnelle à la décision, l'objectif poursuivi dans la réalisation du système DACFOOD est de disposer d'un outil facilitant la réflexion des personnes impliquées dans la décision. Au stade actuel de maquettage, la participation à des exercices n'a pour but que de permettre de juger de l'intérêt de DACFOOD et de mettre en évidence ses insuffisances.

ÉTUDE SUR LE COMPORTEMENT ÉVENTUEL DES BÉNÉVOLES APPELÉS À EFFECTUER LA DISTRIBUTION DE PILULES D'IODE EN CAS D'ACCIDENT À LA CENTRALE NUCLÉAIRE DE GENTILLY II

Dirigée par Raymond Corriveau
Unité de recherche en communication et communauté
Université du Québec à Trois-Rivières

Study Pertaining to the Distribution of Iodine Pills in the event of a Nuclear Mishap at the Gentilly II Station.

This study seeks to understand how volunteers, whose task it is to distribute iodine pills in the event of a nuclear mishap, are likely to react in such a situation. Our postulate is that the uniform application of preventive measures in an emergency situation requires that volunteers adhere to the principles of the ideological apparatus (civil authority). Our findings are that current measures are inadequate for an effective emergency strategy.

Cette recherche vise la compréhension du comportement éventuel d'un groupe de bénévoles appelés à distribuer des pilules d'iode à la population en cas d'accident nucléaire. Nous tenterons de mieux saisir, comme Lucien Goldmann (1971: 9) le postulait, non pas la conscience réelle des individus, mais bel et bien leur conscience possible. Les travaux furent menés grâce à une étroite collaboration avec le Département de santé communautaire Ste-Marie, dans le cadre de l'élaboration d'un plan de santé en cas d'accident à la centrale nucléaire Gentilly II. Rappelons qu'un aspect particulier de ce plan de santé traite du processus de distribution des pilules d'iode. Cette procédure recommandée par l'OMS (1988: 30) pose de sérieux problèmes de prévisibilité comportementale: en situation de danger appréhendé, les bénévoles voudront-ils exécuter la tâche qui leur a été confiée? C'est à partir de questions de cet ordre que nous avons orienté notre protocole de recherche.

Objectif général de la recherche

Développer une vision plus raffinée du comportement des bénévoles appelés à distribuer les pilules d'iode en situation d'urgence.

En corollaire

-fournir aux responsables un cadre de référence afin de mieux appréhender les divers comportements possibles;

-scoutenir l'effort des autorités compétentes dans leur concertation visant l'établissement de mesures d'urgence;

Objectifs spécifiques de la recherche

-identifier le comportement prévisible des individus afin d'améliorer l'efficacité des plans d'intervention en situation d'urgence;

-rendre plus apparentes les faiblesses possibles dans les mécaniques d'urgence qui pourraient relever de ces comportements éventuels;

-aider les citoyens à mieux protéger leur santé lors de situations d'urgence.

Moyens utilisés

-établir une expertise dans l'application de la Méthodologie-Q-;

-réaliser une enquête auprès des bénévoles ciblés dans le cadre des mesures d'urgence;

-produire des recommandations qui viseront à améliorer le travail des bénévoles appelés à distribuer les pilules d'iode lors d'une situation d'urgence.

Une réflexion soutenue sur la problématique des conjonctures extraordinaires nous invite donc à **postuler** que:

pour que des mesures de prévention et de coordination soient efficaces en situation d'urgence, le bénévole doit effectuer un rattachement significatif vers l'appareil idéologique.

En concordance avec notre cadre théorique, le comportement de l'individu sera vu à partir de ses rattachements idéologiques possibles. Ces rattachements constituent les variables de notre enquête.

***Établissement des variables**

Axe d'induction =====>	Rattachement à l'appareil idéologique	Rattachement au réseau idéologique primaire	Rattachement à soi (comportement narcissique)
	DSC/CLSC/Mairie/ Police/Exploitant de centrale/Sécurité publique, etc.	Famille/Parenté/ voisins/Connais- sances/Relations affectives	L'individu et ses préoccupations
Dimensions ↓			
Théorique (expression directe)	se rattache ou identifie une idéologie spécia- lisée	signale son appartenance à la famille	démontre un com- portement narcissique
Comportement individuel	respecte les lois	identifie la for- mation d'habitus coutumes, manières	priorise l'intérêt personnel
Comportement face aux autres	se conforme à la hiérarchie institutionnelle	privilégie la convivance (réseau affectif)	utilise les autres à ses propres fins

La réalisation de notre projet a nécessité l'utilisation de trois types de collectes de l'information: la méthodologie -Q-, le profil contextuel et l'animation des bénévoles. A la lumière des résultats obtenus dans l'ensemble de la démarche scientifique, nous établissons les constats suivants:

- * à ce stade-ci, la structure de distribution nous semble inopérante (selon contexte global de l'enquête);
- * toutefois l'établissement d'une telle structure nous semble difficile mais réalisable (selon les résultats spécifiques de l'enquête statistique);
- * les difficultés de mise en oeuvre relèvent de conditions liées à l'agissement des bénévoles ;
- * les difficultés rencontrées sont d'ordre organisationnel (selon le contexte global de l'enquête);
- * pour rencontrer les conditions de faisabilités souhaitées, les recommandations suivantes **doivent** être mises en application.

Recommandations

- 1 Revoir et mettre à jour la liste des bénévoles appelés à distribuer les pilules d'iode.
- 2 Structurer ou restructurer l'organisme spécifique qui encadre l'action des bénévoles. Pour être plus efficace, il faudrait revoir le rôle même que joue la Sécurité civile.
- 3 Établir un organigramme et un plan de tâche fonctionnel qui devraient tenir compte de la dispersion géographique des ressources en fonction des services à offrir.
- 4 Identifier un nombre restreint de domiciles à couvrir pour chaque bénévole. Le nombre devrait se mesurer selon le rapport temps/distance en prenant en considération une période de temps allouée à l'explication auprès des populations appelées à prendre des mesures préventives. Comme certains répondants nous l'ont mentionné, la barrière du 60 minutes est difficile à allonger. Dans une situation qui évolue rapidement, il peut être risqué de mandater des gens pour plusieurs heures, sans avoir aucun moyen de les rappeler ou de leur transmettre une information nouvelle. Ces arguments introduisent la recommandation suivante.
- 5 Assurer une formation continue et un suivi (principe de continuité) aux bénévoles en greffant leur organisme aux activités d'un corps déjà constitué. À ce stade-ci, les pompiers bénévoles nous semblent un des rares organismes à fournir des affinités suffisantes pour que le regroupement puisse être de caractère organique. Ce rapprochement permettrait également de fournir une alternative à l'utilisation du service des pompiers volontaires pour distribuer des pilules d'iode, car ces derniers pourraient devoir répondre en même temps à une urgence simultanée reliée ou non à l'accident nucléaire. Un tel rapprochement posséderait aussi le mérite de fournir une certaine reconnaissance et une certaine gratification à ceux qui manifestent un intérêt communautaire.
- 6 Prévoir une formation scientifique minimale pour les bénévoles, formation qui devrait comprendre un volet relié aux effets anxiogènes de la nouvelle dont ils seront porteurs. Cette formation s'avère importante d'autant plus qu'il s'agit d'une des rares modalités qui pourrait amoindrir l'«Évacuation Shadow» (Zeigler & Johnson, 84; 208).
- 7 Mettre sur pied des exercices périodiques afin de roder les mécanismes de gestion (notamment au plan de la circulation de l'information) et de coordination reliés à la distribution de pilules d'iode. Assurer les modalités de rétroaction de ces exercices auprès des intervenants de première ligne, soit les bénévoles.
- 8 Soutenir l'activité des bénévoles par une campagne d'information adressée au grand public afin de préparer leur intervention éventuelle auprès de la population. Encore une fois, nous devrions mettre à contribution les structures déjà établies avant de penser à en soutenir de nouvelles. Les municipalités et les institutions d'enseignement seraient des partenaires logiques dans cette activité d'éducation de masse. Cette campagne devrait prévoir une attention toute spéciale envers les médias afin d'assurer, en cas d'accident nucléaire, un minimum de correspondance entre la version médiatique et celle véhiculée par les bénévoles.
- 9 En cas de circonstances exceptionnelles caractérisées par une situation de haute instabilité, le contact avec les bénévoles devrait être constant. À défaut de pouvoir fournir un équipement de

communication personnel à chaque individu, une station de radio devrait être réquisitionnée afin d'assurer un canal de communication officiel, non seulement pour les gens impliqués dans la distribution des pilules d'iode mais aussi pour assurer la coordination générale des opérations.

**OCCUPATIONAL EXPOSURE TO URANIUM OXIDES (UO₂ - U₃O₈)
METHODS AND RESULTS**

ABSTRACT

Chronic exposure to uranium compounds such as UO₂ and U₃O₈ led to the development of a methodology, based on the recommendation of ICRP, involving four main steps : the measurement of the uranium concentration and the particle size distribution at the workstation, the assessment of physico-chemical properties of the compound, the study of in-vitro solubility using a chemical test and the monitoring of workers.

Results and comments on UO₂ and U₃O₈ are given.

INTRODUCTION

Le but de cette étude est de décrire une méthodologie permettant d'évaluer les risques au poste de travail, de définir le comportement biologique des composés afin d'orienter la surveillance radiotoxicologique. Cette méthodologie appliquée aux composés UO₂ et U₃O₈ comporte quatre étapes :

- L'étude du poste de travail sur plusieurs jours, à l'aide de prélèvements individuels, en ambiance et de mesures de la distribution granulométrique afin d'évaluer le diamètre aérodynamique médian en activité ou DAMA et la déviation géométrique standard σ_g .
- La détermination des caractéristiques physico-chimiques des composés UO₂ et U₃O₈, comprenant la surface spécifique, l'identification par diffraction X et spectrométrie infra-rouge, la composition isotopique par spectrométrie de masse.
- L'étude de la solubilité chimique in-vitro à l'aide d'un test chimique décrit par Ansoborlo et Hengé-Napoli (1), permettant de déterminer la cinétique de dissolution, de calculer la périodes de chaque composé suivant la classification ICRP (2)

et de comprendre les mécanismes chimiques de dissolution. Le solvant est un liquide de culture cellulaire ou Gibco, tamponné à pH = 7,3, utilisé à 37°C sous 5 % de CO₂. Pour ces essais la poussière est présélectionnée par sédimentation à un DAMA de 3 µm.

- La surveillance du personnel avec suivi des selles, des urines, le contrôle de la charge pulmonaire par anthropogammamétrie et éventuellement des prélèvements et analyses sur mouchoir.

RESULTATS ET DISCUSSION

Les deux composés industriels étudiés UO₂ et U₃O₈ ont été prélevés sur un poste correspondant à un basculement de fut dans un container, impliquant donc une exposition du personnel, équipé en tenue spéciale avec port de masque.

Deux campagnes de prélèvement de trois jours chacune, correspondant aux deux composés UO₂ et U₃O₈ ont été réalisées, et les résultats sont présentés dans la figure 1 : la concentration en UO₂ varie entre 2,1 et 88,5 Bqm⁻³ et celle d'U₃O₈ entre 0,05 et 1,6 Bqm⁻³.

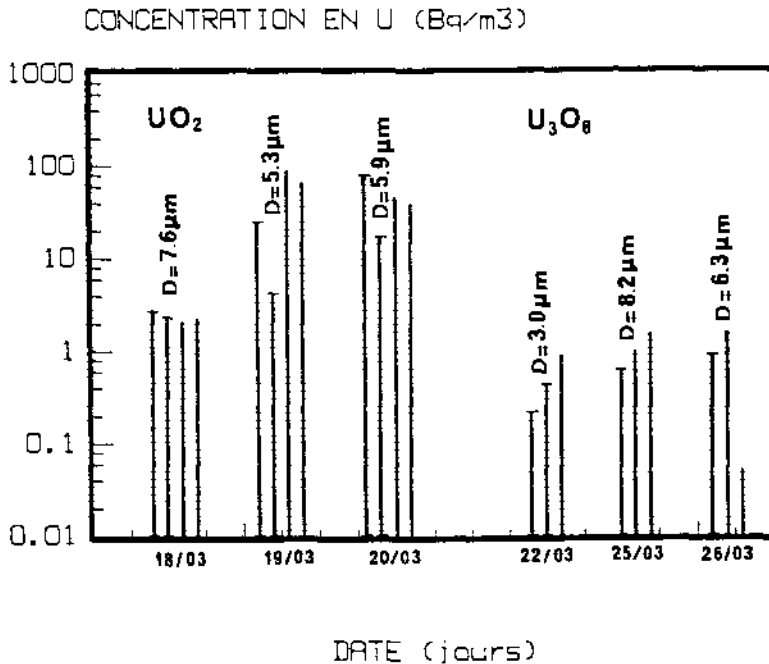

Figure 1 = Mesures de concentrations en Uranium et de diamètre aérodynamique sur un poste de travail - Composés manipulés UO₂ et U₃O₈.

Les concentrations en UO₂ sont supérieures à celles obtenues avec U₃O₈ d'un facteur 40. La mesure des DAMA varie de 5,3 µm

à 7,6 μm avec σg compris entre 2,1 et 2,5 pour UO_2 et de 3 μm à 8,2 μm avec σg compris entre 2,76 et >4 pour U_3O_8 . Les σg supérieures à 2 traduisent des distributions hétérogènes et le calcul du DAMA moyen sur les 6 prélèvements soit $6,1 \pm 1,6$ μm , permet d'estimer, suivant le modèle ICRP (2), que 78 % des particules inhalées seront déposées au niveau du naso-pharynx.

L'étude des caractéristiques physico-chimiques à l'aide de spectres de Rayon X et d'infra-rouge solide a permis d'identifier les 2 composés UO_2 et U_3O_8 sans trace d'impuretés. Leur composition isotopique correspond à celle de l'uranium naturel. La mesure des surfaces spécifiques a donné $4,3 \text{ m}^2\text{g}^{-1}$ pour UO_2 et $5,9 \text{ m}^2\text{g}^{-1}$ pour U_3O_8 , surfaces relativement faibles.

La figure 2 représente les résultats obtenus lors des essais de solubilité chimique en milieu Gibco. Notons une solubilisation toujours importante le premier jour correspondant à une phase rapide de dissolution, suivie d'une deuxième phase beaucoup plus lente ; l' U_3O_8 se dissout à raison de 7,5 % en 1 jour et 92,5 % en 51,8 jours, et l' UO_2 à raison de 7,4 % en 1 jour et 92,6 % en 212 jours. Si la phase rapide est identique, la deuxième phase est très différente et implique une classification de type W pour U_3O_8 et de type Y pour UO_2 .

Figure n° 2 : cinétique de dissolution des composés UO_2 et U_3O_8 en milieu de culture cellulaire Gibco.

La classification ainsi déterminée in-vitro et la valeur moyenne de 6 μm pour le DAMA, permettent de calculer à partir du modèle ICRP des limites de concentrations admissibles dans l'air ou LDCA, propres à chacun des composés étudiés : ainsi pour U_3O_8 (92,5 % classe W) la LDCA calculée en uranium naturel est de $36 \text{ Bq}\mu\text{m}^{-3}$ et pour UO_2 (92,6 % Classe Y) la LDCA est de $2 \text{ Bq}\mu\text{m}^{-3}$.

Dans ces conditions nous pouvons considérer sur la figure I que l'exposition à U_3O_8 donne des valeurs inférieures à la LDCA de

36 Bqm⁻³, alors que pour UO₂ la LDCA de 2 Bqm⁻³ est dépassée. Les résultats d'analyses urinaires, sur mouchoirs et en anthropogammamétrie sur une période de 2 mois et qui ne correspondent pas uniquement à l'exposition des deux composés étudiés, sont inférieurs aux valeurs limites de détection, soit : (5 à 6 mBq.g⁻¹ de créatinine) pour les urines, 40 mBq pour les mouchoirs et 150 Bq pour l'anthropogammamétrie. Toutefois, il est intéressant de noter que la valeur moyenne obtenue par analyse des selles (12 personnes), durant la même période est de 357 mBq par 24 h pour des valeurs très dispersées allant de 20 à 850 mBq par 24 h (la valeur moyenne d'une population non exposée est de 20 à 70 mBq par 24h). Ce résultat est très difficile à corrélérer avec l'exposition observée, dans la mesure où il ne correspond pas à une exposition unique, mais à une exposition sur 2 mois à différents postes et sur différents composés allant de l'uranium naturel à l'uranium de retraitement.

CONCLUSION

La méthodologie d'étude d'un poste de travail décrite pour deux composés UO₂ et U₃O₈ met en évidence l'importance de la connaissance de deux paramètres essentiels, à savoir le DAMA et la classe de transférabilité, d'une part pour calculer une LDCA propre à chaque composé et d'autre part pour orienter la surveillance radiotoxicologique.

Les variations importantes de concentrations mesurées au poste de travail semblent liés au mode de travail des personnes : l'expérience montre que des équipes postées, travaillant sur un même produit, entraînent des valeurs très différentes de concentration dans l'air. La corrélation difficile entre les valeurs de concentration mesurées et les résultats de mesure dans les excréta ou par anthropogammamétrie, vient du fait que les travailleurs sont équipés de protections efficaces et qu'ils changent souvent de poste et de composé.

Ces observations mettent donc en évidence l'intérêt de la connaissance de tous les postes et composés utilisés dans un même atelier afin de bien orienter la surveillance radiotoxicologique.

Cette étude a permis, à partir de résultats au poste de travail, de calculer des LDCA de 36 Bqm⁻³ pour U₃O₈ et de 2 Bqm⁻³ pour UO₂.

**INTERNAL EXPOSURE IN FRENCH NUCLEAR POWER PLANTS :
10 YEARS ON**

C. CHEVALIER - M. GONIN

Laboratoire d'Analyses de Biologie Médicale et de Radiotoxicologie -
Service Général de Médecine du Travail - EDF, Saint-Denis, FRANCE

ABSTRACT

Collectively speaking, internal exposure in French nuclear power plants is negligible. However, some quite high individual doses have been recorded.

The details of cases of significant contamination are presented here in table form. A brief discussion of a few particular cases underscores the problems involved.

INTRODUCTION

At Electricité de France (EDF), individual monitoring of internal exposure is carried out by the occupational health services in the power plants. These services are equipped with counters for thoraco-abdominal activity. The radiotoxicological laboratory analyses all the biological samples (urine, faeces, nose-blows) and centralises the results.

Data from ICRP publications n°s 30 and 54 are used for the dose calculations.

The monitoring primarily concerns EDF workers. However, the analyses necessary for estimating internal exposure are also carried out for persons from other companies required to work on-site. Currently, the medical services monitor a total of about 30,000 people per year.

RESULTS AND DISCUSSION

1 - COLLECTIVE DOSES

Column 1 of the table shows that the collective effective dose equivalents are extremely low : 0.16 man-Sv over 10 years. Compared with those resulting from external exposure (which will be the subject of other papers), they are negligible.

French power plants are therefore, in general, "clean" and the protection methods used are efficient.

2 - INDIVIDUAL DOSES

The second part of the table (columns 2) shows the distribution of the effective dose equivalents among the different persons, and the major radionuclides measured. The table takes into account only those persons from whom, in addition to body counting, biological samples were taken.

TABLE : INTERNAL EXPOSURE (EDF + OTHER ON-SITE WORKERS)

YEAR	1	2		
	COLLECTIVE DOSE man-mSv	NUMBER OF WORKERS (EDF AND OTHER ON-SITE WORKERS)		
		HE = 0	0.5 ≤ HE < 5 mSv	5 ≤ HE < 50 mSv
1981	0	130		
1982	0	142		
1983	11	115	1 (I-131)	1 (α)
1984	72	80	1 (I-131)	1 (Ce-144 + α) 1 (Co-60)
1985	3	135	2 (Co-60 + α)	
1986	3	201	1 (Co-60)	
1987	6	121	2 (H-3) 1 (α)	
1988	28	108	2 (Ag-110m) 1 (α)	2 (α)
1989	1	187	2 (α)	
1990	39	197	5 (Co-60 + α) 5 (Co-60) 1 (α)	2 (Co-60 + α) 1 (α)
TOTAL	163	1416	24	8

α : transuranium isotopes

1 - Collective committed effective dose equivalent. (Only dose equivalents higher than 0.5 mSv are recorded).

2 - Number of workers (for whom doses have been estimated), per level of effective dose equivalent (HE). Dominant radionuclide(s) shown in brackets.

2-1 NUMBER OF SIGNIFICANT EXPOSURES

The total number of significant exposures (ie higher than the 0.5 mSv recording level adopted at EDF) is very low : 32 cases in all. Of these only 8 had an effective dose higher than 5 mSv. For these few persons, the doses are not always negligible. Furthermore, adding effective doses to external exposures doses can lead to regulatory limits being exceeded.

2-2 PRINCIPAL RADIONUCLIDES

The most frequently detected radionuclides in retention measurement are Co-58 and Co-60. However, other γ emitters can be dominant in the dose calculations : I-131, Ce-144 and, more recently, Ag-110m.

As far as other types of emitter are concerned, tritium is not a problem (the two cases recorded in 1987 are unrepresentative because the contamination occurred at Brennilis, a heavy-water power plant). However, the same cannot be said for the α emitters. In about half the cases, the transuranium isotopes were very dominant in the dose calculation. But the only test which allows them to be quantified with sufficient sensitivity is faecal analysis. Samples of the faeces must be taken, and specific tests - designed to detect α emitters at very low activity levels - carried out on them.

We were unable to find γ emitters which could consistently indicate the presence of these α emitters. Ce-144 and Cs-137 gave the best results, but Ce-144 is difficult to detect in retention measurements, and Cs-137's presence in the organism can be totally masked by that of Ag-110m.

Two cases of contamination illustrate this :

- the first case occurred in 1984. The mixture inhaled contained a number of radionuclides including Ag-110m. The presence of Cs-137 was detected in the urine, the presence of Ce-144 in the faeces. The contribution of the α emitters to the effective dose was greater than 95 %, the Ce-144 accounting for virtually all the rest. The estimated dose was close to 50 mSv.

- an even more striking case occurred in 1988. The only radioelement detected by retention measurement was Cs-137 (activity : 3 kBq). According to data from ICRP n° 54, the presence of α emitters in the faeces corresponded to an effective dose of about 20 mSv.

2-3 DIAMETER OF THE INHALED PARTICLES

A third case of contamination, which also occurred in 1984, suggests that the question of the diameter of inhaled particles needs to be looked into as well. In power plants, particles may have a diameter such that they are deposited in the naso-pharynx region and later swallowed. When this happens, and it is not uncommon, it represents the equivalent of an oral intake. The activity measured must be compared to the oral ALI.

This was the case in 1984 when a particle containing 22 MBq of

Co-60 was inhaled. The activity was such that retention measurement was impossible. Once the particle had been eliminated in the faeces, a comparison was made with the oral ALI (for a factor $f_1 = 5\%$). This comparison showed that the regulatory limit had in theory been exceeded. In reality, comparing urinary and faecal activity allowed the f_1 factor to be estimated at a value in the region of 10^{-4} . More importantly, a gentle laxative was used to accelerate passage through the intestine, thus diminishing exposure time. The particle was eliminated in 23 hours instead of the 42 hours forecast by the gastro-intestinal tract model. Taking these factors into account, the estimated effective dose was not higher than 25 mSv.

This case of contamination raises a double problem: first of all, the limits of the ALI concept for estimating doses and, more importantly, the problem of "hot" particles. It shows in effect that the inhalation of very active particles can lead to rather high effective doses even when they are later swallowed. From the medical point of view, given the size of these particles, it is to be hoped that they cannot penetrate the trachea, because that would then raise the delicate problem of their extraction.

CONCLUSION

Internal exposure does not represent a problem on the collective level in power plants. However, it can correspond to non-negligible individual doses.

The few examples cited show that :

- transuranium isotopes must be tested for,
- in making dose estimations - calculated from measurement results - the subject's metabolic variations, and the physico-chemical characteristics of the inhaled particles, must be taken into account. In other words, it is necessary to go beyond the ALI concept,
- finally, the existence of "hot" particles points up the eventual need for a therapeutic intervention, were such particles to penetrate the respiratory system. This requires further study.

The first two points implicitly raise questions, not dealt with here, of the reliability of measurement results and the validity of their interpretation in dose terms.

Intercomparison exercises between laboratories are needed to check measurement reliability, particularly in the case of very low transuranium isotope activity. This type of exercise is organised in some countries. In France, for example, the CEA (Commissariat à l'Énergie Atomique) organises voluntary intercomparison exercises among a number of European laboratories.

International intercomparison exercises, less confidential than those which currently exist, are needed to check the reliability of dose estimations. Such exercises will allow specialists from the different countries involved to standardise the procedures used.

ASSESSMENT OF INTAKES AND RADIATION DOSES FOLLOWING EXPOSURE TO TRITIATED WATER

ABSTRACT

Biological half-lives, (T_b) of tritium following exposure to tritiated water (HTO) are reported. T_b varied from 2.5 to 16 days with an average of 6.8 days. Equilibrium conditions existing between HTO concentrations in blood and urine at the time of voiding is demonstrated. T_b is observed to be affected only marginally by age or body weight and significantly by ambient conditions like temperature and moisture content of the air.

INTRODUCTION

Biological half-life is an important parameter in assessment of intakes. ICRP has adopted T_b of 10 days for HTO component for the purpose of internal dosimetry. Second component arising from the intake of HTO in human has been reported by a few authors, as quoted by Rudran [1988], who concludes that CEDE from the second component is about 1.5 to 2.5 times CEDE due to HTO alone. This has not been given due weightage assuming this to be less than 10% of the total (ICRP, 1979). Observations by the authors in the dose evaluation studies following intake of HTO under occupational conditions in 86 cases are reported here. Study of 40 cases of reported earlier (Thampan et al. 1974).

METHODOLOGY

Intake of HTO in heavy water moderated cooled research reactor CIRUS (40 Mw) is negligible under normal working conditions. Following spillage of heavy water and clean up operations urine analysis of concerned persons is carried out. Follow up studies are conducted whenever the first urine samples collected exceeds concentration of 370 KBq l^{-1} . The results are evaluated for T_b , intake and radiation dose. Blood samples are collected from exposed individuals in the morning after overnight urine collection. Tritium as HTO in the blood sample is corrected for HTO at the midpoint of urine collection with T_b of 7 days. At times, ^3H excretion in urine is followed for longer periods. These studies lead to the observation and evaluation of a second component (Rudran 1988). T_b observed in late winter during the month of Feb.-March were separated out and variations of T_b with age and body weight were studied by least square analysis. From the known temperature and humidity conditions existing in Bombay at different periods of the year, moisture content of air (g/m^3) was calculated.

Variation of Tb_1 with temperature and water content in the air at the mid-point of study period was worked out.

RESULTS

Concentration of 3H as HTO in blood and urine are given in table 1 and show that HTO is at equilibrium concentration in urine and blood at the time of voiding.

A study of 86 cases, showed Tb_1 varying from 2.5 days to 16 days. The results are presented in fig. 1. The average is 6.8 days. Thus under climatic conditions around Bombay, 7 days Tb_1 is appropriate for dosimetry.

Variation of Tb_1 w.r.t. atmospheric temperature are shown in table 2 and w.r.t. humidity conditions fig.2. The figures show an inverse relationship for Tb_1 with atmospheric water content. Tb_1 doesn't show any relationship directly attributable to ambient temperature.

26 case studies were made in late winter during Feb.-March under similar climatic conditions. These were analysed for variations due to individual parameters namely age and body weight. Results are shown in figures 3 & 4. The regression lines show that variations attributable to age or body weight are minimal.

Intake and CEDE to exposed individuals were evaluated using standard techniques (Thampan et. al. 1974, Rudran and Kirthi 1984) highest value of CEDE was 9.6 mSv when HTO component alone was taken care of. When contribution from second component is accounted for, CEDE is 25 mSv, 2.5 times that due to HTO (Rudran, 1988) and is within the annual permissible limit.

CONCLUSION

A Tb_1 of 7 days is appropriate for dose calculation from HTO intakes under tropical conditions prevalent in India. Changes in Tb_1 by a factor of 2 to 3 from the average are likely, due to ambient conditions. There is no significant change in Tb_1 due to age or body weight for the occupational group, normally 20 to 60 years and body weight group of 40 to 80 Kg.

INSTITUTO DE PESQUISAS ENERGÉTICAS E NUCLEARES
IPEN-CNEN/SP

FAX: 55 11 2123546 C.P.11049 CEP:05499

SÃO PAULO - BRASIL

^{227}Ac (half-life of 21.8 y) is the daughter of ^{231}Pa ; a beta-emitter and parent of a subseries with five short-lived alpha-emitters. ^{231}Pa (half-life of 3.27×10^4 y) is an alpha-emitter of the actinium series, the decay chain of ^{235}U . As daughters of this uranium isotope they are thought to be unimportant as a radiological hazard, despite the fact that their ALI values for ingestion and inhalation are the lowest of any other radionuclide. Both nuclides can be considered as being in secular equilibrium with uranium in most geological media and so the mass concentration of ^{231}Pa is the same of the ^{226}Ra and that of ^{227}Ac is the same of the ^{210}Po , to mention only two radionuclides of radiological concern. It is shown in this paper that if ^{231}Pa and ^{227}Ac are considered in the evaluations of dose commitments incurred by inhalation of aerosols in mining and milling operations, the results can be 70% higher than those calculated by the methodology of ICRP Publication 47.

ANNUAL DOSE DISTRIBUTIONS FOR THE
OLYMPIC DAM OPERATIONS

Jim Hondros
Olympic Dam Operations
Box 150, Roxby Downs
South Australia 5725

ABSTRACT

Production of uranium and copper from the Olympic Dam Operations' underground mine and metallurgical processing plant commenced in 1988, with underground exploration and development commencing in 1983. Since commencement of operations, employee radiation doses have been monitored and assessed to ensure that they remain well controlled. Total radiation doses to employees are calculated using the standard dose assessment methodology of the ICRP. Dose assessments to date indicate that all employee doses are well controlled.

INTRODUCTION

Olympic Dam Operations is a copper, uranium, gold and silver producer located approximately 600 kilometres north of Adelaide in South Australia. Ore is extracted from the underground mine workings at a depth of approximately 500 metres and is processed in a multifunction metallurgical plant. The ore body was discovered in 1975 and underground exploratory and development work commenced in 1983 when a shaft access was sunk. Following construction of a service decline in 1988, full scale production commenced using the open stoping mining method. The underground operation is highly mechanised and produces 1.6 million tonnes of ore per year. This is set to increase to 2.2 million tonnes at the beginning of 1992.

The ore is treated in the metallurgical plant situated 2 kilometres west of the main shaft and service decline. The plant commenced production in the second half of 1988. The ore is crushed, ground and treated with a flotation agent which results in initial separation of the uranium bearing minerals and the copper sulphide bearing minerals. The uranium minerals are processed to produce uranium oxide using standard solvent extraction techniques. The copper sulphides are dried and treated in a flash smelter to produce blister copper. Electrorefining further purifies the copper. Gold and silver is present in the residue of the electrorefining process. Approximately 48,000 tonnes of refined copper and 1600 tonnes of uranium oxide is produced annually.

At present there are approximately 800 people employed to operate, maintain and manage the operations.

Since commencement of underground operations in 1983, employee radiation doses have been monitored and assessed to ensure that they remain well controlled.

DOSE ASSESSMENT METHODOLOGY

In the mining and processing of radioactive ores, there are three major pathways by which employees can be exposed to radiation. These are;

- irradiation by gamma radiation,
- inhalation of radon daughters,
- inhalation of radioactive dust.

Assessing employee dose relies upon monitoring each exposure pathway to determine worker exposure, then applying an ICRP-based exposure-to-dose conversion factor.

Employee exposures are assessed using the results of a government approved radiation monitoring programme. At the mine, radon daughter levels are measured in all workplaces at least twice per week. Personal dust levels are measured twice weekly for all occupation groups. Gamma radiation levels at all locations are measured routinely, however, employee exposures are assessed using personal thermoluminescent dosimeters (TLD badges). In the metallurgical plant, personal dust samples measure the exposure to dust and TLD badges measure exposure to gamma radiation. The nature of the metallurgical plant means that employees will be exposed to dusts containing different quantities and ratios of radionuclides. This requires routine radionuclide analysis of dust samples. For the mine and metallurgical plant, workplace and occupation based concentration levels are then combined with occupancy time information to derive employee exposures.

The dose assessment methodology is based on the additivity principle of the ICRP. That is, the effective dose from each of the radiation exposure pathways are added together and compared to the annual dose limit. Experience at Olympic Dam indicates that on average, of the total dose received by the underground workers, one third is due to each of the major radiation exposure pathways. For the metallurgical plant, on average, approximately 85 percent of the total dose is derived from the inhalation of radioactive dust and 15 percent from gamma radiation.

ICRP32¹ provides a dose conversion factor of 10 milliSieverts per working level month (mSv/WLM) which is used for the conversion of radon daughter exposure to radon daughter dose. Conversion of employee dust exposure in Becquerel hours per cubic metre (Bq.h/m³) to an effective dose equivalent is more complex and requires the use of ICRP30². Dose conversion factors for radioactive dust are a function of a number of different parameters including dust activity distribution and relative radionuclide content of the dust. TLD badges report a whole body dose and do not require a dose conversion factor.

DOSE STATISTICS

The most recent distribution of doses for the mine and the metallurgical plant employees can be seen in figures 1 and 2 for the period 1/7/90 to 30/6/91.

**ANNUAL DOSE DISTRIBUTION 1990/91
MINE EMPLOYEES**

Figure 1: Mine employees dose distribution

**ANNUAL DOSE DISTRIBUTION 1990/91
PLANT EMPLOYEES**

Figure 2: Plant employees dose distribution

The current dose limit recommended by ICRP is 20 mSv per year, averaged over five years ICRP60³, with a maximum annual limit of 50 mSv. Dose statistics for the years since commencement of full scale production can be seen in Table 1.

FINANCIAL YEAR	MINE		PLANT	
	AVERAGE	90th PERCENTILE	AVERAGE	90th PERCENTILE
1988/89	5.7	15.0	5.0	10.4
1989/90	4.0	11.0	3.6	6.8
1990/91	3.9	8.6	3.1	7.7

Table 1: Olympic Dam Operations Dose Statistics Since Commencement Of Production (all units are mSv)

CONCLUSION

The dose assessments presented in this paper demonstrate that the existing radiation protection mechanisms are adequate for the control of employee exposure, even considering the new ICRP dose limit. Olympic Dam Operations recognises that it is most important to continue to be vigilant and pursue the lowering of employee doses.

ABSTRACT

As part of the IAEA programme to corroborate measurements of internal contamination levels ^{137}Cs in the effected population made by Soviet specialists following the 1986 accident at Chernobyl, the Agency has coordinated an intercomparison programme involving measurements at 8 Soviet whole body counting facilities. Additional measurements were made in the mobile van loaned to the Agency for use in the Soviet Union whole body counting programme by SCPRI, France; and whole body counters in Seibersdorf, Austria operated by the IAEA and the Austrian Research Centre.

INTRODUCTION

During a mission to the Soviet Union in August 1990 it was concluded that an intercomparison of USSR, IAEA and of the Austrian whole body counters used for *in vivo* measurement of ^{137}Cs would be valuable in corroborating large scale measurements of the USSR population.

The IAEA obtained use of a standard, adult phantom from the Battelle Pacific Northwest Laboratories in the United States. The phantom is a "Bush" or "Bottle" type, filled with solid, polyurethane tissue substitute and labelled uniformly with ^{137}Cs . The total quantity at the time of the intercomparison was 11,170 Bq (0.3 μCi). A solid matrix was necessary to avoid the practical problems of handling radioactive liquids during transport. Although accurate measurement of the caesium level in children is a major concern, it was not possible to locate a standard child phantom with a solid matrix.

INTERCOMPARISON SEQUENCE

Counting was performed in the SCPRI counting van, with the IAEA chair counter and with a whole body counter of the Austrian Research Centre during the week starting 17 September 1990. The phantom was then taken to the USSR and used there in various institutes. The intercomparison programme was completed in December 1990 with a final counting of two USSR phantom systems at Seibersdorf. The USSR institutes that participated in the intercomparison programme and the counter characteristics are listed in Table 1.

USSR PHANTOM COUNTING, SEIBERSDORF

At the invitation of the IAEA, two USSR phantoms were brought for counting to Seibersdorf in December 1990; 1) a polyethylene block phantom with inertable ¹³⁷Cs loaded rods from the Leningrad Research Institute of Sea Transport Hygiene and 2) a flexible plastic manikin filled with dried cesium rich green peas grown in the Chernobyl region, provided by the All-Union Scientific Centre of Radiation Medicine. Equivalent configurations from both phantom systems were counted, representing (a) a small child, (b) a child of about age 10, and (c) a small adult. In addition, samples of the dried peas used in the Kiev phantom were assayed. Counting was done both in the IAEA chair counter and the counter of the Austrian Research Centre. It must be noted that the IAEA counter is intended only for adults, and it is not specifically calibrated for children. The Austrian Research Centre also normally only counts adults. Therefore, the results of the measurements made using the child phantoms should be viewed accordingly.

RESULTS

The results of the phantom intercomparison measurements are presented in Table 2. Under the conditions of the intercomparison, it was agreed that the results from the USSR counters would not be specifically identified. Therefore, the participating institutes in the USSR are indicated only by numbers in Table 2. However, each USSR facility has been provided a tabulation of the intercomparison results together with specific identification of its own data.

CONCLUSIONS

The IAEA does not have specific criteria for the acceptability of the performance of whole body counters. However, the quality of the intercomparison results can be compared with guidance provided in IAEA Safety Series No.84, *Basic Principles for Occupational Radiation Monitoring*, paragraph 4.1.5 [1], where it is stated that:

"In the case of routine individual monitoring for external radiation relative uncertainties of -50% and +100% at the 95% confidence level are acceptable for annual dose equivalents in the range of one-fifth of the derived limit. If, however, values are of the order of the annual limits, the relative uncertainties should not exceed -33% and +50% at the 95% confidence level." ...

"Similar requirements should, in principle, also apply in the case of routine individual monitoring for internal contamination, but in practice uncertainties as small as 50% are rarely possible."

In 5 of 36 measurements reported from institutes in the USSR (Table 2), the results were outside of a range of $\pm 30\%$ compared with the reference values. One result was slightly more than 50% above the reference value. In the latter case, the measurement was made with an unshielded probe used with the phantom doubled over in the "Marinelli" position.

Based on the distribution of the intercomparison results, it can reasonably be concluded that the participating institutes are capable of performing internal caesium measurements within an accuracy that is acceptable and adequate for radiation-protection purposes.

It should also be noted that 4 out of the 5 instances of results outside the range of $\pm 30\%$ from the reference value occurred with phantoms representing children. Although the differences are not excessive, they do suggest the need for additional attention to the calibration of counters for measurements of children.

REVIEW OF THE EVIDENCE FOR CANCER PROMOTION
FROM EXPOSURE TO 50/60 Hz MAGNETIC FIELDS

Michael H Repacholi

Visiting Scientist,
Australian Radiation Laboratory, Melbourne

Chairman
International Non-Ionizing Radiation Committee of IRPA

ABSTRACT

There is some evidence from epidemiological studies that exposure of children and adults to 50/60 Hz magnetic fields may be associated with an increased incidence of leukaemia, brain tumours and other cancers. Laboratory studies have demonstrated that 50/60 Hz field exposure of biological systems is not an initiator (damages the DNA of cells) of cancer. This finding is in agreement with the fact that the photon energy of 50/60 Hz fields is much too low to break even the weakest macromolecular bonds. Thus, if 50/60 Hz fields are truly associated with an increased incidence of cancer, then these fields must act as a promoter or co-promoter of cancer in cells that have already been initiated. This paper reviews the evidence produced by the laboratory studies

INTRODUCTION

A cancer or malignant neoplasm is an apparently autonomous new growth of tissue having the ability to invade surrounding tissue and, in most cases, metastasize from the original site to distant sites where metastatic neoplasms may become established. As shown in figure 1, normal cells can undergo a process of initiation, promotion and progression that leads to the formation of a malignant neoplasm. Initiation describes changes in cells that have been exposed to a carcinogen that causes damage to the DNA. The initiating agent must be at sufficient levels to be carcinogenic. An initiated cell is not a cancer cell since the mutation in the DNA is not expressed. No detectable change in DNA synthesis or cell division or any change in enzyme activity occurs. The initiated cell remains dormant awaiting a promoting stimulus before a tumour results.

Cancer promoters cause a response where many changes in enzyme activity occur and cells can take on many of the morphological characteristics of transformed cells (Boutwell, 1990). For a neoplasm to develop, cells must be exposed to an initiator then promoting agent. Progression describes the changes in a neoplasm to a more malignant character, and is a result of mutations in addition to the original initiating event.

There have been experiments in each of these stages of carcinogenesis to determine whether 50/60 Hz fields have a role and these will be summarised. Since the epidemiological evidence for 50/60 Hz field exposure being associated with an increased incidence of cancer is weak, scientists look to the laboratory evidence to provide support for this evidence. This paper reviews the evidence from the laboratory studies.

Initiation

Studies to determine if any damage occurs to the DNA have been conducted on a number of biological systems exposed to 50/60 Hz fields (Cohen, 1986; Cohen et al, 1986a, b; Reese et al, 1988; Livingston et al, 1986; El Nakas and Oraby, 1989; Krueger et al, 1975; Bender, 1976; Frazier et al, 1990; Benz et al, 1987). All concluded that 50/60 Hz magnetic fields are not mutagenic. Thus, it is generally accepted that 50/60 Hz magnetic fields are not initiators in carcinogenesis. Much of the research effort is now conducted to determine if these fields can either promote or progress cancer in initiated cells.

FIGURE 1 Schematic diagram (from Boutwell 1990) of changes that occur in normal cells by:
initiation - unexpressed nuclear changes (DNA damage)
promotion - expression of the phenotype of a benign tumour
progression - further nuclear/mutation-like changes leading to the expression of a malignant phenotype.

Promotion

An increasing number of researchers are investigating the different areas where 50/60 Hz fields could promote or co-promote cancer development in initiated cells or tissues: disruption of cell communication, modulation of cell growth, activation of specific gene sequences, depression of pineal melanotin production, modulation of ornithine decarboxylase activity and possible disruption of hormonal and immune system anti-tumour control mechanisms by triggering a stress response. I will deal with the evidence from the better conducted studies providing evidence for these mechanisms.

(a) In-vitro Studies

Studies with cultured human HL60 cells have reported that an increased level of specific RNA transcripts occurs in response to ELF field exposure as low as 1mV/m (Goodman et al 1990, Wei et al 1990). Using the technique of dot blot hybridization, it was observed that exposure to ELF fields increased the levels of RNA ζ_{00} β -actin, histone H2B and c-myc DNA. The changes in RNA transcripts exhibited a strong dependence on the amplitude and frequency of the applied ELF field, as well as the duration of exposure. A possible explanation of these observations is that the field alters the rate constant for one (or more) of the intermediate sequential reactions involved in RNA synthesis and degradation (Litovitz et al 1990). Increases in the synthesis of specific proteins have also been observed in other studies on cells exposed to ELF fields.

Byus et al (1987) reported that exposure of cultures of malignant cells to 60 Hz fields causes a measurable increase in ornithine decarboxylase (ODC) activity. The induction of the enzyme ODC is the largest known metabolic response to a cancer promoter and is essential but not sufficient to accomplish promotion. The maximum increase in activity reported by Byus et al was 5-fold in a mouse myeloma cell line. The increase in activity was much smaller in a human lymphoma line and the Reuber H35 rat hepatoma line. This maximal activity was observed at the end of a 1 hour exposure or within 1 or 2 hours post exposure. These observations on the extent and timing of the response differ sharply from the effect of tumour promoters on the activity of ODC, namely increases of 200-fold or more at 4 to 5 hours after a single exposure to the promoter (Boutwell, 1990). Further, the relevance of these experiments to the causation of cancer is limited because they were performed on cells that were already cancerous.

Similar experiments on the effects of a 60 Hz field on bone cells and fibroblasts by Cain et al (1986, 1990) resulted in increased ODC activity of 1.5- to 2-fold within 15 minutes to 1 hour after exposure. At 2 and 3 hours post exposure, ODC activity had returned to sham exposed levels. Although these experiments were not done with malignant cells, it is possible that the small, early increases in ODC activity were the result of gene activation. Cain et al argue that this increase in ODC activity attributable to field exposure reflects results consistent with promoting activity for 60 Hz fields. When C₃H10T1/2 fibroblasts, a cell line susceptible

to transformation, were exposed to 60 Hz magnetic fields, Cain et al (1990) evaluated the effects on the number and size of TPA-induced foci. They report that the results are consistent with tumour promotion protocols. It is important to realize, however, that while increased ODC production is an essential element of cancer promotion, the measurement of increased ODC is not per se an indicator of a cancer promotion effect (Boutwell, 1990). There are specific levels of ODC and patterns of ODC increase that must be observed before a research result can be interpreted in this way and the results of these studies do not fit the pattern expected of cancer promoters. Further, Frazier et al (1989, 1990b) using a standard, widely accepted cancer promotion protocol, found that 60 Hz magnetic fields were not able to promote the transformation of the same fibroblast cell line, (C₃H10T1/2) used by Cain et al (1990). Frazier et al do not find that 60 Hz fields cause cancer promotion when they actually test for cancer promotion; the studies by Cain et al do not test for cancer promotion.

Neither increased activation of ODC nor enhanced transcription of genes is sufficient to indicate that 50/60 Hz fields are acting as cancer promoters (Saunders et al 1991). Current in vitro studies do not support the epidemiological findings.

(b) In Vivo Studies

The question is being examined as to whether the hormone melatonin, produced by the pineal gland, can influence the growth of malignant cells. Evidence is accumulating that suggests breast cancer, melanoma and possibly other cancers may be inhibited by melatonin (Blask 1989). Since exposure to 60 Hz electric and magnetic fields may reduce the normal nocturnal rise in melatonin (Wilson and Anderson, 1989), Stevens (1989) suggests exposure to power frequency fields may account in part for an increased human breast cancer risk. However, there are no obvious biological consequences of changes in melatonin levels and the alteration in the melatonin circadian rhythm have no apparent deleterious effect on the health of test animals. Much more evidence is necessary before any suggestion that changes to melatonin levels is associated with cancer promotion.

McLean et al (1991) used an accepted in vivo cancer promotion protocol with Sencar mice (Sencar, for "sensitive to carcinogenesis") and report no difference between mice initiated with a subthreshold dose of DMBA and exposed to a 2mT 60 Hz magnetic field or sham exposed. However, McLean et al presented preliminary findings that a co-promotion effect may be occurring when an increase was observed in both the mean number of skin papillomas per mouse and the percentage of mice with papillomas in DMBA-initiated on mice treated weekly with TPA and also exposed to 60 Hz magnetic fields (2mT, 6h/d, 5d/week for 17 weeks).

Using a classical skin tumour promotion model with large numbers of animals, Holmberg et al (1991) exposed NMRI/HAN mice that had been initiated with DMBA, to 50 μ T and 0.5 mT magnetic fields for 19-21 h/d commencing 8 weeks after initiation and lasting for 103 weeks. There was no difference between exposed and non-exposed groups for

mortality, in the number of tumour bearing animals, latency for the appearance of a first skin tumour or in the total number of tumours per group. While some differences in the number of tumours per animal appeared at given weeks, no differences occurred overall when the exposed and non-exposed groups were compared.

In another large tumour promotion study, Rannug et al (1991) exposed Sprague-Dawley rats that were subjected to 70% partial hepatectomy followed 24 h later by initiation with DENA and then to 50 Hz magnetic fields of 0.5 μ T, 5 μ T, 0.05mT, or 0.5mT for 19-22 h/day. The fields were either continuous or switched (15 min on/off - 5 μ T and 0.5mT fields only). When the number of foci per unit area of liver and the number of foci per unit liver volume were calculated, continuous magnetic field exposures did not result in any consistent differences compared to control groups. Exposures to 5 μ T and 0.5mT pulsed 15 min on/off for 22 h/d resulted in a slight, non-significant increase in the number of foci per cc of liver. Overall the results did not suggest any cancer promotion effect was occurring with liver tumours.

There are a number of large animal studies being undertaken in Canada, Sweden, United States and Australia to determine if 50/60 Hz fields can promote cancer. Some of these studies will take a few years before results become available. However, the current evidence from in vitro and in vivo studies does not suggest that 50/60 Hz fields can promote cancer. There is some evidence that these fields may be cancer co-promoters in tissues that are in the process of carcinogenesis, but the health impact of such a finding remains unclear.

Progression

The effects of 50/60 Hz fields and currents on proliferation and growth of cancer cells have been studied by several investigators. Exposure to 60 Hz magnetic fields (strength 1.2 mT) were reported to decrease growth of neuroblastoma in mice (Batkin and Tabrah, 1977). However, no differences in growth characteristics were observed (Chandra and Stefano 1978) when either cultured human bronchiogenic carcinoma cells or Burkitts lymphoma cells were exposed for up to three days to 60 Hz magnetic fields. Kronenberg and Tenforde (1979) reported a similarly negative finding for mouse mammary tumour cells.

Phillips et al (1986 a,b) studied the binding of transferrin to two human colon tumour cell lines and the ability of cancer cells to form colonies after exposure to 60 Hz electric and magnetic fields (300mA/m², 0.2 mT for 24 hours). Altered expression of transferrin receptors and increases in cell colony growth were reported by Phillips and colleagues, but when their results were subjected to a laboratory visit and peer review (Cohen, 1987), it was concluded that their results were invalidated because of choice of model, experimental design and quality of data. Further Cohen (1987) was unable to replicate Phillips results. Winters (1986) reported that 60 Hz fields (up to 300 mA/m² or 0.1 mT for 24 hours) did not significantly effect responses to mitogens.

Female mice at 8 weeks of age were implanted with P388 leukaemia cells and exposed to 1.4 μ T, 200 μ T or 500 μ T, 60Hz magnetic fields for 3 hours after the implant, for 6 hours daily, 5 days per week until all of the exposed and non treated mice died (Thompson et al 1988). This life-time study found no statistically significant differences in survival, spleen weight or body weight resulting from the P388 cell implant of mice and subsequent exposure or non-exposure to magnetic fields. They also found no effect on the incidence or progression of the P388 leukaemia.

Conclusion

While more studies are necessary to determine if 50/60 Hz magnetic fields are cancer promoters or can progress cancers, the evidence so far suggests this is not the case. However, we await the results of some very large animal studies before we can be conclusive.

DOSE LIMITS REDUCTION CONSEQUENCES ON THE OPERATION OF NUCLEAR POWER PLANTS

E.Palacios, A.Curti, J.M.Espeche, G.M.Massera, F.Spano

Comisión Nacional de Energía Atómica
Buenos Aires - Argentina

ABSTRACT

Occupational doses are evaluated in each stage of the fuel cycle including nuclear power plants operation. Trends in the individual dose distributions and collective doses are analyzed. The maintenance operations with higher contribution to collective dose are identified and the implications of dose limit reduction as recommended by ICRP in 1990, are assessed. It is concluded that no relevant difficulties should appear in accomplishing with the new recommendations for installations designed after 1977. Only in Atucha I nuclear power plant which has been designed in the 60's, different alternatives should be analyzed to reduce individual and collective doses. Among them, the change of the fuel channels by new ones free of cobalt, is an essential decision to get an effective reduction of occupational doses.

INTRODUCTION

The ICRP recommendations, adopted in 1990, keep the basic criteria of dose limitation system. However the ICRP recommends a substantial reduction of the dose limits, the application of dose constraints, potential exposure analysis and the application of intervention levels, all of which have direct implications on the design and operation of nuclear installations. Nevertheless, only the dose limits reduction appears as an innovation for the Argentine regulations since all the other recommendations have already been incorporated to the standards and regulatory requirements for over a decade (1).

The fuel cycle is based on natural uranium - heavy water reactors and all the stages are being undertaken in the country. Even more, it is foreseen that in the next future, the power plants in operation will be fueled with slightly enriched uranium. Since 1983 a gas diffusion enrichment plant is in operation.

Occupational exposures are analyzed from 1981 up to 1990 for the main fuel cycle stages, in particular electric power generation. Also the practical difficulties for the implementation of the new dose limits are assessed.

OCCUPATIONAL DOSES

The collective effective dose, since now named collective dose, was estimated for the above mentioned period in 12 man Sv/year, the 85% of which corresponds to electric power generation and 14% to uranium mining and milling, and less than 1% to the fuel fabrication.

Annual individual doses for the different cycle stages have kept well below 20 mSv with the exception of the nuclear power plants operation. It is necessary to remark that since 1980 the remaining mining activities are only done in open pits.

ATUCHA I NUCLEAR POWER PLANT

The design of Atucha I (CNA I) dates back to the 60's, and as was common for other nuclear installations at that time, reactor internal parts were lined with "Stellite", an alloy with 60% of cobalt, to avoid excessive wearing-out. Co-60 is produced by neutron exposure of the "Stellite", and which in turn is carried by water along the primary circuit producing a high working ambient dose level (2) (3). As a result the collective dose is high and a considerable fraction of the personnel receives annual doses close to the limit.

The annual collective dose for CNA I, averaged over the period 1981 - 1986, is 20 man Sv/GWa approximately (4). The individual dose distributions show that around 30% received annual doses above 20 mSv (figure 1) and that a 15% of the personnel exceeded a five years cumulative dose of 100 mSv (figure 2).

Figure 3 shows the collective doses; total and due to operation excluding the major repair and maintenance works during reactor shut down. For the latter a 50% of the collective dose corresponds to interventions on the primary main pumps and steam generator while a 25% was received during moderator circuit works (5). Internal contamination due to tritium intake, contributes in CNA I with 10% to the total dose.

EMBALSE NUCLEAR POWER PLANT

This power plant was designed in the 70's and has no cobalt alloy in the internals of the primary circuit. The averaged annual collective dose from 1983 to 1990 is 1.5 man Sv; that corresponds to 3 man Sv per GWa of energy generated. The contribution from tritium to the collective dose is about 50%.

The individual dose distributions show that less than 10% of the personnel received annual doses above 20 mSv (figure 1) and that 2% to 3% of workers exceeded an accumulated dose of 100 mSv in five consecutive years.

ICRP 60 IMPLICATIONS

For Embalse the new situation does not seem to have much relevant consequences. Although the number of workers could be increased for some specific maintenance activities, this would not be too much significant from the radiological point of view and for the economical implications.

For CNA I, Regulatory Authority has tolerated that a considerable number of workers received doses close to the dose limit because this plant had been designed before the ICRP 26 were introduced.

It should be mentioned that for the building of CNA II, the Regulatory Authority required in 1981 that the use of "Stellite" should be omitted, keeping the cobalt content low in all reactor components. Nevertheless, with the new ICRP-60 recommendations reducing the dose limit to 20 mSv per year, averaged over five years, the situation in CNA I will be more difficult in the future. Increasing man power and thus fractioning the high doses for solving the problem is an option not acceptable for the Regulatory Authority. Indeed, an even greater number of workers would receive annual doses, year by year, close to the limits, and at the same time the collective dose would remain unchanged or increased. Therefore, other options such as to eliminate the source of Co-60, to decontaminate parts of the primary circuit or to introduce robots in some maintenance operations should be considered.

The Argentine Regulatory Authority has foreseen the implementation of the new recommendations by early 1992, with the necessary provision for accommodating the previous situation as soon as possible.

CONCLUSIONS

No relevant difficulties should appear in accomplishing with the new recommendations for those installations designed after 1977. The impact would be even less for those installations to be designed in the future, with the exception of underground mining, where the present 50 mSv dose limit is the main constrain in the optimization process.

In CNA I the change of the fuel channels by new ones free of cobalt is essential to get an effective occupational dose reduction and consequently to implement the new recommendations. An additional effort to lower even more the occupational doses should be done in both nuclear power plants to optimize the radiological safety.

Recent years have seen several new analyses of the risk associated with radiation exposure based on updated epidemiological data. This paper presents information on a personal computer code under development that will provide decision-makers and researchers with a tool to aid evaluation of these data. The key elements of the code are described in terms of its objectives, and in terms of its content. As one of the principal aims of the code is its friendliness, there is an emphasis on library and graphics facilities, as well as simplicity of use.

INTRODUCTION

During the last few years, two international organisations, UNSCEAR⁽¹⁾ and ICRP⁽²⁾ have undertaken extensive re-evaluations of information on the risks associated with radiation exposure. As a consequence, national bodies have sought to determine how this reflects on their own situation^(eg 3,4). These national studies tend to employ different sets of assumptions, and it follows that the quantitative data on risks often do not readily lend themselves to simple comparative exercises. Given that the flow of new data is unlikely to cease, and given also the range of measures of radiation detriment now being proposed to interpret risk, there is now a distinct need for a system that is capable of rationalising and encompassing all the relevant models, population distributions, and other data sets that are important in the quantification of radiation-induced stochastic effects.

This paper describes PC-based software, ASQRAD (Assessment System for the Quantification of RAdiological Dctriment), that is being developed with this aim in mind. It is the centrepoint of a joint research project between CEPN and NRPB, and largely funded under the CEC scientific programme, with the support of the Radiation Protection Committee of EdF (France).

OBJECTIVES

It is envisaged that ASQRAD (see Figure 1) will be applied in the development of policies where the radiation risk incurred or averted is an important factor in

decision-making. Obviously, it will also be of use for ongoing research on radiation detriment; it should find application in risk communication and training; and perhaps also in compensation issues. To this end, there are several features, not always associated with scientific software, that are deemed essential.

- (i) completeness: ASQRAD will accommodate all the principal health effects models, in particular those that interpret A-bomb survivor and medical exposure data, and a comprehensive range of national population parameters;
- (ii) a capacity for simple up-dating and adaptation: the user will be able to input other demographic statistics, and moreover the code is being constructed in such a way as to ensure that revised models can be readily installed;
- (iii) simplicity of use: the system will be menu driven and contain default pathways for common applications; and will be supported by help and library facilities;
- (iv) sensitivity analysis will be fully integrated; and
- (v) display and graphic facilities: a range of these will be available

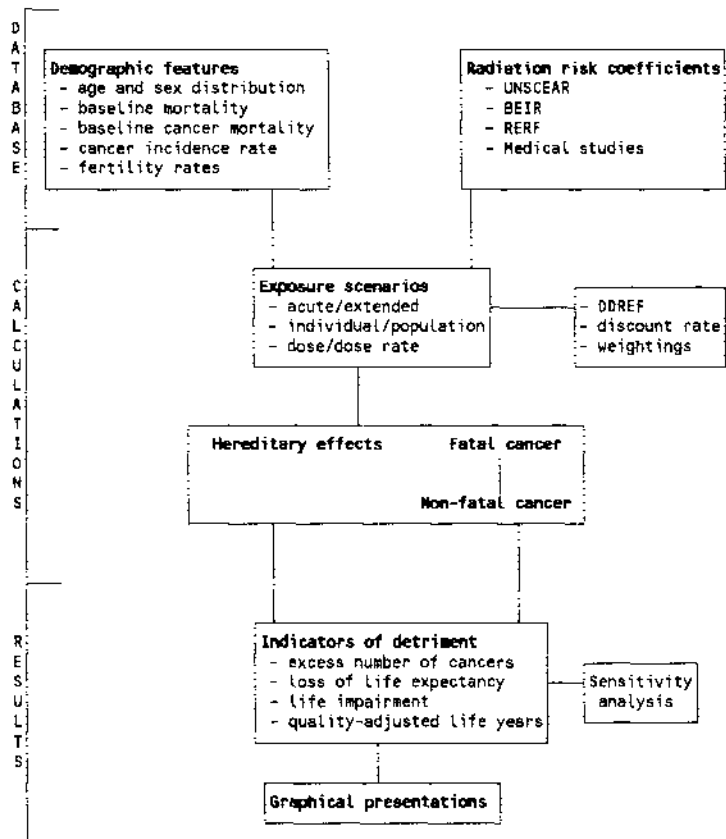

Figure 1. Outline of ASQRAD

HEALTH EFFECTS MODELLING

Risk and detriment estimates are obtained by combining 'fitted coefficients' with demographic details for a given exposure scenario. These health effects models have been developed either for specific organ sites or for groupings of sites, for example 'digestive'. There are two broad types of risk projection model applied. The additive (absolute) is where the results are independent of the baseline cancer rate in the population under consideration, and the multiplicative (relative) is where the results are a function of these baseline rates. Typically, these are becoming more complex as analysts seek to model the data more accurately, and thus often they are neither strictly additive nor multiplicative⁽⁵⁾. The code will, however, provide the user with a choice of all the relevant risk coefficients for each cancer type.

The demographic details required are a breakdown of the populations by age and sex cohorts in terms of numbers, death rates, and the cancer death rates for each site. In addition, two other sets of population statistics are used: the lethality fractions for each cancer type are needed for calculating the probability of non-fatal cancers; and the fertility rates by age and sex (the probability of an individual of given age and sex having a child during the forthcoming year) are used to calculate the probability of hereditary effects in progeny.

With all these data available, it will be possible to perform extensive sensitivity analyses. The library functions will provide background information on the data, and guidance on the legitimacy and consistency of these combinations.

OUTPUT

Measures of detriment will be calculated according to the following scenarios:

- (i) individual whole-body exposure: acute or extended (at variable annual dose), to an individual of given age or sex, or assuming an average for both sexes;
- (ii) population whole-body exposure: a single low dose and dose-rate exposure to a population (either default or user input) of mixed age and sex;
- (iii) non-uniform exposure: assuming doses to a single organ or a combination of organs; and
- (iv) committed exposure: as (iii) but assuming an intake of activity

For each of these situations, probability of cancer and hereditary effects, and associated loss of life expectancy (years of life lost, or YOLL) can be calculated directly using a chosen or default DDREF. Moreover, additional measures of detriment are proposed to take into account the severity of these effects in terms of morbidity and lost quality of life. Thus, two other expressions are introduced: years of life impaired (YOLI), and the quality-adjusted life year (QALY).

In addition, it will be possible to sum risk over different periods, for example probability of fatal cancer prior to age 75, and to make direct comparisons of radiation-attributable death rates against background death and cancer rates. The excess risk will also be assessed in terms of the excess lifetime risk (this subtracts the number of cancer deaths that would have been expected in due course in the population from the total

of radiation-induced cancer deaths) as used by BEIR V⁽⁴⁾, or the lifetime risk of exposure-induced death, as used by UNSCEAR⁽¹⁾, and in most other analyses.

It is worth adding more detail here on the QALY measure. This was originally developed in the field of health economics for the assessment of health care options that take into account the quality of life during and after treatment as well as survival rate and life expectancy. There is therefore a close parallel with the aspects of detriment that are now being incorporated into radiological protection quantities. As such, if the quality of life associated with different non-fatal, radiation-induced effects can be assessed using health indices⁽⁶⁾, then the QALY may provide for a more accurate measure of detriment than has hitherto been available. However, in keeping with the ICRP formulation of effective dose⁽²⁾, there will also be the option in ASQRAD to weight fatal effects according to YOLL, and to add a weighted non-fatal fraction based on 'curability'.

Extensive graphical presentations of the results will be provided as output in addition to the raw data. The library facility will provide information on any other measures of detriment that may be of interest in addition to those calculated, and also information on the variability and uncertainty of the data.

CONCLUSIONS

This paper has briefly presented a computer code, ASQRAD, for the calculation of the risk associated with exposure to low doses of radiation. The key features of the code are its comprehensiveness, and its simplicity of use. The aim is to produce a tool that is relevant to those decision-makers charged with decisions that require quantified assessments of radiation detriment.

ABSTRACT

The paper shows the principle problems introduced by ICRP publication 55 and provides suggestions to maximize the net benefit. The subject attacks six questions. 1- All options needed to maintain the net benefit positive. 2- The decision maker can define the optimum options by the premisses assumed. 3- The detriment of cost increases excessive when linear functions are not used. It is necessary to deal with the individual value of the protection and detriment costs. 5- The value is excessively high. 6- For the same collective dose, the preference to irradiate a large number of individuals at low doses rather than the contrary.

PROBLEM DEFINITIONS

The ICRP publication nº 37⁽¹⁾ which presents the calculation for the optimum analytical solution introduces the techniques of cost-effectiveness analysis, cost-benefit analysis, and extended cost-benefit analysis; this last technique makes the α value variable, that is the unit detriment cost of the collective dose.

The publication nº 55⁽²⁾ introduces two more techniques, the use of multi-attribute utility analysis and multi-criteria outranking analysis, giving leeway for decision taking techniques, relegating to the background the optimization as was up till then intended, that is, maximize the net benefit. This is very well demonstrated in the example of the ventilation system for a small uranium mine where it is shown that any of the first 4 techniques could be the optimum analytical solution based on the premisses adopted. It followed from the cost benefit analysis that the optimum option was nº 1. But when the qualitative manner of individual doses is introduced the optimum option becomes number 2 or 4. When the discomfort factor provoked by the ventilation is included the optimum option becomes number 3. In the extended cost-benefit analysis, considering the individual dose distribution factor, the optimum option returns to be number 3. In the multi-attribute utility analysis the optimum option could be number 3 or 4 depending on the importance given to the discomfort factor produced by the ventilation system. In the multi-criteria outranking analysis it is proven that and exclusion criterion of 0,5 presents two solutions, these being option 3 and 5 and that to eliminate option 5 it must be taken as exclusion criterion the value of 0,6.

This publication disengages a series of problems, six of which are made salient herein:

PROBLEM 1- The ICRP does not take the trouble to show that for not one of the 5 options does the benefit become $B < 0$ in proportion to the sum of protection costs, X , plus the increase in detriment cost, Y . This sum deviates from a factor of 3 for the same options to 2 between different options.

PROBLEM 2- Because an optimum analytical solution depends on the imposed conditions by the decision-maker, the graph of traditional optimization, figure n° 1, passes to that of figure n° 2.

PROBLEM 3- The linearity relationship between collective dose and detriment cost, so much, proclaimed in publication 22⁽³⁾, items 2,3,29 and 30 as well as in publication 26⁽⁴⁾, items 28 and 30 and in publication 55⁽²⁾, item 145, ceases to exist even through it is already considered to conservative. For this case the optimization graph becomes that shown in figure 3.

Fig. 1 - Traditional Optimization.

Fig. 2 - ICRP-Publication 55 - Proposed Optimization.

Fig. 3 - ICRP-Publication 55 - Proposed Optimization with Y Exponential.

PROBLEM 4- We know that B is maximum when $(X+Y)$ is at minimum but nothing is said in respect to each of these two last terms. In many countries these costs come from different sources and each has an interested to minimize expenses. On one side X is a real guaranteed immediate cost spent by executor of the service and Y is a probabilistic cost, not definite, with a long period of time for despenses. In agreement with item 98 of ICRP publication 26⁽⁴⁾ the average life lost by a worker with radiation is uniquely 10 years and when it is necessary to lay out the money now foreseen probably the techniques for cures will have advanced and the cost declined. For example, some years ago carcinogenic breasts were removed which is not done any more; people died of thyroid cancer but now the thyroid is removed and the patient is saved, etc.

PROBLEM 5- The very high value of α is still more than that adopted by ICRP, with an average value for the world of 3 to 5 times higher than the real value as some specialists assert. In

this case the source who pays for the detriment estimates a cost from 6 to 10 times the real cost in detriment to the other source which evaluates real costs. This is contrary to that presented in many ICRP publications that dictate we be as realistic as possible in the evaluation of doses and consequently unfavorable to the detriment cost during the optimization calculation for the purpose to evade discarding. The use of radiation in favor of another technique which offers higher risks but were move realistic in the calculations. Some publications and respective items that assert the realistic condition are: Publication 22⁽³⁾, annex II, Publication 26⁽⁴⁾, item 30, Publication 35⁽⁵⁾, items 36 and 84, and Publication 55⁽²⁾, items 38 and 55.

PROBLEM 6- The ICRP gives emphasis to the preference to irradiate a maximum number of individuals in low dosage rather than a small number with high doses for identical collective doses. Since in both cases the doses for the optimization calculation are below the annual limits and therefore inside the linear zone between dose, detriment, and biological effect, the emphasis should be the contrary.

For example: If 20.000 people were irradiated with a dose of 1 cSv having a probability of death of $4 \times 10^{-4} \text{ cSv}^{-1}$, we can say 8 people die by dose effect. On the other side having 10.000 people irradiated with a dose of 2 cSv with the same probability of death we would have only 4 deaths by radiation. Conclusion, the probability of death increased by a factor of 2 but the number of deaths decreased by a factor of 2.

RECOMMENDATIONS AND POSSIBLE SOLUTIONS

- For the first problem instigate the recognition of the calculation of B for the justification of the activity. With this calculation realized you can evaluate the maximum value of $(X+Y)_{\max}$ which makes $B=0$ and this will constitute a second constraint in addition to dose limits. Item 32 of Publication ICRP-55 discusses the dividing line of $B=0$. We suggest therefore an ICRP publication with a practical guide for the calculation of the justification showing how other factors could be inserted in addition to those of economic and social.

- For the second problem it should be remembered that the decision taken depends on the justification and not on optimization, and this subject is very well explained in items 32 and 33 of ICRP Publication 55. We urge therefore that the technical factors which enter into the calculation make themselves with their relative importance as partial parameters of the X and Y factors and that the sensibility study with its variation should be within technically justifiable intervals. We suggest a re-edition of ICRP Publication 55 with this eminent technical character and leave the decision which has no technical connotation to those which have the authority.

- For the 3rd problem the ICRP should decide what is the most realistic relation in light of actual knowledge between dose, de

triment, and cost when the doses are below the limits and make this relation or relations valid of all cases. The detriment cost should be established by the competent authority of the country based on the ICRP recommendations. The relation or relations between those three parameters, having various bands of dosage, should be published by the ICRP with urgency.

- For the 4th problem we should take into account the pair X and Y and because of reasons put forward we suggest and evaluation of $X=y$ or $X < Y$ in addition to $(X+Y)_{\min}$. The new edition of ICRP Publication 55 should attack this^{min} problem and manage to clarify it.

- For the 5th problem, since the distribution of doses varies in the different options; different values of α change the panorama of the optimum solution and therefore this value should be extremely realistic, even more so than of the proper dose, since that the interest is to encounter the differences between the options. Thus we suggest that the ICRP realizes an evaluation of the calculation for α and publish this as soon as possible. Excessively high values of α permit the choice of high risk techniques only due to the fact that we have excessively conservative numbers.

- For the 6th problem we suggest that the ICRP technically show if our example constitutes a sophism or not. In the negative case we eliminate from ICRP publication 55, since that all considered doses are below annual limits, the discussion with respect to a large number of individuals radiated with small doses or a small number radiated with doses higher for the same collective dose value.

**A STUDY OF THE HUMAN URINARY EXCRETION OF CHRONICALLY INGESTED URANIUM -
INSIGHTS ON THE GASTROINTESTINAL ABSORPTION FACTOR**

M. LIMSON ZAMORA, J. ZIELINSKI, AND R. FALCOMER

BUREAU OF RADIATION AND MEDICAL DEVICES
DEPARTMENT OF NATIONAL HEALTH AND WELFARE
OTTAWA, CANADA

ABSTRACT

A study was conducted in two Canadian towns to determine the feasibility of using urinalysis data to estimate uranium uptake where exposure is through the chronic ingestion of soluble natural uranium in drinking water. Forty-three subjects participated in the study. Uranium levels in drinking water varied from 5 to 376 $\mu\text{g/L}$, and intakes ranged from 3 to 628 $\mu\text{g/day}$. Urinary excretion varied from 1 to 10 $\mu\text{g/day}$. Variation of the gut absorption factor (f_1) correlated poorly with gender, years of residence, and age, while significant negative correlation was obtained with intakes greater than 9.5 $\mu\text{g/day}$.

INTRODUCTION

Despite numerous studies on the metabolism of uranium, there is still considerable uncertainty regarding the most appropriate value of the f_1 factor to use in the calculation of doses from uranium exposures. Values reported in the literature [1,2] have varied from less than 1% to as much as 32%. A number of human studies have been undertaken to estimate its value; but most have been conducted under conditions of acute exposure. Except when accidents occur, most exposures are chronic in nature. This is particularly true of environmental exposures.

This investigation was undertaken to determine how closely urinary uranium reflects uptake in the gut following chronic uranium ingestion, and to arrive at a "best estimate" of the f_1 factor to use in dose assessments.

METHODS

The subjects for the study were selected according to age, gender, health status, and years of residence in the towns that were studied. Twenty-two male and twenty-one female residents of the two towns with as good a spread in age between 20 and 70 years, and who had lived in the area from a minimum of 17 months to a maximum of 43 years, participated in the study. All were in good health, and were not subject to kidney problems or other complicating pathology. Two couples in one community requested that their three children - ranging in age from 5 to 14 years - be included in the study. Participants were asked to submit 24-hour urine specimens and samples of tap water collected at home and at work. Questionnaires were used to estimate total water intake, including water-based beverages, over a 7-day period. Laser-induced phosphorimetry was used to

measure the uranium content of samples.

Two assumptions were made in the design of the study and the interpretation of the results obtained. Subjects were assumed to be in a state of equilibrium insofar as their uranium excretion vis à vis their intake was concerned. Food was assumed to make a minor or even negligible contribution to uranium intake, compared to water. This was considered reasonable, based on the reported [3] factor of 10^{-3} for the bio-concentration of uranium by staples and garden vegetables grown in contaminated soil.

RESULTS AND DISCUSSION

The wide variability reported in the literature [1,2] for the value of the f_1 factor was also observed in this study, with values ranging from 0.2% to 61% of intake. Uptake data, separately or pooled between locations, were found to be gender-insensitive ($p < .60$). There appeared to be poor correlation between f_1 values and years of residence. This observation supports the assumption that the subjects were in a state of equilibrium with respect to uranium intake and excretion.

The variation of the f_1 values with intake expressed as $\mu\text{g}/\text{day}$ was examined. For intakes ranging from 3.0 to 9.5 $\mu\text{g}/\text{day}$, the correlation with the f_1 factor was poor ($p < .40$). For intakes greater than 9.5 $\mu\text{g}/\text{day}$ and up to 628 $\mu\text{g}/\text{day}$ the best fit was obtained with a power function, with negative correlation being significant at the 99% confidence level (Fig.1). One possible explanation for these observations may be that for f_1 values that correspond to lower daily intakes, food uranium may represent more than a minor fraction of the total amount ingested, contrary to what was originally assumed in this study. A second and more intriguing explanation may be that above a certain level of daily intake (9.5 μg in this study), uptake in the GI tract decreases to a minimum, because some "mechanism" for gut uranium absorption becomes saturated when challenged with increasing uranium intakes.

Statistical tests for correlation also demonstrated that the f_1 values were age-independent. However, an examination of Figure 2 suggests that the f_1 factor may not be altogether age-insensitive. The higher concentration of elevated values at ages greater than 54 years might suggest some release of uranium from bone deposits in these individuals; that is, that these individuals may be in negative uranium metabolism, a phenomenon that has been reported, in older humans, for calcium which is also a bone-seeking element. In contrast, the low values (.004 to .025) for the minors (ages 5 to 14 years), might suggest deposition. The assumption that following prolonged exposure, all individuals are in equilibrium and that therefore, their daily urinary uranium output should be approximately equal to their daily uranium uptake, may have to be reexamined. Excretion in urine may indeed be less than the uptake, if in growing children, uranium deposition is actively taking place during bone development.

Fig. 1. Fractional gastrointestinal absorption of uranium as a function of intake ($\mu\text{g U/day}$). Data from a study of two towns were pooled and include uranium intakes ranging from 10 to 628 μg per day.

Fig. 2. Scatter plot of f_1 values versus the age of male (+) and female (*) subjects.

FURTHER STUDY

The above insights suggest certain areas that require further investigation. A mass balance study of total intake (water plus food) versus total excretion (urinary and faecal elimination) is proposed. This should provide answers regarding the role of food in uranium ingestion, as well as the possible existence of a saturable GI absorption mechanism. It is also proposed that a greater number of minors and subjects fifty years of age or older be included in the study in order to reevaluate whether or not the f_1 factor is age-dependent.

EVALUATION OF INTERNAL CONTAMINATION DOSE TO EMBRYO AND FETUS

F. Breuer, L. Frittelli
Italian National Agency for New Technology, Energy and the
Environment, Via V. Brancati 48 00144 ROMA

ABSTRACT

In its Publication n. 60 the ICRP recommends that the methods of protection at work of women which may be pregnant should provide a standard of protection for any conceptus broadly comparable with that provided by the System of Protection for members of the general public. The Commission's policy could not be satisfied following maternal internal contamination before the declaration of pregnancy by some radionuclides homogeneously diffused into the body as ^{137}Cs and ^3H .

Antenatal exposure to ionising radiation seems to be likely to cause (1) an undetectable death of the conceptus before the beginning of organogenesis, deterministic effects (malformations), with an estimated threshold to be about 0.1 Gy, during the period of major organogenesis and an increased probability of cancer in the live-born. To limit to a tolerable level the health effects affecting the conceptus following the mother's occupational exposure the Commission recommends that the methods of protection at work of women which may be pregnant should provide a standard of protection for any conceptus broadly comparable with that provided by the System of Protection for members of the general public. The Commission states that its policy seems to be adequately applied if the mother is exposed, prior to a declaration of pregnancy, according to the recommended protection system, including the respect of the occupational dose limits and of the source-related dose constraints, if any. The exposure of women which may be pregnant is thus not believed by the Commission to require specific arrangements and no special occupational dose limits for women are in general recommended, owing to the substantial reduction (by a factor 2/5) in the dose limits for workers. Once the pregnancy has been declared the conceptus should be protected by applying a supplementary equivalent dose limit to the surface of the woman's abdomen of 2 mSv for the remaining of the pregnancy and by limiting intakes of radionuclides to about 1/20 of the ALI. Exclusion should be considered from jobs carrying a significant probability of high accidental doses and intakes.

The application of these recommendations seems to be straightforward in the case of external exposure, but a deeper analysis could be required in the case of internal exposure. Some computations (2) of the fetus equivalent dose received following the continuous internal exposure of the mother under the annual limit recommended for the members of the public

(roughly 1/20 of the Annual Limit on Intake for workers) confirm that the resulting dose can be very small and satisfying the general Commission's policy regarding the occupational exposure of women. Some doubts could however arise in the case of occupational exposure of women which could be pregnant, owing to the flexibility in averaging the intakes over five years allowed by the Commission's Recommendations. This is because keeping the exposure of women which may be pregnant at an approximately regular rate, is no longer recommended. Some exposure scenarios should be investigated to verify that a significant dose to the conceptus can be excluded following the occupational exposure of the mother before the beginning of the pregnancy, even if the recommended exposure conditions are satisfied.

The equivalent dose to the different organs or tissues following the intake of a radionuclide into the body depends on the type and energy of emitted radiations, on the distribution of the radionuclide in the source organs, and on the mean residence time in the different organs and tissue, determined by the physical half-life and by the biological retention period. There are not general methods for calculating equivalent dose to the developing embryo and fetus following intake of radionuclides by the mother before the declaration of pregnancy (2). Two different aspects should be considered for the irradiation of the conceptus: a) by penetrating radiation emitted from radioactive materials deposited in the mother's organs; b) by non penetrating radiation emitted from material deposited in the fetal organs and tissues. In the first case, owing to the lack of more complete information, it can be generally assumed that the dose to the embryo up to the end of the second month of gestation is equal to the dose to the uterus. For the second case the selectivity of the placenta will be very often the most important factor. Following the entry into fetal and mother's body fluids, information is ideally required on the initial uptake of radioactivity by the fetal tissue during the very early stages of gestation, on the activity distribution and retention in developing fetal organs and tissues and also on the extent in which activity is translocated to the fetus from the maternal tissue, which could behave as a reservoir after the end of the direct intake by the mother. In the different exposure scenarios discussed in the following reference is made to the radioactive materials which are mostly present in the work-place, by selecting from the different groups characterized by a particular metabolic behaviour the radionuclide which can produce a not negligible exposure of the embryo and fetus.

A continuous exposure to 1 ALI per year of ^{239}Pu (i.e an intake of 300 Bq for class W (3)) has been assumed as critical with reference to bone seekers radionuclides. The largest fraction of bone seekers taken-up into the body-fluids is deposited in the mother's bone and only a minor fraction is available for the fetus, even without taking into account the placental discrimination factor. Literature data (4) relative to ^{90}Sr , for which the placental discrimination factor seems to

be very small, show that the concentration in fetal bone at time of birth is equal or lower than in mother's bone. According to other results (5) we can thus expect for actinides a low concentration in fetal bone, causing to it a dose lower than that received by the mother's bone. The actinide concentration in soft tissue can also be assumed to be equal to the concentration in maternal uterus. Considering a biological half-life of 500 days and a dose-factor of 1 $\mu\text{Sv/Bq}$ (6) we obtain for a continuous constant intake at the level of 1 ALI/year, stopped after the first month of gestation, a total fetal dose of about 0.34 mSv. According to the flexibility allowed by the System of protection in averaging the intakes over 5 years we can also consider a further acute intake of 1 ALI just before the beginning of the pregnancy, because the requirement of an approximately regular exposure no longer holds. The fetus could so receive an additional dose of 0.24 mSv during the following gestation time, with a total dose amounting up to 0.58 mSv. For bone-seeker radionuclides, in particular actinides, the occupational exposure of the mother under the exposure conditions recommended in 1990 ICRP Recommendations seems to bear no problems for the exposure of the conceptus.

Owing to its importance in industry, in research places and in nuclear medicine ^{131}I has been selected among the radionuclides characterized by a selective affinity for an organ or tissue. Human data on which a dosimetric model can be based are also available for this radionuclide (7). Owing to short physical half-life the acute exposure to 1 ALI (800 kBq) can be assumed as critical. Fetal and maternal tissues other than the thyroid will receive an equal dose around 0.032 mSv, assuming a committed dose of 40 pSv/Bq (6). No significative thyroid irradiation could reasonably be assumed before the declaration of the pregnancy, owing to the short half-life of ^{131}I . A larger, but always small thyroid dose could be evaluated for ^{125}I . Exposure during the pregnancy at the recommended value of 1/20 of the ALI could cause, between the third and the sixth fetal months, the dose to the thyroid of the fetus to exceed the maternal thyroid dose by a factor no larger than two. Maternal exposure to radioiodine under the conditions suggested by the Commission would cause no deleterious deterministic effects to the fetus, but only a small overcome of the risk of stochastic effects allowed for the members of the public.

For radionuclides which diffuse homogeneously within the human body (i.e. ^{137}Cs and ^3H) an homogeneous diffusion into the fetal tissues is assumed, with a dose rate equal to that delivered to maternal soft tissues. Assuming a continuous constant inhalation of 1 ALI/year (2 MBq/y) of ^{137}Cs an equivalent dose of about 1.7 mSv will be received by the embryo during the first month after the beginning of the pregnancy (i.e. up to the time of the diagnosis). Moreover, considering for cesium in the pregnant woman a biological half-life of 50 days, an additional dose of 3.8 mSv will be received over the next months, up to the exhaustion of the maternal cesium

burden, leading to a total fetal dose of 5.5 mSv. In the case of a single intake of 1 ALI just before the beginning of the pregnancy, taking into account the different biological half-life during the pregnancy, the embryo will receive a dose of 12 mSv during the first two months, and a dose of 8 mSv during the following seven months. For internal contamination by tritium the total dose will be received in short time after a single acute intake, namely 99% in the first 60 days. The whole committed dose to the soft tissues of the embryo (about 20 mSv) can therefore be received soon after the intake. As a conclusion, when the exposure conditions recommended in ICRP Publication 60 are satisfied, maternal exposure from radionuclides homogeneously diffused within the body could cause the fetus to receive a dose significantly larger than that allowed for the members of the public, even if the value of the dose seems not to be large to cause deterministic effects. The Commission's policy aimed to protect the conceptus by protecting the mother seems to be not completely satisfied.

For trace radionuclides like zinc, nickel, cobalt, technetium, etc. literature data (4) show in some fetal organs values of concentration larger than in maternal organs. Since the kinetics of these radioelements in fetal organs is not known, it is not possible to calculate the fetal dose due to the maternal contamination. It seems proper therefore to recommend a particular caution in the exposure of women of reproductive capacity to this group of radioelements.

APPLICATION OF THE PROPOSED NEW ICRP LUNG MODEL TO BIOASSAY

J. R. Johnson, A. C. James, and R. L. Hill

Pacific Northwest Laboratory
Richland, Washington 99352

ABSTRACT

The new lung model being proposed by the ICRP for use in radiation protection dosimetry requires calculating doses to separate regions of the respiratory tract, multiplying these doses by factors proportional to the risk per unit dose to each region, and summing over all regions of the lung to give a "weighted" lung dose. This paper compares the doses that would be calculated from bioassay measurements using the new model with those calculated using the current model, which basically uses total lung burden to estimate lung dose.

INTRODUCTION

The current ICRP lung model was developed over twenty years ago.⁽¹⁾ In its Publication 30, the ICRP modified the model only slightly in developing the Limits for Intakes of Radionuclides by Workers. Research during the past twenty years and experience with the model have indicated a number of areas where the current model can be improved for radiation protection purposes. Although the current model is sufficiently accurate for developing limits for intake of radionuclides for occupational exposures,⁽²⁾ it has a number of inadequacies. It does not allow for calculation of doses to airways in the head region; the clearance categories based on solubilities of radionuclide compounds are not valid in many cases; and the model is not readily useful for interpretation of bioassay data. These and other inadequacies, as well as the desire to incorporate the results of studies undertaken in the last 20 years, led the ICRP to initiate the development of a new lung model.

MODEL DEVELOPMENT AND CALCULATIONAL RESULTS

The process of developing the new lung model has been one of developing models of deposition, clearance, risk, and dosimetry. Development of these models has been described in detail previously.⁽³⁾

The underlying concepts for the model development are shown in Fig. 1. Material deposited in the extrathoracic (ET) region of the respiratory tract is known to clear quickly, both externally as well as to the gastrointestinal (GI) tract [$G_{ET}(t)$]. Material deposited in the thorax is either cleared within a few days (T_f), or more slowly (T_s) by mechanical

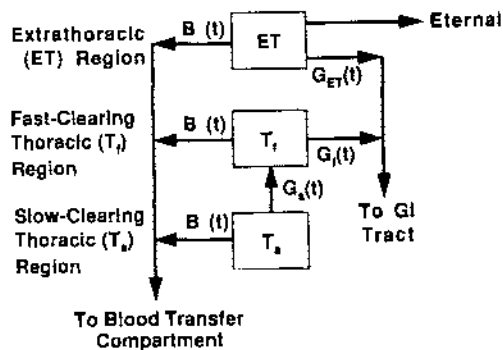

Fig. 1. The underlying concepts used as a basis for developing the new lung model.

processes $[G_i(t)]$. Clearance by translocation to blood takes place from all regions at the same fractional rate $[B(t)]$. The current implementation of these concepts into a compartment model is shown in Fig. 2. Mechanical clearance half times to the GI tract from these compartments are as follows: naso-oropharynx larynx = 10 min; bronchi = 100 min (fast) and 23 d (slow); bronchioles = 8 h (fast) and 23 d (slow); alveolar interstitium = 35 d, 700 d, and 7000 d. Clearance rates to the blood from all compartments are assumed to be equal. Default half lives, which are given for fast (F), medium (M), and slow (S) clearance (F, M, and S are similar to D, W, and Y in the old model), are: 10 min for F; 50% at 3 d and 50% at 100 d for M; and 0.1% at 15 min and 99.9% at 6930 d for S.

Recommended weighting factors for the different parts of the thoracic region are bronchi = 0.8, bronchioles = 0.15, alveolar-interstitium = 0.05, and thoracic lymph nodes = 0.001. These choices cause the ratios of dose-rate to thoracic-burden to vary with the time after an intake. Fig. 3 gives the relationship for Class S material (a). The current model assumes that the dose rate is always proportional to thoracic burden; however, if the activity in the lymph nodes is assumed to have very little risk, as in the new model, the current model (Fig. 3[b]) would also show a decrease in the ratio of dose-rate to thoracic-burden with time.

Fig. 4 gives comparisons of the current and new model results for uranium excretion in urine. The urinary excretion calculated for classes S and Y is much smaller using the new model because of the much lower predicted clearance to blood. Similarly, the peak in the ratio at about 100 days in the M/W ratio results because the current lung model has essentially emptied the lung by this time; hence, very little material is available for mechanical clearance. Ratios for fecal

Fig. 2. The compartment model developed by the Task Group to implement the conceptual model shown in Fig. 1. The first order kinetics with constant fractional clearances used with the model results in easy computer implementation.

Fig 3. Ratio of lung dose rate to lung content for Type S (Class Y) alpha-emitting material.

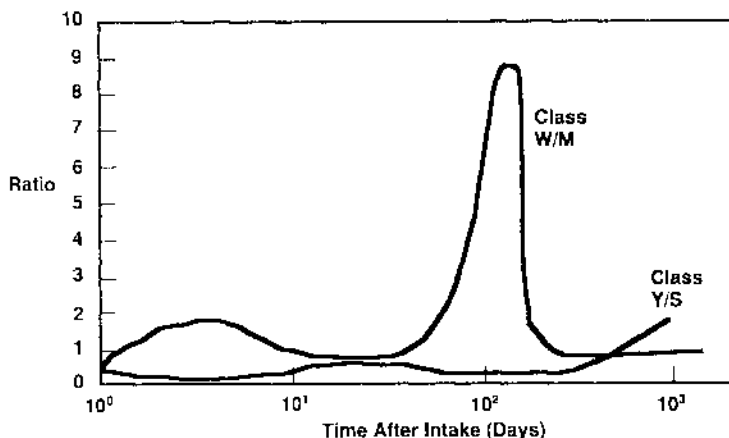

Fig. 4. Ratio of uranium excretion rates for the current and new lung models.

excretion of Y/S material show a broad peak at 5 to 50 days because the new model predicts much higher mechanical clearance of insoluble materials during this time period.

CONCLUSION

The new lung model is nearing completion. Its structure will allow easier matching of bioassay results to model predictions, and dose estimates will be better related to risk. However, the estimates of dose will be somewhat more difficult, and a conservative approximation of the actual dose may be necessary.

A ROLE OF THE HYBRID SCALE IN RADIATION PROTECTION

Shigeru Kumazawa

Department of Health Physics
Japan Atomic Energy Research Institute
Tokai-Mura, Ibaraki-Ken, 319-11, JAPAN

ABSTRACT

The hybrid scale, first introduced for the purpose of reasonable control of occupational exposure, has been expanded to generally apply it to various subjects in radiation protection. The merit of using the hybrid scale is discussed so as to control radiation risks as best as possible. New graph papers derived from the hybrid scale are systematically presented and their potential application is suggested.

INTRODUCTION

Both linear and logarithmic scales are widely used in radiation protection. The former is apt to describe variations of the same order of magnitude, e.g. levels of natural gamma radiation by time, while the latter is apt to describe variations of the different order of magnitude, e.g. levels of workplace radiation varied by operation of a nuclear facility. In radiation protection, however, there is another type of variations which consists of both the different order of magnitude in the lower range of variations and the same order of magnitude in the higher range. This type of variations needs a new type of scale of hybridizing a logarithmic and a linear scale in various ratios.

The first example of the scale for the hybridization was the variate coordinate axis on hybrid lognormal probability paper¹. The scale, termed a hybrid scale, was developed to be given the meaning of variations of individual doses controlled by radiation protection practices^{2,3}. The hybrid scale seems to be useful for assessing not only the control of dose to workers, but also the control of other quantities in radiation protection. Especially it is important to discuss how degree the system of radiological protection recommended by the ICRP needs the hybrid scale.

The 1990 ICRP Recommendations provide detail background information on biological effects of ionizing radiations. Some of the biological effects can be displayed more properly on hybrid graph paper than on linear or log graph paper^{4,5}. Therefore the new graph papers using the hybrid scale are systematically presented to explore the potential application in radiation protection.

METHOD

The standard hybrid scale is defined $y = \text{hyb}(t) = \ln(t) + t$, where the scale has marks of t at distances of y apart. This is the same as the log scale $y = \ln(t)$ or the linear scale $y = t$. The

hybrid scale approaches the log scale for $t \ll 1$ and the linear scale for $t \gg 1$ because the function is $\text{hyb}(t) \approx \ln(t)$ for $t \ll 1$ and $\text{hyb}(t) \approx t$ for $t \gg 1$. If the log term is equal to the linear term, that is, $y=0$, the value of t is about 0.567143.

Suppose a quantity x is of the different order of magnitude in the lower range of x and of the same order of magnitude in the higher range of x , a procedure to use the hybrid scale for x is as follows:

- 1) find a proper positive value of ρ having the reciprocal unit of x so that the value of $y = \text{hyb}(\rho x)$ should be of the same order of magnitude over the substantial range of x ,
- 2) calculate the value of $t = \rho x$ and plot it on a hybrid scale of t , or plot x directly on a hybrid scale of x which has marks of x calculated by t/ρ for a fixed proper value of ρ at distances of y apart.

Thus the locations of quantities x plotted on a hybrid scale represent the distances corresponding to the values of $y = \text{hyb}(\rho x)$. The value of $x_c = 0.567143/\rho$ is corresponding to $y=0$ and is termed a "critical point" between log and linear regions.

APPLICATION OF THE HYBRID SCALE TO DATA

The variations of annual dose to workers must reflect the effectiveness of a system of radiation protection. Analyzing the 1988 data of occupational exposure in Japan, we have the mean 1.7 mSv, $\rho = 0.3249 \text{ mSv}^{-1}$, and $x_c = 1.7 \text{ mSv}$ for nuclear industry the mean 0.4 mSv, $\rho = 0.0293 \text{ mSv}^{-1}$ and $x_c = 9.4 \text{ mSv}$ for medicine. Figure 1 shows quite different hybrid scales between nuclear industry and medicine. However a similar hybrid scale is applicable for each occupation over years.

The variations of annual collective dose per reactor must also reflect the ALARA efforts through regulatory activities. The 1983 data of annual collective dose to workers per reactor of PWRs licensed by the USNRC, was analyzed; $\rho = 0.0790$ (person-Sv/reactor) $^{-1}$ and $x_c = 7.2$ person-Sv/reactor, where the minimum, mean and maximum are, respectively, 0.7, 6.2 and 18.8 person-Sv/reactor.

The variations of radioactive concentration must reflect some controlled or planned procedures. Those of foods contaminated by the Chernobyl accident but inspected in Japan, and those of contaminated metals due to the decommissioning of JPDR are examples of applicability of the hybrid scale.

Figure 1 Examples of standard and actual hybrid scales

Another application of the hybrid scale is for the shouldered survival curves and low-LET radiation dose-response curves. The former is to plot surviving fractions on a hybrid scale with a positive parameter ρ estimated against doses on a linear scale⁴ and the latter is to plot effects on a log scale against doses on a hybrid scale with a positive parameter ρ^5 . These facts suggest to need new types of graph papers.

Figure 2 shows a hybrid hybrid paper which consists of both hybrid scales on a horizontal and on a vertical axis. A hybrid hybrid paper approaches a log log paper near the left lower corner of it, a section paper near the right upper corner, a semilog paper near the left upper corner or the right lower corner. In general a system of hybrid graphs is defined as follows:

(log linear)	(hybrid linear)	(linear linear)
(log hybrid)	(hybrid hybrid)	(linear hybrid)
(log log)	(hybrid log)	(linear log)

The key point of using the hybrid scale is to find an area, on a hybrid hybrid paper, with variations of the same order of magnitude in terms of y-value by selecting ρ parameters. Thus a way to implement a system of radiological protection must be to select a proper control space or area on a hybrid hybrid paper.

CONCLUSION

The hybrid scale has been developed to systematically formulate a quantitative feature of risks controlled by a system of radiological protection. However, as the hybrid scale is applicable for some biological effects of ionizing radiation but repaired by biological protection mechanisms, the hybrid scale is explicitly in future studies.

AN INTERIM UK RESPONSE TO REVISED RISK ESTIMATES AND ICRP 60

W P Bines and P F Beaver

Health and Safety Executive, London, UK

ABSTRACT

Risk estimates were revised in 1987. Since then, regulators have been under pressure to reduce dose limits. The UK government would prefer to await incorporation of ICRP's revised recommendations in a revision of the European Basic Safety Standards Directive. Interim action has therefore been taken, in the form of issuing additional guidance with a quasi statutory status. The new guidance includes the introduction of an investigation if an individual worker's cumulative dose within five years reaches or exceeds 75 mSv, to focus attention on workers being exposed at higher levels of dose.

BACKGROUND

The United Kingdom has had radiation protection legislation since the early 1960s, long before it joined the European Community. This legislation (Ref 1) only applied to the use of ionising radiation in factories however, licensed nuclear installations having radiological protection requirements written into their nuclear site licences; the remainder of users were covered by non-statutory guidance. Since joining the EC, the UK has fulfilled its obligation to implement the Euratom Basic Safety Standards Directive (Ref 2) by making the Ionising Radiations Regulations 1985 (Ref 3). These regulations extend radiation protection legislation to cover all uses and users of ionising radiation.

CURRENT LEGISLATION

The Ionising Radiations Regulations 1985, reflecting the Basic Safety Standards Directive, incorporate not only dose limits but, perhaps more importantly, the requirement for exposure to be kept as low as reasonably practicable (the UK equivalent of as low as reasonably achievable). The regulations contain certain action levels, which are levels of cumulative dose within a calendar year at which investigations must be made as a check on whether exposure is being kept as low as reasonably practicable. The first of these is when an individual's dose reaches 15 mSv. The ensuing investigation focusses on the work practices associated with this dose and whether it would be reasonably practicable to improve them to reduce exposure. The second

practicable to improve them to reduce exposure. The second action level is when a worker receives a dose of 30 mSv within a calendar quarter, in which case the enforcing authority, the Health and Safety Executive, must be informed.

DEVELOPMENTS SINCE 1987

The statement issued by ICRP following its meeting in Como in 1987 (Ref 4) recognised that further information about the Japanese atomic bomb survivors indicated that estimates of risk had been under-stated and should be considered to be two or three times as high as had previously been thought. As a result they would completely review their earlier recommendations, issued in 1977 (Ref 5). The UK National Radiological Protection Board, whose remit includes the duty to advise Government about the acceptability of international recommendations and standards, issued interim guidance in November 1987 (Ref 6). This guidance said that this latest information meant, in their opinion, that it would be prudent for employers to seek to restrict the exposure of their workers to no more than an average of 15 mSv a year over a number of years.

The Health and Safety Commission reacted to this advice from the National Radiological Protection Board by asking their recently appointed Working Group on Ionising Radiation to consider what action might be taken in view of the changing situation. The Working Group's subsequent advice (Ref 7) was that there was no need to reduce dose limits in advance of renegotiation of the Basic Safety Standards Directive, principally because the effect of the requirement to keep exposure as low as reasonably practicable had generally been to keep actual doses well below dose limits. However, they recommended that further statutory guidance on restriction of dose should be issued. This should draw employers' attention to the need to take account of the revised risk estimates when deciding whether existing and future exposures were as low as reasonably practicable, additionally it should focus attention on workers who were being exposed at an average of 15 mSv or more a year.

Following formal consultation with bodies and people likely to be affected by, and therefore interested in, the proposals (a statutory requirement in the UK's framework legislation for health and safety (Ref 8), further guidance was approved and published.

APPROVED CODE OF PRACTICE, PART 4

An Approved Code of Practice has a semi-legal status which is formally explained as follows "Although a failure to observe any provision of the Code is not in itself an offence, that

failure may be taken by a Court in criminal proceedings as proof that a person has contravened a regulation to which the provision relates. In such a case however it will be open to that person to satisfy the Court that the regulation has been complied with in some other way." Three Parts of an Approved Code of Practice supporting the Ionising Radiations Regulations 1985 had already been published, Parts 1 and 2 in 1985 (Ref 9) and Part 3, specifically about occupational exposure to radon, in 1988 (Ref 10).

Part 4, published in 1990 (Ref 11), advises employers to take account of the revised estimates of risk from exposure to ionising radiation when making new decisions about whether exposure is as low as reasonably practicable; it also requires them to review earlier decisions that are still operative to see if they remain valid in the light of the new information. Additionally the Code introduces an investigation if an individual worker's cumulative dose reaches or exceeds 75 mSv within any consecutive five calendar years. Unlike that when 15 mSv is reached within one year, this new investigation should focus on the individual's past dose history and likely future exposure. The final decision as to whether any further action needs to be taken to reduce the worker's future exposure should only be taken after the worker has been consulted and counselled and the views of other relevant people, such as the Appointed Doctor (an approved medical practitioner) and trade union and safety representatives, have been taken into account.

CONCLUSION

The issue of Approved Code of Practice Part 4 updates UK radiation protection to take account of revised risk estimates without changing dose limits. It also focusses attention on workers who have been receiving what is now seen as a relatively high level of dose in recent years, so that appropriate decisions to reduce their future incremental risk may be taken. This interim action will allow the UK to await revision of the Basic Safety Standards Directive before revising the dose limits and other provisions in our domestic legislation. The introduction of an investigation when 75 mSv or more is accumulated within five years is seen as compatible with ICRP '60 recommendations, in that it might quite properly be regarded as a generic constraint applicable to all users of ionising radiation.

TOWARDS UNIFORM STANDARDS OF RADIATION PROTECTION
IN HEALTH CARE IN EUROPE

P P Dendy

Dept of Medical Physics, Addenbrookes Hospital, Cambridge UK
(Chairman of the Professional, Education and Training Committee
of the European Federation of Organisations of Medical Physics)

ABSTRACT

In 1984 the Commission of the European Communities (CEC) issued a Directive for Protection of the Patient (84/466 Euratom). Article 5 of this Directive states that "A qualified expert in Radiophysics must be available to Sophisticated Departments of Radiotherapy and Nuclear Medicine".

This paper describes work carried out by the European Federation of Organisations of Medical Physics (EFOMP) on the interpretation and implementation of this Article.

INTRODUCTION

When Directives are issued by the Commission of the European Communities (CEC), Member States are required to introduce legislation, within a reasonable timescale, embodying the articles of the Directive. A Directive for Protection of the Patient (84/466 Euratom) issued in 1984 is specifically related to health care. Article 5 of this Directive states that "A qualified expert in radiophysics must be available to sophisticated departments of Radiotherapy and Nuclear Medicine" and to assist with the implementation of this Article, CEC Officers initiated a study to answer the following questions:

1. Do suitably qualified medical physicists, experts in radiophysics, exist in the Member States?
2. Are such experts available in radiotherapy, nuclear medicine and diagnostic radiology?
3. Is the basic education and training of the medical physicist in European Countries, a) consistent with the requirements of the proposed Directive of the Community on a general system for the recognition of higher education diplomas (89/48/EEC), b) equivalent in all countries, c) recognised by the appropriate government body?
4. What further education and hospital in-service training is required for the medical physicist to be designated as a qualified expert?

This paper reports on progress and developments resulting from the enquiry.

DESCRIPTION OF A QUALIFIED EXPERT IN RADIOPHYSICS (QE(R))

The first major problem was to define a QE(R). EFOMP has now proposed the following description:

"The Qualified Expert should normally be a suitably experienced physical scientist who would be responsible for the safe

application of radiological techniques in respect of the protection of the patient. This person would normally work in a hospital, or in a recognised analogous institution and would have knowledge and training in radiation physics appropriate to services where the quality of the diagnostic image or the precision of treatment is important and the doses delivered to patients undergoing these medical examinations or treatments must be strictly controlled"

This description has been accepted by the representatives of the National Authorities of Member States.

THE COMPETENCIES EXPECTED OF THE QE(R)

EFOMP is working towards a framework where 5 levels of competency will cover the whole of the career structure of the medical radiation physicist. A good honours degree or equivalent diploma in physics (competency level 1) will be followed by a period of training (competency level 2), then a period of experience. This will result in a qualified medical physicist (competency level 3) who will have an adequate span of practical knowledge, be able to perform given or routine professional tasks without supervision, and communicate with colleagues in related disciplines.

Because of the very advisory nature of the work of the QE(R), often requiring judgment in new or non-standard situations, EFOMP is now considering the view expressed by some Member Organisations that a further period of experience is required, to competency level 4, before becoming a QE(R). Competency level 5 would be appropriate for a Head of Department who was managing a range of routine services.

The duties and responsibilities of the medical radiation physicist in radiotherapy or nuclear medicine can now be assigned competency levels. The example in Table 1 is taken from draft proposals for a radiotherapy physicist.

**Table 1
Radiation protection - Source control**

Responsibility	Competency
a) Maintain source calibration certificates	2-3
b) Maintain records of contamination monitoring	3
c) Maintain source register with records of source purchase, movement and disposal	3
d) Assess adequacy of source storage facilities	2-3
e) Pack sources appropriately for transport with radiation hazard category and transport index correctly labelled	3
f) Arrange authorisation for waste disposal, by discharge to drains, incineration etc. as appropriate	2-3
g) Action to be taken in the event of source loss	2
h) Assessment of hazards and preparation of contingency plan for failure of teletherapy source return mechanism or fire	3-4

TRAINING FOR THE QE(R) IN THE VARIOUS EFOMP COUNTRIES

In 1984, EFOMP issued a policy statement on medical physics education and training¹ and more recently (1990) has conducted a survey of training programmes, with particular reference to training in radiation physics.

Replies have been received from 17 countries, 9 within the European Community and 8 outside it. All had introduced a training scheme in accordance with the EFOMP policy statement but 6 were not entirely happy with existing arrangements for the provision of lectures/seminars/tutorials and 4 felt that current arrangements for on-the-job practical training were unsatisfactory.

Current estimates of the number of physicists completing basic training with the approximate percentages in the ionising radiation related subject areas are shown in Table 2.

Table 2

Estimate of medical physicists completing training by country

<u>Country</u>	<u>Total</u>	<u>Percentage</u>				
		<u>Radthy</u>	<u>Nuc Med</u>	<u>Radlgy</u>	<u>Prot</u>	<u>Non Ion</u>
Belgium	0.5	80%	20%	-	-	-
Denmark	3-4	60%	20%	10%	-	-
France	30	40%	20%	20%	15%	5%
Germany	?					
Ireland	3-4	-	-	-	-	-
Netherlands	17	60%	-	20%	20%	-
Portugal	?					
Spain	8-10	50%	10%	20%	20%	-
UK	5-10	25%	25%	10%	-	40%
Austria	4	-	-	-	-	-
Czechoslovakia	8-10	60%	20%	20%	-	-
Finland	4	25%	25%	25%	-	25%
Norway	1-2	-	-	-	-	-
Poland	10-12	40%	30%	-	20%	10%
Sweden	10-20	-	-	-	-	-
Switzerland	1	-	-	-	-	-
Turkey	8	80%	15%	5%	-	-

EFOMP has also published, a policy statement on the training of a medical physicist as a QE(R)². In addition to the basic training covered in the previous policy statement, it recommends additional specialist training and a period of practical experience.

ADVANCED TRAINING BY EUROPEAN SUMMER SCHOOLS

With financial support from the European Community, the first Summer School for the QE(R) was held in Dublin in July 1991 to cover the advanced material required by the QE(R) in nuclear medicine. The school was very successful with 42 participants (6

lecturers, 2 observers, 5 associate lecturers/demonstrators and 29 students) from 17 different countries. Responses from the participants after the School showed that, in their opinion the objectives of the course were achieved. Following written and oral examination 16 persons were awarded EFOMP certificates of competence in the advanced course for training the QE(R).

INTERPRETATION OF THE TERM "SOPHISTICATED DEPARTMENT" IN ARTICLE 5

EFOMP has suggested that "Sophisticated Departments" should be those departments using ionising radiation routinely on patients, where complex equipment and/or complex procedures and/or frequent radiological examinations/treatments are involved. A meeting with Officers of the Commission in December 1991 acknowledged that this definition still contained subjective terms such as "complex procedures", but agreed that in any revision of the Directive the emphasis should be on the types of work undertaken.

EXTENSION TO DEPARTMENTS OF DIAGNOSTIC RADIOLOGY

Finally, representatives of National Medical Physics Organisations have argued strongly that diagnostic radiology should be included in Article 5. This is based on a number of factors - (i) the source of the highest radiation dose to the population is the use of X-rays in diagnosis, (ii) a number of complex high dose procedures are now in use, (iii) surveys have shown a wide range of doses for the same examination, (iv) the need for proper training of radiologists. Representatives of National Authorities are currently less supportive, some on the basis that the case of need has not been adequately demonstrated, some on grounds of cost and some because a significant proportion of the work is already covered by radiation protection services.

CONCLUSION

EFOMP has already been able to make a significant input to the thinking of Officers of the CEC on the right way to provide medical radiation physics support for the proper protection of the patient. More work remains to be done but an important route of communication from medical physics staff in hospitals through National Organisations of Medical Physics and EFOMP to the Commission has been established.

AN IN VITRO INVESTIGATION ON THE SUBCELLULAR EFFECTS OF 50 HERTZ MAGNETIC FIELDS

W. Malorni, S. Paradisi, E. Straface, M.T. Santini,
and G. Donelli.

Dept. of Ultrastructures, Istituto Superiore di Sanita',
Viale Regina Elena 299, 00161 Rome Italy

ABSTRACT

The effects of 50 Hz ELF electromagnetic fields were investigated in cultured cells using morphological, ultrastructural and cytological techniques. Experiments conducted at different values of exposure intensity (2.5, 5 and 10 mT) and duration (from 24 to 96 hours) demonstrated that these fields seem to modify slightly surface morphology and intercellular relationships without affecting cell reproductive integrity.

INTRODUCTION

In recent years, much interest and debate have developed concerning the possible health risks to humans from exposure to extremely low frequency (ELF) electromagnetic fields (50-60 Hz) originating from a wide variety of sources (power transmission lines, household electric wiring and appliances, etc.). Results from numerous studies conducted *in vitro* have elucidated possible effects of these ELF fields on cells. However, although it has been hypothesized that specific organelles could be targets for electromagnetic radiation and consequently impair cell function (1-6), the mechanisms of action of these fields as well as the health risks to humans still remain unclear. The above considerations together with the controversial nature of the results themselves (2-4), prompted us to study the effects of ELF fields on cultured epithelial cells. Particular attention was paid to the proliferative capability and morphological features of these cells.

MATERIALS AND METHODS

Cell cultures: A431 cells (a human carcinoma cell line) were grown in DMEM supplemented with 10% fetal calf serum, non-essential aminoacids, 5mM L-glutamine, 100 I.U./ml penicillin and 100 ug/ml streptomycin.

Exposure system: The experimental set up was described previously (7). Briefly, homogeneous sinusoidal 50 Hz magnetic fields were generated inside cylindrical coils 50 cm in height and 15 cm in diameter. Electric current densities of up to 24 A circulating in about 300 loops generated different magnetic flux densities. Flasks containing A431 cells were inserted in the center of the coils with the monolayer oriented parallel with respect to

the magnetic field. The magnetic flux density was measured directly at the sample position through the narrow Hall probe of a Namicon MP-U 10/84 gaussmeter. Accuracy of the measurements was $\approx 2\%$. Temperature inside the coils was monitored continuously and kept at 37 ± 0.1 °C. Flasks inside the coils with no current were considered as controls (sham-exposed).

Cell treatments: ELF field intensities used in these experiments were 2.5, 5, 10 mT. Treatments lasted 24, 48, 72 or 96 hours.

Cell growth curves: 2×10^5 cells were seeded with 5ml of fresh medium in culture flasks. The flasks were filled with a 5% CO₂-air gas mixture and kept in the exposure system. Control cells were sham-exposed in the same temperature-controlled coil as experimental A431 cells. Cell counts were made at the end of each of the exposure times in triplicate using a Coulter Counter (Coulter Electronics, Ltd., Luton, England).

Scanning Electron Microscopy (SEM): For scanning electron microscopy cells were grown on glass coverslips. Sham-exposed and exposed cells were fixed with 2.5% glutaraldehyde in 0.1 M cacodylate buffer (pH 7.4) at room temperature for 20 min. Following post-fixation in 1% osmium tetroxide for 30 min, cells were dehydrated through graded ethanols, critical point dried in CO₂ and gold coated by sputtering. The samples were examined with a Cambridge 360 scanning electron microscope.

Fluorescence microscopy: Control and treated cells grown on coverslips were fixed with 3.7% formaldehyde in phosphate buffered saline (PBS) for 10 min. at room temperature. After washing in the same buffer, the cells were permeabilized with 0.5% Triton X-100 (Sigma) in PBS for 5 min. Cells were stained with fluorescein-phalloidin (Sigma) at 37 C for 30 min. After thorough washing, the samples were mounted together with glycerol-PBS (1:1) and observed with a Nikon optiphot fluorescence microscope.

RESULTS

Growth curves. The effect of ELF fields on A431 cell growth is represented on the left (Fig. 1). No statistically significant differences were detectable in the growth rates of sham-exposed cells and cells exposed up to 96 hours to 2.5, 5 and 10 mT.

SEM analysis. In Fig. 2a the surface morphological features of control A431 cells are shown. Exposure to a 5 mT ELF field for 24 hours seems to induce flattening of the cell

cytoplasm accompanied by a rearrangement and redistribution of microvillar structures (Fig. 2b). After 48 hours of treatment, the above-mentioned modifications were also accompanied by an alteration of intercellular contacts. However, despite these changes monolayer confluence was nonetheless observed (Fig. 2c).

Fluorescence microscopy. The actin microfilament network appeared to be modified slightly by 5mT ELF fields. In particular, with respect to control cells (Fig. 3a), a marginalization of F-actin filaments toward the cell periphery occurred after 24 hours of exposure (Fig. 3b). Furthermore, after 48 hours, a microfilament rearrangement characteristic of cell retraction as well as intercellular contact modifications were observed (Fig. 3c)

DISCUSSION

Our data suggest that sinusoidal magnetic fields can alter epithelial cell plasma membrane structure without modifying cell proliferative ability. These data can be paralleled with those of Adey (5, 8) which showed that magnetic fields can reduce the integrity of cell-to-cell contacts without interfering with other subcellular

processes. Furthermore, recent data from our group on chick embryo myoblasts revealed that cell membrane conductivity and permittivity can be affected by exposure to ELF fields (7). In contrast to the previously hypothesized role of ELF fields in promoting rather than initiating tumor development (9,10), our results seem to indicate that proliferative features of A431 cells are not affected by ELF field exposure. This fact could be related to differences in exposure conditions or to the type of cells used. Moreover, "window" effects render any speculation on this matter even more difficult (1).

This study was supported by the CNR-ENEL Project - Interaction of energy systems with human health environment - Rome, Italy.

THE WORK OF COMMITTEE 4 OF ICRP

Roger H Clarke

National Radiological Protection Board,
Chilton, Oxon, UK

ABSTRACT

This paper explains the rôle of Committee 4 of ICRP and outlines its current programme of work with the associated timescales. The topic areas are: probabilistic exposures; radiological emergencies; and radon at home and in the workplace.

INTRODUCTION

Committee 4 of the International Commission on Radiological Protection is established to consider the practical application of the Commission's Recommendations. The current programme of work of Committee 4 ICRP has now been running for three years and was established as the new Recommendations of the Commission were nearing completion. The programme therefore focused on three major issues that were emerging and would not be resolved by the time the new Recommendations were published. The Commission endorsed the Committees proposals for work in these three areas and has appointed a Task Group for each.

The first topic relates to the introduction of **potential exposures** in Publication 60. The Commission gives suggests that risk limits are not to be set and proposes **risk constraints** be developed but no guidance is given on how this is to be done.

The second topic is **intervention for protection of the public in a radiological emergency**. The Commission last gave advice in Publication 40 which was prior to the Chernobyl accident. There is a need to update the principles in the light of experiences gained in the intervening years.

The third topic being considered by Committee 4 is **Measures for protection against radon**. This was the last of the topics to be identified and the relevant Task Group has been in existence for a shorter period than the other two. The main thrust of the work relates to the establishment of intervention levels for radon in homes and in the workplace. The terms of reference specifically exclude radon in mines. However, the Commission accepted a recommendation of Committee 4 that it should clarify its position with regard to occupational exposure in mines. It has set up a Task Group of the Main Commission with the intention that the situation should be resolved in a relatively short time.

The work of each of the three Task Groups is considered in turn. The status of the work is as of mid-1991 in this paper. All of the Task Groups will be meeting and producing amended drafts for the next Committee 4 meeting in April 1992. An update of the progress will be given in the presentation at the IRPA meeting.

TASK GROUP ON THE ASSESSMENT AND CONTROL OF RISK FROM POTENTIAL EXPOSURES

This Task Group is chaired by Richard Cunningham of the US Nuclear Regulatory Commission and has as members, Adolf Birkhofer (Germany), Abel Gonzalez (IAEA), Lars Hoeberg (Sweden), and Bert Winkler (South Africa).

Potential exposures may arise from the introduction of any practice and may involve a wide range of consequences. Some practices utilise simple sources and the consequences of accidents may be fairly limited in terms of the numbers of people and areas affected. This may apply to the failure of

interlocks on an irradiation facility, or an accident involving an industrial radiography source. Other practices lead to a complex series of "source terms", such as nuclear installations, where the consequences of an accident may range from the almost negligible to significant social and economic disruption as well as severe health effects. Other effects may arise in the far future such as those from the deep disposal of solid radioactive waste.

The Commission has recommended that a risk limit should not be set on the grounds that it is impossible to regulate such a limit. On the other hand it is feasible to set constraints which may be sequence specific depending on the type of practice. The Task Group is considering generalised constraints on probabilistic events along the following lines:

- (a) events which result in doses below the dose limits and are treated as part of normal exposure: 10^{-1} to 10^{-2} y^{-1}
- (b) events which result in doses above the dose limits but are stochastic in nature: 10^{-2} to $10^{-6} y^{-1}$
- (c) events where some radiation effects are deterministic, but not fatal: 10^{-5} to $10^{-9} y^{-1}$
- (d) events when early death is likely: $< 10^{-7} y^{-1}$

These figures are intended to illustrate the types of constraint that may be imposed based on judgements of what can be accomplished and could be revised in the light of operational experience gained.

One of the more difficult issues for the Task Group is to try to recommend levels of probability that are sufficiently low as to make the event acceptable, regardless of the consequences. The acceptable level depends on whether the consideration is of justification, optimisation or individual risk.

In justifying a practice involving potential exposure there are many considerations other than radiological consequences and some events will be accepted, even if they are severe, because of the benefits expected from the practice. This will lead to a natural acceptance of some low probability events. In deciding on the optimisation of the safety of a particular plant, there will be an aggregation of various attributes for the purpose of comparing alternatives. In this case some sequences will not contribute significantly to the aggregated "risk" from the plant and may be ignored. These sequences may be of relatively high probability, but of little consequence, or may be of high consequence, but with negligible contribution to the "risk". In either case there is reason to accept events without further attempt to reduce their probabilities. Finally there will be grounds for accepting an event when the individual health risk is low enough. There are reasons for thinking that a risk of death to an individual of less than $10^{-7} y^{-1}$ is so low as not to be of concern to the individual.

The work of this Task Group will be of importance to the nuclear safety community as well as to the radiological protection world. However the report must not be written so as to appear dominated by nuclear power, since more accidents occur in the industrial and medical fields.

TASK GROUP ON PRINCIPLES FOR INTERVENTION FOR PROTECTION OF THE PUBLIC IN A RADIOLOGICAL EMERGENCY

This Task Group is chaired by Roger Berry of British Nuclear Fuels and has as members: Larry Channey (Canada), Frances Fry (UK), Yuri Konstantinov (USSR), Guy Lamaire (France), and Anneli Salo (Finland).

This Task Group is applying the principles of ICRP 60 for INTERVENTION. These are:

- (a) The proposed intervention should do more good than harm, i.e. the reduction in detriment resulting from the reduction in dose should be sufficient to justify the harm and costs, including social costs, of the intervention (JUSTIFICATION)

- (b) The form, scale, and duration of the intervention should be optimised so that the net benefit of the reduction in dose, i.e. the benefit of the reduction in radiation detriment, less the detriment associated with the intervention, should be maximised (OPTIMISATION)

Dose limits do not apply in the case of intervention, but Publication 60 states that the application of principles (a) and (b) will lead to dose levels where intervention is appropriate. The major objectives of the work of the Task Group are to develop the techniques of optimisation to be applied to each specific countermeasure. This should help clarify the difference in using individual or collective dose as the variable in the optimisation depending on the countermeasure. It is clear that an optimisation may lead to there still being no net benefit. The optimisation process is most likely to lead to a dose within a range of doses between which the intervention is justified. The Task Group is planning to use the justification principle to derive levels of dose, well below those at which deterministic effects would be observed, at which intervention is almost always likely to be justified. The resulting intervention levels are shown in Table 1.

There will thus be no lower levels of doses below which the Task Group recommends that intervention is not warranted because of the difficulties in finding common values which apply across a wide range of individual and societal benefits and disadvantages. It still remains clear that the dose limits for normal operation of the practice are not necessarily the correct figures at which to start intervention, although intervention below dose limits must be unjustified.

Table 1

Levels of individual dose at which intervention is almost certain to be warranted

Protective Action	Quantity	Intervention Level (mSv)
Sheltering	Effective Dose	50
Evacuation	Effective Dose	500
	Skin Dose	5000
Stable Iodine	Thyroid	500
Food Control	Effective Dose	10
Relocation	Effective Dose	Dependent on circumstances

The report will not address the exposure of emergency workers, either those who are involved in the immediate action to control the event, or those who become exposed as a result of the deliberate programme of decontamination. The Task Group will give guidance for the restriction of exposures for those people whose work takes place in a contaminated environment as a result of an accident, but whose work would not otherwise involve radiation exposure.

TASK GROUP ON MEASURES FOR PROTECTION AGAINST RADON

This Task Group is chaired by Richard Osborne (Canada) with members: John Harley (USA), Tony James (USA), Mike O'Riordan (UK), Gun-Astrid Swedjemark (Sweden), and Pierre Zettwoog (France).

The report addresses the situation of radon in dwellings first as that is the area where intervention as described by ICRP is most easily understood. The principles are identical to those referred to above and in this case everyone appears to be quite clear that dose limits for practices do not apply. The Commission has previously given advice in this area, but since then two things have happened. First the risk estimates have increased and second, more importantly, there is a new model of the human respiratory tract under development by a Task Group of Committee 2 of ICRP. This new model gives doses per unit intake that are at present 2 or 3 times greater than those given by the present

lung model. The reasons are that the new model identifies the secretory cells on the bronchi as being the cells at risk rather than the deeper basal cells previously thought to be those at risk. This increases the dose per Bq inhaled. In addition the model apportions the w_T of 0.12 for the lung in the ratio of the natural incidence of lung cancers. These are smoking related, and occur in the major bronchi which leads to a greater weighting being placed on the dose to those bronchi. The Commission has asked its Committee 1 (Biological Effects) to advise on the two features of the new model. The outcome will be of major significance to the work on radon.

The report will deal with the physical and biological fundamentals as well as movement and measurement, followed by remedial and preventive measures.

The more difficult area is the workplace. There will be situations where there is a high radon level in a workplace and intervention may be indicated, but are the workers to be regarded as occupationally exposed with all the associated considerations of monitoring, record keeping and medical examinations. The Commission has rather left this to National Authorities in Publication 60. If that Authority declares that a workplace is affected by radon, then the workers are radiation workers. The Task Group is trying to develop guidance which would help the decision making. Two possible approaches are being considered:

- (a) only that exposure to radon that is increased above the general level in the area is regarded as occupational exposure and this additional exposure is subject to control;
- (b) where the worker is not involved with handling radioactive materials and the additional exposure to radon is not considered occupational exposure.

The first proposal would treat radon as artificial radiation sources are treated in that natural background radiation is excluded from that for which management has responsibility. The second proposal means that radon at work would be dealt with in exactly the same way as radon at home and intervention alone would apply.

CONCLUSIONS

The three Task Groups of Committee 4 are meeting during the autumn of 1991 and will produce new texts for the Committee 4 meeting in April 1992. The intention is that Committee 4 will submit those three reports after any corrections and amendments, to the Main Commission at its meeting in November 1992. If the Commission adopts any or all of the reports, they should appear in the Annals early in 1993.

CHAMPS ELECTRIQUES ET MAGNETIQUES ET CANCERS :
EXISTE-T-IL UNE RELATION ?

L'enquête épidémiologique d'Electricité de France

ELECTROMAGNETIC FIELDS AND CANCERS : IS THERE A RELATIONSHIP ?
THE EPIDEMIOLOGICAL STUDY OF ELECTRICITE DE FRANCE

Electricité de France, Hydro-Québec and Ontario-Hydro are put together to grant a nested case-control study regarding possible effects of occupational exposure to EMF. Outcomes of interest are various cancers (leukaemia, brain tumor, melanoma). The cohort consists of 20 000 thousand electricity utilities male workers. Cases (4 controls for each case) were collected from an occupational cancer register.

A subset of 1 000 subjects underwent EMF dosimetry (POSITRON dosimeters).

A job-exposure matrix was also set up in order to assess concurrent exposures to potentially carcinogenic chemical as classified by IARC.

Results are expected to be published by the end of 1992. The study is coordinated by the Pr G. THERIAULT (Mac Gill University).

L'éventualité d'une relation entre l'exposition aux champs électriques et magnétiques de très basse fréquence (50-60 Hz) et la survenue de certains types de cancers demeure une question très controversée, malgré l'importance des travaux épidémiologiques et biologiques qui y sont consacrés.

Electricité de France s'est associée à ONTARIO-HYDRO et à HYDRO-QUEBEC pour entreprendre une étude épidémiologique en milieu professionnel visant à apporter des éléments de réponse.

 4. Service Général de Médecine du Travail EDF-GDF
 5. Direction des Etudes et Recherches EDF - Les Renardières, route de Sens, Ecuelles - 77250 MORET-SUR-LOING

Nous présentons ici les principales modalités de l'étude pour sa partie française. Elle ne diffère pas d'ailleurs fondamentalement dans sa composante canadienne.

LA POPULATION

Il s'agit d'une enquête cas-témoins au sein d'une population de 120 000 travailleurs.

- Les cas :

Le critère d'inclusion est la survenue d'un cancer chez les travailleurs statutaires en activité, de sexe masculin, entre janvier 1978 et décembre 1989. Les données sont recueillies dans un registre professionnel des cancers.

Pendant cette période 2075 cas de cancer ont été dénombrés. Les leucémies sont au nombre de 74. Les mélanomes cutanés sont au nombre de 39 cas. Enfin 90 tumeurs cérébrales ont été dénombrées.

L'incidence des tumeurs malignes tous types confondus dans la population considérée et pendant la période de recueil (12 ans) est en moyenne de 138 cas pour 100 000.

- Les témoins :

Les témoins sont tirés au sort. Il s'agit de travailleurs de sexe masculin, nés la même année que les cas auxquels ils sont appariés, présents depuis au moins un an dans l'entreprise à la date du diagnostic. Il a été sélectionné 4 témoins par cas.

- L'historique de carrière :

Le fichier du personnel permet, pour chaque cas et chaque témoin, de décrire l'ensemble des postes occupés dans l'entreprise depuis l'embauche jusqu'à la date du diagnostic.

L'EXPOSITION PROFESSIONNELLE

Elle comprend deux volets, l'exposition aux champs électromagnétiques mesurée par dosimétrie et celle aux autres facteurs potentiellement cancérigènes.

L'évaluation individuelle des expositions est assurée par une matrice emploi/exposition.

- La dosimétrie :

La dosimétrie est assurée par des dosimètres POSITRON mesurant le champ électrique et le champ magnétique dans la fréquence considérée (50 Hz). Les mesures sont stockées dans 16 cases d'amplitude dont la première enregistre les valeurs $< 0,0031 \mu\text{T}$ pour les champs magnétiques et pour le champ électrique, entre 2,4 V/m et 40 kV/m.

Le dosimètre est porté par l'agent pendant une semaine, accroché à sa ceinture, pendant toute la journée de travail, mais aussi en dehors de l'activité professionnelle, lors des loisirs ou à son domicile. Pendant le sommeil, il est posé en lieu "neutre", à distance d'appareils et d'installations électriques, mais toujours à la même place pendant la semaine de dosimétrie.

Il est demandé aux agents, de remplir en parallèle une fiche d'activité, où est mentionnée l'heure du lever, les heures de travail et les tâches effectuées pendant cette période (lieu de travail, voltage, travail sous tension ou hors tension...). La fiche d'activité prend en compte également les activités de loisir et l'heure du coucher.

Pour chaque agent, le dosimètre enregistre toutes les minutes, une mesure de champ électrique et une mesure de champ magnétique. Les données sont ensuite traitées par logiciel, qui permet d'établir des histogrammes. Il est également établi un bilan hebdomadaire d'exposition, où figurent en particulier la dose totale, la valeur moyenne et l'historique de l'exposition. Il est possible de séparer l'exposition purement professionnelle de l'exposition totale.

La campagne de dosimétrie a concerné environ 1 000 travailleurs, qui se répartissent dans les différentes branches d'activités de l'entreprise. Les travailleurs ont été sélectionnés pour représenter les principaux métiers pouvant entraîner une exposition aux champs. Des sujets non exposés ont également été inclus dans l'échantillon.

Actuellement nous ne disposons encore que de données partielles. Il ressort cependant une différence nette entre les sujets professionnellement exposés et ceux n'ayant qu'une exposition de base. A titre d'exemple, les ouvriers d'entretien des postes ont une exposition moyennée hebdomadaire de 2,6 μ T, les monteurs souterrains 0,7 μ T, le niveau moyen des "non-exposés" étant de 0,14 μ T. Il s'agit de données qui ne portent que sur 600 dosimétries et qui sont susceptibles de modifications, lorsque l'ensemble des données viendra à être disponible. Il faut également remarquer que certaines activités, dans le groupe des exposés, ne diffèrent pas quant à leur dosimétrie, du groupe des non exposés, il s'agit des agents de petites interventions.

- La matrice emploi-exposition pour les facteurs de confusion

Outre l'exposition aux champs électriques et magnétiques, la matrice emploi-exposition permet d'évaluer, pour les emplois existants ou ayant existé à EDF, l'exposition à d'autres produits potentiellement cancérigènes des liste 1, 2A et 2B du Centre International de Recherche sur le Cancer, et bien sûr, utilisés dans l'entreprise.

Il s'agit donc d'une évaluation des expositions moyennes attachées aux métiers exercés à EDF.

Les colonnes correspondent aux expositions professionnelles et les lignes correspondent aux emplois. A l'intersection des lignes et des colonnes, sont notés le niveaux moyens d'exposition définis selon l'intensité, la fréquence, la durée, et la probabilité de l'exposition.

Il en résulte une définition individuelle pour chaque sujet inclus dans l'étude de son niveau d'exposition, dans les différents emplois exposés.

L'établissement d'une matrice emploi-exposition est une approche pragmatique pour apprécier quantitativement des expositions dans les différents postes de travail. Elle n'est cependant pas exempte de limites. Il a été nécessaire de regrouper les fonctions occupées car la définition initiale à EDF était de 1 321 fonctions auxquelles s'ajoutaient 650 codes de spécialités.

Le regroupement a permis de définir une série de "métiers", mais ces métiers étant eux-mêmes évolutifs, avec souvent une modification du mode opératoire ou limitation de l'exposition ou l'utilisation de procédés de protection efficace, il a été nécessaire de définir des "métiers périodes". L'exemple du plomb est à ce type démonstratif : l'exposition au plomb a notablement décru depuis 1975 où les conduites neuves sont en polyéthylène, les niveaux d'exposition ont été définis en 4 échelons :

- exposition égale à la population générale
- exposition supérieure à la population mais inférieure à la VME
- exposition élevée variant entre le niveau de la VME et 3 VME
- exposition très élevée supérieur à 3 VME.

LE CALENDRIER DE L'ETUDE

- Le recueil de l'ensemble des données a été complété fin mars 1991
- Leur analyse pendant plusieurs mois et les premiers résultats seront disponibles vers la fin de l'année 1992.

HEALTH EFFECTS OF ELECTRIC AND MAGNETIC FIELDS:
PROGRESS AND NEW DIRECTIONS

Maria A. Stuchly

Department of Electrical and Computer Engineering
University of Victoria
Victoria, British Columbia, V8W 3P6

ABSTRACT

For decades there has been a scientific interest in interactions of electric, magnetic and electromagnetic fields with biological systems. Most of research and interest in the last few years have been in the area of extremely low frequency fields. Research of biological effects of electromagnetic fields is complex, comprising many areas, and it usually requires an interdisciplinary approach. Two distinctive, if sometimes overlapping, streams of studies have been conducted; one concerned with effects that may detrimentally affect human health, and the other exploring properties of electromagnetic fields for medical purposes, in either diagnostic or therapeutic applications. A brief overview is given here of the main directions in this field, progress and unresolved problems, and current directions of the research.

INTRODUCTION

Areas of research can be broadly divided into four categories, as illustrated in Figure 1. Measurements and dosimetry, and interaction mechanisms, provide an integral support in both the assessment of health effects and medical applications. The appreciation of the role of measurements and dosimetry in biological experimentation during the last two decades has brought a remarkable progress in quantification of biological effects and in development of exposure standards at radiofrequencies (RF) [1,2]. Dosimetry and interaction mechanisms provide important links between studies performed on various levels of organization of biological systems and the ultimate goal of determination of risks to the human health or therapeutic medical treatment, as illustrated in Figure 2. The importance of such an integrated approach has become particularly apparent in the research of biological effects of fields at extremely low frequencies, ELF, (1-300 Hz).

In contrast to early studies in bioelectromagnetics, which were mostly of exploratory nature, frequently only qualitative in assessment and often subject to artifacts, current studies are in many cases conducted by interdisciplinary teams. These studies include a careful characterization of exposure conditions, dosimetric evaluation where possible, and a meticulous control of artifacts. Many of the studies are aimed at testing and extending specific hypotheses [3]. Starting in the eighties the main research effort has been at ELF. Research activities and knowledge in bioelectromagnetics are too vast and diverse for a comprehensive overview, therefore, the remarks that follow are only a selected glimpse at some of the areas.

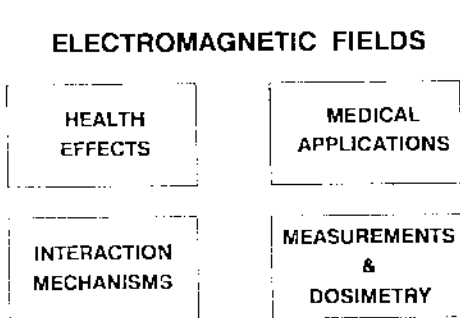

Figure 1

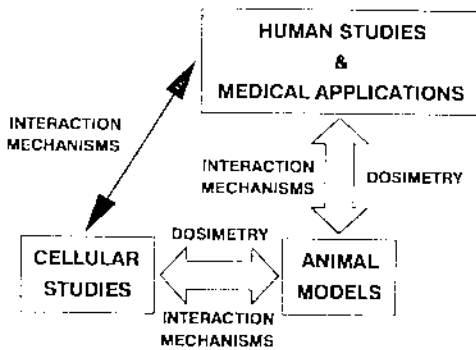

Figure 2

EXPOSURE ASSESSMENT

Measurements of electromagnetic exposure fields are of fundamental importance in many aspects of bioelectromagnetics. In experiments with cell preparations, animals and human volunteers, it is very important that exposure fields are comprehensively and accurately determined. Similarly, in medical applications, where it is important that either the exposure field or the electric field induced in the treated tissue have well defined specific characteristics, accurate measurements of fields are essential. Epidemiological studies have only a limited value, unless they include exposure assessment through actual measurements or other well-based quantitative methods. Finally, only through reliable measurements or estimation of exposure fields can compliance with exposure standards be ensured and protection against over-exposures implemented.

Exposure assessment at ELF and in particular at power line frequencies (50 or 60 Hz) is an area of a currently active pursuit. This is particularly important in support of epidemiological studies. A number of sophisticated personal dosimeters have been developed for this purpose [4]. One of the problems in this area is that the existing biological data do not clearly indicate what dosimetric parameters are of importance in eliciting interactions. Some studies suggest that the waveform, or perhaps transients or changes are important, which would indicate that measurements extending beyond the amplitudes of the electric and magnetic fields might be required.

Measurements of transient fields and pulsed electric and magnetic fields have recently become of growing interest, as there is a need to assess exposures associated with the electromagnetic pulse (EMP), as well as many other exposure situations such as large switching current at switchyards and transformer stations, arc-welding, induction heating, and RF heating. Several novel active and electro-optical sensors and measurement techniques have been recently developed [5,6].

DOSIMETRY

For ELF electric and magnetic fields dosimetric measures have

not yet been established. Although induced current densities from exposure to these fields have been calculated and can be measured [7,8], at present there is no compelling evidence that the current density in tissue is the critical dosimetric measure. Perhaps, calculations of current densities and induced potentials on the microscopic (subcellular) level will prove useful when used in conjunction with biophysical models of interactions.

HEALTH EFFECTS

Most of the studies conducted with ELF fields, are at the power line frequencies (50 and 60 Hz) [9]. A number of studies are motivated by beneficial effects of exposure rather than a potential hazard. These studies often utilize complex waveforms with energy contained below 1000 Hz. Magnetic fields are more often used rather than electric fields. The on-going investigations can be divided into three groups: (1) human studies, (2) animal studies, and (3) in vitro studies.

On-going human studies are mostly epidemiological and concerned with cancer [10]. Environmental exposures of children to electric and magnetic fields at 50 or 60 Hz are being scrutinized for a possible association with childhood cancers, particularly leukaemia and brain cancer. Epidemiological assessment is also underway for various occupational groups that are more exposed to electromagnetic fields than workers in other occupational groups. What distinguishes these studies from a number of already published studies is that actual measurements of exposure are performed, if only on the sample basis. In these studies, personal dosimeters are used for a certain period of time (e.g. 48 h) to determine an average exposure of the studied cohorts to electric and magnetic fields. Usually, current studies also have more statistical power than the previous studies, and some are prospective rather than retrospective. A very interesting human study with volunteers looks at effects on cardiovascular and nervous system responses [11]. This study is characterized by careful dosimetry, as well as elimination of artifacts.

To elucidate the question of a possible association between exposure to ELF fields and cancer, a number of animal studies have been undertaken. Long-term chronic studies which encompass an animal lifespan are presently underway and include lymphoma development in mice, brain cancer in rats, liver cancer in mice and skin cancer in mice. In some of these studies, a specific cancer is initiated (with a chemical agent or ionizing radiation) and the investigations are aimed at determining whether the field acts as a promoter. Also short-term studies looking at specific interaction mechanisms (e.g. melatonin suppression, or copromotion) have been undertaken.

The number of cellular in-vitro studies in progress is relatively large, many of them focused on a biological interaction mechanism. There appears to be a better convergence among the studies undertaken by researchers concerned mostly with potential hazards from environmental, occupational or medical exposures and those who are primarily interested in beneficial uses of ELF fields.

Conclusions

Interactions of electromagnetic fields with biological systems have been a subject of scientific inquiry for quite a long time. There are many common features of studies of potentially hazardous health effects and of studies of medical applications. At present there appears to be better appreciation of this fact and considerable cross-fertilization. Another positive characteristic of many investigations today is that they are aimed not only at the identification of an effect, but that they explore testable hypotheses in search of interaction mechanisms.

"HYPERSENSITIVITY TO ELECTRICITY" - A WORKPLACE PHENOMENON RELATED TO LOW-FREQUENCY ELECTRIC AND MAGNETIC FIELDS

B. Knave, U. Bergqvist and R. Wibom

National Institute of Occupational Health
S-171 84 Solna (Stockholm), Sweden

ABSTRACT

The present study describes the symptoms in "hypersensitivity to electricity" on basis of the medical histories of 32 afflicted people. Thirty-one of the 32 subjects (97%) reported vague skin complaints, such as blotchiness, pinkness, reddening, itching etc. Twenty subjects (63%) reported symptoms from the nervous system, such as dizziness, fatigue, headache, sweating, depression, heart palpitations, memory lapses etc. There were no symptoms indicative of organic lesions of the nervous system. The symptoms, however, were often pronounced and resulted in sickness registration in 25% of the cases. Twenty-nine of the 32 subjects (91%) cited the VDU as the triggering factor, but other triggering factors were also mentioned: fluorescent lighting, sunlight, electrical devices and wiring, ventilation units etc. Discontinuing VDU work was the most frequent adopted measure and the method achieving the greatest symptom alleviation.

INTRODUCTION

In the 1980's a number of studies have attempted to determine whether work at video display units (VDU's) was capable of producing certain slight and otherwise commonplace skin symptoms and disorders (see the tabulation in WHO Offset Publication No. 99, 1987; Knave et al., 1985; Lidén and Wahlberg, 1985; Svensson and Svensson, 1987; Berg and Lidén, 1990.) These studies consistently found that certain subjective skin complaints did increase in VDU work, but clinical diagnoses failed to find any equivalent increase in objective findings.

Over the past 4-5 years, attention has also turned to a small group of people (primarily VDU users) reporting more pronounced problems, usually in combination with other symptoms from e.g. the nervous system, sensory organs, upper respiratory tract, gastrointestinal tract etc. The complaints were not solely related to VDU's. The proximity of electrical wiring indoors and outdoors, electrical machines and devices, fluorescent lighting etc, have been reported to be triggering factors. Many people in this group are heavily affected and have been officially registered as ill for long periods of time. The patients have coined the term "hypersensitivity to electricity," since they feel that the proximity of electrical equipment, devices and wiring is a least common denominator. They recently founded the "Association for People Injured by VDU Work and Electricity," an organization in Sweden which now has about 1300 members.

The objectives of the present study were to report on and tabulate subjective symptoms in "hypersensitivity to electricity." The medical histories of 32 people reporting this hypersensitivity served as the basis of the tabulation.

METHOD AND MATERIAL

Each subject's medical history was taken by one of us (BK) and the information obtained was systematically tabulated and analysed. Thirty-two (32) people participated in the study. They were recruited in three different ways:

- Ten were selected at random from members of the "Association for People Injured by VDU Work and Electricity" resident in the Stockholm area (group A).
- Employees of the National Telecommunications Administration, referred to us by the Administration's central Occupational Environment Unit. The first 10 employees (living in different parts of Sweden) in this category were selected (group B).
- Twelve people were referred to us in some other way, primarily from local occupational health & safety services (group C).

Eleven of the 32 subjects (34%) were men, and 21 (66%) were women. The mean age of the men was 37 (range 20-61) years, and the mean age of the women was 41 (range 21-60) years. At the time they were afflicted, 20 of the 32 subjects (62%) worked as secretaries, telephonists, VDU operators with routine duties etc., whereas 12 (38%) worked as economists, engineers, managers etc.

SUMMARY OF RESULTS AND DISCUSSION

Symptoms and symptom prevalence. Thirty-one of the 32 subjects (97%) reported diffuse skin complaints, such as a rosy and reddened skin, hot, warm and burning sensations, pain, itching etc. Twenty persons (63%) reported functional symptoms from the nervous system, such as dizziness, tingling, fatigue, weakness, headache, difficulty in breathing, sweating, depression, heart palpitations, memory lapses etc. There were no symptoms indicative of any organic lesions of the nervous system. Seventeen of the 32 subjects (53%) also reported symptoms from eyes and vision, which did not, however, distinguish this group from other groups of VDU-users.

Initial and predominant symptoms. For 19 of the 32 subjects (59%), skin complaints were the first symptoms of "hypersensitivity to electricity". For 10 subjects (31%) and 7 subjects (22%), symptoms from the nervous system and the eyes respectively were the first symptoms detected. There was a similar distribution of the predominant groups of initial symptoms: skin symptoms were most common (63%), followed by symptoms from the nervous system (41%). Other groups of symptoms displayed a much lower prevalence.

Course of illness. The disorder proved to be of strikingly recent date; 25% fell ill in 1988, 60% in 1986 or later and 85% in 1983 or later. More than 60% of the subjects had symptoms which remained unchanged or became progressive after onset. Illness symptoms were often pronounced and resulted in official illness registration in 25% of the cases.

Triggering factors. Twenty-nine of the 32 subjects (91%) cited the VDU as the triggering factor in current symptoms. Other triggering factors ultimately developed (fluorescent lighting, electrical devices and wiring, ventilation units, cars, trains, sunlight etc.). The high proportion of VDU users in the material may have been due to various selective mechanisms. As a result of the current public debate on VDU's, symptomatic VDU workers may have been selected to the study more readily than symptomatic people with no VDU work duties. The temporal link between symptoms and VDU work (e.g. in the development of skin symptoms after an employee switched to a different VDU) may be more informative in this context.

Effects of certain countermeasures. The effect of adopted countermeasures appeared to depend on the type of symptoms displayed. When a person only had skin symptoms, she/he had a good chance of improving. But when symptoms were from the nervous system, the adopted counter-measures failed to produce any improvements. The present study was unable to ascertain the reason for this discrepancy. "Hypersensitivity to electricity" may consist of different sub-components, some of which possibly more resistant to therapy than others.

Discontinuing VDU work was the most common and even the most effective symptom-alleviating measure. However, switching to a low-emission VDU usually did not result in any improvement. On the contrary, several cases of deterioration were noted.

Comparisons between recruitment groups

The different recruiting methods probably enabled different selection mechanisms to affect the composition of the sub-groups. In group B (with the smallest percentage of symptoms from the nervous system, the smallest percentage of symptoms in general and with a more favourable recovery), subjects were all working full-time. This was in contrast to group A in which most of the subjects were registered as ill. People with moderate symptoms were often able to continue working, despite their symptoms.

It may be that the Telecom Administration employees in group B represented an "early" stage of "hypersensitivity to electricity," whereas people "injured by electricity and VDU work" in group A may have represented a later stage in development of that disorder. Or the people in groups A and B may have actually represented two different symptomatologies.

Skin symptoms and symptoms from the nervous systems. Despite the limited

scope of our study, some differences in the material were discernible in respect to skin symptoms and nervous system symptoms. People with these two symptom categories differed in e.g. age and sex distribution, possible triggering factors, the efficacy of remedial measures and prognosis (see Table 1.)

Table 1. Differences between subject groups with skin symptoms and nervous system symptoms in the studied group"

Condition	Skin symptoms	Nervous system symptoms
Age variation	None	Increased with age
Symptoms from a VDU	Rapid symptom onset more common	Onset usually insidious
Symptom when switching to a different VDU	Occurred in some cases	Did not occur
Symptoms from electrical equipment	Uncommon	More common
Treatability	Most improved	Few improved
Prognosis	Relatively good	Relatively poor

An Approach To Tackle Visual Display Unit User Health Problems

H.M. McCallum and B. Heaton,

Department of Bio-medical Physics, Aberdeen Royal Infirmary, Foresterhill,
Aberdeen AB9 2ZD, SCOTLAND.

Abstract

Reported health hazards from video display units (VDUs) vary from headaches to miscarriage and there is some concern that health problems experienced by VDU users could be associated with extra-low-frequency (ELF) electromagnetic field emissions. While investigating an individual case of 'VDU Syndrome' a procedure was developed which could be used to investigate and evaluate other complaints of a similar type. A relationship between the number of hours monitor work and severity of symptoms was observed along with a cyclic nature to the operator's sensitivity to VDU work.

Introduction

There is much public concern over the possible health hazards of ELF magnetic fields, especially amongst those who may be occupationally exposed. Working with video display units has been linked with health problems from eyestrain to miscarriage. Two studies published in 1988 found a significant risk of spontaneous abortion in women who worked more than 15 hours a week at a VDU (McDonald et al, 1988) and more than 20 hours VDU work per week (Goldhaber et al, 1988). However these studies did not measure the electromagnetic fields which were suggested to be harmful. A recent study by Schnorr et al (1991) measured both extra-low-frequency (45-60 Hz) and very-low-frequency (15kHz) electromagnetic fields around a sample of VDUs. This study concluded that the use of VDUs and exposure to accompanying electromagnetic fields were not associated with an increased risk of spontaneous abortion. However, VDU operator anxiety continues along with reports of eyestrain and headaches, as shown in a well controlled study (Rossignol et al, 1987) which found an increased prevalence of adverse conditions related to vision, musculoskeletal discomfort and headaches amongst clerical workers who used VDUs.

The data presented in this paper were gathered during a six month survey on the health of an individual VDU operator who suffered from severe headaches, nausea and eyestrain.

Methods

The VDU operator who was suffering from health problems was given a health questionnaire to quantify the range, severity and frequency of her health complaints. The questionnaire listed a short range of symptoms e.g. sore eyes, headache, nausea, which she was asked to grade daily on a scale of 0 to 4 where 0 corresponded to an absence of symptom and 4 extremely severe discomfort. The number of hours worked at a VDU were also noted.

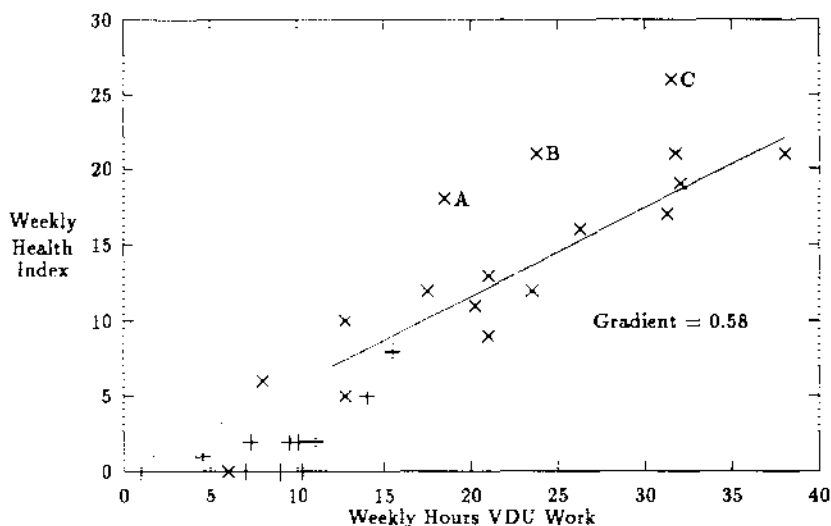

Figure 1: Weekly Health Index against Weekly Hours VDU Work:
 × - initial 3 month survey period, + - final three month survey period

The health of the VDU operator was monitored initially for three months whilst in a VDU intensive post and then for a further three months whilst in a post requiring significantly fewer hours VDU work, although the work was carried out on the same monitor.

Results

From the health survey data, the total hours worked at a VDU and the total of symptom gradings, defined as the weekly health index, were calculated for each week. Figure 1 shows a plot of weekly health index against weekly hours VDU work. A clear dose-response relationship was found, which is probably a personal characteristic. The survey showed that the effects of VDU work seemed to accumulate during a week's work; symptoms worsening towards the end of a week with complete recovery during weekends. If the total weekly VDU hours worked was more than 13, then the weekly health index was directly proportional to the number of VDU hours worked in that week. When the total was less than 13, the relationship was less clear, but the data suggests a threshold at approximately 7 hours, below which little or no adverse health effects were experienced.

As can be seen from Figure 1, points A, B and C lie significantly above the dose-response curve, indicating a particularly sensitive week where the stated number of hours VDU work caused much greater discomfort than might be expected. To investigate this further, a sensitivity index was defined as:

$$\text{Sensitivity} = \frac{\text{Weekly Health Index}}{\text{Weekly Hours VDU Work}}$$

Figure 2: Sensitivity against Time

Figure 2 shows how Sensitivity varies with time. The graph shows a distinct cyclic quality which has an average period of 26 days.

Discussion

Whilst investigating an individual VDU operator suffering from severe headaches, nausea and eyestrain, a clear personal dose-response relationship was found which was a straight line fit when there were more than 13 VDU hours worked in one week. Excluding the three high sensitivity points, the data have a surprisingly small spread, indicating that the health problems seemed to be associated with VDU work and not some other work task. During the initial 3 month survey period, the following ergonomic changes were made in an attempt to reduce discomfort:

- half of the overhead fluorescent lighting was removed to reduce brightness and dazzle,
- screens were positioned behind the operator to eliminate glare, and
- fluorescent lighting was replaced with tungsten lamps to alter the quality of the light.

The workstation was already of a high standard, with a grounded anti-static mesh fitted over the monitor screen, and no significant improvements could be introduced. Although the operator felt more comfortable after these changes, this was not reflected in her health gradings which continued to be high enough to reduce her productivity and at times require sick-leave. When the operator's tasks were altered to require fewer hours VDU work, a significant improvement in health was observed, and the data obtained during this period suggests a shoulder to the dose-response curve with a threshold at approximately 7 hours. The variation of sensitivity with time was investigated during the initial survey period only,

and revealed a cyclic nature with a mean period of 26 days. This relationship may suggest a possible hormonal link and although stress is a possible explanation, this seems unlikely since the high sensitivity points are distributed throughout the range of weekly VDU hours and high stress might be indicated if these points were all due to a high number of weekly hours VDU work.

Any case of VDU user health problems could be tackled in a similar way. By filling in a daily health questionnaire, both the sufferer and employer are able to gauge the severity of the symptoms, and grading symptoms numerically discourages an emotional response. If ergonomic improvements can be made, or alterations in working practice, then a lessening of severity of symptoms would be reflected in the health gradings over a period of time.

This case study of VDU health problems has yielded interesting results, which were consistent throughout an extended survey period. However this is only one case and the symptoms of some other cases have been successfully relieved by altering the workstation design or using the ergonomic changes described earlier. Further research is required to determine whether a high sensitivity group of VDU workers exists, and if so, what factors influence their health symptoms. One such study is being carried out in Aberdeen.

ETUDE DE L'EXPRESSION DES ONCOGENES DANS DES FIBROBLASTES HUMAINS
APRES IRRADIATION AVEC UN LASER A IMPULSIONS TRES BREVES

STUDY OF THE ONCOGENIC EXPRESSION IN HUMAN FIBROBLAST CELLS
AFTER EXPOSURE TO VERY SHORT PULSED LASER RADIATIONS.

The aim of this study is to evaluate the capacity of a laser, delivering very short pulses in the near infrared spectrum with a high pulse ratio frequency, to induce genetic modification on biological tissues. The absence of dicentric among chromosomal aberrations on human lymphocytes suggests that a repetitive very short pulses irradiation has a relatively low capacity to induce genetic abnormalities. The studies of the radiation effects on the cellular growth and the oncogenic expression show that the modifications, induced at the cellular level, do not seem the origin of a cellular transformation and a possible mechanism of carcinogenesis.

INTRODUCTION

Les études antérieures, conduites dans le but de protéger le personnel exposé, ont montré que l'irradiation par un laser, délivrant des impulsions très brèves ($<10^{-8}$ s), peut induire des effets cytogénétiques sur des lymphocytes du sang circulant. Ces effets sont essentiellement caractérisés par une augmentation des fragments chromosomiques [1]. L'absence de dicentriques suggère que ce mode d'irradiation par impulsions brèves présente, par rapport aux autres modes d'irradiation [2, 3, 4, 5], une capacité à induire des anomalies génétiques relativement faible. Pour confirmer cette hypothèse, nous sommes convenus d'étudier d'une part, les effets biologiques du faisceau sur la croissance cellulaire et d'autre part, l'expression oncogène après exposition au même faisceau. Ceci permet d'apprécier, à un niveau moléculaire, si les altérations susceptibles d'être induites par un tel rayonnement peuvent être à l'origine d'une transformation et d'un mécanisme de cancérogénèse.

MOYENS ET METHODES

Le laser utilisé dans l'étude émet à 1064 nm et la durée de l'impulsion est de 50 ns. La variation d'énergie est obtenue en faisant varier la durée du train d'impulsions. Deux niveaux extrêmes d'énergie sont étudiés, 25 mJ et 250 mJ. L'irradiation s'effectue sur des cellules trypsinisées, recueillies dans un tube conique de 10 ml après centrifugation et aspiration du milieu de culture. Parallèlement des fibroblastes humains non irradiés ont été manipulés dans les mêmes conditions.

Les cellules étudiées sont des fibroblastes de poumon embryonnaire humain (IGI G7). Les cellules ne clonent pas en agar mou et ne sont pas tumorigènes chez la souris athymique. Les cultures cellulaires s'effectuent à 37°C en atmosphère humide contenant 7 % de CO₂ dans du milieu d'Eagle modifié additionné de pénicilline (25 U/ml) de streptomycine (25 mg/ml) et supplémenté avec 10 % de serum de veau fœtal.

Vingt-quatre et soixante-douze heures après l'irradiation les cellules ont été lavées au PBS et les ARN cellulaires ont été préparés selon la méthode de Chirgwin et Coll. Les cellules ont été lysées par addition de thiocyanate de guanidium 5.5 M et les ARN ont été purifiés par centrifugation. Les culots ont été dissous puis les ARN ont été précipités à l'éthanol en présence de 200 mM d'acétate de sodium. Après centrifugation les précipités ont été lavés à l'éthanol 70%, séchés et redissous dans de l'eau stérile. Les ARN ont été quantifiés par mesure de la densité optique à 260 nm et leur qualité a été vérifiée par une électrophorèse.

RESULTATS

1. Etude de l'effet d'un faisceau laser sur la croissance cellulaire

Des boîtes de culture ont étéensemencées avec $7 \cdot 10^4$ fibroblastes irradiés à 25 mJ ou 250 mJ ou non irradiés.

- Les fibroblastes non irradiés ont, en phase exponentielle de croissance, un temps de doublement de l'ordre de 35 heures. L'inhibition de contact est atteinte au 6ème jour avec une densité moyenne de $4,7 \cdot 10^5$ cellules par boîte correspondant à une densité de saturation d'environ $4,9 \cdot 10^4$ cellules par cm².
- Après irradiation, on note d'une part un allongement du temps de doublement (délai respectivement égal à 55 et 48 heures) et une réduction de la densité de saturation celle-ci atteignant au 6ème jour respectivement $3,5 \cdot 10^4$ et $3,4 \cdot 10^4$ cellules par cm². Les deux courbes de croissance de cellules irradiées à 25 et 250 mJ sont globalement superposables suggérant ainsi qu'il n'existe pas d'effet-dose à l'intérieur de cette gamme de doses (Fig 1).

2. Etude de l'expression oncogène après irradiation laser

a. Analyse qualitative de l'expression des oncogènes:

La première étape de cette étude a été de déterminer quels étaient les oncogènes qui s'exprimaient normalement dans nos conditions expérimentales et ceux qui s'expriment après irradiation laser. Dans ce but 1 µg des oncogènes suivants: v-abl, c-erbA1, c-erbB2, c-fes, v-fms, c-mos, c-myb, c-myc, L-myc, N-myc, c-raf, c-Ha-ras, c-Ki-ras, N-ras, c-ros, c-src, c-src2, c-sis, c-ycs, et p53 ont été déposés sur des filtres de nitrocellulose. Après rinçage des filtres à l'acétate d'ammonium 2 M les acides nucléiques ont été fixés.

Les filtres ont été hybridés avec des sondes cADN préparées à partir

de ARN de cellules irradiées ou non irradiées. Cette technique a permis de montrer que les fibroblastes non irradiés exprimaient dans nos conditions expérimentales à un niveau notable les oncogènes *C-myc*, *c-raf*, *c-erbB1* et *c-Ha-ras*. Vingt-quatre et soixante-douze heures après l'irradiation les mêmes oncogènes sont exprimés par les cellules irradiées. L'irradiation n'induit donc pas l'expression d'autres oncogènes.

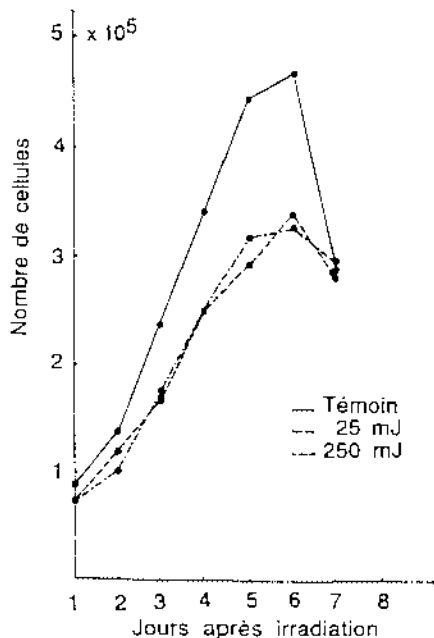

Figure 1: Effets du faisceau laser (1064 nm) sur la croissance des fibroblastes humains embryonnaires. Les doses de 25 et 250 mJ correspondent à des expositions respectives de 16 et 128 impulsions de 50 ns délivrées avec une fréquence d'émission de 1kHz.

b. Analyse quantitative de l'expression des oncogènes:

Afin de comparer le niveau d'expression des oncogènes détectables en dotblot entre les cellules irradiées et non irradiées, les ARN ont été analysés selon la technique Northern. Le marquage des sondes a été effectué par translation de coupure. Leur activité spécifique était comprise entre 1 et 2.10^8 cpm/ μ g.

L'hybridation des filtres avec une sonde dérivant d'un fragment de l'oncogène *c-myc* humain (correspondant au 3ème exon) a révélé une forte expression de *c-myc* dans les cellules irradiées à 16 et 170 mJ, 24h après

leur irradiation mais identique à celle des cellules humaines non irradiées. Soixante-douze heures après l'irradiation le niveau d'expression de c-myc diminue significativement dans les cellules irradiées et non irradiées, cette diminution traduisant très probablement l'arrivée au stade de confluence cellulaire.

L'hybridation des filtres avec une sonde dérivant de l'oncogène raf cloné dans pSP65 n'a pas révélé de différence significative entre les cellules irradiées et non irradiées.

L'hybridation des filtres avec une sonde dérivant du récepteur humain à l'EGF cloné dans pUC12 n'a objectivé aucune différence de niveau d'expression entre les cellules irradiées et non irradiées.

L'hybridation des filtres avec une sonde dérivant du gène EJ-ras s'est heurtée à des problèmes de cross hybridation entre l'oncogène et l'ARN ribosomique 28S ce qui interdit d'interpréter les résultats. Il semble donc indispensable de refaire des Northern en utilisant non plus de l'ARN cellulaire total mais de l'ARN polyA+, ce qui nécessite l'irradiation d'un nombre élevé de cellules. Ces manipulations sont actuellement en cours.

CONCLUSION

Il apparaît que Les fibroblastes de poumon humain embryonnaire présentent après irradiation un allongement du temps de doublement et une réduction de la densité de saturation. Il n'existe pas d'effet-dose à l'intérieur de la gamme de doses étudiées. Dans les limites de nos conditions expérimentales, l'irradiation des fibroblastes humains par un faisceau laser ne modifie pas la gamme des oncogènes normalement exprimés, leur niveau d'expression et leur régulation en fonction de leur croissance. L'étude de l'oncogène Ha-ras nécessite en raison de problèmes techniques une analyse plus fine des ARN messagers des cellules irradiées.

EVALUATION OF CYTOGENETIC EFFECTS OF VERY SHORT
LASER PULSED RADIATIONS

The aim of this study is to evaluate the capacity of a laser, delivering very short pulses in the near infrared spectrum with a high pulse ratio frequency, to induce genetic modification on biological tissues. Chromatid exchanges and chromosomal aberrations studies are used to test this potential effect on human lymphocytes. The laser irradiation induces a significant increase of acentric fragments but the absence of dicentric suggests that a repetitive very short pulses irradiation has a relatively low capacity to induce genetic abnormalities.

INTRODUCTION

Cette étude s'inscrit dans un cadre plus général qui a pour but d'évaluer l'influence éventuelle d'un rayonnement laser à impulsions très brèves sur les tissus biologiques. Des études antérieures ont mis en évidence différentes lésions du matériel génétique produites par l'exposition au faisceau laser. Les anomalies les plus fréquemment rapportées sont d'origine cytogénétique ou affectent le cycle de division cellulaire [1, 2, 3, 4]. Elles sont les conséquences d'une action photochimique ou thermique provoquée par des lasers continus ou impulsions (10⁻⁶ à 10⁻² s). Aucune étude n'a été menée pour étudier au niveau cellulaire les effets des lasers à impulsions très brèves (< 10⁻⁷ s) qui entraînent des effets multiphotoniques et non linéaires. Cette étude a pour but d'évaluer la capacité d'un laser, délivrant des impulsions très courtes à cadence élevée dans le proche infrarouge, à produire d'éventuelles modifications génétiques. Nous avons testé cet effet potentiel sur des lymphocytes humains en observant les échanges de chromatides et les aberrations chromosomiques éventuellement induites.

MOYENS ET METHODES

Les lymphocytes obtenus par prélèvement sont centrifugés et irradiés sous forme de culot dans un tube plastique stérile. L'irradiation est effectuée avec un laser Nd:YAG à la longueur d'onde de 1064 nm. Les impulsions, d'une durée de 50 ns, sont délivrées à la fréquence de 1 kHz. La variation d'énergie est obtenue en faisant varier la durée du train d'impulsions. Dès l'irradiation terminée, les cellules sont mises en culture pendant 48 h et 72 h avant que soient effectuées les recherches des aberrations chromosomiques et des échanges de chromatides sœurs (ECS). A chaque irradiation une culture témoin était effectuée dans les mêmes conditions.

RESULTATS

Le nombre des anomalies observées sur les chromatides après une irradiation laser est élevé, tant sur les cellules irradiées que chez les témoins. Le taux d'ECS par cellule observé chez les témoins ($7 \pm 0,4$) ne diffère que très peu des taux $6,63 \pm 0,4$ et $7,86 \pm 0,5$ relevés parmi les cellules irradiées avec des énergies respectives de 1220 mJ (270 impulsions) et 1612 mJ (410 impulsions). Par contre, le taux d'anomalie portant sur les seuls chromosomes est significativement différent. Les résultats présentés à la figure 1 ont été obtenus pour des énergies de 323, 744, 1154, 1596 et 1865 mJ. Ces valeurs sont les énergies moyennes des expérimentations répétées et réalisées avec des expositions comportant respectivement 100, 200, 270, 410 et 490 impulsions. La plupart des anomalies observées parmi les cellules irradiées sont des fragments acentriques. Aucun chromosome dicentrique n'a été observé.

Figure 1: Taux d'anomalie chromosomiques (fragments) observé en fonction de l'énergie totale, exprimée en Joule, délivrée par le train d'impulsions laser.

DISCUSSION ET CONCLUSION

L'irradiation par un faisceau laser, fonctionnant de manière impulsionnel, peut induire des effets cytogénétiques sur des lymphocytes du sang circulant. Ces effets sont essentiellement caractérisés par une augmentation des fragments chromosomiques. Il est probable que la présence de dicentriques, parmi les anomalies chromosomiques observées par d'autres auteurs, soit la conséquence du mode d'irradiation utilisé. En effet, après une irradiation continue de plusieurs dizaines de minutes, les dicentriques apparaissent dès la première génération de culture cellulaire mais, après une exposition de 1 ms, il est nécessaire pour les observer d'augmenter l'exposition énergétique et d'observer les cultures cellulaires jusqu'à la 3ème génération [1,4].

L'absence de dicentriques dans nos cultures cellulaires suggère que le mode d'irradiation par impulsions brèves présente, par rapport aux autres modes d'irradiation, une capacité à induire des anomalies génétiques relativement faible [5, 6]. Pour confirmer cette hypothèse, il conviendrait d'étudier l'expression oncogène après exposition au même faisceau. Ceci permettrait d'apprécier, à un niveau moléculaire, si les altérations susceptibles d'être induites par un tel rayonnement peuvent être à l'origine d'une transformation cellulaire et d'un mécanisme de cancérogénèse.

A STUDY ON THE INFLUENCE OF 50-Hz MAGNETIC FIELDS
ON THE CYTOTOXIC ACTIVITY OF HUMAN NATURAL KILLER CELLS

C. Ramoni⁽¹⁾, M.L. Dupuis⁽¹⁾, P. Vecchia⁽²⁾, M. Grandolfo⁽²⁾

Department of Immunology (1) and Department of Physics (2)
Istituto Superiore di Sanità, Rome, Italy.

ABSTRACT

The effect of exposure to 50-Hz sinusoidal magnetic fields on the cytotoxic activity of fresh human natural killer cells has been investigated. Either effector or target cells were exposed to a homogeneous magnetic flux density ranging from 0.1 to 10 mT. The experimental results do not show evidence of an effect for any of the exposure conditions, suggesting that magnetic fields do not inhibit significantly the cytotoxic activity of peripheral blood lymphocytes.

INTRODUCTION

In the last years, a continuously increasing attention has been devoted, inside both the scientific community and the public opinion, to the biological effects of extremely low frequency (ELF) magnetic fields. The results of some epidemiological studies⁽¹⁾ have in fact indicated a possible association between long-term exposure to the magnetic fields generated by large electrical plants, in particular power lines, and the development of some kind of tumors.

In order to hypothesize a causal link between magnetic fields and cancer, a plausible biological mechanism of interaction is to be identified, which should account for the promoting action of the magnetic field.

Taking into account the present hypotheses on the potential carcinogenicity of power frequency magnetic fields, the study of possible effects on the *in vitro* immune response is deemed of uppermost interest.

In the light of the important role of the immunosurveillance system, we investigated the effect of power-frequency magnetic fields on the cytotoxic activity exerted by a small population of peripheral blood mononuclear cells, named natural killer (NK) cells. These cells have recently become the subject of extensive laboratory investigation.

NK cells are operationally defined as cells capable of mediating spontaneous *in vitro* cytotoxicity against a variety of target cell populations without apparent prior sensitization. They are involved in a large number of different immunological functions including cytotoxicity against tumor cells and virally transformed cells, resistance to some microbial, fungal, and parasitic agents, regulation of some lymphokine secretion, regulation of hemopoiesis, and natural resistance to allogeneic grafts.

In this study, the effect of 50-Hz sinusoidal magnetic field is investigated on the allogeneic cytotoxicity reaction conducted *in*

vitro by peripheral blood lymphocytes (PBL) effector cells acting on K562 target cells (specially sensitive to NK lysis).

EXPERIMENTAL

A sinusoidal 50-Hz magnetic field was generated inside coils of 18 cm diameter and 50 cm height, with a winding of 6 turns/cm. That allowed a quite homogeneous field in all the central region of the coil, where the samples were located. The current intensity was controlled by a Variac potentiometer, so that the magnetic flux density could be varied up to about 10 mT. The actual value of the magnetic field density was continuously monitored by the narrow Hall-probe of a gaussmeter, which was inserted in the coil at the sample location.

Although the magnetic flux density could be set within a precision of 2%, variations of the order of 5% generally occurred throughout the exposure period, due to instability in the electric network.

Through a Variac potentiometer, the magnetic flux density was varied between 0.1 and 10 mT, i.e. of the same order of magnitude of exposure limits for workers and population recommended by the recent IRPA/INIRC guidelines⁽²⁾.

PBL from fresh human blood, freed of adherent cells, were divided into two samples at 10^6 /ml concentration and suspended in culture medium. One sample was exposed to the magnetic field, while the other was sham-exposed.

All the exposure system was included in an incubator at 37 °C and 5% CO₂. Exposure lasted the whole incubation time (70 h).

Cytotoxicity was then assayed by mixing effector cells to ⁵¹Cr-labelled cells with effector-to-target (E/T) ratios ranging between 50:1 and 6.25:1. The reaction mixture was incubated for 3 h at 37 °C. All groups were tested in triplicate.

The percent ⁵¹Cr release R_s was calculated as:

$$R_s = 100 (R_t - R_s) / (R_m - R_s)$$

where R_t , R_s , and R_m are the test, spontaneous, and maximum release, respectively.

RESULTS AND DISCUSSION

Results of 3-hour ⁵¹Cr-release cytotoxicity tests are reported, for three different magnetic flux densities, in Figs. 1-3. Data relative to other exposure levels exhibit the same behaviour.

It has been suggested^(3,4) that the cellular plasma membrane may be a major target for ELF magnetic fields. Possible effects on cell-mediated lysis might therefore be related to action on either the effector or target cell membrane.

The experimental data do not show any significant change of the cytotoxic activity by NK cells after exposure of either effector cells (Fig. 1), or target cells (Fig. 2), or both (Fig. 3).

Fig. 1. Comparison of cytotoxic activity of exposed (●) and non-exposed (○) NK effector cells on K562 target cells.

Fig. 2. Comparison of cytotoxic activity of NK effector cells on exposed (□) and non-exposed (○) K562 target cells.

Fig. 3. Comparison of cytotoxic activity of exposed NK effector cells on exposed K562 target cells (●) and non-exposed NK effector cells on non-exposed and non-exposed K562 target cells (□).

Repeated experiments on blood from different donors show the same behaviour, independently on the individual variability.

Our findings therefore suggest that the exposure to 50-Hz sinusoidal magnetic fields do not have relevant effect on the behaviour of NK cells. In contrast, Lyle et al.⁽⁵⁾ reported a significant inhibition of allogeneic cytotoxicity by murine T-lymphocyte line CTLL-1 exposed to 60-Hz electric field, suggesting a possible effect on activated cells.

To test this hypothesis, research is in progress on activated lymphocytes. Preliminary results seem to indicate a significant inhibition of the cytotoxic activity when activated effector cells are exposed to 50-Hz sinusoidal magnetic fields.

ELECTROPHYSIOLOGICAL CHANGES IN RATS AFTER MODULATED MICROWAVE IRRADIATION

Szabo L.D., Thuroczy G., Kubinyi G., Bakos J.
Natl. "Frederic Joliot-Curie" Res. Inst. for Radiobiology and
Radiohygiene, Budapest H-1775 POB.101., Hungary

ABSTRACT

The effects of modulated microwave irradiation on the electrophysiological changes in rats were studied. The response of the central nervous system (CNS) was observed simultaneously to the cardiovascular system by using quantitative polygraphic measuring system.

In acute experiments on rat the electroencephalogram (EEG), rheoencephalogram (REG) as an index of cerebral blood flow (CBF), brain tissue DC impedance and temperature, ECG were recorded in parallel before, during and after exposure of the brain localized amplitude (AM) modulated (16 Hz) and continuous wave (CW) microwave exposure. The average specific absorption rates (SAR) in the brain were 8.4 mW/g, 16.8 mW/g and 42 mW/g (CW) respectively.

At thermal level CW exposure the delta band of EEG increased. In case of low intensities modulated exposure the beta band of EEG spectrum increased. No changes were observed during athermal CW irradiation on the EEG. Moderate modulation depended changes were measured in cerebral metabolism, cerebral blood flow and cardiorespiratoric system during microwave irradiation.

INTRODUCTION

The psychophysiological background of complains of workers occupationally dealing with microwave and radiofrequency (RF) equipments which are related to the effects of weak electromagnetic field on the central nervous system (CNS) have not been clarified nor the question: which physiological modalities are in correlations with the intensity, carrier frequency or modulation of microwave and RF radiation. The compensation factors of regulation which are involved in response to the radiation may have an important role in the mechanisms.

We suppose that effects on the brain tissue and cell membrane which are exposed of microwave and RF radiation mostly depend on the frequency and type of modulation, specially the amplitude modulation (AM) below 100 Hz [1,3,9]. Adey et al. showed a special "window" effect by using Ca^{++} -efflux measuring methods in the brain cortex of cat [1,2]. They have found frequency and intensity bands in which the Ca^{++} -efflux were changed in the presence of weak electromagnetic fields below 100 Hz (ELF) and ELF modulated RF fields.

The increase in the cerebral blood flow after microwave exposure is known to occur and these changes depend on the duration of exposure [4,5]. Otherwise it was found that the slow waves of EEG raised after RF or microwave exposure [9].

Our experiments are based on the following questions:(i) An athermal weak modulated or continuous wave (CW) electromagnetic microwave and RF field cause measurable effects

on the systemic and/or localized regulation mechanisms of the central nervous system ? (ii) Does the signal processing evaluation of measured biopotentials (ie. quantitative polygraphy) give more information on the basis of the electromagnetic fields interaction with living systems ?

METHODS

MICROWAVE EXPOSURE AND DOSIMETRY

The irradiation were performed in a waveguide system setup TE-cell. A standard WR 40 waveguide was extended up to 100X60 mm and connected a horn to the waveguide. The incident, reflected and transmitted power were measured by directional couplers and power meters in the 3.4-4.4 GHz frequency [10]. The spatial pattern of SAR distribution in the brain cortex was measured with a thermocouple (0.18 mm, 40 mV/°C). The animal head was placed toward the generator.

The average SAR in the cortex was 8.4 mW/g, 16.8 mW/g and 42 mW/g using 300 mW, 600 mW and 1500 mW incident power respectively. The microwave frequency was 4 GHz and the modulation frequency was 16 Hz sinus (mod.depth 70 %). The duration of exposure was 30 min.

ELECTROPHYSIOLOGICAL PROCEDURE AND RECORDING

On F1-hybrid male anesthezied rats (180-200 g, Nembutal 60 mg/kg ip.) standard electrophysiological procedure were performed. The NICROTHAL stainless steel metal electrodes were placed symetrically to the saggital suture. The irradiation and registration were performed 2 weeks after the surgery (n=40).

In acute experiments (5 in each group, Nembutal 40 mg/kg ip.) the following electrophysiological modalities were registered simultaneously: EEG (70 Hz/0.3 s), DC brain tissue impedance (2.5 kohm/V), rheoencephalogram-REG (Time const.: 3s), brain tissue and rectal temperature, ECG (150 Hz/0.3 s).

SIGNAL AND DATA PROCESSING

The signal and data processing were based on the microcomputer IBM-AT with the following hardware and software: analogue memory, memory scope, recorders, A/D card (12 bit) and microcomputer aided data acquisition and processing system (A/D conversion, average, SD computation, FFT with 0.4 Hz accuracy, auto- and cross correlation, cursor operations). The obtained outputs of the data processing are the follows:

- Heart Rate (HR) beat/min.
- Pulse Delay (PD): REG ampl. max - ECG R-peak interval time.
- Amplitude of rheoencephalogram (REG ampl.)
- EEG frequency bands derived from the power spectrum by FFT analysis with 0.4 Hz accuracy. The processed interval of EEG signal were 10x2.5 sec and the power spectrum of epochs were averaged parallely. The separated frequency bands: delta (0.4 Hz-4 Hz), theta (4.4-8 Hz), alpha (8.4-14 Hz), beta (14.4-30 Hz).

Respiration frequency: beat/min

Before (baseline), during (3., 20., 30. min) and after (1., 20. min) 25 sec. of registration were processed. The results are expressed and illustrated in the figures in percent of the baseline values.

RESULTS

The signal processing and statistical evaluation of the electrophysiological modalities gave the following results:

- The CW irradiation at 42 mW/g SAR in the brain causes a significant increase in the delta band (0.4-4 Hz) and slight increase in the theta band (4.4-8 Hz) of EEG (Fig 1.). The rheoencephalogram increased simultaneously but there was no significant changes in the heart rate.
- The 4 GHz CW athermal level irradiation with 8.4 mW/g and 16.8 mW/g SAR in the brain did not cause changes in any frequency bands of the EEG, but 16 Hz modulated irradiation causes a significant alteration in the beta band of EEG (Fig.2.).
- The REG amplitude increased during CW non-thermal irradiation but the REG amplitude change during non-thermal modulated irradiation was not significant.
- The DC brain tissue impedance decreased depending on the type of modulation.
- In the slight decreased tendency of the pulse delay (PD) there were no sign.differences between the CW and modulated groups.
- The ECG profile showed slight transient bradycardia during exposure to both of CW and 16 Hz modulated waves as well.
- During the alterations of 8.4 mW/g and 16.8 mW/g no temperature increase was measured in the brain tissue and the rectum ($DT < 0.1^{\circ}C$).

Fig.1. EEG slow waves (delta band:0.4-4 Hz) increase during (3, 20, 30 min) and after (1, 20 min) the 4 GHz, CW irradiation. Values (N=5) presented are in percent of baseline (before irradiation). The 42 mW/g SAR in the cortex of rat represents the averaged value.

Fig.2. EEG beta band (14.4-30 Hz) during (3, 20, 30 min) and after (1, 20 min) the 4 GHz 16 Hz modulated (b) irradiation. Values (N=5) presented are in percent of baseline (before the irradiation). The SAR represents the averaged value in the brain cortex of rat.

DISCUSSION

Slight changes in cerebral metabolism and blood flow were observed during microwave irradiation. These transient alterations did not exceed the range of normal physiological regulation, but had a various involvement of compensating factors with different speed.

In the changes of EEG spectra during modulated irradiation were significant, but did not show dependence on the values of SAR in the brain. These results can not be explained by the EEG only [6,8]. The effect on cerebral circulation was quite definite which is well in agreement with results in the literature [5]. The microwave field interactions has an effect not only on the electrical activity of the brain tissue and the cerebral blood flow but also on the blood vessels. Changes in the measured tissue impedance of the vascular pulsation of the brain tissue (REG) can be explained not only as an effect on the cerebral blood flow and the wall of vessels but also is an effect on the electrical conductivity of the tissue and the rheological quality of the blood [7].

Because of the close correlation in the circulation-metabolism-function system of the brain, the low level of irradiation (ie. 8.4 mW/g, 16.8 mW/g) did not cause considerable changes in the measured polygraphic modalities, namely below the physiological regulation in the brain system the compensation mechanisms can be detectable. However, beyond the athermal level irradiation (42 mW/g) the changes remained in the range of the physiological regulation, but the effects on metabolisms and circulation were more detectable.

IN VITRO STUDY ON THE GENOTOXICITY OF 2450 MHz MICROWAVE IRRADIATION IN HUMAN PERIPHERAL BLOOD LYMPHOCYTES

L. Verschaeve¹, A. Maes¹, A. Arroyo¹, C. De Wagter² and L. Martens³

¹ Dept. Biology, Vlaamse Instelling voor Technologisch Onderzoek (V.I.T.O.), B-2400 Mol, ² Dept. Radiotherapy and Nuclear Medicine, Universitair Ziekenhuis, B-9000 Gent and ³ Lab. of Electromagnetism and Acoustics, Universiteit Gent, B-9000 Gent, Belgium.

ABSTRACT

A cytogenetic analysis was performed on human peripheral blood lymphocytes exposed to 2450 MHz microwaves during 30 and 120 minutes respectively. The exposure system developed allows a temperature control by means of a temperature probe put in the blood sample which gives feedback to a microcomputer. In the present study irradiation was performed at a constant temperature of 37°C for the whole exposure period. We found a marked increase in the frequency of chromosomal aberrations as well as micronuclei. On the other hand microwave irradiation did not influence the cell kinetics nor the sister chromatid exchange frequency.

INTRODUCTION

Microwaves have, like other non ionizing radiations (NIR), a lot of industrial, medical and other applications. They are for example widely used for communication purposes (satellite communication, radar, radio/TV,...), therapy, cooking and a lot domestic or industrial heating procedures. As a consequence everybody is exposed to microwaves. Harmful (and also beneficial) effects on the living organism are sometimes reported but are often questionable^{1,2,3,4}. Although there is much evidence in favor of the non-genotoxicity of microwaves, it

was reported in some papers that microwaves may be mutagenic^{5,6,7}. In order to verify this assumption we performed an in vitro cytogenetic analysis in human peripheral blood lymphocytes exposed to 2450 MHz microwaves. This paper describes some of our preliminar results.

MATERIAL AND METHODS

A freshly obtained blood sample from a 38 year old male donor was divided into three test tubes and resp. irradiated with 2450 MHz microwaves for 30 or 120 minutes, or kept at 37°C in a warm water bath. The exposure system used was developed to provide two modes of operations: temperature control and electric field control^{8,9}. In this study we used the temperature controlled mode in order to work at the constant temperature of 37°C. Therefore a temperature microprobe was put into the blood sample. Connected with a microcomputer it results in automatic adjustment of the microwave output allowing to rapidly obtain and closely maintain the prescribed temperature (37°C) within 0.05°C for the time of irradiation.

After irradiation cells were cultivated during 48 or 72 hrs according to standard methodologies for analysis of chromosome aberrations¹⁰, micronuclei¹¹, cell kinetics and sister chromatid exchanges (SCE)¹⁰.

RESULTS

Results of this preliminar cytogenetic study are summarized in tables 1-3. A marked increase in the frequency of chromosomal aberrations is observed, especially after a 120 minutes irradiation period. These aberrations comprise dicentric chromosomes and acentric fragments that are usually found after ionizing radiation exposure (table 1). The frequency of micronuclei increased equally for both irradiation periods (table 2). Differential staining of BrdU incorporated chromatids allows analysis of the cell kinetics and SCE. Table 3 shows that the cell kinetics nor the SCE frequency were significantly influenced by the microwave irradiation.

CHROMOSOME ABERRATIONS (per 200 metaphases)								
	gaps	breaks	acentric fragments	dicentric +/- ac. fragm.	other aberr.	number of cells		
						1	with 2	3
						aberrations		
CONTROLS	2	2	1	0	0	3	1	0
30 min. irradi.	4	1	3(2)	1 ⁺	0	9	0	0
120 min. irradi.	7(1)	9	13(3)	1 ⁺	3(4)	19	6	2

Table 1: Chromosome aberrations in 2450 MHz microwave irradiated human lymphocytes at a constant temperature of 37°C. (1): including two isogaps, (2): here all acentric fragments are single chromatid fragments (but apparently no chromatid break present), (3): including one acentric ring, (4) includes two translocations and one centromere splicing (no particular staining was used to detect translocations; those mentioned are only the very obvious ones due to a striking chromosome morphology).

MICRONUCLEI (per 1000 binucleated cells)			
	Number of cells		Total number of micronuclei
	with 1 micronucleus	with >1 micronucleus	
CONTROL	3	1(1)	5
30 minutes irradi.	23	0	23
120 minutes irradi.	11	2(2)	17

Table 2: Number of micronuclei in cytochalasin B blocked human lymphocytes irradiated with 2450 MHz microwaves at a constant temperature of 37°C. (1) and (2) : resp. cells with 2 and 3 micronuclei.

	CELL KINETICS (200 metaphases)						SCE FREQUENCY in 50 M2 figures (mean per cell)	
	% of	48 hr cultures			72 hr cultures			
		M1	M2	M3	M1	M2	M3	
CONTROL		91	9	0	14	41	45	5.88
30 min. irradi.		93	7	0	19	47	34	5.56
120 min. irradi.		88	12	0	20	40	40	7.16

Table 3: Frequency of 1st, 2nd or 3rd metaphases and SCE frequency in human lymphocytes irradiated at a constant temperature of 37°C with 2450 MHz microwaves and cultivated during 48 and 72 hours.

DISCUSSION

In this study irradiation was performed at a constant temperature of 37°C which could be obtained by adaptation of the microwave power output. The power intensity was thus variable but low enough as to maintain irradiation at non-thermal conditions. In this respect it is rather surprising to observe chromosomal aberrations. Indeed, 2450 MHz microwaves have a wavelength of 12.2 cm in free space and a photon energy which is much less than 12 eV. This means that even the weakest chemical bond in DNA is not likely to be broken by the microwaves. However, our results are in agreement with others presenting data for other frequencies and power densities^{5,6,7}.

The present study is only a preliminary stage in a series of experiments aimed at better understanding the microwave effects on biological systems, especially on the genetic material of mammalian cells.

²Society for Radiological Protection

6 Church Road, Burnham-on-Crouch, Essex, UK

ABSTRACT

In 1979 the UK Society for Radiological Protection adopted a scheme of Certification of Competence in Applied Radiation Protection. The scheme was linked to the concept of "Qualified Expert" defined in the 1976 Euratom Directive and the translation of the Directive into UK Legislation created the Radiation Protection Adviser (RPA), a statutory appointment for an Health Physicist. In 1983 the Hospital Physicists Association introduced a similar scheme and in 1991 the two schemes adopted a joint Certificate of Competence to Practice and Advise in Radiation Protection, and there are now 300 persons on these registers.

INTRODUCTION

The United Kingdom has never specified statutory qualifications for the professionals who plan, direct or conduct programmes for the evaluation and control of radiation hazards. The lessons learned from the 1957 Windscale Accident indicated a need for suitable categories of radiation protection staff with specified training. The European Directive of June 1976 was translated into UK legislation through the Ionising Radiations Regulations 1985 and three categories of Qualified Expert were recognised, the Radiation Protection Adviser, the Radiation Protection Supervisor and the Qualified Person. Only the first of these can be linked to the international concept of a Health Physicist and the response of the profession to the specification of qualifications for appointment to this category was the inspiration for the Certificate of Competence awarded by the professional societies.

POST WINDSCALE CATEGORIES

In 1960 following the Windscale Accident the Veale Committee (1) made recommendations for suitable training for three categories of staff engaged in radiological protection duties:-

- Category A. Graduates with the capacity to assume higher management duties or to play a leading part in research and development.
- Category B. Graduates or non-graduates with day-to-day management responsibility.
- Category C. Technical and other supporting staff.

This scheme dominated the UK education and training programme (2) and a number of masters courses, post-graduate diploma courses and specialist short courses were evolved to satisfy the needs of Category A and B. However there was no formal recognition of these persons as qualified for any specific appointment. The professional societies demanded a first degree as entry qualification and accepted an MSc as equivalent to one year of experience.

In June 1976 the Euratom Directive introduced the European concept of the Qualified Expert covering a very wide range of duties and standards. At that time it seemed unlikely that a scheme could be produced which would encompass both medical and industrial uses of ionising radiation and in any case no one person could be expected to carry the full range of responsibilities attached to the duties of the Qualified Expert.

The Directive was ratified in the UK when the Ionising Radiations Regulations 1985 were introduced. These gave recognition to three categories of Qualified Expert:-

Radiation Protection Adviser.

A person suitable qualified and experienced to advise "as to the observance of these regulations and as to other health and safety matters in connection with ionising radiation".

Radiation Protection Supervisor.

An employee responsible for supervising the work with ionising radiation "to the extent necessary to enable the work to be carried on in accordance with these Regulations".

Qualified Person.

A person suitable qualified and experienced to supervise the testing of monitoring equipment prior to, and in, service as required by the Regulations.

The RPA is equivalent to the Health Physicists employed by large organisations who would have been identified by the Veale Committee as Category B. They have a strong similarities to the Certified Health Physicist (CHP) of the American Board of Health Physics.

In 1976 the Society for Radiological Protection set up a working party to examine the situation and to make recommendations about setting up a register of people who would be "suitably qualified and experienced" from which employers could appoint RPAs with confidence.

The proposals were adopted and the Certification Scheme was inaugurated in 1976 when a small number of senior members were selected by the executive council for the first awards. In 1983 the Hospital Physicists Association, later to become the Institute of Physical Sciences in Medicine, set up a similar scheme for those radiological protection specialists working in Medicine and Dentistry. From the start both Societies recognised the need for comparable standards and maintained close links; each society was represented on the others assessment panel. In 1991 both schemes adopted a single procedure and awarded a joint "Certificate of Competence to Practice and Advise in Radiation Protection".

CERTIFICATION STANDARDS

The standard required for certification is training, experience and proven ability in one or more fields of radiation protection. An Assessment Panel of senior members with wide experience is appointed by each Society. Successful candidates have to adhere to a Code of Conduct and the validity of both Certificate is 5 years after which the Certificated person must demonstrate continued active involvement in radiation protection. There is no specified need for Continuing Education but evidence of this is taken as an indication of active participation in the field.

The formal requirements are:

1. A degree in Physical Science or exceptionally other qualifications with extensive relevant experience.

2. Three years full time experience in a post directly concerned with operational radiation protection, preferable supervised by a Certificated person or by a person of equivalent status. An approved course may be accepted in lieu of experience up to one year.

3. Professional knowledge of the fundamental principles and operational methods of radiation protection. The candidate must be capable of interpreting and applying radiation protection data and of supervising or carrying out practical measurements and control procedures for work involving significant exposure to ionising radiation.

4. The candidate must be capable of advising management on the implementation of relevant legislation. The candidate must be able to carry overall responsibility for radiation protection of operations in which there is a possibility in the normal course of events that at least one person may receive a dose in excess of 3/10 of the relevant limit.

REGISTRATIONS IN 1991.

The two registers have a total of 300 members. The distribution of field of work of SRP members is the following:

SECTOR	Number
Research including Atomic Energy Authority	20
Fuel fabrication and reprocessing (BNFL)	12
Defence including Royal Dockyards	37
Nuclear power	41
Central Government and NRPB	20
Medical	40
TOTAL.	170

Most of these Certificated Persons work in large organisation where the rôle of RPA is conducted as a corporate body. In the medical field it is estimated that about half of the Certificated persons are appointed as RPAs. Only half of the RPAs appointed in this field are Certificated.

CONCLUSION.

These schemes have been successful but the numbers of people involved is too small to sustain dedicated courses. The UK still has four courses at the MSc level which could lead to this Certification. The Society for Radiological Protection has now introduced the grade of Fellow and the profession seems to be advancing in status towards that of UK engineering professionals but lacks the international equivalence of qualifications. Engineers can attain Chartered Engineer status which is linked to the European profession through the Eur Ing scheme. A cautious move in this direction would be encouraged if an international evaluation of the safety related rôle of the radiation protection profession could be initiated to permit comparison with safety engineers in nuclear technology.

THE NEW ICRP RECOMMENDATIONS: HOW WILL THEY BE TRANSLATED INTO PRACTICE?

O. Ilari, OECD/NEA; A. Gonzalez, IAEA; G. Hanson, WHO;
C. Borrás, PAHO; E. Boutrif FAO

The novel conceptual developments put forward by the new ICRP recommendations need to be converted into terms that can facilitate their transfer into regulatory texts and operational practices at the national level. The main problems that we may face in this conversion, through the revision of the Basic Safety Standards for Radiation Protection, are briefly discussed in this paper.

INTRODUCTION

During the last few years, radiation protection went through a period of significant developments and achievements. The major event in this period was the revision of the basic ICRP recommendations. Although the new recommendations represent an evolution more than a revolution with respect to the 1977 recommendations, they have introduced some important developments and significant elements of novelty. The new ICRP recommendations have been deliberately drafted in general and scientific terms so that sufficient scope for interpretation and application is left to their users, particularly the national authorities. There is, now, a need for a conversion of the ICRP guidance into terms which are sufficiently practical and straightforward to facilitate their transfer into regulatory and operational practices at the national level.

Traditionally, this is the task of the international intergovernmental organisations, in particular through the Basic Safety Standards for Radiation Protection (BSS), jointly issued by the IAEA/NEA/WHO and ILO, and the Euratom Radiation Protection Directives, issued by the CEC. In the past, this international applicative guidance was largely traced on the texts issued by the ICRP. This time, however, the higher degree of generality and flexibility of the ICRP recommendations is suggesting a different strategy in preparing the revision of the BSS. There will be, in fact, the need to make a serious effort of interpretation of the ICRP concepts and intentions, which will require expansions and clarifications from the ICRP text.

TRANSLATION OF THE ICRP RECOMMENDATIONS INTO PRACTICAL GUIDANCE

The first concerted effort to provide unified radiation protection standards to contribute to an harmonised worldwide application of the basic ICRP recommendations was made at the beginning of the eighties by the IAEA, the NEA, the WHO and the ILO. The result was the publication of the BSS issued in 1982 as IAEA Safety Series No. 9.

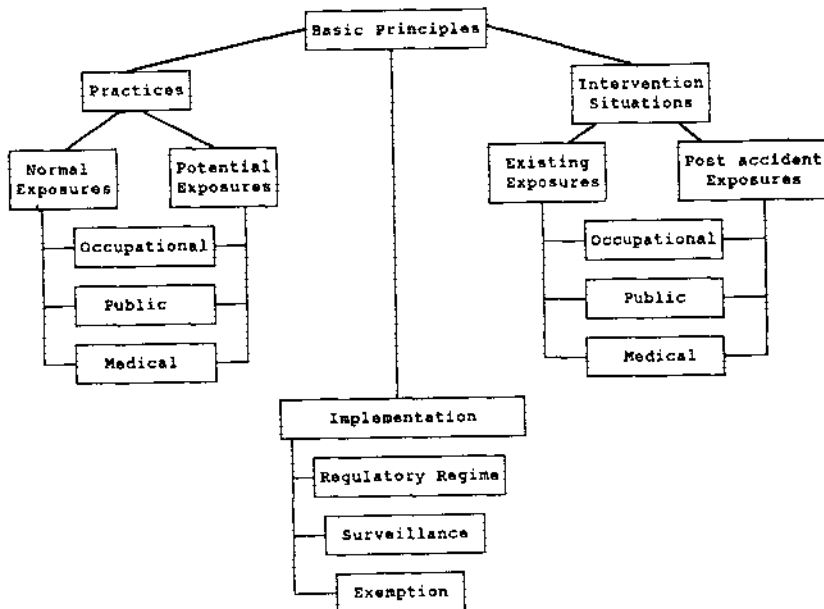

The work for the revision of the BSS was started at the beginning of 1991 with the constitution of a Joint International Secretariat among the four above-mentioned organisations, which were later joined by the Food and Agriculture Organization (FAO) and the Pan American Health Organization (PAHO), and the setting up of a Drafting Group in charge of the preparation of a draft text of the revised BSS to be submitted, in 1992, to international review and approval. It is interesting to note that this review will have a very transparent character in that not only

governmental, regulatory and professional groups, but also worker and employer organisations as well as other interest groups will be involved in the debate and give their contribution of ideas to the preparation of the new BSS.

Although a conclusive idea of the specific features of the new BSS can only be achieved when the international review process is completed, the Joint Secretariat has been able to establish a general strategy and agree on the main lines concerning this work. First of all, it was agreed that the BSS should be given the character of "Standards" that national authorities could use as a regulatory basis for the protection of workers and members of the public. This implies that the BSS should be written in a fully regulatory language; however, the Joint Secretariat quickly recognised that this may be difficult to achieve in practice, in view of the large variety of regulatory systems and associated legal languages used in Member countries. Therefore, it was agreed that, although the document should have a regulatory flavour and be, as far as possible, directly applicable in the preparation of national regulations, it should be kept at the technical level without attempting to be a "legal" text. Another important decision was that the document should be fully consistent with the new ICRP recommendations, unless there are in some points strong reasons which suggest variations in policy or interpretation.

SOME IMPORTANT ISSUES TO BE ADDRESSED IN THE NEW BSS

The guidance given by the previous ICRP recommendations and, subsequently, by the previous BSS was essentially focused on the control of "normal" exposures from what are now defined as "practices" involving artificial "sources". The merit of the new ICRP recommendations is to generalise its guidance to cover the whole network of possible exposure and control situations as it is summarised in the following scheme:

This scheme, in itself highly rational, creates problems of application due to the different degrees of controllability of the exposure which characterise the various situations. Some of the main issues to be addressed in the new BSS are highlighted in the following.

Individual Dose Limitation

Although optimisation of protection is confirmed as the main principle of a correct management of radiation exposures, the limitation of individual doses to workers continues to be the principal issue of concern to those who have the responsibility to implement radiation protection requirements in practice and it may be expected that a heated debate is raised on this issue during the preparation of the new BSS. In fact, several industrial and radiation protection operators have begun to express serious concerns on the feasibility of coping, at reasonable costs, with the new, reduced dose limits recommended by the ICRP. According to these critics, parts of the nuclear industry, and, perhaps, also other activities involving radiation might face major facility redesign and reorganisation of work practices, involving significant labour and cost increases, if this increase in the rigour of the international recommendations is followed by a similar stiffening of national regulatory requirements. Cases where these difficulties may arise include the maintenance of nuclear facilities, the operation of some underground uranium and other mines, some operations involving uranium and plutonium oxides, as well as some industrial applications and medical practices. These cases will have to be carefully examined to make sure that the requirements of the new BSS can be actually implemented.

Another issue which will have to be faced is the concept of flexibility proposed by the ICRP for the application of the dose limits. This concept, allowing a peak dose limit up to 50 mSv in one year against an average of 20 mSv per year over five years, is conceptually correct, but several regulators and operators have serious doubts on the concrete possibility to introduce it into laws and regulations, where only clear-cut rules and limits can fit with the required regulatory and legal language. One potential problem that could emerge with the introduction of a lower dose limit concerns those workers who have received so far doses in excess of 20 mSv per year. These workers and the trade unions might argue that they should now be guaranteed an annual dose limit lower than 20 mSv to compensate for what they could consider an unjustified past detriment. This is not a conceptual issue, nor is it of direct relevance to the text of the BSS, but its implications for the ensuing national regulations could not be overlooked.

All these considerations will have to be accommodated in the new BSS and the situation will be further complicated by the need to assign a place and a specific regulatory meaning to the new concept of source-related dose constraint introduced by the ICRP to limit the range of options considered in the procedure of optimisation of protection.

Exposure Situations not Fully Covered in Previous ICRP Recommendations

Historically, the ICRP recommendations mainly focused on the control of exposures that can be anticipated in advance and assumed to be delivered with virtual certainty and predictable magnitude. The new ICRP recommendations address two types of radiation-related activities not fully

covered by previous recommendations, namely the practices that may give rise to "potential exposures" and the "interventions". Not surprisingly, the available international guidance on radiation protection mainly concentrate on normal exposures. Apart from international standards for nuclear reactor safety, virtually no guidance exists for potential exposure situations and only general guidance is given internationally for intervention situations.

Clarification is, therefore, required of the role of the current principles of justification, optimisation and individual risk limitation in such situations. Any policy development should be tested against practical problems, such as specific requirements for the reliability of safety systems, the control of exposures due to radon in dwellings, and intervention levels for unanticipated situations. A particular and difficult problem to be dealt with in treating the question of potential exposures is that of solving the significant issues of interface with the philosophy and techniques used by the nuclear safety community in the safety analysis and prevention of nuclear accidents, which have been raised by these developments within the ICRP.

There are also problems in the area of interventions. For example, the new emphasis which is given nowadays to radon is not limited to the area of public exposure. The new ICRP recommendations suggest, in fact, to include exposure from natural sources as part of occupational exposure, but they do not provide unequivocal guidance on the choice of situations which should fall into this category. This will require interpretation and choice of options by those in charge of the preparation of the new BSS.

General Solutions: Standardization

A major shortcoming of the current radiation protection and safety policies is the lack of generic standardized objectives similar to those used in other safety disciplines. At a first sight, the rationale of ICRP requirements such as optimisation appears to be incompatible with generic solutions, because the requirements of optimisation seem to lead to case-by-case assessments. However, although there are specific problems for which only a case-by-case approach is feasible, it is worth questioning whether a more standardized approach could be possible for common, routine problems of protection and safety. Success in this endeavour would be very well received by designers and operators.

CONCLUSION

The issues highlighted in this paper are only some of the most important questions to be addressed in the implementation of the new ICRP recommendations. Several other problems of a more detailed nature can be raised by a reading of ICRP Publication 60, and a significant effort of interpretation and choice of options will have to be made in the transformation of the ICRP guidance into international recommendations liable to a concrete application. The new BSS will have to solve these questions in order to give an effective contribution to practical radiation protection in Member countries.

LE CEFRI ET LA CERTIFICATION EN RADIOPROTECTION
DES ENTREPRISES FRANCAISES

J.C Marillier - Cefri - Paris la Défense - France

THE CEFRI AND RADIOLOGICAL PROTECTION CERTIFICATION
OF FRENCH COMPANIES

In 1990, French nuclear operators and the nuclear industry set up a system for certifying the companies involved in industrial work with exposure to ionizing radiation and the concerned training organizations. Inspectors have been recruited and trained. The first certificates were issued during the past few months. The extension of this certifications to cover all work on nuclear sites is being envisaged.

INTRODUCTION

Le développement rapide du programme électro-nucléaire français a amené un grand nombre de travailleurs de l'industrie à travailler dans des zones où peuvent exister des rayonnements ionisants.

Il importe de veiller à ce que la radioprotection de ces travailleurs soit assurée compte tenu des normes les plus récentes et de la libre circulation des travailleurs à l'intérieur des Communautés Européennes prévue dès 1993.

C'est pourquoi les exploitants et les industriels ont jugé nécessaire la mise en place d'une organisation certifiant la formation et le suivi du personnel exposé aux rayonnements ionisants.

CONTEXTE

Si l'on ne tient pas compte du milieu médical, 50 000 travailleurs de l'industrie française sont amenés à travailler sous rayonnements ionisants dont 30 000 exploitants et 20 000 autres travailleurs appartenant à près de 1 000 entreprises extérieures et qui interviennent pour des opérations de maintenance concernant en particulier près de 60 réacteurs électro-nucléaires en exploitation.

Les interventions lors des arrêts pour rechargement de ces réacteurs peuvent demander l'intervention de plusieurs centaines de personnes durant des périodes courtes mais avec des débits de dose ambiante pouvant dans certains cas atteindre, voire dépasser, 100 mGray/heure.

Plus de 80% des doses d'irradiation sont reçues lors de ces interventions par le personnel des entreprises extérieures et en 1990, 1 500 personnes ont reçu une dose annuelle supérieure à 20 mSievert.

Afin de minimiser la radio-exposition, il est fait appel à des équipements de plus en plus sophistiqués mis en oeuvre par des techniciens spécialisés, se déplaçant fréquemment sur les différents sites français ou étrangers et en particulier dans la Communauté Européenne.

Pour s'assurer du bon respect de la réglementation en vigueur dans le domaine de la radioprotection, a été créé en France en 1990, à l'initiative des industriels réunis au sein du Groupement Intersyndical de l'Industrie Nucléaire (GIIN) le Comité français de Certification des Entreprises Pour la Formation et le suivi du personnel travaillant sous Rayonnements Ionisants (CEFRI).

Ont été associés au sein du CEFRI, outre les employeurs de travailleurs de catégorie A ou B et les organismes de formations spécialisés en radioprotection :

- les exploitants, à savoir CEA, COGEMA et EDF,
- la Caisse nationale d'assurance maladie des travailleurs salariés (CNAMTS),
- Le Service central de protection contre les rayonnements ionisants (SCPRI),
- la Société française de radioprotection (SFRP).

Le Ministère du Travail et le Ministère de l'Industrie ont témoigné de leur accord et leur soutien à la création du CEFRI.

ROLE ET FONCTIONNEMENT

Les objectifs fondamentaux de la création du CEFRI sont au nombre de trois :

- contribuer pour le personnel à l'amélioration de la prévention des risques liés aux travaux dans les installations nucléaires,
- permettre aux entreprises françaises intervenant sur les marchés du nucléaire de faire la démonstration objective des actions de prévention qu'elles mènent,
- améliorer pour les entreprises françaises intervenant sur les marchés du nucléaire leur accès aux marchés européens et internationaux.

Les entreprises (employeurs) et organismes de formation ainsi certifiées s'engagent à respecter une spécification dont les bases sont les suivantes :

- pour l'employeur, désignation d'un responsable qui suit les opérations de recrutement, de contrôle médical, de formation et de surveillance dosimétrique du personnel de catégorie A ou B,
- pour l'organisme de formation, mise en place d'une organisation, de méthodes et de moyens de formation, d'un contrôle de connaissances des stagiaires à l'issue du stage, conformément à la spécification pour la formation du personnel de catégorie A ou B établie par le CEFRI.

Le CEFRI délivre un certificat valable 3 ans au vu d'audits réalisés dans les entreprises extérieures (employeurs) et organismes de formation. Ces audits s'assurent que l'organisation et les moyens mis en oeuvre sont en conformité par rapport à la réglementation française et aux spécifications du CEFRI.

Le CEFRI se compose d'un Comité de certification qui constitue l'instance de décision et d'une Commission technique qui qualifie les auditeurs et donne son avis au Comité sur les questions relatives à la prévention à la radioprotection et à la formation.

Le Comité a également qualité pour faire connaître la démarche française au plan européen et international et pour négocier tout accord international de réciprocité ou d'équivalence.

La structure et le fonctionnement du CEFRI ont été étudiés pour être conformes à la normalisation européenne s'appliquant aux organismes de certification des entreprises.

Lorsqu'une entreprise ou organisme demande à être certifié, le CEFRI lui adresse les spécifications à respecter et un questionnaire à remplir. A réception de la réponse à ce questionnaire et des pièces jointes, le CEFRI décide ou non, à la vue de ces documents, du lancement de l'audit. L'audit est effectué par deux personnes dont une au moins spécialisée en radioprotection.

Au vu du rapport d'audit, signé par les auditeurs et le responsable désigné de l'entreprise ou de l'organisme audité, le CEFRI délivre ou non son certificat ou le renouvelle pour une période de trois ans.

SITUATION

En 1990, ont été mis en place le Comité de Certification et la Commission Technique.

Cette dernière a mis au point les spécifications et les questionnaires pour les entreprises et organismes de formation.

En 1991, ont été recrutés et formés après une sélection sévère des candidats, plus de 40 auditeurs, la plupart expérimentés en radioprotection ou en technique d'audits.

Un grand nombre de demandes de certification ont été reçues, les premiers audits effectués et les premières certifications délivrées.

L'objectif actuel du CEFRI est d'avoir, d'ici fin 1992, certifié la plupart des grandes sociétés et organismes de formation intervenant en France dans ce domaine.

Il est envisagé par les exploitants de rendre obligatoire cette certification pour toute entreprise intervenante.

CONCLUSION

Avec le CEFRI, l'industrie nucléaire française, soucieuse de sa réputation, dispose du moyen de garantir la formation et le suivi des travailleurs exposés aux rayonnements ionisants tant sur le territoire national que lors d'interventions à l'étranger en particulier dans les différents pays de la Communauté Européenne.

Il lui semble souhaitable que ce type de certification soit généralisé et harmonisé entre les pays intéressés.

The Role of CEDR in Worker Health Protection

The development of the Comprehensive Epidemiologic Data Resource (CEDR) is one of the major elements in the Secretary of Energy's initiatives to establish a credible state-of-the-art epidemiologic and health surveillance program in the Department of Energy (DOE). The aim of this program is to identify human health effects that may be associated with energy production and technology. The CEDR program being undertaken by the Department of Energy (DOE) will be the focus for organizing, integrating, and disseminating data from the DOE's epidemiologic activities. The CEDR information system will facilitate the acquisition, storage, access, and analysis of data collected from past and ongoing research, as well as from future activities. It is anticipated that substantial use of CEDR will be made by DOE staff, scientists at national labs, persons with university affiliations and public interest groups. The paper will describe the structure of the CEDR information system, the types of data being incorporated, the accessibility of the data and the uses being made of the data.

Prepared by: Barbara G. Brooks, CEDR Program Manager (301-353-4674)

DOSIMETRIE DU PERSONNEL : SES POSSIBILITES ET SES LIMITES

** EDF, SPT, Département Sécurité Radioprotection
Environnement, St Denis, France

PERSONNEL DOSIMETRY : CAPACITIES AND LIMITATIONS

Two dosimetric systems are implemented for EDF nuclear plant personnel : legal, with photographic films, and operational, with electronic dosimeters. They have similar detection thresholds and are designed for radioprotection purposes. Occupational exposure levels are comparable to natural irradiation. So, these data must be used cautiously for epidemiology.

INTRODUCTION

Les textes réglementaires sur la radioprotection en France prennent en compte les principes fondamentaux émis par la CIPR tels qu'ils figurent dans les directives européennes, à savoir l'optimisation et la limitation des expositions individuelles. La dosimétrie du personnel constitue un moyen essentiel d'assurer pour le travailleur le respect de ces deux principes. Par contre ses caractéristiques ne lui permettent pas d'utiliser ses résultats à des fins épidémiologiques sans prendre un certain nombre de précautions.

LES DEUX FORMES DE LA DOSIMETRIE DU PERSONNEL A EDF

Cette dosimétrie du personnel se présente sous deux formes : la dosimétrie réglementaire et la dosimétrie opérationnelle. Elle concerne uniquement l'irradiation par les rayons gamma, considérée à priori homogène du corps entier.

- La dosimétrie réglementaire

Elle est du type photographique à relevé mensuel. Elle contrôle à posteriori les expositions individuelles, vérifie le respect des limites individuelles autorisées et permet la détection du dépassement de ces limites. Elle a seule valeur médico-légale et relève de la compétence du SCPRI, organisme du Ministère de la Santé.

- La dosimétrie opérationnelle

Les résultats de la dosimétrie mensuelle réglementaire ne sont connus qu'à la fin du mois suivant [1] : ils ne permettent pas un suivi en temps réel des conditions d'exposition. La dosimétrie opérationnelle qui emploie des dosimètres électroniques à lecture directe

permet ce suivi en temps réel. Avec son dispositif d'alarme, elle assure une fonction de sécurité, mais son but principal est la dosimétrie analytique : gestion des doses individuelles, des doses collectives par chantier et par poste de travail et mettre en application le principe d'optimisation (Démarche ALARA).

SIGNIFICATION DES DOSES

Les doses reçues par le personnel sont très dispersées parce que les personnes sont affectées à des tâches spécifiques [2]. Mais ces doses sont en majorité faibles : 50% des doses annuelles sont inférieures à 0,5 mSv (50 mrem) [3]. Avec les seuils de détection propres à chacun des systèmes dosimétriques toutes ces doses ne sont pas toutes significatives, loin de là.

- Cas de la dosimétrie réglementaire

- Influence des seuils de détection :

La dosimétrie par film est obtenue par interpolation à partir de films étalons avec prise en compte d'un film témoin qui est censé enregistrer les doses hors zone contrôlée et pendant le transport des dosimètres.

L'incertitude sur la lecture des doses à partir d'un film est variable en fonction de la dose [4]. A 2σ , elle est de l'ordre de 0,12 mSv (12 mrem) à la dose zéro et de 0,9 mSv (90 mrem) à la dose de 5 mSv (500 mrem), soit une incertitude relative de 18%. Avec la composition des écarts-types, cela conduit à un seuil de détection S_D mensuel de 0,17 mSv (17 mrem) et une limite de détection L_D de 0,34 mSv (34 mrem). Cela veut dire que toute dose relevée à partir des films et inférieure à 0,17 mSv n'a pas de signification statistique et que ce relevé doit être supérieur à 0,37 mSv pour avoir 95% de chances de représenter une mesure.

Il s'en suit que les modalités de l'exposition et sa répartition dans le temps, liées au poste de travail, ont une influence sur la signification statistique des doses enregistrées. Si l'on part de l'hypothèse d'une exposition à débit de dose constant :

- 0,5 mSv (50 mrem) cumulé sur 2 mois est significatif (Incertitude : 0,24 mSv).
- 0,5 mSv cumulé sur 12 mois n'est pas significatif (Incertitude : 0,59 mSv).
- 0,5 mSv par an cumulés sur 30 ans, soit 15 mSv (1,5 rem), sont largement significatifs (Incertitude : 3,22 mSv).

Les données annuelles sur les faibles doses n'ont pas de signification statistique : il faut des durées

d'observation de l'ordre de 5 ans pour disposer de résultats utilisables en épidémiologie.

- Influence des modalités de prise en compte des doses.

Le seuil de prise en compte des doses est actuellement de 0,1 mSv (10 mrem). Avec une limite de détection de 0,34 mSv, on peut déclarer nulles les doses inférieures à cette valeur : cela a une influence relativement faible sur les doses collectives mais on perd toute information sur les cumuls individuels des doses sur la vie professionnelle.

- Cas de la dosimétrie opérationnelle

Les dosimètres électroniques ont un mouvement propre de 20 μ Sv (2 mrem) par jour et ils n'enregistrent que des doses supérieures à 10 μ Sv (1 mrem). Le temps moyen de séjour d'un travailleur en zone contrôlée est d'environ 3h par entrée où il y a, au maximum, 2 entrées journalières. Dans l'hypothèse d'une exposition à débit de dose constant et pour une quarantaine d'entrées par mois, la dose cumulée minimale détectée dans le mois est de l'ordre de 0,15 mSv, équivalente à celle des films. La dosimétrie opérationnelle ne permet pas de lever les doutes sur les faibles doses.

- Possibilités des systèmes dosimétriques

Les faibles doses annuelles ne peuvent être que des repères : quel que soit le système utilisé, seul leur cumul sur plusieurs années constitue des données statistiquement fiables. L'emploi de dosimètres individuels nominatifs à mémoire, en abaissant le seuil de détection d'un facteur au moins égal à 4, est un des moyens de rendre les faibles doses annuelles significatives.

FACTEURS DE RISQUE A PRENDRE EN COMPTE DANS L'EVALUATION DE L'IRRADIATION DU PERSONNEL

L'irradiation du personnel des centrales nucléaires pendant le travail, avec une moyenne de 2 mSv par an, est de l'ordre de grandeur des irradiations non professionnelles : l'irradiation médicale et l'irradiation naturelle.

- L'irradiation médicale : en dose efficace, elle est en moyenne de 1 mSv, avec des variations d'un facteur 3 d'un pays à l'autre et d'un facteur 2,5 d'une région à l'autre en France.

- L'irradiation naturelle : avec une dose efficace moyenne annuelle de 2,4 mSv, elle varie en France d'un facteur 3 d'une région à l'autre.

Ces facteurs introduisent un biais dont il faut tenir compte dans les enquêtes épidémiologiques. Si l'irradiation naturelle est relativement facile à estimer, l'irradiation médicale est d'accès plus difficile : elle est individuelle, couverte par le secret médical, avec une dosimétrie approximative du fait des incertitudes de toute enquête rétrospective sur ce sujet.

CONCLUSION

La dosimétrie du personnel à EDF est conçue dans un but de radioprotection : elle permet de gérer les doses par des procédures relevant du principe d'optimisation et de s'assurer que les limites individuelles ne sont pas dépassées. Elle apporte des informations utiles aux enquêtes épidémiologiques mais elle a ses limites et il faut être prudent quant à leur usage.

IDEAS ON A PRACTICAL METHOD TO MAKE MORE UNIFORM THE MEASURE AND THE ACCOUNT OF DOSES

ABSTRACT : The CIPR 60 publication and its consequences on the revision of CEC regulations and basic norms, discussions on dosimetry of outside workers and more generally on the development of exchanges of information between users have led EDF to question its practices for measuring counting doses. Faced with this wide range of french practices and in a desire for harmonisation, an EDF and CEA work team has established a summary of present methods, an evaluation of the consequences of these different strategies and have then suggested a harmonisation of dosimetric measures based on systematic methodology.

1 - INTRODUCTION

Si la mesure et la comptabilisation des doses corps entier dues au rayonnement γ est en général bien comprise par les exploitants, la dosimétrie due aux autres types de rayonnement (neutron, α , β) ou à des voies d'exposition différentes (dose peau, doses aux extrémités, exposition interne) a toujours fait l'objet de nombreuses interrogations. Cependant, même la dosimétrie corps entier suscite encore des questions suite, par exemple, aux écarts constatés entre la dosimétrie réglementaire (film) et la dosimétrie opérationnelle (électronique).

Le développement du parc de réacteurs nucléaires français, l'apparition de nouvelles sources d'exposition (combustible MOX) ou le vieillissement des tranches ont renforcé ces interrogations. Parallèlement, les études comparatives avec les centrales étrangères, le suivi dosimétrique des travailleurs extérieurs et en particulier des travailleurs transfrontaliers ont conduit EDF à réfléchir sur la pertinence des informations ou la validité des choix effectués au début du lancement du programme nucléaire français, voire antérieurement.

C'est pourquoi un groupe de travail mixte EDF-CEA s'est attaché, courant 1991, à comparer ses pratiques, les évaluer et proposer une harmonisation des méthodes de mesures.

2 - BILAN DES PRATIQUES A EDF ET DANS LE GROUPE CEA

Au sein du parc des centrales REP d'EDF, une très forte cohérence est observée par suite de sa standardisation. En revanche, une grande variété existe si l'on compare EDF et les différentes filiales du groupe CEA. Les moyens de surveillance individuels et collectifs sont différents suivant les catégories de travailleur (A, B ou non exposés), les types de détecteurs sont également différents (film, thermoluminescence, etc.) et enfin les fréquences de traitement et la nature des enregistrements varient également.

Cette diversité est due à la fois à la nature des risques propres aux activités des sites concernés, mais également à des choix de stratégie dosimétrique.

3 - MISE EN PLACE D'UNE METHODOLOGIE STRATEGIQUE GLOBALE DE LA DOSIMETRIE ET EVALUATION DES DIFFERENTS CHOIX POSSIBLES

Une conception globale de la dosimétrie repose sur une évaluation des doses qui doit prendre en compte les aspects suivants :

- A quel usage est destiné la mesure (respect des limites individuelles, analyse dosimétrique de chantier ou études épidémiologiques) ?
- Quels sont les types de rayonnement réels ou potentiels auxquels sont soumis les travailleurs ?
- Parmi ces rayonnements, quels sont ceux qui méritent un suivi individuel actif (en temps réel) ou passif (en temps différé), un suivi collectif actif ou passif ?
- Parmi ces rayonnements, quels sont ceux qui ne méritent pas de suivi, mais simplement une évaluation calculée, associée ou non avec une détection d'alarme ?
- Avec quel type de détecteur le suivi est-il réalisé ? Comment est-il étalonné ? Quel est le pas de la mesure ?
- Quel est le seuil d'enregistrement, c'est-à-dire l'équivalent de dose au-dessus duquel le résultat de la mesure présente un intérêt suffisant pour valoir d'être enregistré et conservé ?
- Quel est le pas d'enregistrement ? Comment est fait l'arrondissement ?
- Comment sont enregistrées les expositions internes (à la date de l'exposition ou étalées dans le temps) ?
- Quelles données élémentaires sont conservées ?
- Quels traitements de données sont effectués (cumuls dans le temps, cumuls de doses efficaces, contrôle de dépassement des limites) ?
- Quels types de conservation et d'archivage utilise-t-on ?

- Quelle utilisation des résultats est effectuée, vis-à-vis des doses des travailleurs de l'exploitant comme de ceux des entreprises extérieures ? Quelles études statistiques sont effectuées et quelle diffusion leur est-elle accordée ?

La réponse à l'ensemble de ces questions constitue la stratégie dosimétrique retenue et EDF a essayé, pour quelques domaines, d'évaluer les conséquences d'autres options que celles actuellement utilisées en centrales nucléaires.

Le tableau ci-dessous montre par exemple (pour la dosimétrie réglementaire film), les variations de la dose collective des agents EDF en 1990 en fonction du seuil d'enregistrement, par rapport à la valeur de 27,9 Sv obtenue avec le seuil de 0,10 mSv actuellement utilisé à EDF.

Seuil d'enregistrement	Dose annuelle non enregistrée		Répartition de la dose annuelle individuelle (12 mois consécutifs) avec le seuil d'enregistrement à 0,1 mSv		
	en mSv	en Sv	en % dose totale	dose en mSv entre	Nombre d'agents
0,2	2,42	8,7	0 et 0,04	3112	19,6 %
0,3	4,10	14,7	0,05 et 0,14	2475	15,5 %
0,4	5,57	19,9	0,15 et 0,24	1458	9,2 %
0,5	6,91	24,7	0,25 et 0,34	905	5,7 %
			0,35 et 0,44	624	4,0 %
			0,45 et 0,54	423	2,7 %
			> à 0,55	7000	43,3 %

Le simple choix d'un seuil d'enregistrement à 0,1 ou 0,5 mSv fait donc varier la dosimétrie globale des agents EDF de 25 %.

4 - PROPOSITION D'HARMONISATION DES STRATEGIES DOSIMETRIQUES

Les raisons qui ont guidé les choix de stratégie dosimétrique, lors du développement de l'industrie nucléaire française ont privilégié les aspects spécifiques et locaux, ce qui explique les écarts constatés dans les pratiques des exploitants. Par ailleurs, l'utilisation de la dosimétrie résidait essentiellement dans la vérification du respect des limites individuelles.

Aujourd'hui, les échanges d'information, la circulation de nombreux travailleurs de site en site, le suivi des personnels changeant d'entreprise, nécessitent une plus grande harmonisation de l'enregistrement et de la comptabilisation des doses.

C'est pourquoi, le groupe de travail EDF/CEA a proposé dans un premier temps les mesures suivantes :

- étalonnage des dosimètres film selon la norme ICRU,
- valeur du pas de la dosimétrie opérationnelle de 0,01 mSv pour les détecteurs électroniques et de 0,05 mSv pour les TLD (Détecteur par thermoluminescence),
- valeur du pas de la dosimétrie film réglementaire et mensuelle de 0,1 mSv,
- seuil d'enregistrement par lecture pour une entrée en zone contrôlée de 0,01 mSv (ce seuil fait partie du cahier des charges pour les constructeurs de détecteurs),
- seuil d'enregistrement mensuel pour la dosimétrie film réglementaire de 0,2 mSv.

Par ailleurs, une revue des stratégies dosimétriques sera effectuée en particulier dans certains domaines (dose neutronique, dose peau, dose aux extrémités, radon). L'objectif est de définir l'ensemble des éléments à mesurer ou contrôler, puis à enregistrer et conserver.

Ces éléments constitueront une base de gestion analytique fine des données dosimétriques. Enfin, une sommation globale des doses efficaces permettra d'obtenir un indicateur unique d'évaluation globale de la dosimétrie individuelle et collective, même si cet indicateur présente peu d'intérêt sur le plan strictement médical.

5 - CONCLUSION

Les différentes pratiques observées dans la gestion des doses laissent à penser que des écarts dans les doses comptabilisées peuvent varier dans des proportions allant jusqu'à 50 %.

Cependant, la réduction des normes de base, le suivi au plus près des doses dans la mise en oeuvre de politiques ALARA, la prise en compte de nouvelles expositions, les échanges d'information conduisent les exploitants à mieux définir ce qui est pris en compte dans les valeurs annoncées et donc d'harmoniser leurs pratiques. La mise en place d'un indicateur global utilisant la somme des doses efficaces apparaît à ce titre indispensable.

Le travail réalisé entre EDF et le CEA a permis à cette occasion de mieux appréhender, dans leur globalité, les options qui avaient été prises (au moins implicitement) dans leurs stratégies dosimétriques, et la méthodologie mise en place donne une grille d'application utilisable pour toute révision de ces stratégies.

³²P PERSONNEL MONITORING IN U.S. RESEARCH INSTITUTIONS

Victor N. Evdokimoff

Boston University Medical Center
Radiation Protection Office
88 East Newton St.
Boston, Ma. 02118

ABSTRACT

Phosphorus-32 is used extensively in medical research. Because our ³²P personnel monitoring costs are significantly increasing especially for low exposure potential < 37 MBq, we surveyed 13 similar U.S. institutions to aid a review of our present badge policy. Our 3 year exposure data show that the extremities have a greater potential for exposure than the skin of the whole body. Despite significant costs, fifty-four percent of institution surveyed issued only a whole body badge for use < 37 MBq. Liability and registration are reasons other than exposure potential to monitor at < 37 MBq. Almost all issued a whole body badge and ring badge at 37 MBq.

INTRODUCTION

BUMC MONITORING AND COSTS FOR ³²P

Individuals using less than 37 MBq (1 mCi) of ³²P are issued a commercial TLD finger ring badge worn name side at the palm to assess extremity dose. Individuals using 37 MBq or more of ³²P are also issued a whole body film badge to assess the dose to the skin of the whole body.

In reviewing 3 years of exposure data for ³²P users through December 1989, the highest annual whole body badge dose was 5.1 mSv (510 mRem). For our ring badges, 25% had positive readings above the minimum detectible exposure at < 37 MBq ³²P use and 32% positive at 37 MBq and above. Our whole body badges had 12% positive exposures at 37 MBq and greater.

From 1987 to 1989, our ³²P badge costs have doubled accounting for 55% of all badges issued for radioisotopes. In 1990, our annual badge cost was over \$12,000 with approximately 35% of these costs due to issuing badges for ³²P use less than 37 MBq.

SURVEY

Our office contacted by telephone the health physics offices of 13 selected institutions throughout the United States known to have large broad scope or broad medical radioisotope licenses. These institutions were asked their policy for personnel monitoring of persons using only ³²P.

SURVEY RESULTS

Of the 13 institutions surveyed, 69% issued whole body badges for ^{32}P use < 37 MBq. At the 37 MBq level, 100% of the institutions surveyed issued a whole body badge and 77% issued a ring badge. At the 37 MBq level, four institutions that did not issue a badge at less than 37 MBq did issue a whole body badge and ring badge at the 37 MBq level, suggesting this as an action level for personnel monitoring.

Reasons given for issuing badges at < 37 MBq include: assess exposure potential, registration and protection from liability. Reasons for not issuing badges at < 37 MBq include: cost, low exposure potential, and because their health physics department surveys ^{32}P use.

Some institutions were unclear whether the whole body badges were assessing whole body ^{32}P exposure or skin of the whole body exposure.

CONCLUSION

1) Phosphorus-32 exposures at less than 37 MBq (1 mCi) appear to have a low exposure potential to researchers and are not likely to approach the current USNRC criteria of monitoring at 25% maximal permissible dose. However, determining what that dose is, i.e., skin vs. whole body, is not entirely clear from this preliminary survey of 13 institutions. In our opinion, the skin is at risk and the skin dose limit should apply.

2) The majority of the institutions surveyed issued a whole body film badge for less than 37 MBq ^{32}P use and a whole body film badge with a TLD ring badge at 37 MBq or greater ^{32}P use. There was a greater degree of uniformity in personnel monitoring for ^{32}P at levels of 37 MBq and greater.

3) Liability and registration are reasons other than exposure potential that some institutions issue a whole body badge to investigators using less than 37 MBq.

4) Should an institution decide to issue a badge for ^{32}P use under 37 MBq, it would be more appropriate to issue a ring badge worn with the name side at the palm to monitor extremity dose than to issue a whole body badge (32% versus 12% positive).

5) Should an institution decide to issue a badge for ^{32}P use under 37 MBq, the costs may be significant.

ABSTRACT

This paper describes the functions, operation, types and method of data transfer, and summarised data to be published relating to the Central Index of Dose Information.

INTRODUCTION

The Central Index of Dose Information (CIDI) is a national database of occupational exposure to radiation operated by the National Radiological Protection Board (NRPB) as agent for the Health and Safety Executive (HSE). It receives annual summaries from Approved Dosimetry Services (ADSs) of the radiation doses to classified persons in the United Kingdom. At present, there are approximately 40 dosimetry services approved in Great Britain for keeping records and approximately 60,000 classified workers. All the data provided to CIDI are treated as confidential with respect to individual persons and employers.

FUNCTIONS OF CIDI

CIDI has a number of functions as listed below:-

- (a) To enable data to be transmitted from the previous ADS to the next, when a classified worker changes employer.
- (b) To provide an index to show which ADS is responsible for the monitoring of a classified person, allow revised dose data to be passed from one ADS to the next, and to act as a back-up source of dosimetric information about the person.
- (c) To conduct an annual audit of the persons monitored by an ADS to ensure that the number of persons monitored agrees with the total for the previous year, allowing for additions and deletions during the year.
- (d) To provide statistics to guide policy making on a national basis.

TYPES OF RECORD EXCHANGED BETWEEN CIDI AND ADSs

Registration report: This is sent from an ADS to CIDI to notify CIDI that a dose record is being started by the ADS for a classified person.

Entry report: This is sent from CIDI to the ADS to notify the ADS that CIDI has started a record for the classified person.

Termination report: This is sent from the ADS to CIDI to inform CIDI that a classified person has left employment, and should be sent to CIDI as soon as possible after all outstanding dosimeters have been processed.

Annual return: This is sent from the ADS to CIDI and includes

summaries of the annual doses received by all classified workers for which the ADS kept records, irrespective of whether they ceased to be classified during the year. Note: a person can only be declared as having ceased classified work at the end of the year.

Amended records: These are records that are sent from the ADS to CIDI to correct previously submitted information. It is recognised that records may need to be provided occasionally, but amendments should be exceedingly rare in order to minimise the operating costs of CIDI.

In addition to the above, the ADS has to inform CIDI of the name and address of any employer for whom the ADS is keeping records. CIDI then allocates to the ADS a CIDI code number for that employer.

DOSE DATA FOR CIDI

The following is a summary of the dose data contained within the annual return, termination report and entry report. Precise details of the dose data and personal data are contained in The Reference Manual for Data Transfer to CIDI'. Not all the data are obligatory.

Current year dose data:

(a) Sum of effective dose equivalent from external radiation and committed effective dose equivalent from internal emitters.

(b) Neutron component of (a).

(c) Notional component of (a) (where this exceeds 10% of the total).

(d) Sum of dose equivalent from external radiation and committed dose equivalent from internal emitters to organs and tissues (where doses exceed 10% of the proportion of the annual dose limit for the period in question).

(e) A flag if (a) above includes a component from long-lived or other internal emitters.

Lifetime dose data:

(a) Effective dose equivalent from external radiation (including (b) below).

(b) Notional component of (a) (where this exceeds 10% of the total).

Note: Termination and entry reports will now be required to include separate dose summaries for each of the previous four years (excluding any year before 1/1/88).

PERSONAL DATA FOR CIDI

The personal data sent to CIDI includes the following:-

(a) Surname and forenames.

(b) Sex and date of birth.

(c) National insurance number (the unique identifier).

(d) Identifier of the ADS supplying information.

(e) Occupational classification of the employee.

(f) CIDI code number of the individual's employer.

(g) Date of commencement/termination of classified work in this employment.

(h) Employers work activity coded as Standard Industrial Classification (1980).

METHOD OF DATA TRANSFER

It is intended that the majority of data will be transmitted to and from CIDI in the form of magnetic media i.e. magnetic tape or floppy discs depending on the amount of data, in accordance with precisely defined data formats¹. In addition to the previously defined data, each computer compatible record has a field for: record type, record counter, record key, and amendment flag. The computer dose record(s) have a field to distinguish whether the record is for doses for the current year or lifetime doses, and fields that describe the dose type and organ/tissue type as per CIDI classification.

PUBLICATION OF CIDI DATA

Although the individual data on the database are treated as confidential, an annual summary of statistics for each year, commencing for the year 1986 will be published. In order to facilitate comparison between years, it is the intention that wherever possible, the format of succeeding summaries will remain unchanged. Also, in addition to these annual summaries, it is expected that further analyses will be published at likely intervals of five years that will assist in the identification of any trends.

The tabulated data is divided into three parts; Part A - Whole body doses, Part B - Dose variation with age and sex, and Part C - Doses to specific organs and tissues. A common feature of the tabular presentation is that all doses are related to Occupational Category. The majority of the tables present the data distributed within dose intervals, together with total workers, collective doses, and mean doses for each Occupational Category. There is also a table that gives the distribution of workers, by age and sex, that exceeded 15 mSv for the year.

As a matter of policy, the statistical summary includes a minimum of analysis. This is in order to ensure that any subsequent analysis of data will be based on the "raw" data as received by CIDI. However, there is an additional table that gives the distribution of effective dose equivalent plus committed effective dose equivalent where pro-rata doses have been substituted for notional doses. The reason for this is that it is believed that such a table is likely to give a more realistic impression of actual doses.

Figures 1 to 3 are taken as examples from the 1986 Summary of Statistics², they show respectively, mean doses, the number of workers exceeding 15 mSv, and collective doses per Occupational Category.

IMPACT OF ICRP60 ON DOSES RECEIVED BY OCCUPATIONAL EXPOSED WORKERS IN EDUCATIONAL ESTABLISHMENTS IN THE UNITED KINGDOM

A. G. RICHARDS
RADIATION PROTECTION SERVICE
UNIVERSITY OF LEEDS
UNITED KINGDOM.

ABSTRACT

The doses received by University workers lie generally in the range 1-3 mSv. This paper discusses how the doses received by workers can be kept down by considering the changing working practices in laboratories with the revised dose limits and annual limits on intake.

INTRODUCTION

The International Commission on Radiological Protection (ICRP) in 1977 published its recommendations known as ICRP26.¹ Following the publication of ICRP 26 the Commission of the European Communities issued the Euratom Directive in 1980.² This directive is binding on all the countries in the European Economic Community (EEC) but has no legal status for countries outside the EEC.

The Euratom Directive required the members countries to produce requirements governing persons exposed to sources of ionising radiations. In the United Kingdom these requirements were implemented by means of the Ionising Radiations Regulations 1985 (IRR 85),³ under the Health and Safety at Work Act⁴. These regulations are only legally binding in the United Kingdom. They set out rules relating to the employment of workers who use ionising radiations. In addition certain duties are imposed on manufacturers of equipment or articles to ensure that any article is constructed to restrict so far as is reasonably practicable exposure to ionising radiations. There are certain exemptions to these regulations for members of the armed forces and to work for the Secretary of State for Defence.

Persons who are exposed to ionising radiations in the course of medical treatment are covered by different regulations.⁵

Under the Ionising Radiations Regulations a worker who is likely to receive three tenths of any relevant dose limit shall be designated a classified worker. A requirement of the IRR85 is that a dosimetry service used for the measurement of doses received by classified workers be approved. These services known as Approved Dosimetry Services (ADS) are approved by the body in the UK called the Health and Safety Executive. ICRP 60⁶ recommendations differ from ICRP26.

DOSE LIMITS

DOSE LIMITS IN ICRP60	OCCUPATIONAL	PUBLIC
Effective dose	20 mSv per year (i) averaged over 5 years	1 mSv per year.
Annual equivalent dose		
in the lens of the eye	150 mSv	15 mSv
the skin	500 mSv	50 mSv
the hands and feet	500 mSv	

Figure 1: ICRP 60 DOSE LIMITS

(i) The further provisions that the effective dose should not exceed 50 mSv in any single year.

The whole body doses received by workers in educational establishments are on average less than 2-3 mSv⁻¹ and since the introduction of the IRR 85 the mean dose is now much lower as the

data provided by an ADS shown in figure 2 and figure 3 indicates.

	0 - 5 mSv	5 - 15 mSv	15 - 50 mSv	Man mSv
University staff	1394	10	16	568

Figure 2: 1986 Dose Statistics

	0 - 5 mSv	5 - 15 mSv	15 - 50 mSv	Man mSv
University staff	1537	3	4	134

Figure 3: 1989 Dose Statistics

Clearly ICRP60 can not have too much effect on doses received by University workers⁷ and different criteria other than dose received would be needed to decide which groups to monitor.

Occupational Exposure of Women

The basis of control of occupational exposure of women who are not pregnant is the same as for men. If a woman is pregnant then additional control has to be taken. The effects on the unborn child from the 3rd week after conception are deterministic in effect and are estimated from animal experiments to have a threshold of 100 mGy⁸ but there is no definite evidence for the susceptibility of the human foetus. ICRP have decided that once the pregnancy has been declared the dose limit to the surface of the abdomen should be 2 mSv for the remainder of the pregnancy. Essentially pregnant women should not carry out high risk tasks.

Equivalent dose to the surface of the womens abdomen	$\leq 2 \text{ mSv}$
intake of radionuclides	$\leq \frac{1}{20} \text{ ALI}$

In Universities in the UK a small number of workers carry out work on cyclotrons and accelerators. The largest number undertake work with open sources or sealed sources and x-ray crystallographic work. A requirement of the UK Ionising Radiations Regulations is that for certain categories of work the employer appoints a Radiation Protection Adviser (RPA)

Should the adviser restrict the pregnant workers to $\frac{1}{20}$ ALI when handling open sources? or what criteria should an adviser use in relation to pregnant workers. Lets look at the implications of restricting the work $\frac{1}{20}$ ALI.

COMPARISON OF THE ACTIVITIES OF THE FIVE MOST COMMON RADIONUCLIDES USED IN UK UNIVERSITIES WITH $\frac{1}{20}$ ALI

	Activity in common use Bq	$\frac{1}{20}$ ALI Bq
³ H	1×10^{11}	5×10^7
¹⁴ C	1×10^7	2×10^6
³² P	$10^6 - 10^9$	4×10^5
³⁶ S	$10^6 - 10^8$	5×10^6
¹²⁵ I	$10^6 - 10^8$	5×10^4

Figure 4: Activities of common radionuclides

With the exception of Carbon 14 and some experimental work with Phosphorous 32 and Tritium most other work would be precluded if the level of $\frac{1}{20}$ ALI marked the upper limit for a pregnant worker to handle.

Work of Pregnant Employees in relation to external radiation.

A very small number of workers in the UK Universities are cyclotron workers. Pregnant workers may be exposed to an external radiation hazard when handling open/closed sources or when carrying out x-ray crystallography with the interlocks overridden. The risk of exposure needs to be considered in each case.

Large sealed sources which are housed in irradiation units or similar enclosures usually produce a very small risk and thereby would not present a problem in relation to pregnant workers.

Most problems are likely to occur in relation to the handling of open sources of radionuclides by pregnant workers.

Classification of Working Areas/Workers

ICRP 26 defined Working Conditions A, Working Conditions B and then went on to introduce the classification of the work place as Controlled Areas and Supervised Areas for these conditions. In line with ICRP 26 and the Euratom Directive the UK legislation defined **Classified Workers**.

The criteria for designating a controlled area as set down in UK legislation "is essentially an area is designated controlled if the dose rate is likely to exceed $7.5\mu\text{Sv}\cdot\text{h}^{-1}$ " The occasions when dose rates above this level are encountered have been considered in relation to pregnant workers. Generally whole body doses are negligible and extremity doses small.

Work with some machine sources and irradiation units may present a problem. The handling of some sources will generate dose rates above $\mu\text{Sv}\cdot\text{h}^{-1}$ but generally these sources can be dealt with by the use of remote handling tools and shielding as at present. Clearly this is working in the case of UK Universities as the whole body doses demonstrate. The ALARA principle is practised quite well.

Designation of Areas in Relation to Internal Radiation

The UK legislation requires that an area is designated as controlled in respect of internal radiation if there is a risk of airborne contamination or surface contamination above specified levels and the quantities in use are greater than 10 Annual Limits on Intake (ALI).⁹

Contamination above the levels specified are not found on a regular basis in UK Universities and other criteria have to be used to designate an area as controlled. Once an area is however designated as controlled it then becomes subject to the legal requirements relating to access.

One way forward which is being considered in relation to designating controlled areas in UK Universities is to consider the total activity handled.

There have been attempts in the past to relate the activity taken into the body to the activity being handled. A factor of 10^{-3} of the activity handled as an average could be used. Clearly this factor will be governed by the circumstances under which the activity is handled. Using this principle and restricting the intake to 1/10 ALI.

Laboratories would be designated a controlled area if the activity handled exceeded 100 ALI.

Using the criteria of 100 ALI very few laboratories in UK universities would need to be designated controlled areas. These would be the few laboratories that work with tritiated water in large quantities or where ^{32}P is used in hybridisation experiments or where perhaps iodinations are carried out.

ICRP 60 AND THE CLASSIFICATION OF WORKING AREAS

The Commission in the 1990 recommendations now regards the distinction between controlled and supervised as being too arbitrary. Not all workers in controlled areas received doses above 3/10ths of the occupational dose limit. Certainly workers in educational establishments do not receive doses above this figure whether in controlled or supervised area. ICRP now regard the decision in relation to area classification is better taken at a local level.

One aspect is quite clear that outside an area designated for occupationally exposed persons the

doses received should be below the dose limit for public exposure of $1\text{mSv}\cdot\text{y}^{-1}$. This dose is not measured easily and so it is difficult to implement.

ASSESSMENT OF DOSES

In UK Universities the practice of which workers to classify does vary. Whole body external doses are monitored in the usual way, urine monitoring being undertaken for a small number of high activity Tritium workers. Non-classified workers are generally also monitored although not required it provides reassurance to the worker.

ICRP 60 recommends that monitoring for external radiation is used for all who are occupationally unless it is clear that their doses will be consistently low.

Now we know that the doses occupationally exposed workers in UK universities receive are low because we monitor them already. The data accrued helps establish the designation of the working areas. So perhaps we should consider monitoring all radiation workers routinely!!

TRAINING

ICRP 60 suggests that the most important factor in implementing the recommendations is training. A substantial commitment should be undertaken by all educational establishments to training. This should include radiation protection advisers, radiation protection supervisors, and workers.

CONCLUSIONS

The implementation in the UK of the ICRP recommendations will not lead to a general reduction in doses. Careful consideration by the Regulatory authority of some of the problems posed will be needed, such as occupational exposure of pregnant workers and classification of areas. Better management of occupational exposure should result.

CUMULATIVE RADIATION EXPOSURE AT BNFL SELLAFIELD:
A HISTORICAL PERSPECTIVE

K BINKS, R WAKEFORD, R STRONG, D J COULSTON

British Nuclear Fuels plc, Risley,
Warrington, Cheshire, WA3 6AS, U.K.

ABSTRACT

The temporal distribution of the average cumulative whole body annual recorded external radiation doses of 15,182 monitored male Sellafield employees is presented. Results are given for successive pairs of years of first monitoring, from 1949-50 to 1985-86, and for successive single years of follow up for each of these cohorts. The results show: there is a reduction in average cumulative dose with later years of first monitoring at any length of follow up; a marginal reduction in the increase in the average cumulative dose for any given cohort with longer length of follow up; and the pattern of average dose in the first year of follow up is similar to that previously reported, in [1].

INTRODUCTION

Historical annual recorded whole body dose data for Sellafield employees were computerised as a special exercise by a dedicated team of British Nuclear Fuels plc (BNFL) Sellafield staff in the late 1970's. This computerised annual dose database has had the annual dose data for all Sellafield employees added to it up to 1986. These dose data together with personnel and tracing return data form part of the BNFL Company Epidemiology database and are held on computer in the Company Medical Office at the Sellafield site. Extracts from the Epidemiology database have been supplied to researchers for use in a range of studies, published and forthcoming eg. [1,2,3,4]. The Sellafield employee data have been combined with equivalent data for the Atomic Energy Authority (AEA) and the Atomic Weapons Establishment (AWE) by Harwell staff to form the Nuclear Industry Combined Epidemiological Analysis (NICEA) database. These data, which will be analysed by epidemiologists at the London School of Hygiene and Tropical Medicine (LSHTM), have been transferred to the International Agency for Research on Cancer (IARC) for combining with American and Canadian data, for analysis by IARC staff.

THE DISTRIBUTION OF ANNUAL EXTERNAL DOSE DATA

The Sellafield whole body annual dose data are, as with other such data [5], in their own right of considerable epidemiological interest. There are 15,182 male radiation workers on this database who have been occupationally exposed to 1307 Sv during 112,582 person years of employment. Only the first episode of continuous employment as a monitored worker and those annual external doses recorded during that employment period are used for the results of this paper.

Years of follow-up	10	9	8	7	6	5	4	3	2	1

The distribution of average cumulative whole body annual recorded doses for these male Sellafield employees (all ages) is given in the table. The upper triangular part of the table gives the average cumulative dose by successive pairs of calendar years of first year of monitoring and for successive years of follow-up through to 1986. The lower triangular part of the table gives the respective numbers of workers.

Comparison of the average doses in the first year of follow up for these cohorts with those of figure 3 of [1], shows that the average dose patterns are similar when it is noted that a worker will not normally contribute a full year of dose during his first year of employment.

Examination of the pattern of average cumulative dose for each successive pairs of years of first monitoring suggests an initially constant annual rate of accumulation of dose, with this rate reducing in later years of follow up. This dose accumulation rate is higher in earlier cohorts. An examination of the data for those workers continuously employed through to 1985 (eg. 20 for the 1949-50 cohort, 94 for the 1969-70 cohort, etc) supports this notion of a genuine reduction in individual average annual dose with increasing length of follow up.

CONCLUSIONS

This preliminary analysis draws out some features of these data, but further work is needed to better understand these data, particularly with respect to age at exposure and occupation. These results are consistent with a reduction in annual external whole body doses received by Sellafield workers over the follow up period.

Division of Radiological Protection
Bhabha Atomic Research Centre
Bombay (INDIA)

ABSTRACT

More than 20,000 radiation workers are monitored in India using TLD badges⁽¹⁾ containing three teflon CaSO₄:Dy discs fixed on an aluminium card. A microprocessor based semiautomatic version of the TLD reader has been developed to handle about 2000 cards per month. It is having features like automatic dark current cancellation, autoranging, user selectable calibration factor, printer interface, digital glow curve storage, RS-232 serial interface and a built-in LED light source for system stability check. The Reader covers a range of 0-10 Sv with a minimum measurable dose of 50 μ Sv for X and gamma radiation. The hardware and software details of the TLD Reader are discussed.

INTRODUCTION

Personnel monitoring of radiation workers in India is carried out using both film dosimeters and TLD. However, TLD is preferred to film dosimeters owing to the advantages such as amenability to automation and stability under extreme climatic conditions of high temperature and humidity existing in most parts of India. Personnel monitoring in India is carried out by regional centres and an elaborate quality assurance programme by the Division of Radiological Protection (DRP), Bhabha Atomic Research Centre (BARC) ensures compatibility between centres. A manual type TLD reader indigenously developed was found to be satisfactory for dose evaluation in small centres which handles upto about 1000 cards per month. A microprocessor controlled data logger is used to interface these readers, to an IBM PC/XT for data transfer, glow curve display and storage. This paper discusses the design considerations of a semiautomatic personnel monitoring system having features like built-in interface for a PC/XT, motorised mechanical arrangement to read the three dosimeters of the TLD badge⁽¹⁾ sequentially, a self test diagnostic software, storage of digital glow curve data with high or low resolution etc.

SYSTEM DESCRIPTION

The BARC TLD Badge⁽¹⁾ consists of three 0.8mm thick (13mm diameter teflon CaSO₄:Dy) discs fixed to an aluminium card. The card is positioned inside a plastic holder provided with appropriate energy compensation filters, for the three dosimeters. The semiautomatic TLD reader shown in fig.1 is based on a compact 8085 microprocessor system. It consists of a rack

and pinion arrangement coupled to a D.C motor for transporting the dosimeter card to the heating position, a reproducible temperature control circuit for heating TL dosimeter upto 280°C, a multiplier phototube (PMT) having a suitable spectral response (EMI 9924), a regulated EHT(500-1000V variable) for the PMT and a current to frequency (I-F) converter with an automatic dark current suppression circuit. The operation of the TLD Reader is controlled by a ROM based 8K byte assembly language program. Two 6V dc motors are used, the first one for moving the card to the reading position inside the reader and the second for raising and lowering the kanthal heater to make contact with the TL dosimeter. Microswitches are used for sensing proper positioning of the dosimeter over the heater. The TLD reader is provided with a key-board consisting of the numeric and function keys and an eight-digit, seven-segment LED display for displaying various display parameters and the readings. A separate digital panel meter is used for displaying temperature and the EHT. The TLD reader is provided with a centronic parallel printer interface for an on-line/off-line printout of data, and a serial RS-232 interface for connection to an IBM PC/XT. The detailed hardware and software of the reader can be obtained from the authors.

OPERATION CYCLE

The dosimeter card is manually removed from the plastic holder and fed into the reader. A "Start" key is pressed to start the reading cycle. A buzzer prompts the operator to enter the badge number(B.No.) i.e. the dosimeter identification number which is entered using the numeric and "Enter" keys on the front panel. Prior to this, the institution number (I.No.) assigned for a batch of badges from an institution and the location code (LC) to indicate the location on the body where the TLD badge is worn can be entered. A location code of 00 is used for chest, 01 for right wrist and 02 for left wrist. If these numbers are not entered, a code of "00" is taken as default value for the location code and the institution number remains unchanged. On entering the badge number, the dark current of the PMT is sampled and stored on a low leakage capacitor for automatic subtraction from the output during the reading cycle. The TLD card is then transported by a geared dc motor till the dosimeter one is positioned over the heater. A pulse width modulated drive is used for precise control of the dc motor. The reading cycle is started with energising the heater. A heater control circuit heats the dosimeter to 280°C in less than 10 seconds and maintains it till the end of the reading cycle. A typical temperature profile during the reading cycle is shown in fig 2. The anode current from the PMT is fed to an I-F converter. The output pulses from the I-F converter are fed to a microprocessor compatible 8 digit counter (8253). A 10 pps clock interrupt is used to update the display and to read and store the counter readings every second in a non-volatile RAM (random access memory) for obtaining integral glow curve data. At the end of the read-out cycle, the integral glow curve data is transmitted to the PC/XT. A BASIC program finds the difference between the successive readings to

obtain the differential data and displays the glow curve on the PC monitor. The data is also stored on a floppy/hard disk. In addition, at the end of every readout cycle, the dose and the other dosimeter details are stored in a non-volatile RAM which has a capacity for dose data storage of 100 badges and printed on a 24 column dot matrix printer. The dosimeters 2 & 3 are read similarly and the card is ejected out. When the memory is exhausted after readout of 100 badges, the system goes into a lockout mode with a message "FULL" on the display. This ensures that there is no loss of data due to non-availability of memory for storage. The TLD reader cannot be operated unless the memory is cleared by the operator using a code number and pressing the "Enter" key on the panel. The reading stored in the memory can be recalled by using a "RECALL" key and entering the badge number of interest.

RESULT

The TLD reader has a readout time of three minutes per badge⁽¹⁾. A typical glow curve recorded from a 0.8mm TL dosimeter exposed to 6.2 mSv as stored in PC/XT is shown in fig.2. A low resolution glow curve storage with 60 points per curve as shown in fig.2 would provide enough evidence of a correct read-out and genuineness of the dose and to reject an occasional spurious reading⁽²⁾. A software has been written in BASIC to retrieve and display any of the stored glow curves from the database. The dosimeter data stored in the non-volatile memory of the TLD reader is transmitted off-line to a PC/XT for dose evaluation, preparation of the dose reports and record keeping. The system covers a range of 50 μ Sv to 10 Sv for X & Γ radiations.

CONCLUSIONS

The system costs about \$12,000 with 500 badges and the commercial production is already underway. The system will be a low-cost option for any medium scale personnel monitoring centre. The built-in interface in the TLD reader makes it possible to connect two or more such readers to a single IBM PC/XT on time-sharing basis. To achieve a faster read-out time, a modified TLD badge with 0.4 mm CaSO₄:Dy teflon dosimeter and a non-contact hot nitrogen gas heating system are under development.

NEW DATA PROCESSING MANAGEMENT
OF THE DOSIMETRY FOLLOW-UP OF THE
WORKERS EXTERNAL EXPOSURE
DOSDAM APPLICATION

ABSTRACT

The data processing application DOSDAM of the dosimetry follow-up of workers, is characterized by high variables of the treatment, in order to adapt to any evolution of the legislation, a centralised management, common to all the users scattered on the national territory, and above all by a data-processing transfert enabling each local responsible worker to perform specific treatment such as the management of workstations.

INTRODUCTION

Le Centre d'Etudes de Bruyères-le-Châtel a mis en exploitation depuis Janvier 1991 une application informatique appelée DOSDAM "Dosimétrie de la Direction des Applications Militaires", destinée à la gestion du suivi dosimétrique du personnel de la Direction des Applications Militaires du COMMISSARIAT A L'ENERGIE ATOMIQUE (CEA/DAM).

Une gestion commune de la dosimétrie pour tous les centres DAM, une adaptibilité complète à toute évolution de la législation et des techniques dosimétriques et surtout, un traitement spécifique local, comme le suivi des postes de travail, sont les principaux objectifs de cette application dont nous décrivons les principales caractéristiques.

PRINCIPES

L'application repose sur trois principes :

- la décentralisation de la saisie des données et l'édition des résultats dans chaque centre de travail réparti sur tout le territoire français,
- le paramétrage complet des données qui permet une flexibilité totale de l'application, c'est-à-dire son adaptabilité à toute évolution des techniques de dosimétrie ou de la législation, mais également aux caractéristiques particulières de chaque centre administratif,

- le transfert des données (identité agents, doses individuelles, etc...) extraites d'une base commune et transmises sous forme de fichiers informatiques directement exploitables sur micro-ordinateur par les logiciels habituels (dBase III +, Pascal, etc...).

Ainsi, la particularité essentielle de cette application est-elle d'offrir à chaque responsable local de radioprotection à la fois une gestion commune sur une base de données centralisée et à partir des fichiers transférés, une gestion spécifique locale comme le suivi des visiteurs, la détection des doses anormales et le suivi des postes de travail...

DESCRIPTION

L'application DOSDAM est implantée sur un ordinateur DPS7 du Centre d'Etudes de Bruyères-le-Châtel qui gère un réseau informatique entre tous les centres métropolitains de la DAM. Chaque utilisateur dispose comme terminal, d'un micro-ordinateur type IBM PC AT émulé en terminal DKU sur le réseau. Il assure ainsi le suivi administratif, la demande et l'attribution des dosimètres de tous les agents CEA et entreprises exerçant sur le (ou les) centre de travail dont il assume la radioprotection.

Les opérations comme la commande des dosimètres pour tous les centres auprès d'un même fournisseur et l'exploitation des résultats dosimétriques issus du même laboratoire de mesure sont à la charge du Service de Protection contre les Rayonnements du Centre d'Etudes de Bruyères-le-Châtel.

Ces opérations produisent des "états" sous forme de "fichier-spool" d'édition mis à la disposition de chaque responsable local qui décide d'une manière indépendante du moment et des conditions (type imprimante, nombre d'exemplaires...) de l'édition proprement dite.

Le suivi dosimétrique s'exerce sur tous les agents travaillant sur un (ou plusieurs) centre de travail qu'ils soient personnel CEA ou d'entreprises ou visiteur. Il repose, en premier lieu, sur un suivi administratif de chaque individu qui consiste à prendre en compte l'évolution de quelques données, regroupées sous le terme "position administrative" comprenant entre autres, le centre, le service, la classification radiologique associés à des dates de début et de fin de position. La dose individuelle d'une personne est ainsi affectée à sa véritable position administrative à la période de port du (ou des) dosimètre.

En particulier, lors des études de statistiques dosimétriques, la détermination des doses collectives par unité administrative prend en compte les différents mouvements de personnel entre service ou la variation des classifications radiologiques.

DOSDAM permet l'attribution, la commande de tous les types de dosimètres actuellement en service et, grâce à son paramétrage, de tous les futurs dosimètres susceptibles d'être employés. Ces dosimètres peuvent être attribués à toute personne quelle que soit sa classification radiologique suivant toute périodicité de port.

Chaque dosimètre est associé au centre de travail et à l'installation où il est porté par un individu. Ainsi, la dose mesurée peut être affectée à l'installation, voire au poste de travail de l'agent.

Il est possible, par là même, de dissocier par lieu de travail, les différentes doses prises par une même personne sur plusieurs postes de travail.

La diffusion des résultats dosimétriques s'effectue :

- pour chaque personne sous forme d'un "relevé individuel de dose" placé sous pli confidentiel,
- pour chaque unité administrative, sous forme de "situations dosimétriques" qui expriment pour tous les agents de l'unité concernée, la (ou les) dose individuelle mesurée lors de la dernière période de port les doses cumulées sur les trois derniers et les douze derniers mois glissants,
- pour chaque installation, sous forme de "résultats dosimétriques" qui indiquent les doses mesurées sur tous les dosimètres portés dans l'installation concernée au cours de la dernière période de port.

Les services médicaux du travail reçoivent pour leur part, les situations dosimétriques de tous les agents dont ils assurent le suivi médical et les résultats de tous les dosimètres portés sur le centre de travail concerné.

Des statistiques dosimétriques présentées aux organismes de sûreté sont calculées, soit par unité administrative ou par installation en prenant en compte l'évolution de la position administrative de chaque agent et en dissociant les doses calculées par poste de travail.

ORIGINALITE DE L'APPLICATION

Chaque responsable local peut extraire de la base commune centralisée des données relatives aux individus, aux doses et les transférer sur son micro-ordinateur sous forme de fichiers. Il lui est alors possible de mettre en oeuvre des traitements informatiques qui lui sont spécifiques, ou qui mettent en jeu d'autres paramètres particuliers du centre de travail non gérés dans l'application, ou enfin, d'autres traitements non réalisables sur réseau comme les traitements graphiques, le publipostage etc...

En particulier, cette méthode permet de réaliser un traitement immédiat des résultats dosimétriques pour mettre en évidence, dans les plus brefs délais, toute dose anormalement élevée, d'éditer des statistiques particulières (sur des critères très détaillés).

L'utilisation principale de ce mode d'exploitation est le suivi du poste de travail de chaque agent, suivi qui ne pourrait être réalisé sur une application centralisée en raison de la grande mobilité des personnes et l'extrême diversité des postes gérés, mais que permet le transfert des données par voie informatique jusqu'au responsable direct de la radioprotection de l'installation.

APPLICATIONS DES RECOMMANDATIONS DE LA CIPR. UTILISATION DES
CONTRAINTES ET DES NIVEAUX DANS DES CAS CONCRETS

Pr. H. JAMMET

Vice-Président de la Commission Internationale
de Protection Radiologique
Mme A. SUGIER, Directeur Délégué à la Protection
Institut de Protection et de Sécurité Nucléaire

INTRODUCTION

La Commission Internationale de Protection Radiologique dans sa Publication 26 présentait sous le terme de normes (standards) d'une part des limites, d'autre part des niveaux. Dans la pratique la notion de borne supérieure (upper bound) est apparue progressivement dans les processus d'optimisation. Dans la CIPR 60 les normes comprennent des limites, des contraintes et des niveaux.

Les limites recommandées par la CIPR 60 concernent des doses individuelles liées aux personnes (travailleurs ou membres du public) et sont d'application générale. Les contraintes introduites par la CIPR 60 sont liées aux sources, s'expriment en doses ou en risques et sont d'application particulière. Les niveaux continuent d'être conçus comme des guides de référence permettant avec la flexibilité appropriée de traiter des problèmes relatifs aux sources, aux environnements professionnel ou public et aux personnes concernées.

L'expérience en protection radiologique montre que les limites ne sont que d'une utilité très réduite du fait qu'elles constituent la barrière au-dessus de laquelle on entre dans la zone des expositions interdites. Par contre l'avenir est pour une bonne pratique de la protection de recourir à un usage rationnel des contraintes pour l'application du principe essentiel d'optimisation et des niveaux pour guider les actions entreprises dans les cas où une souplesse s'avère nécessaire.

CONTRAINTES GÉNÉRALITÉS

Dans le domaine relatif aux pratiques qui sont maîtrisables le principe d'optimisation de la protection constitue le fondement essentiel. La possibilité d'encadrer les solutions optimales par un système de contraintes judicieusement établies est souhaitable. Ceci peut concerner des situations normales avec des expositions habituelles ou des situations accidentelles éventuelles avec des expositions potentielles. Aux premières correspondent des contraintes de dose, aux secondes des contraintes de risque.

L'établissement de valeurs appropriées pour les contraintes relève d'une méthodologie multidimensionnelle. Celle-ci doit tenir compte de considérations sanitaires, techniques, économiques et sociales. Deux approches sont possibles ; l'une par voie d'optimisation, l'autre par voie statistique. Lorsque l'on procède à l'inventaire des solutions de protection on aboutit à une gamme de valeurs dont l'enveloppe supérieure tend vers la contrainte correspondante. De même lorsque l'on analyse les résultats statistiques des expositions liées à une opération, l'ensemble obtenu peut être cerné par une enveloppe supérieure qui peut correspondre à la contrainte correspondante.

La fixation des contraintes de dose ou de risque relève de responsabilités différentes selon qu'elles s'appliquent de façon plus générale ou plus particulière. Schématiquement on peut admettre que c'est aux autorités compétentes de fixer les contraintes relatives à des catégories de sources. Par contre les contraintes concernant une seule source où des installations même complexes sont spécifiques et peuvent dans beaucoup de cas relever du management. Cette répartition des rôles respectifs des managements et des autorités devrait responsabiliser les premiers en leur permettant de proposer les contraintes relatives à leurs installations et confirmer le contrôle exercé par les autorités.

Les modes d'expression des contraintes varient selon leur application, bien qu'elles soient toujours liées aux sources. Dans certains cas d'exposition il s'agit de contraintes de dose et s'expriment en Sv. Dans d'autres cas de pollution radioactive il s'agit de contrainte d'activité et elles sont données en Bq. Enfin pour les expositions potentielles liées à d'éventuels accidents, elles ne peuvent concerner que des risques et s'exprimer généralement en termes de détriment.

Dans la pratique de la radioprotection, les limites pour les travailleurs et le public sont très générales et peu nombreuses. Par contre les contraintes sont nécessairement nombreuses et variées adaptées aux cas particuliers liés aux différentes sources. Certaines peuvent être plus rigides portant sur une exposition annuelle, d'autres plus souples portant sur des périodes plus longues (5 ans par exemple), d'autres enfin plus adaptées à des circonstances, liées par exemple aux conditions météorologiques ou hydrographiques.

EXEMPLES

Pour mieux comprendre l'intérêt et l'application du concept de contrainte il convient de donner un certain nombre d'exemples à titre purement indicatif. Trois domaines méritent d'être abordés : l'exposition professionnelle, l'exposition du public, l'exposition potentielle.

EXPOSITION PROFESSIONNELLE

Un exemple caractéristique d'exposition professionnelle peut être fourni par l'utilisation des rayonnements en radiologie médicale : radiodiagnostic, radiothérapie et médecine nucléaire. Rappelons que les limites de dose individuelles d'après la CIPR 60

sont de 100 mSv/5 ans et 50 mSv/1 an. Pour le radiodiagnostic on peut choisir deux cas. Le premier concerne les examens radiologiques banaux tels que les radiographies pulmonaires, osseuses, rénales, etc... ; les installations sont telles qu'une contrainte de dose individuelle de 10 mSv an⁻¹ paraît convenable. Le deuxième est relatif à la radiologie d'intervention per-opératoire ; les conditions de travail sont particulièrement délicates et une contrainte de 20 à 50 mSv an⁻¹ paraît adaptée sur une période de 5 ans. Pour la radiothérapie on peut également envisager deux exemples. En radiothérapie externe par source de Co60 ou par accélérateur, les installations permettent d'éviter pratiquement toute exposition du personnel ; une contrainte de 5 mSv an⁻¹ paraît convenable. En radiothérapie par source scellée introduite dans l'organisme, les conditions sont nettement moins favorables et une contrainte de 10 à 20 mSv an⁻¹ semble adaptée.

Pour la médecine nucléaire il convient de distinguer entre les applications diagnostiques et les utilisations thérapeutiques. Dans le premier cas, compte tenu de la nature et de l'activité des substances radioactives utilisées une contrainte de 5 mSv an⁻¹ ne devrait pas poser problème. Dans le deuxième cas, du fait des activités importantes nécessaires au traitement, des contraintes comprises entre 10 et 20 mSv an⁻¹ paraissent raisonnables.

EXPOSITION GÉNÉRALE DU PUBLIC

Il semble qu'un bon exemple d'exposition générale du public soit celui des rejets radioactifs à partir d'installations diverses. Rappelons que les limites de dose individuelle pour les membres du public recommandées dans la CIPR 60 sont de 1 mSv an⁻¹, avec dans des circonstances particulières 5 mSv/5ans.

Les rejets atmosphériques des réacteurs nucléaires fournissent un exemple intéressant de contraintes relativement strictes : dans le cas d'une centrale comportant 2 réacteurs (PWR) de 1300 MWe, le rejet autorisé annuellement est de 1650 TBq pour les gaz rares et 55 GBq pour les halogènes et aérosols, correspondant à une exposition du groupe critique de l'ordre de 20 µSv an⁻¹.

Les rejets radioactifs en milieu aquatique sont très divers selon qu'il s'agit de grosses installations de retraitement de combustible, de réacteurs nucléaires et d'utilisations de sources non scellées en médecine nucléaire. Les installations de retraitement impliquent des rejets importants et de ce fait sont implantées sur de très grands fleuves ou en bord de mer dans des sites favorables. Dans le cas de l'usine de retraitement de la Hague une contrainte de 1700 TBq a été fixée pour le rejet annuel du mélange de radionucléides émetteurs βγ (hors tritium), qui contribue de façon majoritaire à l'exposition : celle-ci est de l'ordre de 15 µSv an⁻¹. Les réacteurs nucléaires ont des rejets radioactifs liquides beaucoup plus faibles, mais sont implantés sur des fleuves plus petits et à débit souvent irrégulier ; il en résulte que la contrainte annuelle de 1,1 TBq an⁻¹ (dans le cas de la même centrale ayant 2 réacteurs PWR de 1300 MWe pour le

mélange des radionucléides émetteurs $\beta\gamma$, hors tritium paraît satisfaisante, avec toutefois une préférence pour l'expression de cette contrainte sur une période de 5 ans. L'utilisation des sources non scellées en médecine nucléaire devrait pouvoir se faire sans pratiquement de rejets radioactifs et par suite des contraintes très sévères devraient pouvoir être imposées.

EXPOSITION POTENTIELLE LIEE A UN ACCIDENT EVENTUEL

On entre ici dans un domaine difficile car les conditions varient considérablement entre les domaines nucléaire et radiologique. La sûreté nucléaire a fait l'objet d'études approfondies et est gérée de façon rigoureuse. On ne peut malheureusement pas en dire autant de la sûreté radiologique concernant les utilisations des rayonnements dans l'industrie, la recherche ou la médecine. Par ailleurs, l'expérience et les statistiques montrent que la fréquence des accidents dans le domaine radiologique est grande alors que les conséquences sont relativement réduites à quelques victimes, bien que dans certains cas un grand nombre de personnes aient pu être atteintes (Goïana). Dans le domaine nucléaire par contre une gamme très étendue de scénarios est possible allant de dysfonctionnements mineurs à des accidents majeurs (Tchernobyl) mais dont la fréquence est extrêmement faible. Il résulte de toute cette complexité que la fixation de contraintes de risque pour les expositions potentielles est particulièrement délicate. Elle apparaît comme raisonnablement valable pour les installations radiologiques et pourrait être envisagée dans une fourchette de 10^{-4} à 10^{-5} .

Par contre pour les accidents nucléaires majeurs à très faible probabilité d'occurrence et à conséquences considérables, il apparaît encore actuellement difficile de rationaliser le choix de valeurs appropriées pour des contraintes de risque.

NIVEAUX GENERALITES

D'une façon très générale la CIPR 60 propose des recommandations plus strictes concernant les limites de dose individuelle et introduit la notion de contrainte comme borne supérieure des processus d'optimisation. Mais elle insiste aussi sur la nécessité d'une souplesse efficace dans la pratique courante de la protection radiologique. Cette souplesse ne doit pas être comprise dans le sens d'un certain laxisme mais au contraire comme traduisant une plus grande rigueur dans la prise en compte des paramètres en jeu. Il faut reconnaître en outre que la CIPR apporte une clarification essentielle entre les situations où le contrôle des pratiques est possible et les situations de facto où seule l'intervention peut apporter une réduction des expositions. Dans le premier cas on peut appliquer le principe de limitation au moyen de limites, de contraintes ou de niveaux. Dans le dernier cas ni les limites, ni les contraintes ne peuvent et ne doivent être utilisées, seuls les niveaux doivent être appliqués. Mais les principes de justification et d'optimisation restent valables pour mener à bien la protection radiologique.

Les niveaux sont des guides qui ne présentent pas la rigidité des limites, ni le respect des contraintes, mais au contraire permettent dans un grand nombre de cas une souplesse indispensable à une protection rationnelle. Souvent les niveaux envisagés apparaissent comme des gammes bornées par des valeurs inférieures et supérieures, afin de faciliter leur prise en considération pour l'aide à la décision. La méthodologie qui préside à l'établissement des niveaux est, comme pour les contraintes, multidimensionnelle. Les paramètres sanitaires, techniques, économiques et sociaux doivent être impliqués dans une fixation rationnelle. Par ailleurs, il peut être utile de tester la validité des choix ainsi faits, par des comparaisons avec les données statistiques de l'irradiation naturelle notamment. En pratique une très grande variété de niveaux peut être utilisée, dont nous retiendrons ici trois types essentiels relatifs à l'application de la réglementation, aux investigations et aux interventions en protection radiologique.

EXEMPLES

Pour illustrer les généralités précédentes nous choisirons des exemples dans les domaines de l'application, de l'investigation et de l'intervention. Le premier est relatif à l'application ou non du système de protection. Le second concerne les études à mener ou les surveillances à exercer pour déceler les sphères d'intérêt pour la protection. Le troisième se rapporte aux actions à entreprendre pour faire face à des situations où l'on souhaite réduire les expositions existantes ou engagées.

APPLICATION

Il s'agit de l'application du système de protection. Ainsi un excellent exemple de niveau d'application général est fourni par les valeurs recommandées du Codex Alimentarius (Organisation Mondiale de la Santé et Organisation pour l'Alimentation et l'Agriculture) concernant la libre commercialisation des denrées alimentaires contaminées après un accident. Des niveaux d'application particuliers portent sur les activités au-dessous desquelles on n'est pas tenu de faire une déclaration ainsi que celles au-dessous desquelles on n'est pas tenu de demander une autorisation préalable.

INVESTIGATION

L'investigation consiste à fixer les niveaux au-dessus desquels les résultats sont tels qu'une attention doit être portée aux problèmes posés à la protection radiologique. Un exemple intéressant est fourni par l'irradiation naturelle. La CIPR 60 demande que l'on prenne en compte dans certains cas l'irradiation naturelle des membres du public ou des travailleurs au cours de leur travail. Des niveaux d'investigation sont à établir au-dessus desquels on considère si l'on doit ou non envisager des mesures de

protection. Ainsi pour les maisons existantes un niveau d'investigation de 200 Bq/m³ en Rn est le point de départ des études statistiques à effectuer. Pour les locaux de travail, notamment dans les mines en général, des niveaux d'investigation devront être fixés afin de sélectionner les conditions de travail qui peuvent poser problème.

INTERVENTION

Le domaine par excellence des niveaux d'intervention concerne les accidents radiologiques ou nucléaires. En général, vu la variété des scénarios possibles, des niveaux sont fixés, dans une gamme assez large de valeurs comprises entre un niveau inférieur au-dessous duquel l'intervention est improbable et un niveau supérieur au-dessus duquel elle est presque certaine. De tels couples de niveaux doivent être établis pour les différentes interventions envisagées : confinement, évacuation, interdiction de consommation alimentaire. De même des niveaux peuvent être fixés pour limiter l'exposition des membres des équipes de secours intervenant en cas d'accident radiologique ou nucléaire.

CONCLUSION

Les généralités et les exemples précédents sont relatifs aux contraintes de dose, d'activité et de risque, ainsi qu'aux niveaux d'application, d'investigation et d'intervention. Ils montrent la voie à la fois souple et efficace offerte par les nouvelles recommandations de la CIPR 60.

Les limites de dose individuelle ne sont que d'un intérêt réduit pour une bonne protection radiologique, vu leur très grande généralité. Par contre, les contraintes apparaissent comme des moyens parfaitement adaptés à la grande variété des sources de rayonnements. De même les niveaux peuvent en tant que guides souples canaliser les décisions vers les solutions les meilleures.

Ce sont certainement deux modalités de normes de protection radiologique qui présentent pour l'avenir le plus grand intérêt.

C.E.A. WORKERS: RADIOLOGICAL AND STATISTICAL STUDIES

The radiological survey of the CEA workers is briefly explained. A preliminary study on the characteristics, the dosimetry and the mortality is presented on a subgroup of 17337 workers. The results of this study indicate the poor impact of the neutronic irradiation, the distribution of doses in function of the worker's attendance. The mortality is compared between three groups. A first group of workers having cumulated a dose less than 10 mSv, a second group having cumulated a dose between 10 and 50 mSv, and a third group having cumulated a dose greater than 50 mSv.

1. INTRODUCTION

L'exposition aux rayonnements ionisants des travailleurs du CEA est mesurée grâce au port d'un dosimètre individuel comptabilisant les différentes composantes de l'irradiation externe β , X, γ , neutrons thermiques et rapides. Jusqu'en 1984, l'attribution de ce film fut mensuelle pour tous les agents du CEA, depuis cette date le port du dosimètre mensuel est limité aux travailleurs susceptibles d'être exposés aux rayonnements ionisants, les autres agents (ceux exerçant essentiellement des fonctions administratives) ont une surveillance dosimétrique trimestrielle. Pour les agents exposés aux neutrons, la dose liée due aux neutrons épithermiques est mesurée depuis plusieurs années. L'irradiation liée aux émetteurs α est déterminée chez les mineurs d'uranium grâce à des dosimètres individuels, mesurant depuis 1982 l'énergie α potentielle des descendants du radon. Durant la période antérieure, cette exposition a été calculée à partir de nombreuses mesures d'ambiance radon effectuées dans les mines, en tenant compte du facteur d'équilibre entre le radon et ses descendants.

Certains travailleurs du CEA ont pu être soumis, selon les postes occupés, à une surveillance systématique d'une éventuelle contamination interne. Des mesures par anthropogamamétrie et à partir de l'analyse des urines de 24 heures permettent de déterminer l'existence d'une contamination par les radionucléides qu'ils manipulent. Ces mesures sont effectuées à des intervalles réguliers. La surveillance de la contamination interne est organisée par le médecin du travail qui en gère les résultats. Après chaque incident, le même processus de contrôle de la contamination

interne est déclenché. C'est donc le dossier médical de chaque agent qui contient les résultats des contaminations internes. L'irradiation externe annuelle de chaque agent du CEA est stockée sur des supports magnétiques depuis 1953. La connaissance de l'exposition totale d'un travailleur est un facteur important du suivi sanitaire et constitue un élément indispensable des études épidémiologiques. D'autre part, un accès à ces informations est nécessaire, si l'administration ou l'intéressé en font la demande.

2. PREMIERE ETUDE STATISTIQUE

2.1. But de l'étude.

Le but de l'étude est la description de l'ensemble du personnel CEA vis à vis de critères généraux, tels le cumul des doses reçues, l'âge, la mortalité.

2.2. L'état de la base de données exploitée.

Les sources d'information pour cette première étude statistique ont concerné 17337 agents CEA, soit 20% du personnel ayant travaillé au CEA depuis sa création. Ce sont les agents ayant reçu une dose cumulée non nulle au cours de leur carrière professionnelle. Pour ces agents, on a disposé de l'ensemble des données dosimétriques et administratives disponibles entre 1967 et 1985.

2.3 Résultats de l'étude.

Cette première étude a permis de définir les caractéristiques dosimétriques de la population CEA, et de définir les études qu'il est nécessaire d'entreprendre ultérieurement. Les caractéristiques suivantes ont été relevées.

2.3.1 Une population essentiellement masculine.

La population CEA ayant subi une irradiation non nulle est essentiellement masculine ; les études ultérieures ne pourront porter que sur une population masculine.

2.3.2 Pas de différence radiologique entre actifs et retraités.

Les études de dépendance n'ont pas montré d'hétérogénéité dosimétrique entre les différents groupes étudiés, c'est à dire les agents actifs, les agents retraités et les agents décédés avant leur départ du CEA. La seule dépendance notée l'a été par rapport au site d'affectation de l'agent.

2.3.3 Absence de mobilité des agents au cours de leur carrière.

85% des agents pris en compte n'ont pas changé d'établissement, c'est à dire de lieu de travail, au cours de leur carrière professionnelle.

2.3.4 Répartition des doses cumulées.

La dispersion des doses a été étudiée selon deux critères : le temps de présence au C.E.A., la nature des irradiations. Les

résultats de cette analyse sont schématisés par le diagramme en barres tridimensionnel ci-dessous. Ce diagramme indique le pourcentage des doses cumulées par les travailleurs :

- en utilisant quatre classes de valeurs de dose (0 à 20 mSv, 20 à 40 mSv, 40 à 60 mSv, plus de 60 mSv).
- en fonction du temps de présence des agents au C.E.A.
- en fonction du type de rayonnement ionisant.

2.3.4.1. Le temps de présence.

Dans cette première étude, on a simplement pris deux classes : les agents ayant moins de 10 ans de présence au C.E.A. et ceux ayant plus de 10 ans de présence au C.E.A. L'observation du diagramme en barres montre que la distribution des doses est indépendante de cette différenciation.

2.3.4.2. La nature des rayonnements.

Dans cette étude où on a pris en compte les irradiations X, γ et neutronique, on a choisi d'étudier l'impact des neutrons, en étudiant la dispersion des doses X+ γ +neutron comparée à celle des doses X+ γ . L'impact des doses neutron est très faible car associé à un effectif limité.

2.3.5. Etude de la mortalité.

Cette étude n'est en aucun cas une étude épidémiologique, mais une observation statistique. L'étude de la mortalité des travailleurs du C.E.A. n'a été effectuée que sur la tranche d'âge 25 à 60 ans. En effet lors de la réalisation de l'étude, il n'a pas été possible de faire le bilan des décès dans la population des retraités et en conséquence il n'a pas été possible de comparer les résultats de la mortalité des agents du C.E.A. avec la mortalité nationale. Par contre la mortalité a été étudiée en fonction des tranches d'âge et des doses reçues. On a donc comparé trois groupes d'agents, ceux ayant reçu une dose cumulée inférieure à 10 mSv, ceux ayant reçu une dose cumulée comprise entre 10 et 50 mSv et ceux ayant reçu une dose cumulée supérieure à 50 mSv. On ne note pas de différence significative entre les trois groupes de 25 à 40 ans. Le pourcentage de décès est plus élevé dans le groupe des doses supérieures à 50 mSv pour les agents âgés de 40 à 55 ans. Le pourcentage de décès augmente ensuite de façon significative après 55 ans pour les trois groupes étudiés. On note cependant une plus forte mortalité du groupe des doses 10-50 mSv. Cependant, la différence de mortalité ne peut pas être associée aux doses reçues car bien d'autres critères devraient être alors pris en compte (notamment les causes de décès).

**Radiological protection in medicine -
current and prospective
work of the ICRP**

J. Liniecki
Chairman, ICRP Committee 3
Medical University of Lodz, Poland

Abstract

Current and planned activity of ICRP in the field of radiological protection in medicine includes work on recommendations aimed at: optimized reduction of diagnostic X ray doses to patients, reduction of probability of potential exposure in medicine, protection of humans in biomedical research, and updating dosimetric information related to radiopharmaceuticals.

The paper provides background information for selection of these subjects and approximate time scheme for completion of the respective recommendations.

Introduction

The ICRP had been called to life in 1928 in Stockholm, by the Second International Congress of Radiology. This organisation has had always a medical character, even if prominent physicists and engineers played a determining role in the progress of radiological technology, health physics and radiation protection.

After World war II, the scope of ICRP activity has enlarged by including problems related to the protection in the nuclear field. However, special relationships with the International Society of Radiology still exists. This relationships is based not only on tradition. It reflects basic observations that population of medical workers exposed to ionizing radiations is very large and that exposure of the public to man-made radiation is dominated by the component resulting from radiological diagnostic activity. In the developed countries all other components, taken together, are lower at least by an order of magnitude compared with ab. = 1 mSv E per annum from the medical sources [U2].

It would, perhaps, be reasonable at this stage to analyse briefly what exposure of the public to the effective dose of this order could mean in terms of biological effects. For brevity let's consider possible magnitude of the expected extra cancer mortality. If one takes the ICRP nominal cancer mortality coefficient as reflection of reality, then at face value, the number of possible cancer deaths resulting from repeated - year after year - mean population exposure (Poland) to = 0.8 mSv per annum (Table 1) may approach 2 % of the actual cancer mortality rate. In absolute numbers this could be ab. 1500 cases per year in a country of ≈ 38 mln people.

Table I.

Possible cancer mortality rate resulting from exposure
of the public to diagnostic X-rays
(Poland, Staniszevska, 1986 [S1]).

Annual mean per caput effective dose:
0.8 mSv
Nominal cancer mortality coefficient (ICRP):
 $5 \cdot 10^{-2} \text{ Sv}^{-1}$
Possible induced cancer mortality rate per year:
 $\approx 40 \cdot 10^{-6} \text{ a}^{-1}$
Actual over-all cancer mortality rate [Z1]:
 $1800 - 1900 \cdot 10^{-6} \text{ a}^{-1}$

The view is sometimes expressed that such an estimate could be biased by neglecting following factors:

1. Difference between age distribution of patients and that of general population for which the risk coefficients have been specified. When comparisons were made, however (Staniszewska) [S1], of the above estimate with that, calculated using: 1/ real age and sex distribution of patients undergoing radiologic examinations in Poland; 2/ size of respective age and sex groups; 3/ age- and sex-specific cancer mortality coefficients for radiation-induced tumours proposed by BEIR V [N1], the difference between the latter estimate and the simple over-all assessment did not exceed + 20 % . This factor does not appear, therefore, to essentially modify the order of risk estimate.

2. The fact that a fraction of radiological examinations is performed in terminally ill patients in whom the risk cannot be expressed [R1]. There are very few credible estimates of the size of this fraction. In some parts of the U.K. the value did not exceed 5 % [R1] and there is no real indication that X-ray doses in the terminally ill are substantially higher than those in the rest of the population.

Therefore, total correction of the primary overall risk estimate appears negligible. Of course, an avoidable fraction of the collective dose (and therefore of the risk) is substantially lower. For instance, detailed considerations and estimates in the U.K. [N2] led the authors to conclude that the fraction amounts to ab. \approx 45 % of the total collective dose from medical sources (7500 out of 17000 manSv per year). In those countries in which the contribution from medical sources to the collective man made dose is higher than in the U.K. (\approx 0.4 mSva⁻¹) the avoidable fraction could also be greater.

In any case, the estimated order of extra risk due to diagnostic medical irradiation, even if on all accounts the health benefits by far exceed the concomitant risks justifies, in opinion of the Commission, radical efforts to reduce unnecessary exposure. This is especially true because this can be done without any sacrifice of the diagnostic benefit (image quality).

With respect to this basic opinion there is no essential difference between Publication 60 [I2] and Publ. 26 [I1] (Recommendations of 1977). However, Publ.26 directed the postulate primarily to medical practitioners (mostly radiologists and nuclear medicine physicians). Accordingly, the series of following recommendations (ICRP, Publ.34, 44, 52, 53, 57) [I3 - I7] had been addressed mainly - if not exclusively - to physicians of these professions, to hospital managements and health physicists.

The Commission took a somewhat different view in Publ. 60 [I2] (para 180). The text reads: "....." As a result, there is considerable scope for dose reductions in diagnostic radiology. Simple, low cost, measures are available for reducing doses without loss of diagnostic information, but the extent to which these measures are used varies widely. Doses from similar investigations cover ranges of as much as two orders of magnitude. Consideration should be given to the use of dose constraints, or investigation levels, selected by the appropriate professional or regulatory agency, for application in some common diagnostic procedures. They should be applied with flexibility to allow higher doses where indicated by sound clinical judgement."

This change in approach results from the conviction that appeals addressed to individual radiologists had not been sufficiently effective (at least on a large scale). This has been borne out by a fundamental, regular observation that frequency distribution of doses (entrance skin kerma or exposure) for a given diagnostic procedure, within a country or region, displayed a typical shape, exemplified in fig. 1 [U1]. When such distributions had been corrected [L1] for variation in patients body size, a variation in dose was less pronounced but that which persisted spanned still an order of magnitude.

Fig.1. Frequency distribution of exposure at skin entrance for selected examinations in the USA (mR); arrow refers to mean exposure value (from [U1]).

This has been a regular finding in numerous surveys and, of course, such wide distributions cannot be accepted as justified, and much more so, as being consistent with requirement of the optimisation of protection. If optimal value of the dose lies somewhere in the shaded brackets (fig.2), the values above may be taken as excessive, and below as most likely insufficient for obtaining a good image. In other words, current situation results from a common lack of a functioning protection system, securing the feedback: magnitude of the dose → correcting action.

Fig.2. Idealised distribution of effective dose per examination
 --- Upper constraint - 75 percentile (?)
 ... Lower constraint - a dose too low for a satisfactory image.
 Arrow - mean dose.

Therefore, the Commission believes that constraints, or investigation levels, applied to diagnostic procedures have become necessary.

A. Task Group on Optimisation of Protection in Diagnostic Radiology

To look carefully into the subject and the experience gained so far in some countries and communities (USA, countries of the EEC) the Commission has made a decision to call into life in a short time, perhaps in 1992, a Main Commission - Task Group on "Image, Dose and Optimisation in Medical Radiology".

This group will collaborate closely with Committee 3. The principle objectives of this action would be:

1. To collect and analyse the experience obtained so far in those countries where such action has been already started on a wide scale, assessing and assuring image quality, combined with dose assessment in selected radiological procedures.

2. To work out and recommend measurement - and analytical procedures for dose-frequency distribution studies and to postulate criteria upon which ranges for exposure could be defined that may be accepted as justified at the current state of practice. (Below and above these some intervention would be warranted).

3. To compare the current state of practice with the available state of radiological art and technique. The latter should reflect nominal (reference) levels of dose that could be taken as representing at present the optimum range. Reaching an optimised level (consistent with the attainable current radiological technology), should be final objective of the exercise.

4. To reach this goal expenditures, sometimes quite high, are of course necessary. On the other hand, several simple modifications of the technique (both material and procedural) are possible which require basically very little or no capital input (stricter referral criteria, minimisation of a number of radiograms per examination, selection of appropriate projection, minimisation of fluoroscopy time, due collimation of the beam, shielding of organs, selection of optimal film/screen combination, optimal processing of the film etc, etc) [N2, I3]. With limited resources for health care in most countries it appears essential to optimise protection of the patient, to specify priorities for action and to obtain the best financial input-dose-reduction ratio. The Task Group shall carefully study both available methodology (generic and formalized optimisation) and will, hopefully, recommend adequate procedures for respective long-term action by professional societies, authorities (policy makers), hospital administrators and chiefs of radiology departments.

At this stage some remarks are warranted regarding selection of a nominal cost of a unit of collective dose for purposes of the optimisation of protection in the medical field. First, the cost of saving human life in various fields of medicine [N2] is lower than the up to now assumed cost of one manSv in other fields of radiation protection ($\approx 2 \times 10^4$ dollars). Therefore, selecting the latter, or even a higher value would, perhaps unduly, shift in most countries the resources in health protection into the less effective direction. Moreover, from the total cost of detriment per unit dose in medicine one should perhaps subtract the value of benefits accrued by the patients themselves (improved diagnosis, therefore more adequate and sometimes cheaper treatment, etc, etc). These questions, and some others, e.g. is it realistic to recommend an α value independent of expenditures for health protection per year per caput in a country, should be addressed by the Task Group.

5. The Task Group, Committee 3 and the Main Commission shall analyse and decide to what extent the question of referral criteria and the connected efficacy of individual radiological procedures shall be dealt with. In my opinion it is a difficult subject. There is, however, an obvious room for reduction of the frequency of practices and procedures of very low efficacy, provided the recommendations will avoid schematic treatment of the subject.

Elimination of a large fraction of retakes is also feasible.

6. There are specific aspects of patients protection in paediatrics, cardiology, interventional radiology, mass screening and dental radiology. In the prospective Task Groups' recommendations they should be treated in form of annexes and addressed to professionals directly concerned and active in these fields.

I believe that the task, just presented, is strategically the most basic and important among those related to the protection in medicine, being undertaken currently by Committee 3 and the Main Commission.

If implementation of prospective recommendations would result in substantial reduction of the total collective dose and within this of the avoidable fraction from medical sources by a factor = 3 or 4 (this seems quite feasible), the merit shall justify the efforts.

B. The project "Potential Exposures in Medicine".

Potential exposure has been defined in Publ. 60 as (para 127): "Not all exposures occur as forecast. There may be accidental departures from the planned operating procedures, or equipment may fail..... Such events can be foreseen and their probability of occurrence estimated, but they cannot be predicted in detail."

There is obviously a room for such exposures (patients, personnel) in medicine. There are well known, dramatic examples of this kind (related mostly to therapy): therapeutical accelerator accidents in Texas, U.S. (1986) and Zaragoza, Spain (1990), a series of accidents with ⁶⁰Co therapy units; misadministrations of therapeutic instead of diagnostic activities in nuclear medicine, etc.

Exhaustive statistics of such incidents or accidents, involving patients and sometimes also medical personnel, are not widely available. The respective working group of Committee 3 (to become most likely a task group), will collect available data on overexposures and mis-administrations (doses in therapy, radiopharmaceuticals), on dominant sources of the failures, and will try to develop recommendations aiming at reduction of the probability of their occurrence to the lowest reasonably attainable (i.e. optimised) level. The recommendations should have both technical and systemic character. The work has just started and will continue for few years.

C. Protection of humans in biomedical research.

The subject has been treated in the past both by the Commission and by other organisations (e.g. World Health Organisation)[W1]. General principles of the Helsinki accord on the subject - as amended in Tokyo in 1975 - [W2], form still an acceptable backbone of the system. Situation is relatively straight-forward in those fields where exposure to various noxae, is reflected by a threshold type dose-response relationship. Ionizing radiation is exceptional in this context as the probability of detrimental stochastic effects decreases with reduction of the dose but is not expected to reach zero level unless the dose does the same.

Assessment of the detriment vs. dose has increased in Publ. 60 by a factor 3-4 relative to that which served as basis for previous WHO documents, pronounced age effects have been documented, and new effects on human conceptus discovered. Ethical committees and other interested bodies are in obvious need for guidance in this field. Committee 3 will prepare a new document providing respective recommendations related to the diagnostic application of X rays and radiopharmaceuticals, to experimental procedures in radiotherapy and biological research, with and without actual or potential medical benefit to the participants. The Committee hopes to be able to issue the document not later than 1993, possibly still in 1992.

D. Updating dosimetric information related to radiopharmaceuticals.

A common Task Group of Committee 3 and Committee 2 works on updating information on doses incurred from radiopharmaceuticals. The subject has received extensive treatment in Publ.53 - "Doses from Radiopharmaceuticals", published in 1987 [I6]. There are, however, one or two new substances of this

kind being introduced into medical practice every year, and substantial proportion of them is going to stay with us for long time. For instance, since adoption of Publ.53 three new substances, utilizing ^{99m}Tc as the radioactive label, have been introduced into a wide use:

1/ ^{99m}Tc -MAG₃ (mercaptoacetyltriglycine) for renal functional diagnostics, and ^{99m}Tc -HmPAO (CERETEC, heksametylopropylencamineoxine) mainly for studies of the regional cerebral blood flow; 2/ ^{99m}Tc -hexakis MIBI (2-metoxiisobuthyl isonitrile) for heart perfusion studies. The latter two are administered at particularly high activities of ^{99m}Tc (500-1000 MBq) and the resulting doses need to be known. There are also other substances, like labelled fatty acids, ^{68}Ga -EDTA, labelled antibodies etc, of sufficient clinical interest to be treated similarly.

For several of these substances respective kinetic (and/or metabolic) models have been developed and organ doses calculated by the Task Group (they will be published in late 1992 or early 1993). In addition, values of E for those radiopharmaceuticals that had been included in Publ.53 will be included in the updating document, recalculated according to the currently recommended procedure, and with organ weighting factors, specified in Publ. 60. Some kinetic models will also be reviewed acc. to the fresh data (e.g. ^{201}Tl). It is perhaps interesting to note that new E values are generally lower than the old H_e , except for those radiopharmaceuticals that irradiate predominantly the thyroid gland [J10] (fig. 3); the latter E values have increased mostly due to the respective change of W_T . For radiopharmaceuticals included in Publ.53 the average value of E per unit administered activity is numerically lower by $\approx 12\%$ than the mean H_e . We hope this information will be useful for the professional community of nuclear medicine in their daily practice, and for optimisation of patients protection (selection of substances, selection of optimal administered activity).

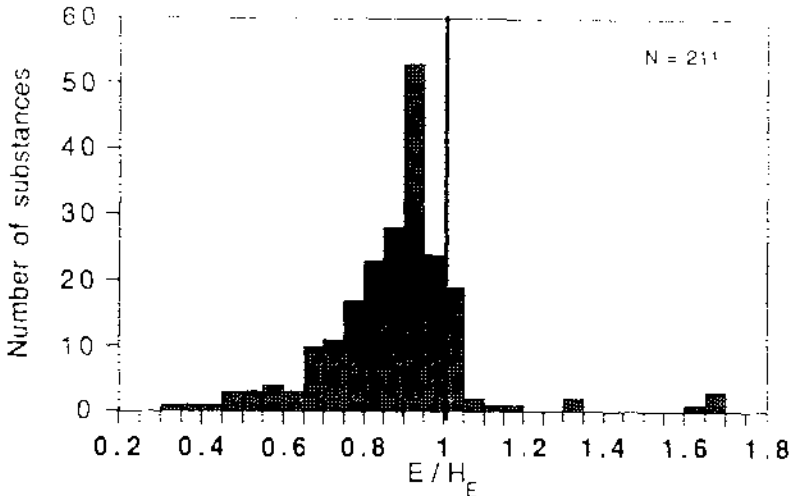

Fig.3. Distribution of the quotient effective dose (E): effective dose equivalent (H_e) using the new (ICRP 60) and old (ICRP 26) weighting factors, respectively. All substances found in ICRP 53 are included [J1].

I believe I have given you a rather detailed picture of Main Commissions' and Committee 3 activity aimed at radiological protection in medicine.

FUTURE WORK OF ICRP COMMITTEE 2

by

Charles B. Meinhold

Abstract: ICRP Committee 2 has an exciting program in virtually all areas of importance to the development of secondary limits. Currently active task groups are working on 1) a new human respiratory tract model, 2) new data on Reference Man, 3) additional elements for age dependent dose to members of the public, and 4) and calculations for internally deposited radionuclides. A new activity is underway in collaboration with ICRU on sorting out protection quantities and metrological quantities for external exposures. All these activities have an important bearing on the next major effort, the revision of ICRP Publication 30.

The program chairman requested that we (the ICRP committee chairmen) speak to you about the future work of our respective committees. He specifically ask that we not address historical issues, meaning, I believe, the development of ICRP Publications 60 and 61.

One might expect that the committee members might feel that the work at this time is somewhat anti-climactic. You may rest assured that this is not the case. Committee 2 has an exciting program of work before it. Before describing this effort, I would like to list the other members of Committee 2: Dr. William J. Bair, Dr. A. Bouville, Prof. Dr. Chen Xing-an, Dr. Gunter Drexler, Dr. Keith F. Eckerman, Prof. Dr. Alexander Kaul, Professor Dr. Ilya A. Likhtarev, Dr. Osamu Matsuoka, Dr. H. Metivier, Dr. N. Parmentier, Dr. Chester R. Richmond, Dr. J.W. Stather, Prof. Dr. David M. Taylor, and Prof. Ralph H. Thomas.

As many of you know, Committee 2 is charged with developing the basic documents which permit the derivation of secondary limits.

The most organized approach to outlining the present and future work of this Committee is to discuss the work of each task group in some detail.

The Task Group on the Human Respiratory Tract

The objective of this task group, under the chairmanship of Bill Bair, is to develop a comprehensive, scientifically justifiable model of the human respiratory tract for use in radiation protection. It would, therefore, provide the basis for the calculation of ALI's for inhaled materials as well as enable individual and population dose assessments. The task group has written a document presenting a clear and eloquent description of the anatomy, physiology, and morphometry of the human respiratory tract. The latest data on deposition in the respiratory tract highlights the work as does the review of the latest information on clearance from the lung by both particle transport and absorption to the blood.

The material is presented in a manner that allows straightforward computer calculations of dose per unit intake as a function of the age and sex of the individual and the chemical and physical characteristics of the pollutant. The task group will, however, provide recommended parameter values of the model for occupational and environmental exposure situations.

In the important case of radon daughter exposure, a problem has surfaced in trying to reconcile lung cancer risks implied by the calculated effective dose with lung cancers actually observed, i.e., it would appear from calculations on radon daughter exposure that the incidence of lung cancer seen in the population should be far greater than predicted from the epidemiological studies to date. Perhaps, the lung risk estimate is the culprit, or maybe an unreasonably high w_R value for alpha emitters is responsible for this somewhat awkward result. Whatever the reason, Bill Bair and his task group can be expected to resolve these issues and a new report on the Respiratory Tract Model should be available in early 1993.

The Task Group on Reference Man Data for use in the revision of Publication 30

The task group on Reference Man had intended to produce a scholarly work- a worthy descendant of ICRP Publication 23. The extraordinary amount of new material and the Commission's desire for completion of the work, coupled with less outside financial support than anticipated, however, resulted in the chairman of the original Reference Man Task Group, Chet Richmond, withdrawing.

At that point, the Commission asked Committee 2 to focus on the data required for the revision of Publication 30. As a result, the terms of reference of the task group have been modified under the chairmanship of Keith Eckerman with a specific mandate to prepare a report on those aspects of Reference Man required for the revision of Publication 30. It is now anticipated that six sections of the Reference Man draft will comprise the body of the new task group work. In fact, the members of the task group are authors of these texts. The topics to be included are:

1. Anatomical and Physiological Characterization of Reference Man - with an Appendix on non-western man.
2. The Skeleton.
3. The Respiratory Tract (to be produced by the Task Group on the Human Respiratory Tract).
4. Gastrointestinal Tract.
5. Values for Gastrointestinal Absorption.
6. Hematopoietic System.

With a little luck, the document or documents on the case may be published in early 1993 as well. There are those who would like to see a complete revision of Publication 23, but specific financial support for the work is required.

Task Group on Dose Calculations

A reorganization of this major activity is taking place. Until very recently, the Commission's calculations on internally deposited radionuclides were centered at the Oak Ridge National Laboratory with assistance from other calculational groups, particularly those at the NRPB in England and the BfS in Germany. This task group, again under Keith Eckerman's chairmanship, has now been enlarged to involve representatives of these laboratories as well as others. This expanded task group will be looking at the question of how the Commission reconciles slightly different methods of computation or if, in fact, such reconciliation is needed. The overall objective is to increase the cadre of individuals willing and able to assist the Commission in this work. For example, Committee 2 expects this task group to assist in the work of the Task Group on Age-Dependent Dosimetry, the revision of Publication 30, and advice on similar calculations by other Committees and task groups.

The Task Group on Age-Dependent Dose (Committed Effective Dose per Unit Intake)

This task group, chaired by Alex Kaul, enthusiastically took on this important and difficult task. As most of you realize, ICRP Publication 56, Age-Dependent Doses to Members of the Public from Intake of Radionuclides Part 1, presents the initial work of this task group. Dose per unit intake values for tritium, carbon, strontium, zirconium, niobium, ruthenium, iodine, cesium, cerium, plutonium, americium, and neptunium have been provided for the 3-month, 1-year, 5-year, 10-year, 15-year, and adult individual. Part 2, which addresses sulfur, cobalt, nickel, zinc, molybdenum, polonium, technetium, silver, tellurium, lead, barium, and radium will be in your hands during 1992. It was held up somewhat due to the decision that the new w_T s should be incorporated and that Part 2 should also contain revised values for the elements given in Part 1, incorporating the new tissue weighting factors. In addition, since the Committee has adopted the task group's new generic bone model for the alkaline earths and lead, the biokinetic model and dose data given for strontium in Part 1 will have to be revised.

Still, the work goes on. The task group members will now take a deep breath and begin again, this time the elements will be antimony, uranium, bismuth, thorium, and iron. In addition, once the new respiratory tract report is approved by the Commission, the task group will prepare a complete set of age-dependent calculations for the inhalation case.

A major activity underway within the task group is an attempt to provide guidance on the dose to the embryo or fetus due to chronic intake by the mother prior to conception, chronic intake post

conception, and acute intakes before or during and specifically at the midpoint of the pregnancy. The task group will also likely incorporate in Part 3 a discussion of uncertainties in the dose calculations.

Revision of ICRP Publication 30

This has been a major topic of discussion within Committee 2 for some time. Fortunately, the Task Group on Age-Dependent Dose to Members of the Public from Intakes of Radionuclides has been evaluating the most recent biokinetic information for a number of elements. A working party of the Committee chaired by David Taylor has been examining the data for those elements not included in the work of the Age-Dependent Task Group. In fact, the work of all the task groups listed above is essential to this revision. New reference man data, a new respiratory tract model, the generic bone model, and the work on dose calculations are all oriented to this task. Although a formal proposal for the conduct of the work on this revision has not been prepared, a number of preliminary decisions have been taken. For example, the following elements will not be included in the revision to Publication 30: lithium, boron, palladium, neodymium, terbium, dysprosium, holmium, erbium, thulium, ytterbium, lutetium, rhenium, francium, berkelium, einsteinium, fermium, and mendelevium (this will reduce the pressure to revise ICRP Publication 38, "Radionuclide Transformation.")

With regard to chemical form, normally only those compounds encountered in occupational situations will be considered. Chemical toxicity will be included with the radionuclide data when it is important. The bone model used by the Age-Dependent Task Group for the alkaline earth metals, with the possible extension to all bone seeking radionuclides, has been adopted. The inclusion of urinary bladder among the tissues explicitly assigned weighting factors has encouraged Committee 2 to formulate biokinetic models which will meet the needs of both dosimetry and bioassay. An interesting concept developing within the Committee is that committed effective dose per unit intake is a much more useful quantity than the ALI. The revision of ICRP Publication 30 will very likely focus the presentation on dose per unit intake and still provide ALIs based on 20 mSv per year as was done in ICRP Publication 61.

ICRP/ICRU Task Group on Providing Data for Use in Radiation Protection

This joint task group under the chairmanship of Ralph Thomas will provide the information to replace ICRP Publication 51. Its secondary mission is to ensure that there is close cooperation and consistency between the ICRP and the ICRU. From the prospective of the Committee 2 chairperson, the issue is quite clear: the ICRP deals with the radiation protection quantities and ICRU deals with the metrological quantities. For example, the Q-L relationship, w_R , w_T , and effective dose are ICRP concepts, whereas absorbed dose, ambient dose equivalent, and individual dose equivalent are ICRU concepts. Completion of the work specified in the terms of reference of the task group should allow the two commissions and the practitioners, as well,

to determine if the ICRU metrological quantities meet the needs of assessing exposure against the requirements of the ICRP dose-limiting recommendations. It would appear that the work denominated in the first two terms of reference will supply the information needed, i.e., provide conversion factors for fluence to effective dose calculations for a variety of radiations and energies for reference man, woman, 15-year, 5-year, three-month old children, and provide fluence to ambient dose equivalent, directional dose equivalent, individual dose equivalent penetrating, and individual dose superficial.

In summary, I would like to reiterate that the Committee has an exciting and important program before us and the Commission is fortunate in having such excellent and dedicated scientists on its committees and task groups.

The Department of Energy Tiger Teams; Analysis
of Findings and Plans for the Future

Paul L. Ziemer, Ph.D.
Assistant Secretary for
Environment, Safety and Health
U.S. Department of Energy
Washington, D.C.

Since mid-1989, the Department of Energy (DOE) has used "Tiger Teams" to provide independent oversight and assessments of the compliance and management of environment, safety, and health programs in DOE facilities. These assessments have provided the Secretary of Energy with not only the current compliance status of each facility together with the associated vulnerabilities, but also have identified root causes for noncompliance. By mid-1992, Tiger Team assessments will be completed for all major DOE facilities (production, research, and testing facilities) as well as a number of smaller or less complex sites.

An analysis of the findings from all assessments including root causes and trends, will be presented. Particular emphasis will be placed on the technical safety appraisals of the radiation protection programs and on related industrial hygiene, occupational safety, and environment compliance issues. The emerging role of "self-assessment" offices within DOE program offices, and the subsequent changing role of independent oversight through Tiger Team assessments will be discussed.

The Department of Energy Tiger Team Analysis:
Analysis of Findings and Plans for the Future

U.S. Department of Energy
Washington, D.C.

ABSTRACT

Since mid-1989, the Department of Energy (DOE) has used "Tiger Teams" to provide independent oversight and assessments of the compliance and management of environment, safety, and health programs in DOE facilities. These assessments have provided the Secretary of Energy with not only the current compliance status of each facility together with the associated vulnerabilities, but also have identified root causes for noncompliance. By mid-1992, Tiger Team assessments will be completed for all major DOE facilities (production, research, and testing facilities) as well as a number of smaller or less complex sites.

INTRODUCTION

Through Tiger Team assessments implemented by the Office of Environment, Safety and Health, the Department of Energy (DOE) has provided oversight of DOE's facilities and assurance of facility compliance with environment, safety, and health (ES&H) requirements throughout the DOE complex. Tiger Teams are typically composed of at least 30 well-trained, highly qualified professionals who spend approximately three to four weeks in preparation and followup activities, and approximately four to six weeks on site during an assessment. Tiger Team assessments have worked to determine the causes as well as the symptoms of compliance issues in order to help facilities initiate appropriate changes and interact sooner with regulators.

A trend analysis of the findings from the first sixteen assessments was published in May 1991¹. This paper provides a synopsis of the key findings found during those first sixteen assessments, including root causes and trends common to the facilities. The role of on-site self assessment is addressed in this paper, and the future role of the Tiger Team assessment program is also discussed.

By June 1992, thirty-five DOE facilities will have been assessed. A final synopsis covering these thirty-five Tiger Team assessments will be completed in late 1992.

ROOT CAUSES

The common underlying causes identified by the Tiger Teams

vary in degree, ranging from probable causal factors to root causes (i.e., the cause that, when removed or corrected, will eliminate the potential for recurrence of a similar problem or incident). An analysis of all root causes revealed the following three general root causes common to a majority of the assessments:

- o ES&H compliance is not emphasized as a primary goal. Complacency or lack of attention to safety and health issues exist because workers do not perceive this to be important. Other workers feel that ES&H compliance is incompatible with research or line position duties.
- o Monitoring programs, assessment controls, and corrective action implementation programs are insufficient. A number of the reports show that the facilities have not been able to develop and implement self-assessment plans/programs. Furthermore, facilities fail to identify existing ES&H problems.
- o Management is ineffective in assessing or enforcing compliance at the facilities. Management systems and controls should be reviewed and revised to include accountability, monitoring, feedback/reporting, and oversight performance to ensure implementation of required ES&H objectives. Lack of effective management at the facilities impedes ES&H programs.

Other common root causes identified by the Tiger Teams included failure to implement Federal, state, local and DOE policy; insufficient training (especially within the Safety and Health discipline); inadequate budgetary controls; and a need for technical staff.

TREND ANALYSIS

The trend analysis revealed weaknesses and deficiencies clustered in the following six key areas:

Management and Oversight of ES&H Activities. ES&H authority and responsibilities are not clearly defined or understood. Facilities tend to operate in a reactive mode. Comprehensive management systems have not been implemented (or have been implemented slowly). Adequate self-assessment programs are lacking. Operations and Area Offices provide insufficient direct oversight of day-to-day contractor activities. Conclusion: Review/revise management systems and controls to include accountability, monitoring, feedback/reporting, and performance oversight.

Conduct of Operations/Formality and Discipline. Lack of sufficient formality and discipline exists in ES&H management systems. Conditions and practices that clearly do not satisfy ES&H requirements are accepted at DOE facilities. Conclusion: The discipline and formality of DOE's management systems must be improved.

Communication and Implementation of ES&H Policy. Although improvement is evident, ES&H policy is not being communicated to all levels of DOE and contractor staff. Policies, goals, and objectives have not reflected a strong commitment to ES&H excellence. Conclusion: A consistent set of performance expectations and technical requirements must be communicated throughout the entire system. The DOE compliance policy must be effectively implemented through orders, guidance, and employee and contractor performance objectives.

Resources/Training. Difficulties exist in securing staff with appropriate qualifications and in obtaining security clearances in a timely manner. Conclusion: Identify/document staff resource requirements. Find ways to speed up recruitment process. Additionally, expand and improve Departmental training programs.

Occupational Safety and Health. The most important areas of noncompliance found during the Department of Labor's Occupational Safety and Health (OSHA) review of nine sites included construction activities, machine guarding, and electrical safety. DOE does not have programs in place that routinely identify (let alone prevent) noncompliance with OSHA requirements. Conclusion: Immediate attention needs to be focused on workplace safety and health. The lack of importance and attention assigned by management to OSHA compliance must change.

Technical Issues. Deficiencies in the following technical areas/programs were identified: Radiological Protection, Emergency Preparedness, Waste Management, Management of Inactive Waste Sites, and Environmental Monitoring.

SELF-ASSESSMENT PROGRAMS

As noted above, many of the DOE facilities lacked adequate programs to ensure that ES&H deficiencies were identified, reported, and corrected. In particular, facilities lacked adequate self-assessment programs, and had deficient systems for reporting and tracking ES&H programs and corrective actions. All line organizations were directed to implement comprehensive self-assessment programs to identify and characterize ES&H concerns relating to their operations. Ultimate responsibility was thus placed on program senior officials.

A comprehensive ES&H self-assessment program should cover all facilities, buildings, sites, and activities under the control of the line management organization. Such a program includes all applicable disciplines under environmental protection, safety and health, and management and organization. The self-assessment program is built upon existing programs and activities including those specifically required by DOE Orders. These programs/activities include functional and management appraisals of contractors by DOE line management as well as internal appraisals conducted by contractor or, in some cases, DOE operating-level staff. In addition, management performance within the DOE line organizations is assessed.

On-site activities are assessed for compliance with Federal, state, and local laws, regulations, and permit requirements; compliance with agreements, orders, and consent decrees; compliance with executive orders and DOE orders; compliance with implementation plans developed pursuant to DOE orders; compliance with internal guidance and procedures; and conformance with other best management practices. Compliance and conformance are judged on the basis of both a review of applicable documentation and physical inspection of facilities. In addition to identifying actual compliance problems, an effective self-assessment program also includes a diagnosis of the causes of compliance problems as an aid to preventing recurrence. Full compliance with applicable regulatory requirements is the minimum acceptable level of performance. The self-assessment program is intended to be an ongoing activity, not just a one-time pre-Tiger Team visit activity.

FUTURE ROLE OF TIGER TEAMS

Beginning in October 1991, the Office of Environment, Safety and Health initiated a series of followup assessments. Team sizes were reduced, length of on-sight assessments was shortened, and the assessments became more focused, concentrating on ES&H management, ES&H corrective actions, self-assessment programs, and root-cause related issues. Small/focused assessments will continue to be phased in as larger/comprehensive assessments are phased out in the first half of CY 1992. Beginning in August 1992, larger assessments will be performed on an as-needed basis only (i.e., at potential problem facilities).

The smaller, focused assessments will include a review of self-assessment programs (from Headquarters down to the field level) and the current status of ES&H corrective actions, with the major focus on ES&H program management and root cause analysis. A Departmental Oversight Coordination Committee will establish a process/procedures to coordinate scheduling and to define the scope of future individual assessments.

Tiger Teams have been successful in providing independent oversight and assessment of the compliance and management of ES&H programs throughout the DOE complex. Future assessments will continue to help ensure that DOE operations are conducted in a manner that is safe and environmentally sound, and that protects the health and safety of the Department's employees as well as that of the public.

STOCHASTIC MODELS AND RADIOCANCER RISKS ESTIMATES: PRESENT DIFFICULTIES

In radiation protection, models are traditionally used for the assessment of radiological risks. Proposed several decades ago for the assessment of low dose risks, stochastic models have been periodically improved. However, during the same period a number of new biological data have been obtained, many of them being not consistent with the more sophisticated mathematical stochastic models. As a result of these important biological data, there is now an excessive state of uncertainty in the risk estimates of low doses and low doses rates as obtained using traditional conservative hypothesis; these uncertainties make difficult the interpretation of both effective doses and moreover collective doses.

INTRODUCTION

Longtemps considéré comme le seul recours à l'estimation des risques de radiocancers dans les domaines de doses intéressant la radioprotection, l'utilisation des modèles pose aujourd'hui plus de difficultés qu'elle n'en résout. Loin de s'atténuer, ces difficultés se sont accrues avec le temps et il semble que l'on aboutisse maintenant à une impasse devant l'impossibilité d'intégrer dans des modèles mathématiques les acquis complexes mais cependant très solides de la biologie moderne.

Deux variétés de modèles méritent aujourd'hui une attention particulière: les modèles dits, à tort, d'extrapolation vers les faibles doses (il s'agit en fait d'interpolation) et les modèles de projection des risques sur la vie entière: par l'utilisation conjointe de ces deux variétés de modèles, on obtient en effet des résultats, et c'est sur ces résultats, considérés alors comme des acquis, que l'on se fonde aujourd'hui pour apprécier les risques et définir les normes de radioprotection.

Souvent utilisés pour apprécier ce qu'il est convenu d'appeler le niveau supérieur du risque, ces modèles fournissent des prédictions dont les incertitudes atteignent aujourd'hui des valeurs excessives, difficilement compatibles avec l'intérêt pratique recherché.

Parmi ces modèles, ceux qui apparaissent aujourd'hui les plus critiquables, et qui entraînent les plus importantes confusions sont les modèles probabilistes utilisés pour tenter d'apprécier quantitativement les risques associés à des doses faibles d'irradiation délivrées à des débits forts, moyens ou faibles. On se limitera ici à discuter les difficultés liées à ces modèles particuliers.

LES MODÈLES DITS D'EXTRAPOLATION* VERS LES FAIBLES DOSES

Rappelons tout d'abord brièvement quelles sont les données de base dont on dispose pour appliquer ces modèles, soient les seuils d'action décelable et les relations dose-effet observées aux doses moyennes ou fortes.

1) Les données de base

a) Les seuils d'action décelable

Il n'existe pas un seuil, mais toute une série de seuils correspondant chacun à une variété de cancer, une variété donnée de rayonnement et une modalité donnée d'irradiation (globale ou localisée, fractionnée ou non, fort ou faible débit). Chez l'homme les seuils les plus bas (0,3 à 0,5 Gy) ont été observés pour les rayonnements de faible TLE délivrés à débit extrêmement élevé (supérieur à 1 Gy par sec.) en irradiation totale (survivants d'Hiroshima et Nagasaki) pour certains cancers comme les leucémies (7).

Pour d'autres cancers comme ceux du rectum, du caecum, de l'os ou de l'utérus, le seuil est de 10 Gy pour les rayonnements de faible TLE délivrés à débit fort ou moyen, à doses fractionnées ou non (1).

S'agissant des faibles débits de dose, le seuil est de 0,8 Gy (dose à l'os) pour les rayonnements de TLE élevés, pour les cancers des os provoqués par les rayonnements alpha du radium (5).

On ne connaît pas, par contre, ni chez l'homme ni chez l'animal, la possible action cancérogène des rayonnements de faible TLE d'un élément aussi important que le césium irradiant à faible débit le corps entier après contamination.

b) Les appréciations quantitatives des effets observés aux doses moyennes ou fortes et leurs difficultés.

On sait que ces estimations sont imprécises et limitées à une gamme de dose trop étroite (de 0,5 à quelques Gy chez les survivants des bombes A) pour qu'on puisse les extrapoler sans l'aide de modèles. On se contente alors de faire des interpolations depuis un point de cette courbe jusqu'au point zéro. Cette interpolation est elle-même difficile car, le point d'origine est mal défini. Il ne se situe pas au niveau du seuil d'action décelable. A ce niveau, le risque ne peut pas être apprécié quantitativement compte tenu des exigences statistiques. L'appréciation quantitative ne peut donc être faite qu'à des niveaux plus élevés (de l'ordre de 1 Gy par exemple chez les survivants japonais). Rappelons ici que pour mettre en évidence, avec un intervalle de confiance de 95% un excès de 5% de leucémie, dans une population d'adultes irradiés à 0,2 Gy, l'échantillon nécessaire devrait être de 100.000 personnes auxquelles il faudrait associer un nombre identique de sujets témoins (3). Ce nombre est loin d'être atteint chez les survivants japonais: 6.375 personnes irradiées entre 0,2 et 0,49 Gy (7).

2) Les modèles utilisés et les difficultés actuelles

a) Les modèles d'extrapolation vers les faibles doses délivrées à fort débit

L'aspect quantique et le caractère essentiellement aléatoire du dépôt d'énergie radiative dans les tissus, ainsi que la très faible probabilité que l'une des 10^{14} cellules d'un organisme irradié se transforme en un cancer ont longtemps paru justifier une approche probabiliste de la radiocancérogénèse. Le choix souvent fait d'un modèle linéaire-quadratique semblait conforté par certaines données radiobiologiques rendant compte de phénomènes comme ceux observés sur cellules isolées ou chez les plantes (transdescantia).

Ces modèles sont-ils encore aujourd'hui transposables à un phénomène aussi complexe que le développement d'un radiocancer se développant au sein d'un organisme supérieur ?

Les difficultés sont les suivantes : on sait aujourd'hui que le développement d'un radiocancer est un phénomène bien plus complexe qu'on ne le supposait autrefois. Le mécanisme ne se limite pas à une lésion initiale du génome induite par un dépôt localisé d'énergie. Le phénomène est multifactoriel et de multiples étapes doivent être franchies avant que la tumeur ne se manifeste : initiation, immortalisation, promotion, formation d'un clone, prolifération de ce clone, développement de la tumeur (2, 4, 6). A chacune de ces étapes, des phénomènes stochastiques ou non, de nature enzymatique (réparation de l'ADN), hormonal ou immunologique entrent en jeux aux étapes ultérieures, favorisant ou inhibant cette progression.

Au terme de ces différentes étapes, l'aspect stochastique du phénomène initial a quasiment disparu et les modèles traditionnels apparaissent aujourd'hui inadaptés.

C'est sans doute dans les domaines de l'immunologie et de l'hormonologie que les connaissances ont le plus progressé ces dernières années. Parmi les 10^{11} lymphocytes dont nous disposons certains ont pu être individualisés: lymphocytes T cytotoxiques, cellules LAK (Lymphokine Activated Killer Cells), cellules TIL (Tumor Infiltrating Lymphocytes). Leur rôle est de supprimer les cellules anormales ou étrangères à l'organisme dont les cellules cancéreuses. Ils agissent sous l'influence d'hormones d'action locale. Ce système de défense peut être stimulé et il est capable alors de faire régresser les cancers parmi les plus redoutables. Bref l'organisme dispose d'un système d'immunosurveillance et de défense très élaboré et puissant, indispensable à sa survie. A titre d'exemple, il rend illusoire toute tentative d'extrapolation vers les doses inférieures à 1 Gy des données observées chez les survivants japonais au-dessus de cette dose à partir de laquelle ces sujets ont été dans un état d'immunodéficience par destruction des lymphocytes.

h) Les irradiations à faible débit de dose et le problème des facteurs de réduction du risque.

On connaît assez bien les effets redoutables des contaminations par les émetteurs alpha (radium, thorium) délivrés à très faible débit durant de très longues périodes, mais les données sont quasi inexistantes sur les possibles effets des rayonnements de faible TLE délivrés à ces mêmes débits, soit la situation la plus fréquente en radioprotection des travailleurs ou du public. Tenter d'estimer ces effets à partir des données observées aux forts débits est assez peu réaliste car il existe 7 ordres de grandeurs entre 1 Gy par sec. (survivants japonais) et 1 Gy par an. Dans le premier cas (20.000 ionisations par sec.

dans chaque noyau des 10^{11} cellules de l'organisme soit 2×10^{11} ionisations), les mécanismes de défense enzymatiques (réparation de l'ADN) ou immunologiques sont dépassés alors qu'ils fonctionnent normalement dans le deuxième cas, dans lequel le débit de dose (10^{11} ionisations par sec.) se rapproche de celui de l'irradiation naturelle (10^9 à 10^7 ionisations par sec. chez un homme de 70 kg).

Le facteur de réduction qu'il conviendrait d'appliquer ici est complètement inconnu car les données dont on dispose aujourd'hui sont très insuffisantes pour en donner une estimation même très approximative.

CONCLUSION

L'utilisation des modèles pour l'estimation des risques de radiocancers se heurtent à des difficultés plus importantes qu'autrefois. Conscients de ces difficultés, les comités internationaux ont adopté des attitudes conservatrices, définissant ce qu'il est convenu d'appeler le niveau supérieur du risque. Cette attitude certes légitime ne doit pas cependant masquer les difficultés actuelles. Certes les risques liés aux doses plus fortes que 1 Gy sont connus avec une précision meilleure qu'autrefois mais, dans le même temps les incertitudes concernant les plus faibles doses se sont considérablement accrues pour atteindre des valeurs excessives. Il résulte de ces incertitudes que la notion de dose efficace, ne tenant pas compte des débits de dose, devient d'interprétation difficile, de même et surtout que la notion de dose collective entièrement fondée sur l'hypothèse d'une interpolation linéaire.

L'estimation scientifique du risque de radiocancers a longtemps reposé sur le recours à des modèles mais l'aspect scientifique s'est progressivement estompé en même temps que son aspect pratique et la question peut être posée aujourd'hui de l'opportunité d'utiliser des méthodes plus simples mais plus réalistes pour l'estimation du risque radiologique et la définition des doses biologiquement efficaces.

A PROPOSED FRAMEWORK FOR CONSISTENT REGULATION OF
PUBLIC EXPOSURES TO RADIONUCLIDES AND OTHER CARCINOGENS*

D. C. Kocher and F. O. Hoffman
Oak Ridge National Laboratory
Oak Ridge, Tennessee 37831, U.S.A.

ABSTRACT

This paper discusses a proposed framework for consistent regulation of carcinogenic risks to the public based on establishing *de manifestis* (i.e., unacceptable) and *de minimis* (i.e., trivial) lifetime risks from exposure to any carcinogens at levels of about 10^{-1} - 10^{-3} and 10^{-4} - 10^{-6} , respectively, and reduction of risks above *de minimis* levels as low as reasonably achievable (ALARA). We then discuss certain differences in the way risks from exposure to radionuclides and other carcinogens currently are regulated or assessed which would need to be considered in implementing the proposed regulatory framework for all carcinogens.

INTRODUCTION

We believe there is a fundamental problem with current regulatory policies in the United States for limiting routine exposures of the public to radionuclides and other carcinogens - namely, a clear inconsistency in the levels of acceptable health risk associated with (a) standards for radionuclides only, as developed under authority of the Atomic Energy Act, and (b) standards for any carcinogens, including radionuclides, or for chemical carcinogens only, as developed under authority of other laws. We first describe the apparent inconsistency in the levels of acceptable risk associated with these two categories of standards and propose a set of principles, based on distinguishing unambiguously between unacceptable and trivial risks, which could provide more consistent regulation of carcinogenic risks to the public. The present inconsistency in acceptable risks and our proposed regulatory framework are discussed in more detail elsewhere [1]. We then discuss other differences in the way risks from exposure to radionuclides and other carcinogens currently are regulated or assessed which would need to be considered in implementing the proposed regulatory framework for all carcinogens.

INCONSISTENCY IN CURRENT REGULATORY APPROACHES

The current framework for regulating radiation exposures of the public under authority of the Atomic Energy Act may be referred to as a "top-down" approach. In this approach, a limit on radiation dose to individuals from all sources of exposure except natural background, corresponding to an upper bound on acceptable risk, is established in radiation protection standards. Then, doses are reduced below the limit by requiring that exposures be kept as low as reasonably achievable (ALARA), taking into account such factors as cost vs. benefit, technical feasibility, and societal concerns (e.g., perceptions of risk).

* Research sponsored by the U.S. Department of Energy under contract DE-AC05-84OR21400 with Martin Marietta Energy Systems, Inc.

The submitted manuscript has been authored by a contractor of the U.S. Government under contract No. DE-AC05-84OR21400. Accordingly, the U.S. Government retains a nonexclusive, royalty-free license to publish or reproduce the published form of this contribution, or allow others to do so, for U.S. Government purposes.

The current dose limit in radiation protection standards for the public corresponds to a limit on acceptable lifetime risk of 5×10^{-3} [2]. However, the development in the United States of many standards for specific practices or sources, which represent an application of the ALARA principle, virtually assures that lifetime risks from routine exposures to all man-made radionuclides will not exceed 10^{-3} . The "top-down" approach also is applied to (a) regulation of exposures to naturally occurring radionuclides in mill tailings, (b) remedial action levels for exposure to natural background, principally radon decay products and external radiation, and (c) responses to radiation accidents. In these cases, the limit on acceptable lifetime risk is in the range 1×10^{-3} to 5×10^{-2} , and the ALARA principle is applied to reduction of public exposures.

The current framework for regulating exposures of the public to chemical carcinogens, and for regulating radiation exposures under authority of laws other than the Atomic Energy Act, is quite the opposite of that described above and may be referred to as a "bottom-up" approach. In this approach, there is no standard defining an upper bound on acceptable risk from all carcinogens and sources of exposure. Rather, for specific exposure situations only, a lower bound on acceptable risk is established as a goal, and this goal then may be increased to reflect risk levels that reasonably can be justified.

The "bottom-up" approach is exemplified by current laws and regulations for carcinogenic food additives (e.g., pesticides) and for radionuclides and chemical carcinogens in drinking water. In both cases, a carcinogenic risk of zero has been established as a goal, but this goal has been relaxed to permit lifetime risks up to 10^{-6} for pesticides and 10^{-4} - 10^{-6} for carcinogens in drinking water. Acceptable risks in the range 10^{-4} - 10^{-6} from exposure to radionuclides and other carcinogens also are embodied in standards for airborne emissions of hazardous substances and standards for cleanup of hazardous substances in the environment, e.g., at old waste disposal sites.

The "top-down" approach to regulating radiation exposures under authority of the Atomic Energy Act clearly is fundamentally different from the "bottom-up" approach to regulating exposures to radionuclides and other carcinogens under authority of other laws. Consequently, upper bounds on lifetime risks to the public regarded as "acceptable" clearly are inconsistent in the two cases - i.e., risks of 10^{-1} - 10^{-3} in the former but 10^{-4} - 10^{-6} in the latter.

PROPOSED FRAMEWORK FOR CONSISTENT REGULATION OF ALL CARCINOGENS

In order to reconcile the fundamental inconsistency in regulatory approaches described above and to provide more consistent regulation of carcinogenic risks to the public, we propose an explicit regulatory framework for all carcinogens which contains three basic elements:

- [1] a *de manifestis* lifetime risk in the range 10^{-1} - 10^{-3} , which would define an upper bound on acceptable risk from all carcinogens and sources of exposure and above which regulatory action would be taken to reduce risks regardless of cost;

- [2] a *de minimis* lifetime risk in the range 10^{-4} - 10^{-6} , which would define risks from any carcinogen and source of exposure so trivial that regulatory action to reduce risks would be unwarranted; and
- [3] reduction of lifetime risks above *de minimis* levels based on application of the ALARA principle.

The key to our proposal is to recognize that the lifetime risks of 10^{-4} - 10^{-6} embodied in some standards, as described previously, are *de minimis* rather than *de manifestis* levels. This interpretation is clearly supported by an analysis which showed that regulatory authorities in the United States usually have not acted to reduce risks from chemical carcinogens when the lifetime risk to a few individuals is below 10^{-4} and the average lifetime risk in large populations is below 10^{-6} [3].

The proposed use of ranges for the *de manifestis* and *de minimis* risks would permit taking into account the size of an exposed population in establishing these levels for particular situations [3] and would allow considerable flexibility in applying the ALARA principle. Therefore, complete uniformity of regulatory decisions in limiting carcinogenic risks to the public would not be required.

As indicated previously and discussed in more detail elsewhere [1], our proposed regulatory framework is consistent with virtually all current regulatory policies for limiting routine and accidental exposures of the public to radionuclides and other carcinogens, including proposed exemption levels for radiation exposure. Again, however, this consistency is achieved only if the lifetime risks of 10^{-4} - 10^{-6} embodied in some standards are interpreted as *de minimis*.

We believe that our proposed regulatory framework would encourage consideration of risks from any carcinogen and source of exposure in the context of risks from all sources, as opposed to the rather piecemeal approach embodied in past regulatory decisions, particularly for chemical carcinogens [3]. Furthermore, the proposed *de minimis* levels would ensure that risks much less than largely unavoidable background risks, which average about 10^{-2} for radionuclides [2,4] and greater than 5×10^{-3} for chemical carcinogens [5], do not receive unwarranted attention.

ADDITIONAL CONSIDERATIONS IN IMPLEMENTING PROPOSAL

Implementation of our proposed regulatory framework for limiting risks to the public from all carcinogens would require additional considerations as a result of certain other differences in the way risks from radionuclides and chemical carcinogens are regulated or assessed.

First, the *de manifestis* and *de minimis* levels are expressed as lifetime rather than annual risks. This approach assumes that stochastic health effects are the primary concern in regulating exposures of the public to any carcinogens. Thus, the common practice of apportioning an assumed limit on lifetime risk into equal annualized increments in setting dose limits in radiation protection standards is rather arbitrary for purposes of limiting stochastic risk. Subsidiary limits on acute

exposures to any carcinogens would be needed only if prevention of nonstochastic (i.e., deterministic) effects is of concern.

Second, there are inconsistencies in the factors for converting exposure to risk. In particular, radiation risk factors usually are best estimates [2], but upper 95th percentile confidence limits are used for other carcinogens [6]. In addition, radiation risk factors take into account risks from irradiation of all organs and tissues [2], but current risk factors for chemical carcinogens usually take into account only one organ or tissue at risk [6].

Third, the primary measure of risk from radiation exposure usually has been cancer fatalities [2], whereas the primary measure of risk for other carcinogens has been cancer incidence [6]. Risk factors for radiation exposure that include weighted nonfatal cancers as well as fatal cancers have been introduced [2], and a similar approach could be used in developing risk factors for chemical carcinogens.

Finally, in assessing radiation doses to maximally exposed individuals, the intent usually is to estimate average doses to members of critical population groups using reasonable assumptions for likely exposure scenarios and pathways. However, risk assessments for chemical carcinogens often emphasize unreasonably pessimistic assumptions [6], and the resulting estimates of risk may exceed values that could be experienced by any members of the public.

Systems to Measure Airborne Radioactive Substances in the Reactor Containment in Event of a Severe Accident

R. Hock, Siemens; H. Eisgruber, RWE; G. Kalber, VGB

Abstract

In the event of a major release of radioactive substances into the containment atmosphere, the presence of aerosols and iodine may pose a larger threat than the noble gases. They tend to deposit in sampling lines to a varying degree. This makes precise measurement difficult, particularly if small volumes have to be handled, because of high activity. Most systems on the market do not solve these problems. Four different systems have been evaluated and optimized with respect to this task. They allow sufficiently accurate measurement of these substances in the containment atmosphere over a wide range of conditions and temperatures (dry atmosphere up to 100% steam

In the event of a major release of radioactive substances into the atmosphere of a reactor containment, countermeasures inside and outside the plant can only be optimized if the actual potential radiological hazard can be determined.

Substances which accumulate in the human body and are deposited in the biosphere represent a higher potential hazard than gases with low or no reaction with other substances. It is therefore important to know the actual concentration particularly of these substances. Even if they are absent or at low levels it is important to be aware of that fact. Countermeasures usually pose other hazards and therefore they have to be optimized, which is only possible if the actual threat is known.

In contrast to noble gases, the concentrations of aerosols and airborne iodine not only depend upon the degree of core degradation but also on a number of other parameters which are unlikely to be known in the actual case. "Conservative assumptions" which are meaningful for the design of protective devices may lead to wrong decisions in an actual case as has been demonstrated in the assumed radiolysis during the accident at TMI.

It is therefore important that a wide range of concentrations of these substances can be measured even in the presence of a high background of radioactive noble gases. This background of noble gases can easily be estimated at an early stage from a dose rate measurement inside or close to the containment. Only within the first hours of an extreme event may aerosols contribute significantly to that dose rate. Fig.1 shows the dose rate which would result from the various substances at a distance of 50 cm from just 1 ml containment atmosphere. Their relative contribution to the radiation from the entire containment is approximately the same. In addition this figure shows how large a volume could be handled safely in such an extreme situation.

The measurement of aerosols and airborne iodine may be distorted by their tendency to deposit on surfaces in sampling lines. The degree of such deposition is highly dependent on the velocity, particle size distribution, temperature and material. Because some of these parameters are not known in the actual case correction factors may be highly inaccurate. Fig.2 gives an example of these effects. The losses of aerosols (diameter 5 μ) and elemental iodine have been calculated as a function of the velocity for a specific configuration of a slightly heated sampling line to avoid condensation.

The losses in the sampling line are tolerable at a specific velocity only.

Losses in unheated sampling lines could become extremely high if steam is present in the containment atmosphere: If the sampling line passes through cooler areas the inner surfaces may become wet. This would effectively filter out these substances. Depending upon the actual conditions varying with time and location, this liquid may reach the sampling station hours later. It could then show a concentration in the containment which may not exist any more at that time due to deposition and washout effects.

It has been decided by those German utilities operating nuclear power stations that they want to obtain more accurate measurement results for these most important substances and that it should be made possible to perform the analyses in the radiochemical laboratory using routine methods. In a high-stress situation such routine methods are less prone to operator error.

Existing systems were first analyzed and found not to meet these requirements. Then four different systems were selected for more detailed investigation and development according to the given specification. All of them now meet the requirements.

In system 1 the sampling lines are heated to prevent condensation. The flow is regulated independently of the pressure within the containment. Directly outside the containment noble gases are separated from the other substances by a washer (Fig.3). A small sample of the gas and the water phase will be taken remotely without further losses by deposition in sampling lines. This fraction will then be further diluted for analysis in the laboratory.

In system 2 a small sample is taken by means of a container which is transported by a shuttle system to a location inside the containment (Fig.4).

The essential part of system 3 is a remotely operated snapper inside the containment which also takes only a small sample (Fig.5). In contrast to system 2, it operates with a liquid transport medium. Substances which are airborne in the containment are transported as a gas bubble or dissolved or suspended in the liquid. Temporarily deposited substances would immediately be resuspended or dissolved by the circulating fluid. This fluid simultaneously dilutes the high concentrations.

In system 4 the gases and other substances are separated by a gas washer within the containment (Fig.6). This washer operates without condensation because it is at the same temperature as its environment. Gases which pass the washer together with steam and/or air are analyzed first. The other substances will remain in the washing liquid. At the end of a short sampling period part of the liquid will be taken to the outside and the concentrations will be determined. Because the volume of the liquid and the containment volume which has passed the washer are known, the concentrations in the containment atmosphere can be evaluated.

Each of these systems tolerates extreme concentrations of radioactivity as well as a large variety of conditions with respect to temperature, pressure and composition (from 100% air to 100% steam). Which system is the optimum depends on the specific circumstances of the plant, e.g. the number of required measuring points in the containment, the distance to the nearest location accessible after a major release of radioactive substances within the containment and the availability and cost of isolation/transfer valves through the containment.

RADIATION PROTECTION LEGISLATION IN THE NORDIC COUNTRIES

Lars Persson

Swedish Radiation Protection Institute, Box 60204, S-10401
Stockholm, Sweden

ABSTRACT

A close collaboration exists in the Nordic countries in the field of radiation protection. The radiation protection authorities attach major importance to a uniform interpretation of the international recommendations. The legal situation of the Nordic countries in the radiation protection field will be reviewed with the main emphasis on the new Swedish and Finnish laws.

INTRODUCTION

The Nordic radiation protection authorities attach major importance to a uniform interpretation of the international recommendations. However, no attempt has been made to formulate identical laws and regulations for all the five countries, since the legal and administrative framework of the five Nordic countries differs. A survey of the Nordic co-operation in radiation protection is available in ref (1).

DENMARK

The X-ray law was enacted already 1930 and the Radiactive Substances law in 1953. The laws are supplemented with orders issued by the National Board of Health. In refs (1), (2), and (3) the orders until end of 1990 are reviewed. In 1991 the following order is published:
No 319. On electron accelerators for the treatment of patients with energies from 1-50 MeV.

FINLAND

The new law published as no 1991:592 will come into force on 1st January 1992. The scope of the new Finnish law is rather extensive. Except for the utilization of radiation, it shall apply to activities involving exposure to natural radiation and non-ionizing radiation. Its basic objective is to protect human health.

The generally approved basic principles of radiation protection are contained in the law as the guiding principles of regulatory control:

- justification,
- optimization of radiation protection (ALARA), and
- individual dose limitation.

Any licenced employer using radiation or whose activities involve exposure to radiation shall be responsible for the safety of the activity. Any carrying out such an activity shall

with radiation. The employees are, in turn, obliged to collaborate in maintaining radiation protection.

The new law contains provisions concerning radioactive waste. The starting point has been that the same requirements should apply to all radioactive waste, regardless of whether it comes from nuclear or other operations. According to the model in the Swedish law on nuclear activities, the new law therefore lays down that persons conducting activities involving radiation must be responsible for the handling of radioactive waste and its storage in a satisfactory manner. Another similar rule is the scrapping of equipment that may produce radiation. A source of X-ray radiation may, for example, constitute a hazard by being connected to the electricity grid. In view of this, it is prescribed that equipment capable of generating hazardous radiation must, before being scrapped, be rendered harmless.

According to the radiation protection law, a licence is in principle required for activities involving sources of ionizing radiation. Where non-ionizing radiation is concerned, the principle is that a licence for such activities involving the source of radiation is required only after a specific decision by the Swedish Institute of Radiation Protection.

According to the new law, penalties may be imposed both for intentional offences and for offences committed as a result of negligence. Depending on the seriousness of the offence, the penalty may vary from a fine to imprisonment for a maximum of two years.

According to the statement issued by the Parliament, it is essential for the main responsibility for radiation protection to be concentrated in a single radiation protection authority (the Swedish Institute of Radiation Protection). The intention is that the law should, in many respects, obtain its specific content from regulations imposed by the Institute.

ACKNOWLEDGEMENTS

My sincere thanks go to the legal experts of the five Nordic radiation protection authorities for sending me the relevant documents.

The purpose of the new law is to protect people, animals and the environment against the harmful effects of ionizing and non-ionizing radiation. Ionizing radiation is defined in the law as the radiation of gamma rays, X-rays and particles or other radiation with similar biological effects, i e with such a high energy content that, in passing through materials, it is capable of releasing ions. Non-ionizing radiation is defined as optical radiation, radio-frequency radiation, low-frequency electric and magnetic fields and ultrasound or other radiation with similar biological effect. The law covers radiation that is both natural and produced or caused by human action.

The new law contains regulations concerning general obligations to be observed with respect to radiation protection. These regulations cover both ionizing and non-ionizing radiation. The central provisions concerning general obligations apply to persons conducting activities involving radiation. It is incumbent on such persons not only to follow the directives and conditions laid down but also, on their own initiative, to take all the measures required to maintain radiation protection. The duties of the person responsible therefore include planning and arranging activities in a manner that is acceptable from the viewpoint of radiation protection. Radiation protection must conform to a reasonable extent with technical development and be improved as new opportunities are afforded by development. The person responsible for activities must organize all the work in such a way that exposure to radiation is as low as may be reasonably demanded. This responsibility covers both employees engaged in the activity concerned and outsiders.

One obvious prerequisite of all activities involving radiation is that the person conducting the activities concerned is skilled in handling the equipment and the source of radiation. The training requirements must simultaneously be defined according to the potential hazardousness of the source of radiation, the nature of radiation protection and the other circumstances that may affect radiation hazards in a factory, or in the handling of radioactive substances. The provision may also entail, for example, a duty on the part of persons conducting activities involving radiation to ensure that the doses of radiation to which employees are exposed are registered. This may be done by general monitoring of the radiation level in the work premises or by measurements of doses received by individuals.

One important element in radiation protection is that facilities, premises, machinery and other technical devices, as well as protective equipment, are continuously checked and well maintained. This responsibility is included in the duties to be observed by the person conducting activities involving radiation.

According to the law, persons conducting activities involving radiation should, by means of clear and comprehensible instructions, signs or in some other way obtain a good knowledge of the conditions under which the activities are conducted and be informed of the risks that may be associated

thus be responsible for the safe performance of the activity and for having available the appropriate expertise.

The so-called safety license sets the basis for the regulatory control of the utilization of radiation. The licensing procedure is intended for ensuring that

- radiation is used sensibly and acceptably,
- radiation equipment and shields are technically acceptable,
- the operating personnel and organization are competent, and
- radioactive waste is appropriately taken care of.

Type testing is a form of regulatory control which applies to i a radiation sources used as consumer goods and many devices producing non-ionizing radiation.

The law also contains provisions concerning i a patient safety, monitoring of natural radiation, radiation work as well as radioactive waste.

Finland has a modern nuclear energy law which entered into force in 1988 on which the enforcement of the regulatory control of the use of nuclear energy mainly rests. Therefore, the provisions of the radiation protection law which apply to the use of nuclear energy are restricted to:

- The requirements concerning justification, optimization and individual dose limitation apply to nuclear energy, too. By virtue of the radiation protection law, maximum radiation doses are confirmed by which individual dose limitation is implemented, and
- The monitoring and registration of doses of nuclear power plant workers shall comply with the radiation protection law.

The Finnish Centre for Radiation and Nuclear Safety is entrusted with the enforcement of the regulatory control.

ICELAND

The Radiation Protection Act and its complementary ordinance were issued in 1985 and 1986, ref (1). In ref (2) the regulations published since then are reviewed.

NORWAY

The radiation protection law relating to the use of x-rays and radium, etc. published in 1938 has remained unchanged since then, ref (1). The complimentary Royal decrees and regulations are reviewed in refs (1) and (2). Recently the process has started to propose a new law to the Norwegian parliament.

SWEDEN

With effect from 1st July 1988 a new radiation protection law came into force in Sweden. In ref (2) the legal text of the act and its complementary ordinance is given. Regulations issued by the Swedish Radiation Protection Institute are reviewed in refs (1), (2), and (3).

QUANTIFICATION OF RADIATION DETRIMENT

GAM Webb and JD Robb

National Radiological Protection Board
Chilton, Didcot, Oxon. OX11 0RQ, UK

The quantification of the various components of radiation induced detriment has been developed by ICRP in particular over a number of years. In Publication 60 the process reached a level of development such that weighted detriment judgements are a fundamental component of the definition of one of the primary dosimetric quantities, Effective Dose, and were used explicitly in reaching a recommendation on dose limits. There is still some way to go in the further development and application on the concept of quantified detriment and this paper explores both the problems and some possible avenues to solve them.

HISTORICAL INTRODUCTION

The recently revised ICRP recommendations⁽¹⁾ have seen the Commission apply quantitative measures of detriment to several areas in order to support their recommendations. This is clearly a more extensive use of the detriment concept than has hitherto been seen in radiological protection. It has however, taken a number of years to get to this stage as, after all, detriment was initially introduced in ICRP Publication 26⁽²⁾. Here it was defined as the mathematical 'expectation' of the harm incurred from an exposure to radiation, taking into account not only the probability of each type of deleterious effect, but also the severity of the effect. These deleterious effects included both effects on health and other effects.

In practice though, attempts to quantify detriment thereafter were limited. The one area where some progress was made was the monetary costing of detriment for cost-benefit analysis (CBA) and optimisation purposes.⁽³⁾ We at NRPB used a pragmatic variation of the ICRP recommendations on detriment to derive monetary values of unit collective dose for general use in CBA. The objective health detriment was calculated by estimating the gross economic loss associated with the latent fatal and non-fatal stochastic effects. To this a multiplying factor was added to reflect individual aversion to increasing levels of individual dose. Although the application of CBA is limited to its use in optimisation studies,⁽⁴⁾ we have not for some years gone further in accounting for the severity of radiation-induced effects in other formal advice, until recently that is.

ICRP PUBLICATION 60

ICRP have clarified that for radiological protection purposes detriment should be taken to include primarily the risk to health, and that a separate allowance within a decision-making process should be made for other forms of detriment. The two principal purposes for which aspects of detriment are now quantified are for the definition of effective dose, and to assess the consequences of continued or cumulative exposure in order to recommend dose limits.

In the definition of Effective Dose, the radiation weighting factors are primarily determined by scientific judgements based on physical or biological observations. For tissue weighting factors, however, the probability of fatal cancer in each organ is weighted for relative loss of life should a cancer occur in that organ. This is adjusted further using the probability of non-fatal effects in each organ weighted by the severity of each cancer type, using a quantified form of the judgement that the relative importance of a non-fatal cancer is inversely proportional to the curability. In addition provision has been made for a more structured weighting of the hereditary consequences although for the present definition a reasonably straightforward judgement has been included. Thus the familiar quantity, Effective Dose, that some might even have considered a 'physical' quantity, is loaded with judgements as to the quantification of detriment.

To assess the consequences of continued exposure at a number of given dose regimes, the Commission quantified these elements together with some others such as years of life lost and the age at which the fatality would occur to construct a multiattribute assessment of the detriment. Based on these measures and further judgements as to their relative importance, a recommendation was made as to suitable dose limits.

CURRENT WORK

The amount of detail on detriment that can be calculated requires commensurately detailed research tools to carry out the analysis, and to examine the implications for standards in different exposure situations. NRPB has developed a PC-based computer code that allows rapid assessments of detriment assuming radiation exposure over a chosen time period to individuals or to a population⁽⁵⁾. This is based on health effects models for the UK⁽⁶⁾, currently under revision. The beauty of such tools is that the consequence of varying the weights on the different aspects of health detriment is immediately apparent. The combination of calculational speed and sensitivity analysis, allied to simplicity of use is transforming risk analysis in radiological protection.

However, the danger is that this power becomes addictive. The more detailed the analyses, the more numbers that can be produced without stopping for breath to assess the information. In the context of radiation detriment, there are three clear aspects to be addressed.

1. For what quantities and/or judgements is the quantification of detriment important ?
2. What attributes of detriment are of interest for each of these ? The same attributes, or the same aggregation will not be important in all areas. Indeed, it may be that some quantities are relatively insensitive to the inclusion or the weighting of, certain detriment factors, which therefore are an added complication where simplicity would be preferable.
3. What criteria should components of detriment be assessed against ?

Answering any one of these questions is a formidable task in itself. Here we make no attempt to do so for naturally this represents a long-term work programme. Instead, we focus on two related aspects. Firstly, the final point above, risk criteria, has to be a matter of concern, and is discussed below. Secondly, ICRP 60 introduced the term 'constraint' as

an aid to the optimisation process. We discuss here what attributes of detriment may be important in deriving these.

Risk criteria

The two key reference points for risk criteria in the UK are the study group report of the Royal Society⁽⁷⁾ and the Health and Safety Executive's document developing a philosophy of risk control⁽⁸⁾. These bodies have suggested 'acceptable' and 'tolerable' annual levels of death probability for occupational and public circumstances. These criteria have been useful, but for a full consideration based on detriment, additional questions arise.

For example, because the risk rate varies with time, it is necessary to consider whether it is the average or maximum annual risk that is important, or whether it is the age of reaching a particular risk rate that is more relevant to the judgement on acceptability. Another consideration would be whether there is a maximum acceptable lifetime risk irrespective of the time distribution of that risk. Following exposure, most of the risk of additional cancer death arises at older ages. Is there then an argument that risk at different ages should be treated differently? It could be said that the risk of premature death should be weighted more heavily because, beyond normal life expectancy, the cause of death becomes less relevant. Also in this context, we have tended to concentrate on incremental increases in death rates rather than looking at the relative increase in death and cancer death rates. This aspect may become a more important focus.

So far we have only dealt with fatal effects. We have not started to develop criteria against which one can assess the significance of non-fatal cancer, hereditary effects, years of life lost and impaired, and aggregated detriment. Weighted detriment assumes that acceptability of other effects can be assessed on the same scale as fatal effects, but this is for the moment only a working assumption.

Detriment and Dose Constraints

As noted above a number of aspects of detriment were taken into account by ICRP in making a judgement on appropriate dose limits. The general nature of the dose limits means that fairly broad assumptions are made concerning individuals, and the population groups for whom the limits are intended to apply. Dose constraints are intended to be more sector specific, derived using levels of reasonably achievable individual dose. However, although partitioning of work categories is not straightforward, and inevitably there will be overlaps, this narrowed specification means that considerations other than recorded levels of dose become important. For instance, there is a clear difference in the induced detriment per unit dose between a population of industrial radiographers, and a population of radiotherapy nurses. Moreover, for medical exposure, there are specific procedures, or situations, where solely paediatric, obstetric or geriatric exposure is practiced. For these also the detriment incurred per unit dose will clearly differ. The question is whether, and by how much should this influence the numerical choice of constraint.

What is needed therefore is a thorough review of exposure groups to determine both current levels of recorded dose and the detriment that this implies to average members of each population. This would then be fed into the decision-making process for the setting of a dose constraint. It may be, for example, that some groups of workers may be consistently

older than the average workforce. In this case, because the probability of passing on hereditary effects will be reduced, and because the bulk of the excess risk would occur at very old ages, the annual risk of effects over the remaining life expectancy would be low. Thus if individual doses are already within a nationally set constraint, there would be no need to set an additional more restrictive sector-specific constraint. The employer may, however, choose to set an internal restriction for workers of certain ages.

On the other hand, in paediatric medical exposure, the risk incurred in terms of the additional cancer probability relative to the background rate, in the years following that exposure, is considerably greater than the average in a population and could be deemed excessive, leading to very restrictive constraints.

CONCLUSIONS

There is much work to be done before our ideas on the quantification of radiation detriment can be fully refined. The number of attributes of detriment can proliferate almost indefinitely, and it is necessary to develop clear procedures to decide which are sufficiently useful for their inclusion in radiological protection quantities or as other inputs to decisions. Furthermore, yardsticks against which single or aggregated attributes can be assessed are of prime import.

Not long ago some of these ideas would have seemed too complex as would the number of weighted aspects of detriment included in the ICRP formulation of Effective Dose. However, we must recognise that the real world is complex and ICRP have shown that detriment is not only a more satisfactory measure of the health impact of radiation exposure, but it can be useful and practical. The challenge is to build on this during the next few years.

**THE REVISED INTERNATIONAL COMMISSION ON RADIOLOGICAL
PROTECTION (ICRP) DOSIMETRIC MODEL FOR THE HUMAN RESPIRATORY
TRACT**

William J Bair
Pacific Northwest Laboratory
Richland, Washington USA

ABSTRACT

A task group has revised the model of the respiratory tract recommended by the ICRP for use in radiation protection dosimetry¹. The revised model can be used to project respiratory tract doses for workers and members of the public from airborne radionuclides and to assess past exposures. Doses calculated for specific extrathoracic and thoracic tissues can be adjusted to account for differences in radiosensitivity and summed to yield two values of dose for the respiratory tract that are applicable to the ICRP tissue weighted dosimetry system.

INTRODUCTION

The dosimetric model currently used by the ICRP¹ to estimate doses from inhaled radioactive particles was published in 1966². During the past 25 years, research has yielded new knowledge relevant to modeling the intake, deposition, and clearance of inhaled particles and gases. Also, the needs of the ICRP have expanded well beyond those that can be addressed by the current model. This led to an ICRP Task Group* being asked to develop a revised model.

FEATURES OF MODEL

The model is based on the premise that large differences in radiation sensitivity of respiratory tract tissues and the doses they receive from inhaled radioactive particles and gases argue for calculating doses to specific tissues. The current model^{1,2} leads to calculation of doses averaged over the mass of blood-filled lungs.

Parameters needed to calculate doses are assigned values for the reference worker and members of the public. However, values relevant to individuals and to specific exposure situations can be used in the model. Guidance is provided for adjusting the model to account for the possible influence of smoking, respiratory tract diseases, and exposure to airborne toxic substances.

The model is useful for assessment of doses from inhaled radioactive particles and gases as well as for calculating limits on intakes. Tissue average doses calculated for defined regions of the respiratory tract can be adjusted to account for radiation sensitivity differences to yield a single value for the extrathoracic and another value for the thoracic region.

*Members are: M Bailey, FT Cross, RG Cuddihy, P Gehr, AC James, JR Johnson, R Masse, M Roy, W Stahlhofen and WJ Bair, Chairman

These two values of dose are applicable to the ICRP tissue weighted dosimetry system for calculating effective dose.

MORPHOMETRIC MODEL

For purposes of modeling, the respiratory tract is represented by five regions identified on the basis of their respiratory function, cytology, and what is known or can be measured with reasonable confidence about the deposition and clearance of inhaled particles and gases. The two extrathoracic regions are the anterior nasal passages (ET_1) and the posterior nasal and oral passages including the mouth, larynx, and pharynx (ET_2) with associated lymphatics (LN_{ET}). In the thorax are the bronchial (BB), bronchiolar (bb), and alveolar-interstitial (AI) regions with associated lymphatics (LN_{TH}).

For calculating radiation doses, the cytology and histology, as well as morphometric structures, are modeled for each region. Reference values for dimensions important for dose calculations are specified.

DEPOSITION

In modeling the deposition of airborne particles, inhalability and each region of the respiratory tract are represented by a series of equivalent particle filters. The extrathoracic tissues are represented by two filters, one for inhalation and the other for exhalation. The deposition efficiency of each region of the respiratory tract is evaluated by considering particle deposition by aerodynamic and thermodynamic processes, acting competitively. It is assumed that the reference worker is a nose breather, shifting to 50% mouth breathing at respiratory rates greater than about $2.1 \text{ m}^3\text{h}^{-1}$.

To model deposition in the extrathoracic airways, an empirical approach based directly on experimental data was used. To evaluate regional deposition, a theoretical model of particle deposition and gas transport was weighted empirically to fit the mean of experimental data.

CLEARANCE OF INHALED MATERIALS

The model describes three clearance pathways (Figure 1). Material deposited in the ET_1 region is removed by extrinsic processes, such as nose blowing. For the other regions, clearance is competitive between particle transport processes (such as macrophage uptake and ciliary action to the G.I. tract and to lymph nodes) and absorption into blood. The rate of clearance by each process is a time-varying factor of the residual amount. It is assumed that the rates of clearance by particle transport are the same for all materials. Rates were derived from studies with human subjects.

Absorption into blood is a two-stage process: dissociation of the particles into material that can be absorbed into the blood (dissolution) and absorption into blood of inhaled soluble

material and of material dissolved from particles. Absorption is material-specific and is assumed to act in all regions except region ET₁. The model can use observed absorption rates of compounds for which reliable human or experimental animal data exist. In the absence of such data, absorption rates are specified as "fast" F, "moderate" M, or "slow" S, based on the current D, W, and Y classification system of the ICRP². The default values, expressed as half-times, are: 10 min for F materials, which are rapidly absorbed into blood; 3 d for 50% and 100 d for the remaining 50% of M materials with intermediate rates of absorption; and 7000 d for S materials, which are very insoluble.

DOSIMETRIC MODEL FOR GASES AND VAPORS

The model addresses three classes of gases and vapors. The first, SR-0, insoluble and nonreactive, results in exposure of all airways. The second, SR-1, either soluble or reactive, results in exposure of all airways. However, these gases and vapors can also be absorbed into tissues and blood throughout all airways. The third class, SR-2, consists of highly soluble and reactive gases and vapors that are completely absorbed by tissues and blood in the extrathoracic tissues.

CALCULATION OF TISSUE AVERAGE DOSES

Doses are calculated by the ICRP system in which energy absorbed is averaged over the mass of the target tissues in each region. These doses can be adjusted to account for differences in radiation sensitivity and summed separately for the extrathoracic and thoracic regions. These two adjusted doses can be used with the ICRP tissue weighting factors in calculations of effective dose³.

It is proposed that the doses calculated for each region be adjusted on the basis of the best estimates of their relative sensitivity to radiation-induced cancer. These estimates and the factors used to adjust regional doses cannot be very precise because of the scarcity of information and of unknowns such as the influence of smoking and exposure to air pollutants. However, the impact on the summed doses is not large.

SUMMARY

The new respiratory tract model provides for calculating average doses to specific tissues rather than to the total lung mass. The model is more complex than the current model because it describes deposition of inhaled radioactive material in and clearance from several tissues and regions of the respiratory tract and is applicable to the worldwide population of both workers and the public.

IMPROVEMENTS IN RADIATION PROTECTION USING A PROPRIETARY AUDIT SYSTEM

K W Bowker & J M Stevenson

University of Oxford Safety Office,
Oxford, United Kingdom

ABSTRACT

The paper describes the International Safety Rating System (ISRS) and its application and suitability to auditing an organisation's radiation protection arrangements. Particularly pertinent elements in the audit system are identified and briefly described. The benefits derived from the practical application of the audit are identified.

INTRODUCTION

All health and safety management systems need to be tested in order to evaluate whether they are suitable, complete and working satisfactorily. Auditing is a tried and tested way of carrying out this process. Following a study of the proprietary audit systems available and of current audit methodology, the authors introduced ISRS at Oxford University during 1990. Departments or units within the University are audited individually. The system has been applied to all aspects of safety, including radiation protection. ISRS is the most comprehensive safety management audit system in the world. The audit provides for a methodical, detailed analysis and evaluation of each aspect of an employer's policy, organisation and arrangements for safety. The systems in place at the unit being audited are compared for completeness against the model safety system of ISRS. Auditors using ISRS are required to undergo a course of training which has been organised by or under the auspices of the system's authors, the International Loss Control Institute. They are also required to pass an examination at the end of the course.

ISRS identifies the likelihood of accidents occurring before they become either property damaging incidents or an accident involving people and this is particularly important for activities with both a potential for high cost and a public perception of high risk.

THE AUDIT SYSTEM

The audit measures up to twenty elements of a model safety management system (see table). It is a scheme of precise questioning with built-in verification techniques. A full audit consists of asking all questions in all elements. With a total of six hundred and fifteen questions being involved. However, the system is normally applied in a progressive manner through ten stages. At the lowest level (known as Standard One), only a total of eighty-six questions in a total of thirteen elements are asked. Points are awarded according to the verified answers given. In order to move to the next level in the system, a minimum points total must be achieved. In addition, a physical inspection of a representative sample of the unit being audited is carried out and scored again with a minimum score being necessary to progress. It is at Standard One that ISRS was introduced at Oxford University.

20. Off-the-job Safety.

* Not used at the lowest level of auditing.

Following the questioning, verification, physical inspection and scoring phases of the audit, the auditors write their report on each of the elements. When the head of the unit and his team have had the time to digest the report, a full review meeting, involving the auditors, the head of the unit and various members of the safety management team, is held to discuss the audit's findings.

In addition to applying ISRS in the conventional manner, managers of high-risk activities often wish to ensure that certain elements of their management system are at a more advanced level than Standard One. Radiation protection arrangements are a prime example where the activity warrants the audit to be carried out at an advanced level. In these cases, they may ask for all questions in selective elements to be addressed. This enables auditors to determine the level a unit has achieved in a particular key element and to identify matters for development. The authors regard six of the twenty elements to be particularly relevant to radiation protection arrangements. These are task analysis, task observation, emergency preparedness, personal protection equipment (PPE), engineering control policy and planned inspections.

KEY ELEMENTS FOR RADIATION PROTECTION

Task analysis means that the components of the task or work are systematically examined in order to establish safe and effective procedures.

Task observation is a structured process by which there are checks on employees performing critical tasks (ie: those which have produced and/or possess the potential to produce a major loss to people, property or process, when not performed properly). Performance is expected to be in accordance with approved procedures.

Organisations need comprehensive emergency plans and this element measures the validity and comprehensiveness of emergency planning and questions the arrangements in place against the system standard.

Sound engineering and the proper maintenance of plant and equipment help to minimise exposure to harmful agents, such as ionising radiation. If engineering controls alone cannot provide sufficient protection, then the use of PPE is often necessary. The requirements for PPE need to be identified and thereafter, its proper selection, use and maintenance is essential. The questions in this element of the audit test that these arrangements are suitable and satisfactory.

Engineering control policy requires proper design installation and modification of both process, plant and equipment. In addition, before commissioning or recommissioning takes place, proper review procedures are required. Engineering policy is also meant to define responsibilities and questions in the element determine whether these matters have been addressed satisfactorily.

The purpose of planned inspections is to identify hazardous situations and organise remedial work before any losses can occur. There should be equipment inspections and general inspections to detect deviations from the required standards. Also necessary are inspections of critical parts and items and pre-use inspections of equipment. All inspections, regardless of title, should be planned at regular intervals and the inspections themselves should be monitored and accompanied by an effective written follow-up procedure. This elements' questions, therefore, are concerned with the effectiveness of inspections in the department, including those concerning preventative maintenance.

CONCLUSIONS

Auditing of University departments using ISRS is continuing at Oxford and is bringing about major improvements in safety. The work has demonstrated that it is possible to successfully audit particular management systems, ie: radiation protection arrangements within the overall system and the authors believe believe it is practical to make the necessary changes to ISRS scoring. In practice, auditing is proving to be an excellent aid to determining the areas requiring additional resources and in the prioritisation of remedial actions. Auditing emphasises the concept that safety must be managed. It has also become clear that auditing should always be set against a background of regular, thorough, physical inspections and other monitoring exercises.

The authors recommend that the use of a formalised audit system should be promoted as a method of significantly improving radiation safety arrangements.

OPTIMIZATION (ALARA) OF RADIATION PROTECTION
AT DEPARTMENT OF ENERGY FACILITIES

A. A. Weadock and C. Rick Jones

Office of Health Physics and Industrial Hygiene
U.S. Department of Energy
Washington, D.C. 20585

ABSTRACT

Maintaining worker and public exposures As Low As Reasonably Achievable (ALARA) is a key objective of the Department of Energy (DOE). Responsibility for occupational ALARA program policy and guidance resides within the DOE Office of Health. Current Office of Health initiatives related to ALARA include the development of additional regulatory guidance related to ALARA program implementation at DOE contractor facilities, the review of ALARA program status at various facilities and the production of technical reports summarizing this status, and the support of various mechanisms to improve communication among the DOE ALARA community. The Office of Health also monitors revisions to radiogenic risk estimates and radiation protection recommendations to evaluate adequacy of current DOE limits and impacts of potentially revised limits.

REGULATORY INITIATIVES

Current occupational ALARA program requirements applicable to DOE contractor facilities are identified in DOE Order 5480.11, "Radiation Protection for Occupational Workers." Specific requirements include the need for formal ALARA plans and programs, the use of optimization methodology in radiological design, the provision for worker training on ALARA techniques, routine audits of ALARA program implementation, and maintenance of ALARA records. DOE Order 5480.11 and its inclusive ALARA program requirements are currently being codified into a draft rule (10 CFR 835) for publication in the U.S. Code of Federal Regulations (CFR) in November 1991.

To supplement basic regulatory requirements contained in Order 5480.11 and the draft rule 10 CFR 835, the Office of Health is developing an ALARA Implementation Guide (IG), scheduled for initial distribution in November 1991. The ALARA IG will identify those basic program elements and functions necessary for an acceptable ALARA program. In recognition of the broad diversity of DOE contractor facilities and missions, the approach taken in the IG is to identify the specific programmatic functions that should be in place, and include a stipulation that the formality and extent of their implementation should be commensurate with the hazard and the potential exposure savings.

The Department has also published a broad scope manual (PNL-6577) which provides extensive guidance on ALARA program implementation, including program enhancements and good practices. Once finalized, the ALARA IG will serve as a intermediary or bridge between the basic requirements in Order 5480.11 and the good practice guidance of PNL-6577.

As a corollary to its responsibilities for policy and guidance development, the Office of Health also monitors and evaluates revisions to radiogenic risk estimates and basic radiation protection recommendations to assess the adequacy of existing DOE occupational worker radiation exposure limits in controlling exposure and the impact of potential revisions to the occupational exposure limits. During 1990, DOE conducted a formal review of the potential impacts of the National Academy of Science Biological Effects of Ionizing Radiation (BEIR V) Report.

As part of this review, the Office of Health evaluated current exposure trends and also identified projected increases in facility costs, staffing, and collective exposure that would result from implementation of a reduced occupational exposure limit. The review of DOE exposure statistics identified that both collective and individual exposures within DOE have showed significant decreasing trends over the 1979-1989 period, as shown in figure 1. These decreases can be attributed to increasing emphasis on ALARA and, particularly in the last few years, to curtailments on facility operations or shift in facility mission. The DOE study report, published in 1990, concluded there was no immediate need for revision of current DOE occupational exposure limits, but emphasized the importance of ALARA program and dose reduction efforts in optimizing individual and collective exposures.

REVIEW OF PROGRAM STATUS

Utilizing contractor support from the Brookhaven National Laboratory ALARA Center, the Office of Health has initiated various reviews to identify the current status of ALARA program implementation at DOE contractor facilities. During 1989-1990, a survey of ALARA program implementation at 12 major contractor facilities was conducted. The report, to be published in 1991, identifies overall status of ALARA program implementation within DOE; identifies the generic strengths, weaknesses, and areas for improvement; and lists specific dose reduction methods that have been found effective for specific radiological jobs and activities. A supplemental volume to the report includes "good-practice" examples of generic ALARA program documents (i.e., policy statements, Radiation Work Permit (RWP) forms, pre-job planning checklists, ALARA lesson plans) that can be easily modified and utilized by specific facilities in their ALARA programs.

A second such study, focusing on high-dose workers and work activities and radiological design criteria, was initiated in 1991.

Figure 1- DOE Collective and Average Individual Exposures for 1979-1989 (average exposures shown for personnel with measurable exposure).

IMPROVING COMMUNICATIONS

The Office of Health also supports several activities designed to improve overall communication among the members of DOE and DOE contractor ALARA community. Towards this end, the Office of Health has contracted with the BNL ALARA Center to provide their ALARA technical expertise and information sharing capabilities to the DOE community. Specific task or initiatives undertaken in this area include:

- Publication of a continuing series of ALARA bibliographies containing references particularly applicable to DOE and its contractors.
- Development of a DOE ALARA Radiological Contacts List, which is frequently updated and distributed within the DOE community to promote communications.

- Conduct of conference sessions and workshops specific to ALARA programs. Several sessions during the August, 1991 DOE Radiation Protection Conference were devoted to DOE ALARA programs. A two-day DOE ALARA Workshop is planned for Spring, 1992.

CONCLUSIONS

Efforts in ALARA program implementation and dose reduction have resulted in significantly decreasing trends in collective and individual exposure at DOE contractor facilities over the past several years. Current Office of Health initiatives related to the development of ALARA policy and guidance, review of ALARA program implementation, and the promotion of communication and exchange of ideas within the DOE community reflect a continued emphasis on dose reduction and should prove effective in reducing DOE exposures to ALARA levels.

ANGULAR DEPENDENCE OF ORGAN DOSES AND EFFECTIVE DOSE
FOR EXTERNAL PHOTON IRRADIATION

Y. Yamaguchi and M. Yoshizawa

Japan Atomic Energy Research Institute,
Tokai-mura, Naka-gun, Ibaraki-ken, 319-11 Japan

ABSTRACT

Based on the new ICRP recommendations, the equivalent doses in organs and tissues and the effective dose were calculated using the Monte Carlo method for monoenergetic photons incident at each of 86 different angles. The results which were obtained for incident photon energies of 45, 90 and 1250 keV are demonstrated and the angular dependence of these dosimetric quantities is also discussed.

INTRODUCTION

The ICRP has, in its new basic recommendations¹⁾, defined a new dosimetric quantity, the equivalent dose H_R , for radiation protection purposes with the newly introduced radiation weighting factor w_R . The ICRP has also amended the tissue weighting factor w_T and the definition of the remainder organs or tissues, which should affect directly the assessment of the effective dose E , previously called the effective dose equivalent H_E ²⁾. Since these new dosimetric quantities are expected to be different from the former ones, it is quite important to estimate them based on the method newly recommended. In addition, it is also worthwhile to make clear their characteristics to ensure the reasonable dose estimation in actual radiation protection practices. Since the quantity E cannot be measured, computer simulation is considered to be the best solution to estimate E at this moment. In the present work, the values of H_R in organs and tissues and E were calculated using the Monte Carlo method for external photon irradiations, and the results were analyzed to clarify their dependence on the radiation incident angle.

METHOD

The equivalent doses H_R for 61 different organs and tissues were calculated for external photons using a revised version of the DEEP code³⁾ in which the MORSE-CG code⁴⁾ is incorporated to calculate the radiation transport. Used was a MIRD-5 type phantom^{3),5)}, defined by mathematical formulae and with limited number of human media with different elemental compositions and densities: soft, lung and skeletal tissues. The photon cross sections were taken from the DLC-15 library⁶⁾ and the photon energy from 5 to 12000 keV was collapsed into 24 groups. The kerma approximation was employed for dose calculation, which is considered to give a good approximation for photons of energies less than several MeV. While three kinds of human media were used in the photon transport calculation, the red and yellow bone

marrow tissues were added to them in the dose calculation. One of the biggest problems in calculating E with the MIRD-type phantoms is that they do not have the oesophagus. Hence the phantom was modified to have the oesophagus which was represented by an elliptical normal tube descending along the spine from the neck to around the diaphragm and an inclined tube attaining to the upper part of the stomach. The effective dose E was evaluated as a sum of weighted doses, $\sum w_T H_T$, with a set of the values of w_T specified in the new recommendations. The value of the w_T of 0.05 was allocated to the dose averaged over organs and tissues specified as the remainder by the ICRP.

The dose calculations were performed for monoenergetic photons incident in parallel beams at each of 86 different angles, defined at the spherical lattice points including both poles. Three photon energies were selected: 45, 90 and 1250 keV. All the calculated results were given as the values per unit absorbed dose to air in free air.

RESULTS AND DISCUSSION

From a number of calculated results, some typical examples are shown in this paper. The statistical error (one relative standard deviation) of the results is less than 5% for H_T and less than 3% for E.

The angular dependence of weighted equivalent doses ($w_T H_T$) relative to the horizontal axis of the human body is shown in Figure 1 for the gonads, red bone marrow and breasts for the incidence of 90 keV photons. The equivalent doses for these organs have a symmetric response with respect to the anteroposterior axis, reflecting their symmetric configuration in the human body.

Figure 1. Angular dependence of weighted equivalent doses ($w_T H_T$) per unit absorbed dose to air in free air, relative to the horizontal axis of the human body for the gonads, red bone marrow and breasts. Incident photon energy is 90 keV.

An enhanced response for the photons from the front-half-around angle can be observed for the gonads and breasts. It is quite reasonable considering their location in the body. On the contrary, the red bone marrow has a slightly higher response for the back-half-around angle and it can be explained by its high content in the spine and pelvis. From observation of angular dependence of $w_R H_T$ in organs for all the 86 incident angles, it can be concluded that the gonads provide a dominant component of E , especially for the photons incident from the forward 2π solid angle.

Figure 2. Angular dependence of the effective dose per unit absorbed dose to air in free air, relative to the horizontal axis of the human body for the photons of 45, 90 and 1250 keV.

Figure 3. Angular dependence of the effective dose per unit absorbed dose to air in free air, relative to the vertical axis of the human body for the photons of 45, 90 and 1250 keV.

Figures 2 and 3 shows the angular dependence of E relative to the horizontal axis and vertical axis of the body, respectively, for the photons of 45, 90 and 1250 keV. In Figure 2, a symmetric response of E can be observed with respect to the anteroposterior axis in spite of asymmetric configuration of some organs such as stomach and liver. In Figure 3, an extremely depressed response of E can be seen for the photons incident from the top and bottom. This is because the principal organs are located at around the center of the body and they are shielded by the human tissue against the photons incident from such angles. Observing these two figures, it can be said that while the angular response of E for low energy photons, at 45 keV, appears enhanced in the forward 2π solid angle, the response becomes more and more isotropic with increasing the photon energy. It can be pointed out as an important characteristics of E that the response of E appears most enhanced for the photons incident at the just front angle for external photon exposure. It suggests that dosimeters worn at the surface of the front trunk gives the best indication in the general situation of personal monitoring. Finally, Figures 2 and 3 suggest also a need of special measures to monitor the dose for the photons incident from the top and bottom.

CONCLUSIONS

The equivalent doses H_T in organs and tissues and the effective dose E were calculated using the Monte Carlo method for external photon irradiations. The angular dependence of these dosimetric quantities was analyzed with the calculated results. A significant angular dependence is observed in both H_T and E. An interesting characteristics is that E appears most enhanced, for the photons incident at the just front angle.

**ANALYSE COMPARATIVE DES DIFFÉRENTS SYSTEMES
JURIDIQUES EN MATIERE DE RADIOPROTECTION**

**MM. Delpirou - Fiquet
Electricité de France - Service Juridique - Paris - France**

L'objet de cette étude est de présenter sous forme comparative les systèmes juridiques de radioprotection mis en oeuvre par la communauté européenne et ceux de trois principaux Etats membres ayant recours à la production d'électricité d'origine nucléaire : Allemagne, Royaume-Uni et France.

L'analyse portera sur les principes généraux de radioprotection et plus précisément sur les trois domaines qui constituent le fondement des normes de base visées par le traité EURATOM :

- les doses maxima admissibles;**
- les expositions et contaminations maxima admissibles;**
- les principes fondamentaux de surveillance médicale des travailleurs.**

Pour chacun de ces domaines, seront comparées sur la base de la réglementation communautaire, les normes nationales des trois Etats considérés, tant du point de vue "quantitatif" (montant des doses...) que "qualitatif" (exposé des motifs ayant présidé à l'instauration de législation nationale, champ d'application couvert par les textes, risques particuliers pris en considération compte-tenu de la nature des installations, mise à jour de la réglementation en fonction des progrès techniques réalisés...).

La communication permettra de souligner les éventuelles différences quant à l'approche de cet impératif de sécurité, l'état de comptabilité des droits nationaux avec les règles européennes et mesurera en quoi l'institution du traité de la Communauté européenne de l'énergie atomique a contribué ou non à unifier les réglementations nationales dans ce secteur particulier.

THE REVIEW OF SAFETY CASES WITHIN BNFL

J P Shepherd
A H Fishwick

British Nuclear Fuels plc
United Kingdom

ABSTRACT

The British regulatory process requires BNFL to make safety submissions for all major activities, ie design/construction, commissioning, operation, modification and decommissioning. As part of the regulatory requirement, an independent review of the safety is necessary. This paper describes how the review takes place within BNFL.

INTRODUCTION

BNFL operate processes which cover the whole of the nuclear fuel cycle. Fuel manufacture takes place at Springfields near Preston, enrichment at Capenhurst near Chester, whilst the reprocessing operation is conducted at Sellafield in West Cumbria. Additionally, BNFL operate the original Magnox power reactors at Sellafield, and a similar installation at Chapelcross, Scotland.

The British regulatory process requires the licensee (BNFL) to make detailed safety submissions for all major activities, ie design/construction, commissioning, operation, modification, and decommissioning. The regulatory body issues consents as appropriate when it is satisfied with the safety submissions.

The preparation of safety submissions is the responsibility of the various operating divisions within BNFL. These submissions are extensive, and generally include probabilistic analyses as well as deterministic demonstrations.

As part of the regulatory requirement a second opinion, or Peer Review is required by the Regulator - for all Safety Cases. The review process is the responsibility of an independent group which is part of the Central Health and Safety Directorate, and which has no line management ties to Operating Divisions. It is the purpose of this paper to describe how this activity functions within BNFL.

METHODOLOGY

Safety cases are categorised according to their safety significance and the depth of their review depends on this categorisation. The categorisation is done in advance of the main safety case preparation. The first task of the reviewer is to agree or disagree with the categorisation which has been made. The first few steps in the flowchart in Figure 1 shows this process.

In a safety categorisation system which has categories 1, 2, 3 and 4 (with 1 having the highest safety significance), the review exercise is structured as indicated in the following table.

Category	Summary of Review Exercise
1 2 3 4	Categorisation of safety case check
1 2 3	Audit <ul style="list-style-type: none"> - procedures - methods
1 2	Completeness <ul style="list-style-type: none"> - plant/modification itself - other interacting plant
1 2	Inventory library check
1 2	Logic and methodology <ul style="list-style-type: none"> calculations - risk estimates - check (sample)
1	Logic and Methodology <ul style="list-style-type: none"> calculations - risk estimates - check (representative selection) - first principles (sample)
1	HAZOP <ul style="list-style-type: none"> - sample

* Only if the reviewer judges it to be warranted.

The degree of attention given to separate parts of the safety case should be commensurate with the reviewer's opinion of the risks involved. The review could range from simply a check of the safety case categorisation to a fundamental evaluation of the safety case depending on the safety significance and the reviewer's initial assessment of the safety case.

As can be seen from the table, the methodology involves an "inventory library". This makes use of a library of historical data compiled from safety analyses of a range of plant such that a given safety analysis may often be compared against a similar previous one to see whether or not the result is of the right order. The other steps in the table are self explanatory.

The reviewers only review completed safety cases, ie cases which are ready for submission to a safety committee. The result of the review will be one of three conclusions.

- case satisfactory
- case generally satisfactory but further work required
- case unsatisfactory

This result and its associated report are routed to the project sponsor who is usually a senior manager in the operating division. The interaction between the review, the safety committee and the regulator, is shown in Figure 1.

STAFFING

The review team consists of a small nucleus of BNFL staff with each principal reviewer being responsible for a BNFL division or divisions. The principal reviewer then calls on the assistance of experienced specialists to examine particular aspects of the safety case in more detail as appropriate. These specialists may or may not be BNFL employees, but they must be independent of the authors of the safety case under consideration.

CONCLUSION

The independent review of safety cases is established within BNFL and is seen as an important step in the process of self regulation.

The U.S. Department of Energy Laboratory Accreditation Program
for Testing the Performance of Extremity Dosimetry Systems:
A Summary of the Program Status

F.M. Cummings, R.D. Carlson, T.F. Gesell, DOE/Idaho Falls
and
R.M. Loesch, DOE/Office of Health

Introduction

In 1986, The U.S. Department of Energy (DOE) implemented a program to test the performance of its personnel whole-body dosimetry systems. This program was the DOE Laboratory Accreditation Program (DOELAP). The program parallels the performance testing program specified in the American National Standard for Dosimetry - Personnel Dosimetry Performance - Criteria for Testing (ANSI N13.11-1983), but also addresses the additional dosimetry needs of DOE facilities. As an extension of the whole-body performance testing program, the DOE is now developing a program to test the performance of personnel extremity dosimetry systems. The draft DOE standard for testing extremity dosimetry systems is much less complex than the whole-body dosimetry standard and reflects the limitations imposed on extremity dosimetry by dosimeter design and irradiation geometry. A pilot performance test session has been conducted to evaluate the proposed performance testing standard.

DOE Laboratory Accreditation

The process for gaining accreditation of a dosimetry system follows. The laboratory seeking accreditation completes an application form that identifies the irradiation categories in which testing is required and that describes the dosimetry system being tested. This application is submitted through the local DOE Field Office to the Performance Evaluation Program Administrator. At the direction of the performance testing laboratory, the applicant sends an appropriate number of dosimeters for testing. The testing laboratory irradiates the dosimeters and returns them to the applicant. This process of sending, irradiating and returning the dosimeters is repeated two more times. The duration of the dosimeter testing phase is approximately five months. The applicant reports the dosimeter results to the testing laboratory where the results are evaluated using the performance criteria defined in the testing standard. If a dosimetry system does not meet the specified performance criteria, the applicant must repeat all or a portion of the performance test.

When the performance test criteria have been successfully met, the administrator assigns two assessors from other laboratories to evaluate the applicant's ability to conduct a credible personnel dosimetry program. The onsite assessment includes evaluation of quality assurance, documentation of the system, personnel training, personnel competency, facilities and equipment, equipment maintenance and calibration and recordkeeping. Using the results of the performance test and the onsite assessment, the administrator collects a file of supporting information which is used by the DOELAP Oversight Board for recommending accreditation actions to the DOELAP Program Administrator at DOE Headquarters. If the applicant feels an action is incorrect, the applicant and DOE Field Office may petition a

Board of Appeals.

To maintain accreditation, DOE laboratories must pass performance testing and onsite assessment every two years. A laboratory which does not pass all of the performance testing may be granted conditional accreditation for a subset of the testing requirements specified in the application. If a laboratory is not fully accredited it must submit and implement a remedial action plan to correct the deficiencies prior to achieving full accreditation.

Testing Categories

The draft extremity dosimetry standard applies to dosimetry performed for health protection under controlled (protection level) and uncontrolled (accident level) conditions. Tests for accident dosimetry are approximately represented by a high dose category. Performance studies for angular dependence and lower limit of detectability are required one time only for each dosimeter type submitted for evaluation.

The testing categories are summarized in Table 1. With the exception of the uranium slab source, all of the irradiation sources in the standard are consistent with specifications in ISO documents. With the exception of neutron irradiations, the reference depth for the specification of dose or dose equivalent to the extremities is 7 mg/cm². The testing criteria are:

$$|B| + S - |E| \leq L$$

- where
- B is the average bias of dosimeters in a particular category or subcategory,
 - S is the standard deviation of the measurements for a particular category or subcategory,
 - E is the estimation of the fractional uncertainty in the delivered dose or dose equivalent rate and
 - L is the tolerance level (L = 0.3 for category I and 0.5 for categories II through IV)

Performance tests for neutron dosimetry are included in the draft standard because neutron exposures are currently measured and reported by DOE and DOE contractor facilities where the extremities of workers are exposed to significant dose equivalents from neutron fields. It is recognized that numerous complexities exist in assigning a dose to the extremities from neutron radiation. For purposes of dosimeter performance evaluation, the testing standard uses the existing neutron fluence to dose equivalent conversion factors specified in International Standard ISO-8529 for the whole body. While there are significant technical inadequacies with this approach, including the depth for dose evaluation and the use of quality factors, the approach is consistent with practices used at this time to record dose equivalent. A study by DOE to determine more meaningful and technically based quantities for extremities is planned. As that information becomes available, the standard will be revised.

Categories comprised of mixtures of sources (e.g., low and high energy photons or beta particles and high energy photons) have not been included at this time. In general, the extremity dosimeters that are currently in

use cannot discriminate between radiation types and energies unless they are multi-element dosimeters. In addition, extremity dosimeters are typically used to monitor specific exposure situations where the source of exposure is known or the response of the dosimeter has been previously characterized.

Table 1. Irradiation Categories

<u>Test Category</u>	<u>Energy</u>	<u>Test Range</u>
IA. Photons, Accident, General NIST M150 X ray ¹³⁷ Cs	70 keV (Average) 662 keV	0.1 to 5 Gy
IB. Photons, Accident, Special NIST M150 X ray	70 keV (Average)	
IC. Photons, Accident, Special ¹³⁷ Cs	662 keV	
IIA. Low Energy Photons NIST M30 X ray NIST M150 X ray	20 keV (Average) 70 keV (Average)	2.5 to 100 mSv
IIB. High Energy Photons ¹³⁷ Cs	662 keV	2.5 to 100 mSv
IIIA. Beta Particles, General (point geometry) ²⁰⁴ Tl ⁹⁰ Sr/ ⁹⁰ Y	0.76 MeV (Maximum) 2.3 MeV (Maximum)	2.5 to 100 mSv
IIIB. Beta Particles, Special (point geometry) ⁹⁰ Sr/ ⁹⁰ Y	2.3 MeV (Maximum)	2.5 to 100 mSv
IIIC. Beta Particles, Special (point geometry) ²⁰⁴ Tl	0.76 MeV (Maximum)	2.5 to 100 mSv
IIID. Beta Particles, Special (slab geometry) Uranium	2.3 MeV (Maximum)	2.5 to 100 mSv
IVA. Neutron, General ²⁵² Cf (D ₂ O-moderated) ²⁵² Cf (unmoderated)		2.5 to 100 mSv
IVB. Neutron, Special ²⁵² Cf (D ₂ O-moderated)		2.5 to 100 mSv
IVC. Neutron, Special ²⁵² Cf (unmoderated)		2.5 to 100 mSv

Dosimeter Phantoms

Five phantom designs shall be used for extremity dosimeter irradiations: one to represent a lower arm or leg to test wrist or ankle dosimeters for photon and point geometry beta exposures; a second similar phantom for neutron irradiations; a third to represent a finger to test ring or hand dosimeters; a fourth to represent a lower arm or leg to test wrist or ankle dosimeters for uranium slab exposures and a fifth to represent a finger to test ring or hand dosimeters for uranium slab exposures. Originally, the standard specified only three phantoms, but two additional phantoms were required to perform uranium slab irradiations. The arm/leg phantoms used

for photon and beta exposures are right circular cylinders of aluminum with a diameter of 60 mm nested inside a tube of polymethylmethacrylate (PMMA) with an inner diameter of 60 mm and an outer diameter of 73 mm. The length of the aluminum insert and the PMMA tube are both 300 mm. The arm/leg phantom used for neutron irradiations is a right circular cylinder of PMMA with a diameter of 73 mm and a length of 300 mm. The finger phantoms are right circular cylinders of PMMA with a diameter of 19 mm and a length of 300 mm.

The phantoms used for uranium slab exposures incorporate sections of phantoms as specified above, but allow all the dosimeters to be placed on the slab at once and float in such a manner to allow dosimeters of different thickness to be in contact with the slab source simultaneously without being tilted.

The factors for the photon fields which convert exposure to dose equivalent (Sv/R) at 7 mg/cm² have been measured by Roberson, et. al. and incorporate a quality factor of unity. The factors are:

	<u>Arm/Leg Phantom</u>	<u>Finger Phantom</u>
M30 X-Ray Technique	9.9	9.5
M150 X-Ray Technique	11.4	10.1
¹³⁷ Cs Gamma-Ray Source	10.2	9.8

The neutron fluence to dose equivalent conversion factors are for the torso phantom and have been specified in International Standard ISO-8529. Those factors are 9.1×10^{-11} Sv·cm² for the D₂O-moderated ²⁵²Cf source and 3.33×10^{-10} Sv·cm² for the unmoderated ²⁵²Cf source. The factor for the moderated Cf source is further modified to account for the loss of thermal neutrons in the cadmium shield surrounding the D₂O.

Performance Testing Pilot Study

A pilot test session has been conducted to evaluate the proposed performance testing standard. Six DOE laboratories submitted a total of six ring dosimeters and two wrist dosimeters for testing. While not all test sub-categories were included in testing, all sources were included (e.g., testing occurred in category IA, Photons, Accident, General using M150 and ¹³⁷Cs, but not in the special categories IB and IC for which a single source is specified.)

Extremity DOELAP Status

The draft Standard and Handbook for the DOELAP for extremity dosimetry have been submitted to all DOE Field Offices for review and comment. The comments will be evaluated and included as appropriate into the final Standard and Handbook. The DOE Order 5480.15 which regulates the performance of personnel dosimeters will be modified during 1992 and submitted for comment. The DOE will begin a phase of voluntary testing starting January, 1993. When the DOE Order has been modified to include extremity dosimetry performance testing and published, performance testing for extremity dosimetry systems will be mandatory for all DOE laboratories.

CRITICAL REMARKS ON THE EURATOM BASIC STANDARDS

M. Heinzelmann, R. Hille
Forschungszentrum Jülich GmbH
D-5170 Jülich, Bundesrepublik Deutschland

ABSTRACT

The data in the Annex to the EURATOM Basic Standards give rise to criticism in the following points:

- The classification of radionuclides does not correspond to that of the relative radiotoxicity for some nuclides.
- The derived limit of tritium concentration in air does not make allowance for elemental tritium autooxidation.
- The limits of annual intake are in some cases higher than permissible due to the chemical toxicity.

INTRODUCTION

The "Basic Safety Standards for the Health Protection of the General Public and Workers Against the Dangers of Ionizing Radiation" [1,2] of the Commission of the European Communities, which are presently being revised, are the essential basis for the health physics regulations in the countries of the European Community. A few data in the extensive Annexes to the Basic Standards give rise to these critical remarks which primarily concern the figures given in the Annexes. The points in question will be discussed in the following.

RADIONUCLIDES WITH AN ACTIVITY CONCENTRATION BELOW $100 \text{ Bq} \cdot \text{g}^{-1}$

The activity concentration of the long-lived radionuclides Cd-113, Te-123, Gd-152 and Ta-180 is lower than $100 \text{ Bq} \cdot \text{g}^{-1}$ even for pure isotopes. These radionuclides are grouped in a radiotoxicity class, so that an activity limit is stipulated for these nuclides. For activities above this limit an authorization is required for handling these nuclides. This is not consistent with Article 4 of the Directive [1] according to which the requirements for reporting and obtaining prior authorization are not applicable if radioactive substances with a concentration of less than $100 \text{ Bq} \cdot \text{g}^{-1}$ are involved.

CLASSIFICATION OF RADIONUCLIDES ACCORDING TO THEIR RELATIVE RADIOTOXICITY

The most important radionuclides are grouped in Annex I to the Directive according to their relative radiotoxicity [2]. A comparison of the nuclides in the different radiotoxicity groups with the limits of annual intake in Annex 3 to the Directive shows that the limits of annual intake do not

correspond in each case with the radiotoxicity. Radiotoxicity is the toxicity of an incorporated nuclide and its daughter products due to ionizing radiation. The limits of annual intake should thus be a measure of radiotoxicity. Table 1a shows the isotopes of an element which have been incorrectly classified insofar as the isotope with the same or even higher limit of annual intake was allocated to a higher radiotoxicity group. Table 1b shows corresponding values for different elements.

DERIVED CONCENTRATION LIMITS FOR TRITIUM

Derived limits of concentration in the air inhaled are specified for elemental tritium and for tritiated water. The limit for elemental tritium ($2 \cdot 10^{10} \text{ Bq} \cdot \text{m}^{-3}$) is higher than that for tritiated water ($8 \cdot 10^5 \text{ Bq} \cdot \text{m}^{-3}$) by a factor of $2.5 \cdot 10^4$. In determining the derived concentration limit for elemental tritium, the autooxidation of tritium in air has obviously not been taken into account. According to Casaletto [3] the oxidation rate of elemental tritium in air is 1.5 % per day. Tritiated water is formed relatively quickly from elemental tritium due to autooxidation. A concentration of tritiated water amounting to $1 \cdot 10^{-4}$ of the concentration of elemental tritium is already formed after 10 minutes. The concentration ratio of tritiated water to elemental tritium is practically always higher than the ratio of the derived concentration limits. Moreover, in radiation protection monitoring it is hardly possible to detect concentrations of tritiated water amounting to less than 1 % of the concentration of elemental tritium using normal air monitoring devices. The high concentration limit for elemental tritium is thus not conservative and should be changed so that it covers at least the 1 % concentration of tritiated water which is difficult to measure.

ALLOWANCE FOR THE CHEMICAL TOXICITY

The limits of annual intake due to inhalation do not make allowance for the chemical toxicity with one exception (uranium). For various long-lived nuclides the limits of annual intake due to inhalation are higher than the values which can be derived from the maximum permissible workplace concentrations (MAK values) of conventional safety regulations [4]. For the nuclides Cd-113, In-115, Te-123, Ta-180 and Re-187 the limit of annual intake is higher by more than a factor of 10^3 than the corresponding value of conventional safety regulations. In such cases, the Euratom directives should make allowance - similar to uranium - to the chemical toxicity or at least refer to the values of conventional safety regulations.

LIMIT OF ANNUAL INTAKE THROUGH THE GASTRO-INTESTINAL TRACT FOR LONG-LIVED NUCLIDES

For certain long-lived isotopes (Cd-113; In-115; Te-123; Ta-180; Re-187) the limit of annual intake through the gastro-intestinal tract for individuals is so high that the amount corresponds to an average intake of 1 kg per day or more. A specification of these limits should be omitted since hardly 1 ‰ of these values is incorporated inadvertently.

LES PROBLÈMES DE L'IMPLANTATION D'UN PROGRAMME UNIVERSITAIRE DE RADIOPROTECTION

J.C. Borges, K.C. Caballero

EE/COPPE/UFRJ - Caixa Postal 68.509
Rio de Janeiro - RJ - Brésil

IMPLANTATION OF A RADIOPROTECTION PLAN FOR BRAZILIAN UNIVERSITIES

In 1984, the Federal University of Rio de Janeiro started a wide radioprotection program, installing a Radiological Control Service. The experience acquired, dealing with its own problems, plus data concerning similar problems obtained from other Brazilian universities, as well as the national legislation for this kind of activities, permitted the establishment of a standard radioprotection program for these universities.

INTRODUCTION

L'Université Fédérale de Rio de Janeiro a démarré en 1984, un vaste programme de radioprotection, pour attaquer des problèmes comme:

- 1 - une bonne connaissance:
 - a) des activités liées à l'utilisation des radiations ionisantes sur le campus ;
 - b) des niveaux dosimétriques et des risques concernés à ces activités;
- 2 - le contrôle médical des employés;
- 3 - la fiscalisation des activités plus dangereuses;
- 4 - la concession des bénéfices prévus par la législation brésilienne, surtout ceux concernant à des aspects financiers;
- 5 - l'entraînement des employés, selon leur tâche et niveau technique;
- 6 - la centralisation du contrôle dosimétrique des travailleurs;

D'un autre côté, on a aussi bien analysé la législation nationale concernant les activités avec des radiations, séparée en deux blocs:

- 1 - les normes e procédures de travail;
- 2 - les droits travailistes.

Les problèmes les plus cruciaux rencontrés dans l'implantation du programme ont été d'ordre juridique, c'est à dire, comment établir des procédures de radioprotection et concéder des bénéfices travailistes face à l'ambiguïté et même les contradictions

de la législation mentionnée.

RECOMMENDATIONS

Un programme si général, pionnier dans le contexte des universités brésiliennes, a permis d'établir:

- 1 - le modèle d'un plan général de radioprotection pour les universités brésiliennes dont les principales recommandations résident sur:
 - a) l'établissement d'un Secrétariat Spécial de Contrôle des Activités Nucléaires, dans le contexte d'un Secrétariat Général de Médecine et Sécurité du Travail, déjà prévu par loi;
 - b) l'établissement d'un Laboratoire de Dosimétrie et Radioprotection, lié, si possible, à un département dont les activités soient essentiellement nucléaires;
 - c) le Laboratoire doit fournir au Secrétariat Nucléaire, le support technique pour les contrôles et décisions administratifs.
- 2 - des recommandations aux pouvoirs publics de changement de la législation actuelle, surtout son protectionnisme exagéré et anachronique:
 - a) la concession de bénéfices financiers selon les niveaux de dose des activités;
 - b) le droit à des bénéfices comme:
 - la réduction de la durée de travail semanal;
 - les vacances semestrales.

**INTRODUCING UNIKORNES - (United Kingdom Occupational
Radionuclide Exposure Study)**

WOODHOUSE J A, SLOVAK A J M, WOOD R

Post-mortem studies on occupationally exposed workers represent a major potential source of information for the development of improved metabolic models for use in radiological protection dosimetry. They are particularly valuable in the context of exposure to materials such as plutonium and uranium, which are widely encountered in the nuclear industry, and for which in vivo monitoring possibilities are limited given the lack of sufficiently energetic photon emissions.

Within the UK an initiative has now been taken to set up a joint industry programme of post-mortem studies to investigate the deposition patterns of radionuclides in occupationally exposed persons. Partners in the joint programme are currently BNFL, NRPB, AEA Technology and MoD. It is intended to maintain close links with the USTR and USUR programmes and with any future developments that may arise in Europe.

The timing of this initiative is important. As radiological protection practices have developed over the years the frequency of occurrence and severity of events leading to internal contamination has decreased. There is, therefore, a dwindling population of cases believed to have sustained levels of internal contamination which would constitute the most "useful" cases for post-mortem investigation. The window of opportunity is ever closing.

This paper outlines the objectives of the studies proposed and describes progress to date in setting up the project. The philosophy of approach is discussed along with the particular problem areas which must be addressed in setting up and managing a study of this nature.

THE ROLE OF RADIOACTIVITY MONITORING PROGRAMMES IN THE STUDY OF ENVIRONMENTAL PROCESSES

G. J. Hunt
Fisheries Radiological Inspectorate
Fisheries Laboratory
Lowestoft, Suffolk, NR33 0HT, England

ABSTRACT

The objectives of environmental monitoring are briefly reviewed. The suggestion is made that the potential for data to provide information on environmental processes should be borne in mind when setting up monitoring programmes. Two examples of the type of information that can be gained are given relevant to the marine environment near Sellafield. First, studies of dispersion timescales for actinides show that there has been an apparent increase in these timescales in recent years. Secondly, studies of remobilisation of caesium-137 show that about 700 TBq have been remobilised from the sea bed near Sellafield in the period 1983-1990.

OBJECTIVES OF ENVIRONMENTAL MONITORING PROGRAMMES

In designing monitoring programmes for radioactivity in the environment full consideration is needed of the objectives which the programmes are required to fulfil. Relevant objectives have been reviewed in many fora: the International Commission on Radiological Protection (ICRP) and International Atomic Energy Agency (IAEA) have provided guidance in an international context (ICRP, 1985; IAEA, 1975). These authorities are in general agreement that there are primary objectives related to:

- a) assessment of actual or potential doses to critical groups and populations;
- b) demonstration of compliance with regulations;
- c) assessment of the adequacy of controls on sources including surveillance for any unplanned releases to the environment.

There are also subsidiary objectives which may be considered when a need for monitoring has been established, and may be summarised as:

- d) improvement of knowledge of the relationship between sources and exposures (including sub-critical exposures) under different conditions so as to keep under review the transfer models and dose predictions, including those in the event of emergency;
- e) recording of long-term changes or trends due to sources;
- f) provision of information for the public;

© Crown copyright

g) provision of information relevant to elucidating environmental processes.

In practice, different degrees of importance may be attached to these objectives by different organisations and under different circumstances. For example, an operator of a nuclear installation would probably see (b) as quite important while a regulator might place more emphasis on (a) and (c). ICRP (1985) make the distinction between source-related and person-related environmental monitoring; the latter applies to multiple or widely distributed (including natural) sources, and here objectives (c) and (d) might be adjudged important by a national authority. In an emergency, the main objective would be likely to be (a), with the emphasis on rapid compilation of data to enable judgements on the need for countermeasures, their extent, and to review their effectiveness.

PROVISION OF INFORMATION ON ENVIRONMENTAL PROCESSES

It is necessary to draw a clear distinction between research as the direct investigation of environmental mechanisms, and environmental monitoring, the results of which can contribute to understanding of such mechanisms. Research and monitoring properly have different objectives, and the main objectives of environmental monitoring are given above. However, when designing monitoring programmes, it is reasonable to bear in mind the potential for providing data on environmental processes and to seek to maximise the information that can be gained. Because of the objectives of environmental monitoring, there can be some advantages over research programmes in the type of data available. One particular advantage is that monitoring programmes can cover a long time series, such that when data are comparable, useful information can be derived on processes of long characteristic timescales. This is in contrast with many research programmes which, often through funding requirements, can tend to be more short-term.

This paper now presents two recent examples of the information which has been gained from monitoring programmes in relation to the dispersion of radionuclides in the Irish Sea from the British Nuclear Fuels plc (BNFL) Sellafield plant.

TIMESCALES FOR DISPERSION OF ACTINIDES IN THE IRISH SEA

Discharges of plutonium and americium to the Irish Sea from Sellafield, which are authorised by the UK Government, have decreased significantly over the past ~15 years. The reductions are due to the operation of treatment facilities, and further treatment plant is due to be commissioned in 1992. Marine discharges of alpha emitters in 1990 were some 2.5% of levels in 1975. Resulting concentrations of actinides in environmental materials are also decreasing, and for ^{241}Am this is happening despite ingrowth from past discharges of ^{241}Pu . Reliable monitoring data from this laboratory for actinides, in time series which allow analysis, date from the early 1970s and this data has been used to investigate the timescale over which the effects of discharges remain reflected in marine materials. A simple model was used, based on a sum of exponential terms to represent the availability of plutonium or americium in a given year due to discharges in previous years (Hunt, 1985). Fits to monitoring data were reasonable and gave values of characteristic "availability times" for different materials. More data are now available than when this technique was first used, and investigations are being made of the adequacy of this simple approach. Table 1 compares availability times estimated with data up to 1983 with those using the same simple methodology and data up to 1989.

Table 1 Availability times for Pu and Am in marine materials near Sellafield

Material	Sampling area/ landing point	Availability times (years)			
		Plutonium		Americium	
		Data to 1983	to 1989	Data to 1983	to 1989
Winkles	St Bees	4	5	7	8.5
Mussels	St Bees	3	4	6	8
Crabs	Sellafield shore area	1.5	3.5	4	5
Plaice	Whitchaven	2	4.5	4	5.5
<i>Porphyra</i>	Braystones	2	2	6	5
Surface sediment	Newbiggin	4	5	6	6.5

It can be seen that there are increases in availability times using the longer time series, and these increases are significant (on the basis of paired "t" tests, $p < 0.01$ for plutonium data, $p < 0.05$ for americium data). This suggests that the environmental processes governing the dilution and dispersion of these nuclides (mainly by uptake on sediments) are more complex than may be described by a simple exponential, with the possibility of a contribution from terms with longer time constants than were first identifiable. This apparent increase in timescale for dispersion could be due to slower release than in the past of actinides from sediments; the remainder could be more strongly bound, or more deeply buried.

REMOBILISATION OF RADIONUCLIDES FROM THE SEDIMENT OF THE IRISH SEA

It is known that a large proportion of the undecayed radioactivity discharged to the eastern Irish Sea from Sellafield resides in the muddy, scabed sediments; this applies particularly for plutonium and americium, but also to radiocaesium (Woodhead, 1988). Under conditions of decreased sea water concentrations, as has resulted from the reduced discharges, it might be expected that sediment-bound radionuclides might be remobilised into the water column. This phenomenon has been examined by modelling methods, but has also been studied using data from the regular monitoring of seawater near Sellafield (Hunt and Kershaw, 1990).

Table 2 shows the results of regular monitoring of caesium-137 in sea water near Sellafield from 1983 to 1990, and the concentration expected on the basis of the discharge alone using a normalised concentration of 8.5 ± 1.9 (1σ) Bq l^{-1} per TBq year^{-1} discharged. This factor was derived for the period 1977 to 1982, when discharges were decreasing less rapidly than from 1983. The excess concentration measured was converted using this same factor to estimate the annual activities of caesium-137 remobilised in the Sellafield vicinity. This vicinity is taken to be that of the relatively well-mixed tidal plug over which the measured concentrations were averaged. It is estimated that a total of about 700 TBq have

Table 2 Remobilisation of ^{137}Cs in the Sellafield offshore vicinity

Year	Sellafield Discharge, TBq	Mean concentration in sea water, Bq l ⁻¹	Concentration without remobilisation ^a , Bq l ⁻¹	Concentration difference ^b , Bq l ⁻¹	Remobilised ^{137}Cs ^b , TBq
1983	1200	11.06	10.2	0.9 ± 2.5	100 ± 300
1984	434	4.63	3.7	1.0 ± 1.1	100 ± 120
1985	325	4.25	2.8	1.5 ± 1.0	180 ± 110
1986	17.9	0.97	0.15	0.8 ± 0.2	80 ^c ± 20
1987	11.8	0.65	0.10	0.55 ± 0.15	65 ± 18

1989	28.6	0.62	0.24	0.38 ± 0.14	44 ± 16
1990	23.5	0.53	0.20	0.33 ± 0.12	39 ± 14
TOTAL.					700 ± 300

^a On basis of concentration normalised to discharge rate for 1977-82 (see text).

^b Errors represent ± 1 standard deviation based on propagated sampling uncertainties.

^c After subtraction of about 10 TBq due to input from Chernobyl.

been remobilised in this area from 1983 to 1990. In 1987, the rate of remobilisation of caesium was over five times as much as the amount discharged, but the difference has now decreased as equilibrium with the lower rates of discharge is being achieved.

CONCLUSIONS

Data collected for monitoring purposes near Sellafield have been used to provide information relevant to environmental processes. The potential for monitoring programmes to provide information of this nature should be recognised when setting them up.

**IMPLICATIONS OF 1990 ICRP RECOMMENDATIONS ON RADIATION
PROTECTION PRACTICES IN THE MINERAL SANDS INDUSTRY**

J. ("GEORGE") KOPERSKI

Westralian Sands Ltd, P.O.Box 96, Capel W.A. 6271, Australia

ABSTRACT

Implementation of the 1990 ICRP recommendations would require engineering, metallurgical and human aspects of the mineral sands dry separation processes to be addressed. The primary objective is to minimise radioactive dust levels within the dry plant environment. Refinements of radiation monitoring and dose assessment protocols are also warranted. To date, the engineering aspects have had the major impact on minimisation of radioactive dust levels in the dry plants. Effective doses from internal exposure to airborne dust of the most exposed workers should be at approx. 10 mSv/y level.

INTRODUCTION

Australia is the world's largest producer and exporter of heavy minerals (HM; specific gravity over 2.9) namely: ilmenite, leucoxene, rutile, zircon, monazite and xenotime. The last two are classified as radioactive HM, with monazite being of primary radiological safety concern. Monazite, a rare earth phosphate, typically contains 6% of thorium and 0.3% uranium.

There are two stages of HM production. Firstly, a heavy mineral concentrate (HMC), which is a mixture of HM, is extracted from the ore by applying wet, gravitational separation process. Subsequently, individual minerals are separated from the HMC. This process applies dry electrostatic and magnetic mineral separation techniques and takes place in dry separation plants. No chemical extraction of minerals takes place.

Mineral sands industry workers are exposed to external gamma radiation and internal, principally alpha, radiation from inhaled radioactive dust. Here, the impact comes from inhaled long-lived radionuclides of Th-232 and, to a lesser extent, U-238 series associated with airborne dust generated during the process. To date, internal irradiation has been the major source of the radiological impact on the industry workers (1). The radioactive content of the dust is mostly due to the monazite content in the HMC and, subsequently, due to imperfect monazite separation from other minerals.

In order to comfortably comply with the annual dose limit of 20 mSv implied by the 1990 ICRP recommendations, the engineering, metallurgical and human aspects of contemporary HM dry separation processes should be addressed. Each aspect may influence the amount of dust, hence airborne radioactivity, generated within the plant. A refinement of radiation monitoring techniques and the associated, conservative dose assessment protocols is also warranted.

ENGINEERING ASPECTS

The engineering aspects refer to improvements in dry plant design. Predominantly, this incorporates enclosing all open design dry separators, including mineral feed and collection systems, and installation of a ducted system of dust extraction from within the enclosures (Photo). Implementation of such major dust control measures may result in a decrease of ambient radioactivity levels by as much as an order of magnitude (Fig-Part A). Further decrease may be achieved by removal of monazite separation circuit from the main separation plant to an isolated, dedicated plant. Other measures applied to the handling of dry minerals include: enclosing of discharge points onto and from conveyor belts, enclosing of discharge points from gravity transfer chutes and sealing of the housing of bucket elevators used for vertical transport of minerals. Transfer of airborne dust between various parts of the plant by natural and thermal air currents may be prevented by wall partitioning and solid flooring between various plant levels.

Contemporary plants are usually compact, multilevel constructions employing significant gravitational transfer of minerals between multiple separation stages. This promotes mineral abrasion which, in turn, produces fine dust. New plant design should be of a low profile, at the expense of the compactness of the plant size. Downward gravitational movement and upward transfer of minerals by means of bucket elevators should be replaced by less dust generation prone means like eg. conveyor belts.

All those dust control measures could result in a major reduction - by up to an order of magnitude - of alpha activities recorded by personal monitoring devices (Fig-Part B). Hence, the effective doses from exposure to airborne dust of the most exposed workers would be at approx 10 mSv/y level.

METALLURGICAL ASPECTS

The metallurgical aspects refer to improvements in the efficiency of mineral separation and development of alternative processing methods.

Improved attritioning (ie removal of mineral grain coating) of the HMC would increase efficiency of electrostatic separation, thus reducing the number of dust generation-prone mineral separation stages. Depleted grain coating would result in reduced potential for fine dust generation from this source.

Alternative, wet separation processes of the HMC would markedly reduce dust generation in the plant. None of the processes trialled have exhibited both the mineral selectivity and operating costs to consider them as replacement for existing dry processes. However, some wet magnetic and mineral froth flotation techniques hold promise for future developments.

HUMAN ASPECTS

The human aspects refer to minimisation of radiological impact on workers resulting from the adopted work practices. The level of exposure of different workers performing identical tasks in the same dry plant may widely differ. Provision of in-house, uniform, practical work training programs would alleviate the problem. Minimising worker's residence time in the plant would further reduce exposure. This could be achieved by remote plant monitoring and process control and substitution of manual mineral sampling for product quality control analyses by automatic on stream analyses. Whenever feasible, manual removal of mineral spillage should be replaced by vacuuming.

RADIATION MONITORING AND DOSE ASSESSMENT

Contemporary dose assessment and default values used for internal dose estimation in Australia may have been overly conservative (2). More accurate monitoring followed by better estimates of internal doses have been warranted. The former has already resulted in reassessment of the mean personal AMAD of dry plant workers from 5 to over 10 μm (3) and effective respiratory protection factors for half-face particulate respirators of over 20, instead of 3.5 (4). Increased accuracy of personal monitoring could be achieved by replacement of a grab by time integrated dust sampling and by application of sampling heads emulating inspirable dust sampler criteria.

In order to improve present dose assessment protocol a series of radiation research priorities has been suggested (5) for dosimetry of monazite dust. Research on some of the topics has been in progress.

CONCLUSION

To date, the engineering aspects have had the major impact on minimisation of radioactive dust levels in Australian mineral sands dry plants. This should result in effective doses from internal exposure to airborne dust of the most exposed workers being approximately at the 10 mSv/y level.

INTERIOR OF MINERAL SANDS DRY SEPERATION PLANT

DETECTION AND DIFFERENTIATION OF CONTAMINATION THROUGH A
COMPARISON OF OBSERVED LEVELS IN HISTORICAL
ENVIRONMENTAL SAMPLING DATA

D. H. Denham and K. R. Price

Pacific Northwest Laboratory
Richland, Washington

ABSTRACT

In summarizing more than a decade of environmental monitoring data from the Hanford Site, we noted that grouping data by analysis, rather than by medium, enhanced visual as well as statistical interpretations. By plotting running-averages of individual radionuclides on the same graph, for different media, we evaluated environmental trends to determine whether or not a local impact had been observed. This approach may enhance ones ability to interpret environmental monitoring data collected following an unplanned release of radionuclides. This technique provides a more holistic approach to the evaluation of environmental monitoring data than has traditionally been practiced.

INTRODUCTION

Nuclear operations at the Hanford Site have been conducted since the mid 1940s. The Hanford Site, comprising an area of just under 1500 km², is located in a semi-arid region of southcentral Washington State and is effectively bounded on the north and east by the Columbia River. Air, water, and native vegetation samples have been collected for analysis of radionuclide levels since Site operations began. Other media, such as selected foodstuffs and wildlife, were added to the routine program in the 1960s, and during the 1980s fruit, wine, wheat, and alfalfa samples were added.

Establishing appropriate and logical interpretations of environmental monitoring data is difficult in the absence of similar data obtained either concurrently from another location or from an historical trend. Thus, grouping techniques have been used to provide better interpretation of historical Hanford environmental data (over time or space or both) for visual as well as statistical interpretation. The traditional method has been to compare the data representing potentially affected locations (i.e., indicator locations) with data for background or control locations.

Plotting individual radionuclide data together, for each of several media, rather than by medium (the traditional method of grouping environmental data), permits the comparison of trends in one medium with similar or dissimilar trends in another. For long-lived radionuclides, such as strontium-90 or cesium-137, similar long-term trends might be expected for air, native vegetation, soil, and farm products. If similar trends are not observed, then either a sampling and/or analytical bias may have occurred in one or more of the media evaluated, or more importantly a local impact may have been detected. In the former case, these dissimilarities could suggest the need to reevaluate the monitoring program for representativeness of samples and accuracy of data. On the other hand, if a local impact appears to have been observed, additional confirmatory sampling and analysis may be required. It is important to note that short-term changes in some media may not be reflected in other media because of differences in environmental pathways or sampling frequencies.

Determining how to best use environmental monitoring data in the event of an emergency is especially challenging, because the data are often not available until well after protective action recommendations have been made. Because only a limited number of environmental samples are available in the early stages of an emergency, it is essential that the available data be appropriately evaluated and interpreted.¹ During an emergency, having available plots of long-term data trends and preestablished protocols for grouping the data are critical for evaluating environmental monitoring data.

EVALUATION TECHNIQUE

The method used to display data for this paper was sequential plotting of 5-year running averages as a function of time, which has the potential advantage of revealing trends or periodicity in the data. In this technique, 5-year groups of data are averaged to provide the result to be plotted for the last year of that group (e.g., the 1977 through 1981 results were averaged to provide the result to be plotted for 1981). Similarly, the 1978 through 1982 values were averaged to provide the 1982 running-average result. Then, the next 5-year period of values were averaged and similarly plotted and the process was continued until the latest year value was obtained. These running-average graphs were then plotted, by individual radionuclide, for several media collected from a given location or region.

Running-average summaries of the observed radiological conditions in both upwind and downwind locations from the Site are included for strontium-90, cesium-137, and plutonium-239 in several media. The environmental media include airborne particulates (A), milk (M), produce (P, leafy vegetables), soil (S), and native vegetation (V). Although other sampling media (e.g., wildlife, fruit and wine, wheat and alfalfa) are included in the routine Hanford surveillance program, the relatively small number of data available precluded this type of comparative analyses.

OBSERVATIONS

Examples of the long-term trends for strontium-90, cesium-137, and plutonium-239,240 are shown in Figures 1 through 3, respectively, using data from reports for the Hanford Site.²⁻⁸ The dissimilar trend shown in Figure 1 for soil compared to the other media is apparently the result of

FIGURE 1. Five-Year Running Average Concentrations of Strontium-90 at an Upwind, Background Location.

FIGURE 2. Five-Year Running Average Concentrations of Cesium-137 at Two Different Downwind Locations

FIGURE 3. Five-Year Running Average Concentrations of Plutonium-239, 240 at an Upwind, Background Location

sampling or analytical biases. Figure 2 clearly shows the influence of fallout from Chernobyl in 1986 on native vegetation samples collected soon after the accident. The samples from location 1 were collected shortly after Chernobyl fallout in the Tri Cities, whereas the samples from location 2 were collected prior to that time. Figure 3 provides a comparison of long-term plutonium concentrations in air, soil, and vegetation samples from the local environs. The apparent precipitous decrease in airborne levels of plutonium was caused by a change in analytical procedures. However, the overall trend has been downward since the world-wide cessation of atmospheric testing of nuclear weapons occurred in the early 1980s.

CONCLUSIONS

The use of this technique provides a better understanding of historical contamination levels and enhances the ability to detect and differentiate the presence of local contaminants from those contaminants that might have originated elsewhere. This technique may also be useful following the release of contaminants during an emergency situation.

137 CS CONTENT IN COCONUT WATER AND COPRA IN FRENCH POLYNESIA :
CONTRIBUTION TO THE DOSE FOR POPULATION

Coconut tree has the peculiarity to be a good integrator for alkaline metals. The isotope 137 of cesium, which was generated during previous atmospheric nuclear tests, has a high fission yield and a half-life of about 30 years; this nuclide is supposed to be still present in food chain in French Polynesia. In this food chain coconut water and coconut copra are ingested depending upon diet customs and areas of French Polynesia. For some islands, among local foodstuffs, cesium 137 content in coconut highly contributes to the dose.

Spectrometry gamma results and annual doses calculation since 1966 are displayed.

INTRODUCTION

La France a procédé en Polynésie Française à des expérimentations nucléaires atmosphériques de 1966 à 1974, depuis 1975 ces essais sont souterrains. Depuis 1965, un programme de surveillance de la Polynésie a été mis en place pour contrôler la faune et la flore dans les zones intéressées par les essais nucléaires. Il a porté, notamment, sur les denrées alimentaires; parmi celles-ci la noix de coco revêt une importance particulière, d'autant que le cocotier s'avère être un bon intégrateur des métaux alcalins.

L'eau de coco est beaucoup consommée en Polynésie principalement sur les atolls où la ration quotidienne moyenne est estimée, selon les enquêtes alimentaires, à 1 litre par personne. Le coprah entre moins dans l'alimentation humaine, mais participe très largement à l'alimentation du bétail. L'évolution de la teneur en césium 137 des noix de coco prélevées depuis 1967 est présentée ainsi que la méthodologie mise en oeuvre par le LESE, la répartition géographique des radionucléides présents dans l'eau de coco et le coprah. La dosimétrie pour la population est calculée à partir des données d'enquêtes alimentaires.

PARTIE EXPERIMENTALE

Le réseau de prélèvement comprend 43 îles ou atolls, répartis dans la totalité des archipels de la Polynésie Française. On estime que l'alimentation de 90% de la population est constamment et directement surveillée. Pour simplifier la présentation des résultats, on a divisé l'ensemble de la Polynésie en 4 zones en fonction de l'éloignement de la source (Mururoa et Fangataufa).

la zone I de 0 à 20 km
zone II de 20 à 250 km
zone III de 250 à 500 km
zone IV > 500 km

Le nombre des échantillons nécessaires aux mesures a été d'environ 70 000 noix de coco entre 1967 et 1988 inclus. Pour une sensibilité convenable il faut mesurer 50 g de cendres soit environ 10 litres d'eau de coco ce qui correspond au contenu de 30 à 40 noix.

Pour le coprah il faut 4 kg pour obtenir 50 g de cendre: ceci provient d'environ 20 noix.

Les échantillons sont pesés puis séchés à l'étuve à 120°C pendant 48 heures. Puis les échantillons sont incinérés à 500°C pendant 24 heures, les cendres obtenues sont pesées et homogénéisées et comptées dans des boîtes de 60 mm de diamètre et 30 mm de hauteur. La mesure du césium 137 par spectrométrie gamma a été réalisée au moyen d'un détecteur à cristal d'iode de sodium activé au thallium (NaI Tl), afin d'éviter d'introduire une variation au cours du temps. Ce détecteur était placé dans une enceinte blindée au plomb (CBMJ de Lomcr); les temps de comptage étaient de 200 minutes. A partir de 1981, les résultats obtenus par le LESE font l'objet d'intercomparaisons avec le service central de protection contre les rayonnements ionisants (SCPRI) qui est le laboratoire de référence de l'organisation mondiale de la santé (OMS).

Les résultats sont rassemblés dans le tableau ci-après.

-1

Moyennes annuelles de la teneur en césium 137 (en Bq.kg Frais)

Année	Zone I		Zone II		Zone III		Zone IV

1984		1,04	2,66	11,93	0,47	6,88	0,58	2,70
1985	0,20	0,99	2,39	6,85	0,56	2,49	0,85	1,48
1986	0,32	1,48	1,07	5,49	0,23	0,61	0,68	2,30
1987	0,44	0,96	2,05	10,19	0,66	1,31	0,48	5,89
1989	0,92	3,24	1,24	4,99	0,62	3,71	0,55	2,34

CONCLUSIONS

Pour les deux séries d'échantillons, la décroissance de la teneur en césium 137 est constatée depuis le début de la période d'observation et sans discontinuité à partir de 1974, dernière année des essais atmosphériques. Il est, par conséquent, manifeste, qu'aucune injection de radionucléides ne s'est produite dans l'environnement polynésien après la fin des expérimentations aériennes. De plus l'absence de grandes variations pendant la période allant de 1967 à 1974 signifie que les retombées consécutives aux essais aériens de Mururoa et Fangataufa n'ont représenté qu'une partie relativement faible des retombées mondiales (16%).

En tenant compte des rations alimentaires définies après enquêtes auprès des populations, l'équivalent de dose efficace annuel dû au césium 137 chez l'adulte entre 1971 et 1988, en différents lieux est résumé ci-après :

	Equivalent de dose efficace annuel dû au ¹³⁷ Cs (μ Sv.an ⁻¹)				Part de l'eau de coco et du coprah dans le total en %	
	Total par ingestion		Par l'eau de coco et le coprah		1971	1988
	1971	1988	1971	1988	1971	1988
Tureia..	55,10	21,96	35,00	15,52	64	71
Hao..	4,44	0,83	3,55	0,58	80	70
Papeete	2,21*	1,74	0,19*	0,13	9	7

Les résultats présentés (cf. supra) pour la noix de coco sont en cohérence avec l'ensemble des mesures opérées sur les échantillons de la ration alimentaire totale. La noix de coco constitue pour certains atolls le principal vecteur de la dose annuelle pour la population.

L'exposition annuelle actuelle, pour l'ensemble de la ration alimentaire par exemple à Tureia, correspond à 0,44 % de la limite admissible et elle a été au maximum de 1,10 % en 1971.

* données de 1973.

RADIATION PROTECTION RELATED TO THE
ENVIRONMENT OF THE FINNISH NUCLEAR
POWER PLANTS

A. Vuorinen, O. Vilkamo and E. Ilus
Finnish Centre for Radiation
and Nuclear Safety

ABSTRACT

The aim of radiation protection is to keep doses as low as reasonably achievable. In Finland there has been, since 1976, a regulatory limit of 0.1 mSv/a for the maximum individual effective dose commitment in the environment of nuclear power plants. The control of operation at and releases from the Finnish nuclear power plants as well as the monitoring of the environment of the plants have indicated that this goal is clearly achieved. New regulations for the safety of nuclear power plants were issued in 1991 as the decision of the Council of State aiming at further decreasing the risks of postulated and severe accidents.

INTRODUCTION

There are at present four nuclear power reactors operating in Finland. Two of them are 440 MWe PWR-units (in Loviisa, on the south coast of Finland) and the other two are 710 MWe BWR-units (in Olkiluoto, on the west coast of Finland). There are interim spent fuel storages at both power plant sites and a final repository for operational radioactive wastes on-site of the Olkiluoto plant.

The Finnish Centre for Radiation and Nuclear Safety (STUK) is the regulatory body responsible for both radiation protection and nuclear safety. Its regulation of the operation of the nuclear power plants covers all aspects that affect plant safety and the releases of radioactive materials into the environment.

Limitation of radiation exposure in the environment of a nuclear power plant has since the commissioning of the nuclear power plants been based on three main goals:

- ALARA
- a limit for the maximum individual effective dose commitment of 0.1 mSv/a
- prevention of incidents and accidents as well as limitation of their potential consequences.

STUK has also given guidelines for the environmental monitoring programmes of the Finnish nuclear power plants. The aim of environmental monitoring is to extensively cover the ecosystem in order to give a picture of the spreading of radioactive materials released into the environment of a nuclear power plant.

The present Finnish Nuclear Energy Act and Decree came into force in 1988 /1/. A decision of the Council of State on the safety of nuclear power plants was issued in 1991 /2/. This includes regulations concerning the monitoring of releases of radioactive material and the limitation of radiation exposure in the environment of nuclear power plants.

ENVIRONMENTAL SURVEILLANCE

The monitoring of radioactivity in the environment of the nuclear power plants in Finland has been carried out since 1976. The environmental monitoring programme at every Finnish nuclear power plant site is extensive and includes about 500 samples taken annually from both the terrestrial and aquatic environments. Most of the sampling and laboratory analyses are performed by the environmental laboratory of STUK /3/.

The important food stuffs, such as milk, drinking water, grain, meat and garden products are collected. In addition, the monitoring programme includes samples of air, deposition, soil and hair moss in the terrestrial environment, as well as sea water, sinking matter, bottom sediments and indicator organisms in the aquatic environment. The samples are collected either continuously or 1 - 4 times a year depending on the sampling object. The bulk of samples is taken within a radius of 10 km from the power plant. In general the samples are analyzed gamma spectrometrically, but partly also for tritium, radioactive strontium and transuranic elements.

The results of environmental control so far have indicated that very small amounts of radioactivity originating in the Finnish nuclear power plants is regularly detected in certain samples. Most detections have been in the aquatic environment. In sea water samples ^3H is typically detected, sometimes also activated nuclides (^{54}Mn , ^{60}Co , $^{110\text{m}}\text{Ag}$) and fission products (^{134}Cs , ^{137}Cs). These are frequently found in samples of sinking matter and aquatic indicator organisms. However, ^{134}Cs and ^{137}Cs dominantly originate from the Chernobyl nuclear power plant disaster.

The results of the environmental measurements are consistent with the releases measured from the nuclear power plants. Because the actual detections in the environment are very low amounts of radioactivity, the effective dose equivalent commitment cannot be calculated based on them.

Calculated maximum individual effective dose commitments for the annual releases have been so far in the order of a few μSv (Figure 1). The main contribution has been due to ^{60}Co in aquatic discharges, respectively ^{14}C and ^{60}Co in airborne discharges.

Figure 1.
Average doses of critical groups in the environs of Loviisa and Olkiluoto NPPs. (STUK/Blomqvist, Pusa 1991)

EVOLUTION IN REGULATION

During the 1980's STUK issued new guides dealing thoroughly with the safety of nuclear power plants /4 - 6/. These guides were aimed especially at the possible design of new nuclear power plants, but constituted at the same time the basis for the regulatory work dealing with operating plants. These were taken into account when the utilities planned and made further construction changes in their plants.

Based on the new Nuclear Energy Act and Decree this guidance was then followed by the decision of the Council of State on the general regulations for the safety of nuclear power plants /2/.

It is worth to refer to the present limit for a postulated accident: "The limit for the dose of an individual of the population, arising, as the result of a postulated accident, from external radiation in the period of one year and the simultaneous radioactive materials intake, is 5 mSv." and for a severe accident: "The limit for the release of radioactive materials arising from a severe accident is a release which causes neither acute harmful health effects to the population in the vicinity of the nuclear power plant nor any long-term restrictions on the use of extensive areas of land and water. For satisfying the requirement applied to long-term effects, the limit for an atmospheric release of ¹³⁷Cs is 100 TBq. The combined fall-out consisting of nuclides other than cesium-isotopes shall not cause, in the long term, starting three months from the accident, a hazard greater than would arise from a cesium release corresponding to the above-mentioned limit".

The possibility that, as the result of a severe accident, the above mentioned requirement is not met, shall be extremely small. This means that the probability of a severe accident shall be less than $10^{-6}/a$.

IMPROVEMENTS AT THE OPERATING NUCLEAR POWER PLANTS

Since the commissioning of the operating Finnish nuclear power plants, the utilities have made several technical changes at the plant units in order to improve their safety. Some of these improvements are more directly connected to decreasing the radiation risk of the population. Such are e.g. changes aiming at the limitation of the release of radioactive materials caused by a severe accident. Here the emphasis has been on ensuring the engineering safety functions and, especially, on keeping the reactor containment intact during severe accident conditions. In Olkiluoto (BWR) there is a filtered containment venting system and in Loviisa (PWR) an external containment spray system at each plant unit.

The utilities have made changes at the operating plants which would allow reasonable accident management. These include e.g. the sampling and measurement of radioactive material from the containment water and air during severe accident conditions.

The utilities are installing additional automatic radiation monitoring networks in the vicinity of the nuclear power plants. These comprise of four to six measuring stations located at a distance of 1 - 2 kilometers and about ten measuring stations at

a distance of 5 kilometers from the plant. All measuring stations send their results to a central unit on-site and are further connected to a national real time measuring network operated by authorities.

CONCLUSIONS

The safety targets shall be set so that they are clear and can be communicated to and understood by the public. Furthermore, operational experience shall prove that the set targets are clearly achieved.

We feel that the environmental limit of 0.1 mSv/a set in 1976 in Finland for nuclear power plant operation fulfils the requirements above. Besides this the goal has been to prevent accidents and to limit their potential consequences. This has led to more stringent requirements in recent regulation. The adaption of the requirements as well as the advancement of science and technology have produced further improvement at the operating nuclear power plants.

The experience of a single regulatory body responsible for both radiation protection and nuclear safety has been encouraging. A very important thing is the commitment of the operating organisation of a nuclear power plant to safety thinking and doing.

ABSTRACT

After the Chernobyl accident a great effort was made in Italy under the aegis of the Ministry of Health and the supervision of scientific institutions, mainly ENEA/DISP and Istituto Superiore di Sanità (National Institute of Health), to insure a wide coverage of the territory. This was accomplished to set up adequate environmental radioactivity monitoring networks covering the Italian territory as completely as possible.

This paper outlines the main features of the organization of the surveillance programmes. The role played by the scientific institutions and the Ministry of Health is underlined.

INTRODUCTION

The control of environmental radioactivity is one of the main problems faced by the responsible bodies in Italy since the mid fifties. The approach used consisted to monitor both the sites around nuclear plants and the fall-out from nuclear weapon tests.

The methodology adopted for the surveillance consisted both in source (nuclear plants) and person related monitoring (fall-out). In the first case a preliminary study of the site, of the source characteristics and of the radionuclides discharged into the environment, identified the main environmental components, the food samples to be analyzed and the important radionuclides to be mapped. The doses received by critical groups were also evaluated by dedicated calculation programmes.

In case of fall-out, person related monitoring networks were set up where the main environmental samples - air

particulates, deposition, surface and marine waters - were analyzed as well as the typical components of the human diet (cereals, meat, milk, etc.). Hystorical series of these data are available for some samples beginning from the middle fifties (1).

CHERNOBYL ACCIDENT: A LESSON LEARNED

In Italy as elsewhere the Chernobyl accident, because of its peculiarity, was instrumental for testing the adequacy of the overall system set up to control environmental radioactivity. It appears from the beginning that for such type of accident it is necessary to have a real time system to measure air particulates in air. The already existing one, although the sampling points were distributed all over the country in places representative of the air mass circulation, was not adequate. The filters collected in each station were sent to a central institute to be processed causing considerable delay.

Standardized sampling procedures were not available causing some inconsistencies in the collected data: mainly deposition and soil contamination. Moreover, the distribution of sampling points was uneven and difficulties were encountered in obtaining samples from some parts of the country. Consequently, steps were taken to reorganize the environmental radioactivity control system. (2)

PRESENT STATUS OF ENVIRONMENTAL RADIOACTIVITY CONTROL POLICY IN ITALY

The policy adopted in Italy for the control of environmental radioactivity, has produced the new organization of the surveillance (3). According to Italian law the Ministry of Health, under whose responsibility falls the environmental radioactivity control, delegated this activity to the local Authorities. An environmental measurement laboratory is going to be set up in each Administrative District in order to assure a more complete coverage of the territory as new laboratories are added to the existing ones.

The tasks of these laboratories are the following:

- 1) control of the artificial radiation sources distributed over their territory;
- 2) detection of large scale radioactive contamination from inside or outside the territory ;

3) characterization of natural radiation sources.

Each laboratory shall be equipped with basic instrumentation for gamma-ray measurements; specific systems both passive and active are also envisioned to detect radon and radon daughter products. Laboratories were also selected where radiochemical analyses can be carried out to detect beta and alpha emitters.

The apparatuses were provided directly by the Ministry of Health after a national bid. A Commission appointed by the Ministry of Health has the task to coordinate and promote the environmental monitoring activities.

For the early warning system of radioactivity in air, to be set up in case of emergency, several actions have been undertaken during last few years by the ad hoc appointed body of Department of Civil Protection in conjunction with the Ministry of Health. First of all a high sensitivity automatic network to detect radioactivity in air in real time, will be located in representative sampling stations. At present stage, 5 sites have been chosen where the detection systems will be installed. The collected data will be transmitted to a central institute (ENEA/DISP in Rome), meeting point of a Committee in charge to evaluate radioactivity data in case of emergency (CEVAD). This first step will test the performance of the entire system in order to reach the optimal configuration.

A second automatic network to detect radioactive particulates in air in real time will also be located in places selected by the environmental radioactivity control laboratories. This network will integrate the early warning one so that, in case of emergency, a narrower grid will be established all over the territory.

Both the systems will be equipped with high resolution Ge detectors and will have a high sensitivity, 10 - 100 mBq/m³ on Cs-137 peak, according to sampling duration.

RESULTS AND PERSPECTIVES

The organization of the environmental radioactivity measurement system existing in our country, requires a strict system of quality assurance and quality control. In this context, intercomparison exercises are organized on a two year basis among the various laboratories (typically in the number 20 to 30) to guarantee consistency and reproducibility of measurements. The intercomparison results will be presented

during this Conference. The importance of these programmes and the great efforts both technical and economical required to run such networks should be noted.

The funds allocated by the Ministry of Health during the period 1988-91 are of the order 16 Billion Italian lire (1.4 Million dollars) including apparatuses, general expenses, training, etc.

Special attention was paid to the training of personnel. In this context a good example was offered by the national survey on natural radiation indoors (4), where a close cooperation, including training, was established among the Central Institutes (ENEA/DISP and Istituto Superiore di Sanità) and the various laboratories at District level. Other specific environmental surveys are being planned for the future which will create the opportunity to exchange experiences and views.

The laboratories entrusted with the environmental control programme are sending the data of the measurements to the Ministry of Health. A real time network for the transmission of data is being planned. The network will connect each laboratory with the Ministry of Health, ENEA/DISP, the Istituto Superiore di Sanità and the National Institute for the prevention and safety in working places.

ENVIRONMENTAL RADIOLOGICAL MONITORING AROUND URANIUM MINING AND MILLING SITES IN ARGENTINA

A.R. Curti, A.M. Bomben, J.C. Gómez and A.A. Oliveira

Gerencia de Seguridad Radiológica y Nuclear
Comisión Nacional de Energía Atómica
República Argentina

ABSTRACT

Uranium mining and milling development in Argentina started early in the 50's. Initial exploitation was carried out in underground mines, but, since 1978, open pit mining is the main production process. Environmental monitoring in the vicinity of uranium mills is performed on a routine basis. Natural uranium and radium-226 concentrations in surface waters are measured in grab samples taken at selected points up stream and down stream, in the area of influence of the mining and milling facilities. In addition, radon-222 emanation rates from ore tailings are measured. Up to date, no significant exposure results for the population living in the surrounding areas.

INTRODUCTION

Uranium industry began its development in Argentina in 1950. Since then, several installations have operated in uranium underground mining until the late 70's, when mines were closed and open pit exploitation was initiated. Milling plants were installed in the mining areas or nearby.

The waste sources at the mills include: a) barren acid liquors which have been stripped of uranium. These liquors were initially discharged to river waters. Nowadays, they are neutralized and piped to large evaporation and seepage ponds. When the evaporation process is not effective enough, the neutralized liquors are discharged to river waters after passing through small holding ponds; b) Ore tailings from the acid-leach process which are deposited at large tailing ponds located some distance from the milling plants and from the water bodies.

In order to assess the possibility of significant environmental contamination by uranium-mill wastes, routine studies of the dissolved radium-226 and natural uranium concentrations in surface waters up stream and down stream from the plants are being conducted. In addition, radon-222 emanation rates from ore tailings are measured at times.

ENVIRONMENTAL MONITORING PROGRAM

The uranium mining and milling areas included in the environmental monitoring program are the following: Don Otto, in the province of Salta; Los Adobes, in the province of Chubut; San Rafael and Malargüe, in the province of Mendoza; Los Gigantes, in

the province of Córdoba; and La Estela, in the province of San Luis. Figure 1 shows their geographical location.

Water samples are taken from river locations up stream and down stream from uranium mills, according to a special monitoring plan set up for each one of them. The period of exploitation, the annual production of "yellow-cake", the number of sampling points and the number of water samples for each installation are shown in Table 1.

As an example, Figure 2 presents the monitoring area corresponding to the vicinity of the San Rafael mining and milling plant. Water monitoring points are situated at about 10 km, 50 km and 80 km up stream and down stream from the plant. Samples are taken from rivers flowing through the surroundings of the mining and milling area, as well as from streams which they join afterwards. Samples from plant areas are also taken. The location of the sampling points allows the comparison of radium-226 and natural uranium concentrations above and below the plant, providing estimations of the extent and magnitude of water contamination, if there is any.

Dissolved radium-226 in water samples is analysed by the radon emanation technique, while natural uranium concentration is measured by fluorometric procedures [1]. Radon-222 emanation rate from ore tailings is determined by the technique described by Countess [2]. Since 1988, gross alpha counting, using ZnS(Ag) as a detector, is performed on water samples. Only those samples exceeding 70 mBq/l of gross alpha activity are selected for radium-226 analysis.

PRESENTATION OF DATA AND CONCLUSIONS

Figures 3 and 4 show the range of values of radium-226 and the maximum natural uranium concentrations measured in water samples from sampling points located at the San Rafael plant, since 1980. The corresponding ranges of values obtained for all uranium sites, compared with derived limits for drinking water applied in Argentina [3], are presented in Figures 5 and 6. Results before 1980 present a similar pattern [4].

Table 2 shows the radon-222 emanation rates measured at each location. A preliminary evaluation of these results has been presented previously [5].

The application of the statistical test of Wilcoxon [6] demonstrated that no significant difference in the radium-226 and natural uranium concentrations was found between the surface water samples from river locations above and below the milling plants. Besides, the results obtained are well below the derived limits for drinking water. Therefore, it may be concluded that no remarkable exposure occurs for the population living in the vicinity of these areas.

Measuring Network for Environmental Monitoring in Europe: State of the Measuring Technique

Dr. E. Frenzel
EG&G Berthold, Wildbad, Germany

Environmental monitoring of the radioactivity has gained a high priority in Europe in recent years. Today, the local dose rate and air-borne particulate and iodine activity concentrations are monitored fully automatically by measuring networks covering entire regions.

Introduction

In recent years, the large-area immission monitoring of radioactivity in the air has gained a high priority. One reason is certainly the increased awareness concerning environmental issues; moreover, laws exist in several European countries, passed as a consequence of the nuclear accident at Chernobyl, which stipulate the requirements for such a monitoring system.

Since radioactivity is transported very rapidly through the air, special emphasis will be paid to monitoring this medium in large-area contamination situations. The necessary fully automatic monitoring of the environmental radioactivity requires measuring networks covering large areas with stations which record all essential radiological parameters on-line and automatically. The instruments employed in these networks should correspond to the state of the art in science and technology in order to detect very low artificial air-borne activity concentrations within a very short time, with absolute reliability and without requiring any maintenance, to analyze them and to transmit them to the central data station via remote data facilities.

Of special importance is the automatic nuclide identification by high-resolution γ -spectroscopy. The type of accident and its development can be deduced from the nuclide composition; moreover, any information on the nuclide composition is absolutely essential for an accurate and detailed estimation of the dose, because different nuclides yield different doses.

To detect any air contamination as early as possible to be able to respond accordingly and to assess the actual situation and the resulting dose, the following radiological quantities have to be determined in the air:

- local gamma dose rate
- airborne particulate activity concentrations
- iodine activity concentrations

Local Dose rate Measurement

The local dose rate measurement is a non-nuclide-specific method. Together with nuclide-specific measuring methods, it provides complete information on the contamination situation. Local dose rate measurements are an excellent method of providing information covering large areas.

The detectors employed in this measuring networks are energy-filtered and measure gamma energies down to below 50 keV. With regard to sensitivity, these detectors are capable of detecting variations of a few nSv/h in a 2-hour measuring cycle with a high statistical safety. Modern detectors are moreover equipped with an "at-site electronics" which often includes the appropriate interfaces for data transfer.

The detectors are essentially energy-filtered Geiger-Müller counter tubes or proportional counter tubes. In order to cover the required measuring ranges - up to 5 Sv/h - one has to use two detector systems (low and high dose range).

Due to its physical properties, proportional counter tubes offer the best conditions for the use in local dose-rate measurements (low inherent background, sensitive at low energies, short deadtime). In praxis, the slightly less sensitive Geiger-Müller counter tubes are often preferred, due to their less sophisticated electronics and their lower price, so that proportional counter tubes are hardly used these days in large-area measuring networks.

Particulate Measurement

The measurement of air-borne particulate activity concentrations is quite difficult for several reasons. On the one hand, the artificial activity concentrations to be detected are significantly lower than the fluctuating natural activity concentrations; on the other hand, the levels of this air-borne particulate activity concentration are so low that only accumulation methods can be used.

Using powerful pumps (up to 70 m³/h), the air is aspirated through glass fiber filter to accumulate the radioactive aerosols. Depending on the measuring task, a detector is installed above the dusting location, either a zinc-sulphide coated plastic scintillation counter, or a highest grade germanium detector.

Moving filter facilities allowing automatic operation of the moving filter up to half a year are particularly suited for the use in measuring networks.

Although measuring methods according to the alpha-beta ratio method detect only total artificial beta, or when using the pseudocoincidence difference method, total artificial alpha, this method is still being used because it is the only method which permits the detection of nuclide groups which have no gamma transitions, and the fastest for the detection of contamination in the air.

Nuclide-specific identifications with highest grade germanium detectors, fully automatic evaluation software and, if necessary, remote data transfer facilities, are today's state of the art of science and technology. The measuring instrument of the first generation used rather complicated and problem-oriented programming languages; today's trend is clearly to use commercial languages available on the market running on standard PC's.

Nuclide-specific measuring systems, moreover, include an interface for remote data transfer and even allow the data transfer of spectra. To ensure an optimum early warning, these instruments are designed such as to allow the simultaneous alpha-beta measurement and the nuclide-specific measurement.

Iodine Measurement

Since iodine and thus radio-iodine as well is accumulated especially in the thyroid gland, this potential health hazard requires special efforts. Due to the fact that iodine and most of its combinations are very transient, special filters have to be used. Iodine occurs bound to aerosols as well as in a gaseous form. For gaseous iodine one uses special filters, such as silver-impregnated activated carbon. These filters which are particularly suited for gaseous iodine possess, unfortunately, a low retaining capability for aerosol-bound iodine.

If both iodine species are bound to one absorber, one uses special absorbers, such as AC 6120; the consequence will be, however, that filter and detector have to be heated up to avoid that the temperature drops below the condensation level. By combining a particulate monitor and an iodine monitor for gaseous iodine one will be able to detect both species.

In the iodine monitor, the iodine is concentrated in a cartridge which includes the respective absorber. The iodine cartridge surrounds the detector either as a Marinelli container, or it is located directly next to the detector. Usually, the 364-KeV line of the master nuclide ¹³¹Iodine is detected by means of a NaI-detector. Today, one can measure ¹³¹Iodine activity concentrations up to several 100 mBq/m³ per hour with high statistical safety.

Specifications for Automatic Network Operation

The instruments must feature a high level of operational safety. This means that they have to be immune to mechanical trouble; on the other hand, power supply fluctuations and peaks should be filtered such that the usual network operation will not be affected. Also, the instruments must include self-monitoring devices to ensure their proper and safe operation.

Air flow rates have to be measured; detectors have to be monitored with regard to their thresholds and high-voltage, moving filters must be equipped with torn filter facilities. In addition, the instruments used must be secured as far as possible against unauthorized operation and incorrect operation. Since many of these measuring systems are combined in measuring networks, the question if remote control is provided is also important, particularly the repeat tests performed by the central station.

In addition to the communication with the central station, the instruments at site must be capable of operating autonomously in the event the data transfer breaks down, so that all essential and relevant data will be saved on a suitable data carrier for at least a short time.

Conclusions

Today, low level results of some mBq/m³ are available within several hours. In addition, the measuring technique of 1991 even permits to identify nuclides or to classify nuclide groups according to the type of radiation (alpha or beta).

For several years now, automatic measuring systems are available for the immission measurement of radio-iodine in the environmental air. Certainly, in future the germanium detector will replace the NaI-detector, as this is the only way to selectively detect different iodine nuclides.

Automatic measuring networks for environmental monitoring exist in many European countries, for example, Germany, Spain, the Netherlands, Switzerland and others. The measuring network differ in details; however, nearly all networks measure the local gamma dose rate, the concentration of radioactive aerosols and radio-iodine in the air.

Fig. 1 shows a typical instrument for measuring α/β and γ emitting nuclides, including an iodine measuring system.

THE DETERMINATION OF RADIUM, URANIUM AND THORIUM IN LOW SPECIFIC ACTIVITY SCALES AND IN WATERS OF SOME OIL AND GAS PRODUCTION PLANTS

C. Testa, D. Desideri, M.A. Meli, C. Roselli
(General Chemistry Institute, Urbino University, Italy)
A. Bassignani, P.B. Finazzi
(Radiation Protection Institute, AGIP, Milan)

Abstract

Low specific activity scales consisting of alkaline earth metal carbonates and sulphates are often present in some gaseous and liquid hydrocarbon plants; these scales contain a certain concentration of radium, uranium and thorium which can cause a risk of gamma irradiation and internal radiocontamination when they must be mechanically removed. ^{238}U , ^{232}Th and ^{226}Ra were determined in scales, sludges and waters coming from different plants. ^{238}U and ^{232}Th concentrations were found very low; the isotopes ^{238}U and ^{234}U resulted in secular radioactive equilibrium, ^{232}Th and ^{228}Th were not always in equilibrium. ^{226}Ra concentration resulted to be higher in the scales and sludges than in waters.

Introduction

Naturally occurring radioactive materials are known to be present in different concentrations in oil and gas production plants giving rise to the so called Low Specific Activity (L.S.A.) scales (1-3).

The chemical composition of L.S.A. scales varies, consisting mainly of alkaline earth metal sulphates and calcium carbonates incorporating small amounts of radium (1); uranium and thorium can also be present in some extent; the scales production is due to different causes: injection of incompatible waters (75%), evaporation in gaseous wells (10%), pressure changes (10%), temperature drops (5%) (4-6).

L.S.A. scales invariably emit alpha and beta particles and gamma rays (7); their presence in production plants can give rise to a gamma irradiation risk to the staff remaining for a long time in some particular plant areas and to a possible risk of internal radiocontamination to the staff involved in the scales or sludges mechanical removal and disposal.

That being stated a programme was started to determine uranium, thorium and radium in the scales, sludges and waters coming from Italy, Northern Sea and Africa.

Radioanalytical methods

The used radiochemical analysis was as follows. After the sample dissolution, ^{232}U and ^{228}Th were added as yield standards; the residue was dissolved in 2 M HNO_3 and the solution passed through a small column of Microthene (microporous polyethylene) 50-100 mesh supporting tri-octylphosphine oxide (TOPO); thorium was eluted with 1 M HCl and uranium with 1 M $(\text{NH}_4)_2\text{CO}_3$. After electroplating from $(\text{NH}_4)_2\text{SO}_4$, uranium and thorium alpha emitters were detected by alpha spectrometry. ^{226}Ra was determined by

counting Ba(Ra)SO₄ with a ZnS(Ag) detector after its separation from uranium and thorium and the decay of ²²⁴Ra (8). This technique was preferred to gamma spectrometry because of the presence of radioactive disequilibria in the ²³⁸U and ²³²Th families and taking into account the low activity to be measured.

Results and discussion

Taking into account the results shown in the tables I-III, the following conclusions can be drawn:

- 1) ²³⁸U and ²³²Th concentrations are either not detectable or very low ;
- 2) ²²⁶Ra concentration seems to be higher in oil extraction plants (800-3000 Bq/kg) than in other plants (30-400 Bq/kg), ²²⁶Ra concentration in the waters is very low because of its chemical behaviour;
- 3) for any specific plant, ²²⁶Ra concentration seems to be directly correlated to the extraction depth;
- 4) when uranium is detectable, the isotopes ²³⁸U and ²³⁴U are in secular radioactive equilibrium (Fig.1);
- 5) ²³²Th and ²²⁸Th are not always in equilibrium, especially in Tunisian scales, where the ratio ²²⁸Th/²³²Th can reach very high values, up to 700 (Fig.2). This fact can be due to the presence of initially high concentrations of the father ²³²Th from which ²²⁸Ra separated because of the different chemical behaviour of the two elements. Consequently the internal contamination risks could be caused not only by ²²⁶Ra, but also by ²²⁸Th and its daughters (²²⁴Ra, ²¹²Pb, ²²⁰Rn, ²¹⁶Po, ²¹²Po).

OBSERVATION OF TRITIUM BY CONTINUOUS SAMPLING
OF RAIN AND WATER VAPOR IN OSAKA

T.Matsunami*, T.Ishiyama*, K.Megumi* and S.Kimura**

- * Research Institute for Advanced Science and Technology,
University of Osaka Prefecture, Sakai-shi, Osaka, Japan
- ** Osaka University of Pharmaceutical Science, Matsubara-
shi, Osaka, Japan

ABSTRACT

As the results of environmental activity observation for three years made in the vicinity of a facility handling tritium and in an urban station 11km distant from the facility, it was assumed that the tritium concentration ratio of atmospheric water vapor to rain water could be an index to find out very slight release of tritium from a facility handling tritium. In the observation period the influence of Chernobyl accident was detected and rise of tritium concentration in rain water was observed when high concentration of loess aerosol visited Japan.

INTRODUCTION

The main chemical form of tritium in the environment is HTO, so the discharged ^3H enters the water cycle in the environment¹⁾. Monthly tritium activity in rain water was measured for three years in the vicinity of a facility handling tritium (Sakai) and in an urban station 11km distant from the facility (Tondabayashi), together with ^{137}Cs , ^{134}Cs and ^7Be activities. Monthly tritium activity in atmospheric water vapor was also measured for two years and half in Sakai, together with atmospheric activity concentrations of ^{137}Cs , ^{134}Cs and ^7Be . The results of observation are discussed in connection with Chernobyl accident, the visit of loess aerosol from the continent and the possibility of detection of very slight tritium release from a facility handling tritium.

METHODS OF SAMPLING AND MEASUREMENT

Monthly rain water sample was collected with funnel sampler of 490cm^2 in collecting area. 0.5 l was used for tritium measurement, and the rest was evaporated to dryness and used for gamma-ray spectrometry with a Ge(Li) detector.

Atmospheric water vapor sample was collected by passing air through molecular sieves 4A packed in a glass column (50x320 mm) continuously for about one week at a rate of 3 l/min and absorbing water vapor in the column. Four samples were collected in a month.

Airborne dust sample was collected by passing air through a Millipore AA filter with a low volume air sampler continuously for a month and subjected to gamma-ray spectrometry with a Ge(Li) detector²⁾.

Dry nitrogen gas was passed through the molecular sieves heated to 450°C and a cold trap, and usually 50-70ml of water was collected in the trap. Monthly water samples (rain water

samples and water samples released from the molecular sieves) were purified through distillation and 200-250ml was subjected to tritium concentration by multi-electrode electrolysis³⁾.

Tritium activity measurement was made with a low background liquid scintillation counter (Aloka LB-1, TRI-CARB 2250CA), the measuring time being 1000 min.

RESULTS AND DISCUSSION

1. Variation with time in tritium concentration in rain water

In Fig.1 are shown variations with time of monthly concentrations in rain water of ^3H , ^{137}Cs , ^{134}Cs and ^7Be (Bq/l) and monthly rainfall (mm) which were observed at two stations, namely, in the vicinity of a facility handling tritium (Sakai) and in the yard of a house in an urban station about 11 km distant from the facility (Tondabayashi) for three years from January 1986 to December 1988. Correlation coefficients between these monthly observed values obtained at Sakai and Tondabayashi were calculated and are shown in Table 1.

The ranges of variation in the tritium concentrations were 0.3-6.6 Bq/l for Sakai (average: 1.6 Bq/l) and 0.1-4.3 Bq/l for Tondabayashi (average: 0.7 Bq/l). The average tritium concentration was about twice larger in Sakai than in Tondabayashi. The correlation coefficient obtained for the tritium concentration was somewhat smaller than those obtained for the ^{137}Cs , ^{134}Cs and ^7Be concentrations and the rainfalls. Thus, it appears that the difference between the tritium concentrations in rain water observed at Sakai and at Tondabayashi is ascribed to very slight release of tritium from the facility handling tritium in Sakai.

As shown in Fig.1 relatively high concentrations of ^{137}Cs , ^{134}Cs and ^3H were observed in April and May 1986, resulting from the Chernobyl accident of 26 April 1986. (Fresh nuclear debris were detected in rain water 6 May for the first time.)

As apparently seen in Fig.1, conspicuously high tritium concentrations were observed in April (and May) 1988, namely, 6.6 ± 0.4 Bq/l at Sakai and 4.3 ± 0.4 Bq/l at Tondabayashi. It is noticed that ^{137}Cs concentration was also high in April 1988, coinciding with the appearance of high tritium concentration. It is generally accepted that tritium concentration in rain water is lower for ocean-originating rainfall while it is higher for continent-originating rainfall. It is well known in Japan that in 19-23 April 1988 the sky over west Japan was covered with very high concentration of loess aerosol. At that time continental high atmosphere was quite dominant over west Japan. It is also generally recognized that in the time of the year when high concentrations of loess aerosol are observed in Japan, agitation occurs in high atmosphere over Asiatic continent. It is assumed that the air agitation causes descending of old nuclear debris such as ^{137}Cs and ^3H from the high atmosphere, and these old nuclear debris travels with loess aerosol to Japan and then comes into rain water. A small peak of tritium concentration appearing in April 1987 might be also ascribed to visit of loess aerosol.

2. Variation with time of tritium concentration in atmospheric

water vapor

In Fig.2 are shown variations with time of monthly atmospheric concentration of tritium contained in water vapor (mBq/m³) and humidity (g/m³) together with monthly tritium concentration in water released from molecular sieves (Bq/l), namely, monthly tritium concentration in water vapor, which were observed at Sakai in the period from August 1986 to December 1988. The monthly humidity was higher in summer and lower in winter, and correlates relatively well with the monthly atmospheric tritium concentration.

In fig.3 are shown variation with time of atmospheric concentrations of ¹³⁷Cs, ¹³⁴Cs, ⁷Be and airborne dust.

3. Tritium concentration ratio of atmospheric water vapor to rain water

In Fig.4 are shown variation with time of the ratio of monthly tritium concentration in atmospheric water vapor (unit: Bq/l) to that in rain water (unit: Bq/l), which was observed at Sakai in the period from August 1986 to December 1988. The ratio is higher in the period from August 1986 to February 1987 and from August 1988 to December 1988 compared to other periods. Tritium handling was carried out more frequently in the facility in the periods showing high ratio values, and thus it is assumed that the ratio could be used as an index to detect very slight release of tritium from a facility handling tritium, discriminating from global tritium (natural and artificial). For instance, when the ratio is higher than 2, it may be suspected that slight local release of tritium exists. However, it should be remarked that the index value may become much smaller than 2 when less aerosol visits Japan resulting in increase in tritium concentration in rain water. The tritium concentration in atmospheric water vapor is considered to depend more strongly on local origins than that in rain water.

SURVEILLANCE DE L'ENVIRONNEMENT DE LA HAGUE

S. LE BAR, Chef de la Section Prévention-Evaluation
du Service de Prévention et Radioprotection
de l'Etablissement COGEMA LA HAGUE

ENVIRONMENT CONTROL AT FUEL REPROCESSING PLANT COGEMA LA HAGUE

The control of the environment at LA HAGUE is very important because a good survey permits to know the impact of the plant activity on the environment. With many measurements, with various methods, this target is reached. The results over the last ten years show this impact has been divided by three while the amount of reprocessed spent fuel was multiplied by four.

1 PRESENTATION

Etudiée et construite pour le retraitement des combustibles irradiés, l'usine de La Hague a actuellement une capacité d'exploitation de 1 200 T/an. Cette capacité sera portée à 1 600 T/an en 1994.

Un des principaux soucis des exploitants nucléaires est de veiller à l'application des règles de radioprotection et particulièrement de maîtriser les problèmes liés à l'environnement.

2 CADRE REGLEMENTAIRE

Avant la mise en actif d'une installation nucléaire industrielle, il est nécessaire d'étudier attentivement l'impact de son fonctionnement sur le milieu environnant et plus particulièrement sur la population.

Cette étude porte sur les conséquences sanitaires d'un fonctionnement normal de l'usine ainsi qu'en cas d'accident. Elle permet de définir une réglementation publiée au Journal Officiel de la République Française qui indique les limites de rejet à respecter en tout état de cause.

Ces autorisations portent sur les deux types de rejets effectués : liquides et gazeux. Pour chacune de ces autorisations, quatre limites d'activité sont à respecter :

rejets liquides : tritium, émetteurs bêta (hors tritium), strontium 90 et césium 137, émetteurs alpha.

rejets gazeux : gaz autres que le tritium, tritium, halogènes, aérosols.

Le respect de ces autorisations est contrôlé par un organisme ministériel, le Service Central de Protection contre les Rayonnements Ionisants (SCPRI) dépendant du Ministère de la Santé.

Enfin, l'application de ces prescriptions est vérifiée par une surveillance radiologique du site et de son environnement. Tous les résultats des mesures radiologiques retraçant l'évolution du milieu environnant sont transmis pour contrôle au SCPRI.

3 ORGANISATION DE LA SURVEILLANCE

Les moyens de surveillance et de contrôle peuvent se diviser en deux catégories différentes du point de vue de leur exploitation :

- la surveillance en continu qui permet en cas d'évolution d'un paramètre, d'engager rapidement les actions correctives. Le grand nombre

de ces mesures a nécessité une centralisation à un poste de contrôle centralisé (PC environnement).

- la surveillance en différé qui permet au moyen de prises d'échantillons dans l'environnement et d'analyses en laboratoire, de compléter notre surveillance et nos bilans.

3.1 SURVEILLANCE EN CONTINU

Ce contrôle s'exerce sur les rejets gazeux, les réseaux gravitaires et les paramètres météorologiques.

Rejets gazeux :

La surveillance en continu des rejets gazeux de l'Etablissement est conçue comme une série de trois cercles concentriques centrés sur l'Etablissement.

Au centre, les cheminées principales : UP 2 - UP 2 800 et UP 3. Les mesures effectuées sont de type alpha, bêta, gaz et mesure de débit.

Le deuxième cercle est constitué de huit stations de surveillance disposées en périphérie de l'Etablissement, elles permettent de décider si une anomalie peut avoir des répercussions à l'extérieur de l'usine. Les mesures effectuées portent sur la radioactivité des aérosols ainsi que sur l'irradiation ambiante.

Enfin, le troisième cercle est réalisé par cinq stations installées dans les villages avoisinants à des distances de 1 à 5 kilomètres, les mesures en temps réel portent sur l'activité des gaz et l'irradiation.

Gravitaires :

Toutes les eaux transitant sur l'Etablissement font l'objet d'un contrôle avant leur déversement dans le milieu avoisinant. Ce contrôle est effectué à l'aide de 5 contrôleurs bêta sur nappe d'eau (COBENADF). Le débit d'écoulement est mesuré en continu et enfin des analyses chimiques complémentaires sont effectuées.

Paramètres météorologiques :

Les mesures météorologiques doivent permettre d'évaluer les transferts atmosphériques de rejet d'effluents radioactifs gazeux en fonctionnement normal ou en situation accidentelle. L'Etablissement de La Hague s'est doté d'une station météorologique sur le site.

Poste de contrôle centralisé :

Une centralisation du résultat de ces contrôles a été réalisée pour permettre une vision plus générale et instantanée de la situation radiologique de l'Etablissement et de son environnement.

Chaque station de contrôle est équipée d'un automate qui permet d'élaborer et de restituer la mesure en local et de la transmettre au poste de contrôle centralisé de l'environnement (PCE). Le PCE est équipé d'un ordinateur central multitâches qui reçoit ses informations des différentes stations de mesure en continu et permet la restitution instantanée sur un écran vidéo couleur, l'impression des résultats et l'archivage.

3.2 SURVEILLANCE EN DIFFERE

Le contrôle différé consiste à prélever de façon systématique dans l'environnement des échantillons significatifs qui sont ensuite analysés par le laboratoire de l'environnement du service de Radioprotection. Cette surveillance préventive nous permet d'élaborer des bilans précis. Cette surveillance représente le prélèvement de 17 000 échantillons par an pour environ 50 000 analyses. Elle repose sur le contrôle des trois familles de transfert de la radioactivité vers la chaîne alimentaire ou biologique : transferts atmosphériques, hydrogéologiques ou marins.

Transfert atmosphérique :

L'ensemble des mesures constituant le contrôle continu en temps réel est complété par celles effectuées au moyen de filtres ou de pièges au charbon actif installés sur chacun des émissaires de l'Etablissement ainsi que sur les stations de clôture et périphériques.

De plus, cette surveillance est exercée sur les éventuelles retombées au sol : eaux de pluie, herbages, plantations, lait, viande.

Transfert hydrologique :

Les 32 sources ou ruisseaux prenant leur source à proximité de l'Etablissement sont surveillées et analysées. La nappe phréatique fait l'objet d'une surveillance particulière grâce à un réseau de 220 piézomètres. De plus, l'ensemble des eaux potables du district est analysé régulièrement.

Transfert marin :

Les rejets liquides de l'Etablissement se font en mer au travers d'une canalisation immergée de 6 km de long. Cette conduite de rejet fait l'objet d'une inspection régulière.

La surveillance cotière (200 km) s'exerce sur l'eau, le sable, les sédiments, les crustacés, les coquillages et les végétaux qui ont la particularité de fixer les radioéléments rejetés en mer. La surveillance de haute mer s'exerce sur l'eau, le sable, les sédiments et les poissons. Les prélèvements sont effectués de Granville jusqu'au Havre par la marine nationale française. Enfin, cette surveillance est complétée par l'étude de la diffusion marine des radioéléments en Manche et Mer du Nord effectuée par le Laboratoire de Radioécologie Marine du Commissariat à l'Energie Atomique (CEA).

4 RESULTATS

Ce programme de surveillance a l'agrément du Ministère de la Santé et fait l'objet de bilans. L'annexe 1 montre le bilan de la surveillance du milieu environnant pour les dix dernières années complétées par les mesures effectuées en 65 et 66 qui sont les années de référence précédant la mise en service de l'usine.

Les activités les plus élevées sont les plus anciennes et au fond du tableau et concernent la surveillance marine. On y observe une décroissance des activités pour les dix dernières années tandis que la quantité de combustible retraité n'a cessé de croître. Cette décroissance est le reflet de la diminution des activités rejetées en mer. De plus, on peut remarquer que depuis quelques années, l'activité artificielle est de même niveau que la radioactivité naturelle (potassium 40 et béryllium 7) pour les patelles et très inférieure pour les autres types d'échantillon.

Bilan des mesures dans l'environnement de la HAGUE

RADIOECOLOGICAL MONITORING OF THE ENVIRONMENT OF A FRENCH NUCLEAR POWER PLANT AFTER 12 YEARS IN OPERATION

DAUMAS J.*, FOULQUIER L.**, DESCAMPS B.**, ROUSSEL S.**

* Electricité de France - Centrale Nucléaire de Fessenheim

**Commissariat à l'Energie Atomique-IPSN/DPEI. Service d'études et recherches sur les transferts dans l'environnement.

SUMMARY

Taking Fessenheim Nuclear Power Plant as an example, description of various types of environmental test carried out under the responsibility of the Operator of Nuclear Power Plants in France : permanent monitoring of radioactivity, periodic radioecological assessments. Main results of measurements taken, showing the effect of the Plant to be negligible. Policy of openness by publication of these results.

INTRODUCTION

France has a large Nuclear Generating Capacity. The environment must be a constant concern, renewed according to scientific and technological progress. Observing strict regulations, Nuclear Power Plants release effluent, the radioactivity of which is added to radioactive fallout from old nuclear explosions and from Chernobyl. It is indispensable to monitor the surrounding radioecological state in order to ensure that operating these Plants is compatible with conservation. The Site of Fessenheim is given as an example of the various types of test carried out under the Operator's responsibility.

1. FESSENHEIM NUCLEAR POWER PLANT

It is the oldest French 900 MW PWR Plant. It consists of two Units, connected to the grid in 1977. In France, there are currently 54 Units distributed over 19 sites.

The general process for radioecological studies consists of 4 phases :

- Initial radioecological assessment establishing a reference state.
- Permanent monitoring of radioactivity in the area surrounding the Plant.
- Complete radioecological assessment made after approximately 10 years in operation.
- Annual monitoring of main radio-indicators in the earth and aquatic ecosystems.

It is then possible to compare the results obtained with the effluent composition (table 1)

Table 1 : Overall composition of liquid and gaseous effluent released from Fessenheim Nuclear Power Plant.

	total β (GBq)	total α (GBq)	sum of RE* (GBq)	tritium (TBq)	volume ($10^3 m^3$)	Gas (TBq)	aerosols+halogens (GBq)
1985	37	157	82	30	57	93.5	0.12
1986	42	156	79	38	52	100	0.20
1987	27	69	42	36	48	44	0.11
1988	28	96	47	33	68	<12	<0.03
1989	23	81	46	24	59	<11	<0.03
1990	14	56	34	20	57	<8.3	<0.03
**		900		75		1500	110

* Sum of radioelements apart from H3, Ra, K40. These are basically : Co60+58 (about 80% of release), Ag 110m, Sb124, Tl31, Cs137+134. ** Annual authorized limit for site.

2. INITIAL RADIOECOLOGICAL ASSESSMENT

It is obligatory for the study of environmental impact as one of the conditions of the Request to Provide a Utility, before the first Unit is started up. It consists of two facets:

- Evaluation of dose, based on a series of measurements of dose equivalents in the region [1] and analyses of γ spectrometry inside living quarters [2]. Variations due to geology or man-made modifications are observed. In the Plain of Alsace, the results are from 0.66 to 0.96 mSv p.a with a supplementary contribution of between 0.26 and 0.61 mSv p.a, related to buildings. Occasional values are noted: 4.6 mSv p.a. on a farm near a heap of manure and 33 mSv p.a. near uranium-bearing lode.
- Measurements of radioactivity in the environment [3] mainly based, at this time, on soil, vines, corn, honey and tritium of water. The Plant has at its disposal [4] data concerning Rhine fish : the Cs137 content, attributable to radioactive fallout from nuclear tests, varied from 1 to 6 Bq.kg-1 (wet weight).

3. PERMANENT MONITORING OF RADIOACTIVITY

The measurements are carried out by the Operator (table 2) according to a statutory programme controlled by the Central Service for Protection against Ionizing Radiation (SCPRI), which is responsible to the Ministry of Health.

Table 2 : Measurements for monitoring radioactivity carried out by the Operator around Fessenheim Nuclear Power Plant

Type of measurement	Average results 1990	When the cloud from Chernobyl was passing over (maximum values)
(Permanent) ambient radiation	0.01 to 0.04 $\mu\text{Gy.h}^{-1}$	0.15 $\mu\text{Gy.h}^{-1}$
aerosols in air on filter, measured 6 days after sampling	total β : 0.34 to 0.67 mBq.m^{-3}	total β :12 Bq.m^{-3} I131:3.5 Bq.m^{-3}
(Rhine) riverwater during effluent release	total β <1.1 Bq.l^{-1} H3<35 Bq.l^{-1}	I131:46 Bq.l^{-1} Cs137:7 Bq.l^{-1}
(Weekly) rainwater	total β <0.61 Bq.l^{-1}	I131:1030 Bq.l^{-1} Cs137:1388 Bq.l^{-1}
(Monthly) groundwater	total β <0.63 Bq.l^{-1} H3 < 34 Bq.l^{-1}	
(Monthly) land vegetation	total β (excluding K40) = 190 $\text{Bq.kg}^{-1}\text{sec}$	
(Monthly) milk	total β (excluding K40) <0.43 Bq.l^{-1}	total β :290 Bq.l^{-1} I131:140 Bq.l^{-1} Cs137:42 Bq.l^{-1}

Every month, the Plant distributes these results to Local Public Authorities, elected representatives and media. The results are also displayed on Minitel (national public information service). SCPRI carries out complementary tests concerning the whole of France, the results of which are also displayed on Minitel.

4. TEN-YEARLY RADIOECOLOGICAL ASSESSMENT

This study [5] was carried out after 12 years in operation at the time of the ten-yearly outage programme for both units. It consists of γ spectrometry on all samples and measurements of H3, Sr, Pu on some of them. For the earth ecosystem, at stations representative of the compass, samples of soil, milk, irrigation water, produce (corn, wine, wheat, lucerne, etc) are taken and analyzed (table 3)

Table 3 : Artificial γ radioactivity (in Bq.kg^{-1} (dry weight)) in some samples from the land around the Plant :

	Vine soil	Moss	Lucerne	Corn
Cs 134	1.6 \pm 0.5	81 \pm 4	---	---
Cs 137	14 \pm 2	413 \pm 13	0.1 \pm 0.1	0.19 \pm 0.1
Ag 110m	---	0.5 \pm 0.3	---	---
Co 60	---	0.3 \pm 0.2	---	---

The arboreal mosses, excellent radio-indicators, contain radioelements attributable to radioactive fallout from Chernobyl. The traces of Co 60 are probably related to Plant aerosols. A thorough analysis [6] of the concentration and deposit of Cs 137 in the soil, taking into account the effect of radioactive fallout from Chernobyl, has completely exonerated gaseous release from the Plant. Concerning the aquatic ecosystem (water, sediment, vegetation, fish) the results show that the Chernobyl accident has greatly influenced radioactivity levels (table 4).

Table 4: Examples of artificial γ radioactivity in the Rhine (in Bq.kg-1(d.w.) for sediment and vegetation, in Bq.kg-1(w.w.) for fish).

	Upstream			Downstream		
	Sediment	Vegetation	Fish	Sediment	Vegetation	Fish
Cs 134	18 ± 2	5.2 ± 1.9	0.4 ± 0.2	11 ± 3	2 ± 0.9	0.4 ± 0.1
Cs 137	97 ± 10	25.4 ± 2.8	2.2 ± 0.3	57 ± 3	7.5 ± 1.5	2.1 ± 0.2
Co 58	1 ± 0.5	8.5 ± 2.8	---	3 ± 1	69 ± 6	---
Co 60	4 ± 1	10 ± 3	---	3 ± 1	16 ± 2	---
Mn 54	1 ± 0.5	2.8 ± 1.4	---	---	3.3 ± 1.1	---

The presence of radiocobalt upstream from Fessenheim is attributable to effluent from a Nuclear Power Plant on the Upper Rhine. The isotopic ratio of Caesium corresponds to that of Chernobyl. Downstream, the concentration of Co 58+60 in aquatic vegetation can be attributed to liquid effluent from Fessenheim Nuclear Power Plant.

5. ANNUAL RADIOECOLOGICAL MONITORING

EDF has decided on a simplified annual monitoring programme for all Sites. It is currently being perfected technically for implementation in 1992. Thus, approximately thirty radio-indicators on land and in water (continental and marine) can be monitored with γ spectrometry and, if necessary, radiochemical analyses. There will therefore be a data bank permanently updated, according to time and space.

CONCLUSION

The impact of 12 years of operating Fessenheim Nuclear Power Plant is represented by a slight presence of artificial radioelements in the environment. These results underline the importance of radioecological testing before Plant start-up and during its operation, thus enabling any anomaly to be discovered at any time. In accordance with a national desire for openness, the public is informed of the results of these tests by the authorities, elected representatives and media [7]. The results can thus be compared to those of other existing networks of measurement. Moreover, the radioecological studies are the subject of published scientific papers [8]. The link between industry and research is thus correctly developed.

ICRU NEW OPERATIONAL QUANTITIES AND THEIR IMPLICATION ON RADIATION PROTECTION INSTRUMENTATION

In defining the new operational quantities (NOQ) the ICRU sought concepts applicable with the use of existing instrumentation or which do not introduce too drastic modifications for the design of future instrumentation. A short presentation of the last ICRU recommendations on the definitions and conditions of use of these new quantities is given.

The implications of these quantities on the design of radiation protection instrumentation is analysed.

1. INTRODUCTION

L'équivalent de dose et l'équivalent de dose efficace ont été pendant longtemps les principales grandeurs utilisées en radioprotection mais les conditions dans lesquelles elles doivent être déterminées en pratique n'ont été abordées que récemment, par l'ICRU et l'ICRP, dans une série de publications où les "nouvelles grandeurs opérationnelles" (NGO) ont été définies et leur mise en oeuvre précisée (ICRU 39, ICRP 51, ICRU 43, ICRU XX).

Le comité de travail de l'ICRU qui a proposé ces NGO s'était fixé comme règle de rechercher des concepts qui soient mesurables, en pratique, sans bouleverser les méthodes et l'instrumentation existante.

Dans ce document on analyse l'impact des NGO sur les méthodes et les moyens mis en oeuvre en radioprotection.

2. LES NOUVELLES GRANDEURS OPERATIONNELLES.

Les définitions de "l'Equivalent de dose ambiant" " H^* " et de "l'Equivalent de dose directionnel" " H " n'ont pas évolué depuis leur origine bien que les critères d'utilisation aient été précisés différemment dans le dernier document (ICRU XX) à paraître. Les équivalents de dose individuels, profond H_p et superficiel H_s , sont remplacés dans la dernière publication par "l'équivalent de dose personnel" " $H_p(d)$ " où d représente la profondeur de référence: 0.07 mm, 3 mm, 10 mm.

Les points essentiels suivants sont précisés dans ce document.

a/ Les étalonnages doivent être effectués en terme de:

- H^* pour les dosimètres de champ destinés à la mesure des rayonnements pénétrants.
- H pour les dosimètres de champ destinés à la mesure des rayonnements faiblement pénétrants.
- $H_p(d)$ pour les dosimètres individuels.

Ces derniers doivent être placés sur un fantôme; pour des raisons pratiques, il est conseillé d'utiliser pour l'étalonnage en photons une plaque de polyméthylmétacrylate (lucite,

plexiglas, etc;) de 15cm * 30cm * 30cm. La grandeur utilisée pour l'étalonnage est $H_p(d)$ dans un fantôme de même composition que le tissu ICRU et de même dimension et forme que le fantôme utilisé pour l'étalonnage.

b/- Les dosimètres de champ de rayonnement pénétrant doivent présenter une réponse angulaire "isotrope"; leur indication ne doit donc pas varier avec l'angle d'incidence du rayonnement.

- Les dosimètres de champ de rayonnement peu pénétrant et les dosimètres individuels doivent présenter une réponse angulaire "isodirectionnelle"; ceci implique que leur indication I varie avec l'angle d'incidence en accord avec la grandeur considérée. On a alors: I / H' ou $I / H_p(d) = Cste$.

3. ADEQUATION DE L'INSTRUMENTATION EXISTANTE

Les caractéristiques essentielles mises en jeu par l'introduction des NGO concernent la réponse énergétique et la réponse angulaire.

3.1. Dosimètres de champ

3.1.1. Rayonnement pénétrant.

Un instrument destiné à mesurer l'équivalent de dose ambiant doit présenter une réponse angulaire isotrope et une réponse énergétique qui tient compte du rayonnement diffusé par le fantôme.

a/ Pour la dosimétrie des photons et des neutrons, l'instrumentation existante présente déjà une réponse isotrope (Tab.1)

b/ L'instrumentation destinée à la dosimétrie des photons, à l'exception de celle qui est conçue pour la mesure de l'exposition, présente une réponse énergétique très voisine de celle impliquée par la mesure de H^* ou peut être facilement adaptée par l'interposition de filtres permettant d'ajuster l'épaisseur des parois à la profondeur de référence. Il y a lieu de remarquer que certains instruments, comme les GM, sont mieux adaptés à la mesure de H^* qu'à celle de l'exposition (PORTAL 88).

c/ L'instrumentation utilisée jusqu'alors pour la dosimétrie des neutrons était adaptée à la mesure de l'équivalent de dose maximal dans un fantôme cylindrique (MADE); la profondeur de mesure variait donc avec l'énergie des neutrons. En fait l'introduction de H^* n'entraîne une différence significative que dans la gamme d'énergie de 100 eV à 1 KeV; les incertitudes qui en découlent pour les mesures effectuées "sur le terrain" sont minimes.

3.1.2. Rayonnement faiblement pénétrant.

La réponse énergétique de l'instrumentation destinée à mesurer H est similaire à celle de l'instrumentation existante dans la mesure où la profondeur de référence est identique; dans le cas contraire il suffit de petits ajustements pour l'adapter.

La réponse angulaire doit être isodirectionnelle et non isotrope comme c'est souvent le cas avec l'instrumentation destinée à la mesure de la dose absorbée. De ce fait les appareils dont l'élément détecteur présente une géométrie cylindrique ne sont pas adaptés à la mesure de H . Seuls ceux qui sont dotés d'un capteur plan sont utilisables sans modification (Chambre à extrapolation, diodes, etc.) (Table.1).

3.2. Dosimètres individuels

La plupart des dosimètres individuels sont déjà conçus pour déterminer l'équivalent de dose à une profondeur de 0.07, 3 ou 10mm. Leur réponse énergétique est alignée sur la dose absorbée dans le cas des photons et sur l'équivalent de dose maximal (MADE) pour les neutrons. Elle n'est donc pas fondamentalement différente de celle impliquée par l'utilisation des NGO. Si les profondeurs de référence ne sont pas respectées, il suffit le plus souvent d'effectuer des ajustements mineurs pour l'améliorer (Table 1).

Leur réponse angulaire doit être isodirectionnelle. Comme précédemment, ce n'est pas le cas pour ceux qui mettent en oeuvre un élément détecteur de géométrie cylindrique (Compteur proportionnel, Chambre à ionisation, Dosimètre à bulles); leur conception doit être révisée. Ceux qui sont dotés d'un détecteur plan peuvent présenter une réponse isodirectionnelle (Emulsions photographiques et nucléaires, Détecteurs thermoluminescents, Diodes, etc.). Cependant ceci n'est pas toujours exact pour les dosimètres à neutrons qui sont dotés d'un convertisseur (n,p) généralement mince; la profondeur de référence n'est pas respectée (Emulsion nucléaire NTA, Détecteur solide de traces, etc.); leur réponse n'est pas isodirectionnelle (Voir figure 1).

4. CONCLUSION

La plupart des appareils utilisés jusqu'alors peuvent être conservés pour la mesure des nouvelles grandeurs opérationnelles; il suffit le plus souvent d'effectuer un changement d'échelle pour tenir compte du changement d'unité. Le seul problème qui se pose concerne le défaut de réponse isodirectionnelle des dosimètres individuels et des dosimètres de champ pour les rayonnements faiblement pénétrants. Cependant ce problème n'est pas nouveau; c'est par souci de simplification que l'on concevait dans le passé des détecteurs isotropes mais ceci n'était nullement justifié.

En fait l'évolution des dosimètres à neutrons sera surtout imposée par l'application des recommandations de l'ICRP 60 qui exigent des modifications importantes de leur réponse énergétique (du fait des changements apportés aux facteurs de qualité) et de leur seuil de détection qui devrait être réduit d'un facteur 5 à 10 (PORTAL 1991).

ABSTRACT

In order to allow an assessment of the environmental impact due to the operation of the IPEN's facilities and an evaluation of the adequacy of the effluent emission control system, a continuous effluent monitoring program has been carried out. During the year of 1990, the total activity discharged was 7.7×10^8 Bq, diluted on 1.4×10^3 m³ of water. The effective dose equivalent in the critical group was 6.8×10^{-5} mSv, mainly due to the exposure to Co-60, Cs-137 and Cs 134. It should be emphasized, however, that none of these radionuclides has been detected in the environmental samples.

INTRODUCTION

All the radioactive liquid effluents generated at Instituto de Pesquisas Energéticas e Nucleares (IPEN) are discharged, after an adequate treatment, into the aquatic system of Pinheiros river. In order to control such releases into the environment, an effluent monitoring program has been established on a routine basis. In this paper, results of the source-term are presented concerning the period from January/88 to December/90 together with the estimate of the effective dose equivalent to the general public. Data relative to the levels of radioactivity in environmental samples collected in the ecosystem of Pinheiros river during the year of 1989, are also presented.

LIQUID EFFLUENT RELEASE SOURCE-TERM FOR THE PERIOD FROM JANUARY/88 TO DECEMBER/90

The liquid effluents from most of the IPEN's facilities or laboratories are stored and controlled in their respective retention tanks. Each batch of the effluents generated is sampled and measured by gamma spectrometry using a HPGe detector. If the samples contain uranium and/or thorium, the activity of these radionuclides is measured by neutron activation or spectrophotometric analysis. The total activity together with the total volume of water released during the period from January/88 to December/90 is summarized in Table I.

After proper operational controls at the source, a decision is made about discharge of each batch into the sewage system of the Institute, according to the national regulatory rules⁽¹⁾.

EVALUATION OF THE RADIATION DOSE TO THE INDIVIDUALS OF THE PUBLIC

All the low-level liquid effluents authorized for release are discharged into the Pinheiros river. These releases are made through the sewage system of the Institute. The effluents enter into the river at two separated points, two kilometers apart, through two sewage lines; one of them outflows direct into Pinheiros river and the other one outflows into Jaguaré stream before reaching Pinheiros river.

At the moment there is complete lack of aquatic life in this river due to the high quantity of sewage discharged continuously and due to severe industrial pollution. There is no use of the water neither for human consumption nor for irrigation purposes. Only some factories localized at the river borderlines pump the water for industrial machine refrigeration.

In this case, the main exposure pathway to be considered is the gamma external irradiation of the individuals of the public who work at the river bank near the discharge point. The dose received by this critical group was evaluated according to the IAEA model ⁽²⁾ and using adequate dose factors ⁽³⁾. It was assumed a continuous release of liquid effluents into the river. The final results of the annual effective dose equivalent are presented in Table 1. The main radionuclides which contributed to exposure during the period from January/88 to December/90 were Co-60, Cs-137 and Cs-134.

MEASUREMENT OF ACTIVITIES IN WATER AND SEDIMENTS OF PINHEIROS RIVER

Samples of water and sediments were collected at five points of Pinheiros river and analyzed by gamma spectrometry; uranium contents were determined by fluorimetry. The points of monitoring are described below:

- Point 1: Control point, localized about 3 km upstream from the first effluent discharge point.
- Point 2: First effluent discharge point, localized at the mixing point where Jaguaré stream joins the river flow.
- Point 3: Second effluent discharge point about 2 km downstream from Point 2.
- Point 4: Morumbi bridge, about 4 km downstream from Point 3.
- Point 5: Discharge point of Pinheiros river into Billings reservoir, about 10 km downstream from Point 4.

Only natural radionuclides were detected in these environmental samples, as follows: Ra-228, Ra-226, Be-7 and K-40, with activities corresponding to the background levels.

These measurements are made only periodically since sufficient data has been accumulated during the last years, so that the control of radiation doses to members of the public might be reduced solely to the monitoring at the points of discharge of the Institute.

TABLE I - Results of the total activity in the liquid effluents released during the period from January/88 to December/90 and total effective dose equivalent (H_E) in the critical group.

year	total activity released (Bq/y)	total volume (m^3/y)	H_E (mSv/y)
1988	2.0×10^9	2.4×10^3	2.7×10^{-5}
1989	4.0×10^9	1.2×10^3	5.6×10^{-5}
1990	7.7×10^8	1.4×10^3	6.8×10^{-5}

CONCLUSIONS

Results of dose calculations in the critical group showed that radiological consequences to the environment due to radionuclides releases into the Pinheiros river through IPEN's sewage system are negligible at the moment. The levels of radioactivity found in water and sediments river samples are in agreement with the expected values, considering that the effluents released are diluted in a high volume of water by the time they reach the receptor river.

ABSTRACT

We have developed a practical method for mapping variations in gamma activity and electrical conductivity of submerged sediments. Prototype probes are being constructed and tested. The first prototype was essentially a background survey meter (Jones, 1979) packaged in a 53-cm-long by 5.4-cm-diameter waterproof vehicle. This tubular vehicle was towed by boat in contact with the bottom sediments of lakes and rivers. Originally, this vehicle was designed (and is still frequently used) for locating groundwater and contaminant entry areas in surface waters. By logging geographic position and sediment variables, it has been possible to produce contour maps in areas of interest. Thus it is possible to optimize environmental analysis and avoid the "hit or miss" approach of traditional bottom-sediment surveys.

INTRODUCTION

Contaminants present in surface-water discharges as a result of industrial effluents can accumulate in bottom sediments. Because of the overlying water, it has been difficult to determine the areal distribution of contaminants in these sediments. Consequently, environmental questions often cannot be addressed without great cost. Mobile methods for rapid detection and mapping of sediment contamination would greatly enhance the value of laboratory analyses required for monitoring. If areas of potential contamination were surveyed and the results shown on a map, it would be possible to verify the effectiveness of monitoring, reduce its cost or focus on corrective action.

Most instruments, presently used for underwater surveys, are designed to operate some distance above the bottom, not in contact with it, to avoid snagging, abrasion or damage. Although many contaminants are preferentially associated with sediments, they cannot be readily detected without direct sediment contact. Several devices have been designed to be lowered to the bottom to make point measurements, but they do not provide information between the points of measurement. A continuous line of data along the bottom can be decisive because contaminants are rarely distributed uniformly. Some large devices have been designed for towing behind oceanographic vessels. These devices are unsuited for surveys on the bottoms of lakes, estuaries or rivers, particularly near shore-based industrial areas.

Many radionuclides that may be present in industrial discharges become associated with bottom sediments. Shielding by water prevents detection unless the detector is within a few centimeters of the radioactivity. Consequently, most radiometric surveys of bottom sediments are done by sediment coring and subsequent laboratory analyses. However, coring is a point sampling approach. Without a measure of spatial heterogeneity, coring can not provide satisfactory coverage without enormous effort. Therefore, the detailed, quantitative information from sediment cores can rarely be used fully.

The project outlined here was designed to provide continuous line data that could be used to generate contour maps of gamma activity distributions. Such a map could be used to select coring locations and to reduce the numbers of cores required. Quantitative information from these cores can be used to calibrate the mapped distributions. A map of sediment radioactivity could also help form conceptual models for aquatic transport, dispersion and deposition. Information on the lateral distributions of gamma activity of bottom sediments could also help to verify the results of effluent monitoring programs, improve the information quality of bottom samples that are taken to answer allegations regarding release of contaminants, and to establish representative monitoring points. Where there are valid concerns that sediments may be contaminating invertebrates or fish, a contour map of gamma activity can help target areas for definitive study.

BOTTOM-CONTACT SEDIMENT SURVEY PROBE

The probe serves as an underwater gamma radiation survey vehicle that can be towed along the bottom of a body of water with minimal snagging. Another requirement was that the vehicle remain oriented so that detectors in the probe would "look" toward the bottom, or upward toward the overlying water.

The initial prototype was a 53-cm-long x 5.4-cm-diameter tube, closed at both ends and containing a Geiger-Muller tube. Lead was added inside of the 5.4-cm-diameter tube to keep the probe on the bottom during normal towing speeds of 1 meter per second. Mass within the tube was distributed to maintain the orientation of the probe. Orientation also ensured that contact with the bottom could be ascertained while the probe was underway, by monitoring electrical conductance with electrodes located along the lower side of the probe. During towing, the probe did not roll or twist along its longitudinal axis by more than 10 degrees, so that the sensors, which had been fixed within the vehicle, were oriented to "look" up, down, or sideways (Jones, 1979; Lee and Beattie, 1991).

A stretched version of the probe was built to allow adjustment of the probe mass by the addition or removal of lead weights, while at the same time preserving the self-orienting feature of the probe. Where sediments were very soft, it was advantageous to increase or decrease the overall mass for selected runs. Also, in the stretched version, the lead shielding over the upper and lateral sides of the detector was removed so that radiation could be detected from all around.

Because of their robustness, the two detectors used to date have been Geiger-Muller tubes. The two Geiger-Muller tubes used have outer dimensions of 26.7-cm long x 2.25-cm diameter and 99.3-cm long x 5.075-cm diameter. In laboratory tests, the larger tube has been shown to be 16 times more sensitive than the smaller tube. Currently, the larger tube is being incorporated into a second probe and a third device, which will have a NaI detector, is being designed.

FIELD-PORTABLE DATA ACQUISITION

A geographic positioning system has been interfaced to a computer for logging the position of the probe while it is underway. The positioning system is portable, semi-automatic and laser-based. Tests have shown that records of sediment variables and geographic location (to plus or minus one meter) can be logged under field conditions.

A portable computer has been modified and software has been written to convert analog signals to digital data, to store these data and display concurrent, real-time records of gamma activity and sediment conductivity. Having a real-time graphical display, the operators are able to identify key sampling locations, and to form a mental image of the underlying spatial variations of the sediment. Therefore, the density of coverage and the sampling for ground truth was adjusted at early stages of the current investigation of the Chalk River waterfront on the Ottawa River.

With geographic positioning, the system has allowed us to collect data for creating coloured contour maps of the distributions of sediment radioactivity and conductivity. Results of work along the Chalk River waterfront have shown good agreement between laboratory analyses of river sediment and contour maps made with this data acquisition system. Good agreement has also been seen between point data and probe results in a study of a small pond near one of the waste management areas at Chalk River.

CONCLUSION

A new approach to underwater monitoring near industrial sites has been introduced for surveying areas of interest in aquatic environments. The approach has the potential to reduce the costs of monitoring and remediation by identifying specific areas for detailed study. Sediment monitoring or cleanup can be targeted on locations where maximum benefit can be obtained.

RADIOACTIVE SURVEY OF THE ENVIRONMENT OF THE NUCLEAR SITES
OF FRENCH NUCLEAR BOARD : AN OVERVIEW

C.E.A. has set up a network of radioactive survey around its nuclear sites. This network involves terrestrial, atmospheric and marine results of radioactive measurements. This survey is structured in four levels. The level 0 homogenizes stations of measurements, level 1 centralizes real-time measurements of gross α and β measurements of atmospheric radioactivity, level 2 and 3 centralizes postponed α - β spectrometric measurements of radioactivity on water, deposition, grass, vegetables. People can have a squint at these results of measurements using popular MINITEL telephonic network.

1. INTRODUCTION.

La surveillance du niveau de radioactivité de l'environnement des sites du Commissariat à l'Energie Atomique a accompagné, depuis leur création, leurs activités. Cette surveillance est particulièrement rigoureuse autour des sites civils de Fontenay-aux-roses, de Saclay, de Grenoble, de Cadarache; des sites militaires de Valduc, Bruyères-le-Châtel; des sites industriels de La Hague, Marcoule, Pierrelatte. Elle est dirigée par la direction de chaque établissement.

Par décision de l'Administrateur Général du C.E.A. un réseau surveillance de l'environnement a été créé à la suite des besoins d'information précis et rapides qui ont été mis en évidence, notamment, lors de l'accident survenu à la centrale de Tchernobyl.

Par la suite, une directive du Premier Ministre, puis du Ministre de l'Industrie ont insisté sur la nécessité pour les exploitants de l'industrie nucléaire d'informer le public des niveaux de radioactivité enregistrés autour des installations nucléaires. Les résultats de mesures de la radioactivité du réseau de surveillance créé par le C.E.A. ont donc été mis à la disposition du public par divers moyens d'information.

2. LA STRUCTURE DU RESEAU DE SURVEILLANCE.

2.1. Les éléments du réseau.

Ce réseau de surveillance appelé SYTAR (Système de Transmission et d'Alarme Radiologique) relie les sites de BRUYERES-LE-CHATEL, CADARACHE, FONTENAY-AUX-ROSES, GRENOBLE, LA HAGUE, MARCOULE, PIERRELATTE, SACLAY, VALDUC, MONTHLERY. Il intègre également un réseau de surveillance atmosphérique comprenant six stations de mesures de forte sensibilité et un réseau de surveillance marine comprenant quinze stations de prélèvement sur les côtes de la Manche et de la Méditerranée. Ces deux réseaux, ainsi que le réseau SYTAR sont exploités par l'IPSN (Institut de Protection et de Sûreté Nucléaire).

2.2 Les niveaux du réseau

Le réseau est structuré en quatre niveaux fonctionnant parallèlement, avec des fréquences différentes.

2.2.1. Le niveau 0.

Ce niveau 0 a pour objectif de donner toutes informations sur la nature (type d'appareillage, seuil de mesure, radionucléide de référence, ...) et l'état de fonctionnement des matériels de mesure. Un second objectif de ce niveau est l'harmonisation des appareillages et des seuils de mesures. Les éléments de ce niveau sont modifiés lors d'un changement, d'un arrêt ou d'une remise en fonctionnement d'un appareil.

2.2.2. Le niveau 1.

Ce niveau 1 a pour objectif d'homogénéiser et de centraliser les résultats de mesure des radioactivités atmosphériques α et β (radioactivités naturelle, artificielle et totale), les résultats de mesure de l'irradiation γ des gaz. Les mesures de ce niveau sont faites en temps réel, par des balises BFSAB (Balise à Filtre Séquentiel Alpha et Beta). La balise fournit une mesure de l'irradiation γ exprimée en $\mu\text{Gy h}^{-1}$ et une mesure de la radioactivité des gaz en Bq m^{-3} . Les traitements sont effectués à partir de la fréquence des impulsions fournies par les capteurs; pour obtenir l'activité des gaz, le niveau d'irradiation naturelle est soustrait après lissage des résultats. Cette balise permet également des mesures directes et retardées à 24 heures de l'activité α et β des aérosols.

2.2.3. Le niveau 2.

Ce niveau 2 a pour objectif d'homogénéiser et de centraliser les résultats de mesure de la radioactivité par spectrométrie α , β et γ , des prélèvements d'aérosols, des dépôts et des eaux. Ces mesures sont effectuées

hebdomadairement en situation normale.

2.2.4. Le niveau 3.

Ce niveau 3 a pour objectif d'homogénéiser et de centraliser les résultats de mesure de la radioactivité par spectrométrie α , β et γ , des prélèvements d'herbe et de végétaux (fruits, légumes, feuilles). Ces mesures sont effectuées mensuellement en situation normale.

3. LES MOYENS D'INFORMATION DU RESEAU.

3.1. Les aspects médiatiques du réseau.

Ce réseau est un système d'information des autorités du CEA mais aussi du public. Pour le public les résultats de mesures de la radioactivité sont pour chacun des sites et pour chacun des niveaux moyennés sur un mois. Les valeurs moyennes des 12 mois précédents sont également indiquées, à titre de référence. Ces résultats sont alors édités trimestriellement et consultables par le public par l'intermédiaire du réseau télématique MINITEL.

3.2. Tableau de bord de la radioactivité d'un site.

Un exemple de tableau de bord des mesures de la radioactivité fourni à la fois aux autorités et au public est illustré par les graphiques ci-après. Ce tableau de bord est celui relatif au niveau de la radioactivité de l'environnement du site de Grenoble pour l'année 1990 (département de l'Isère dans le Sud-Est de la France). Ce tableau de bord regroupe les résultats mensuels de l'irradiation externe, des activités α et β totales des aérosols de l'atmosphère, des activités β totales des eaux de surface et de l'herbe, ainsi que l'activité en ^{137}Cs de l'herbe et du lait.

ABSTRACT

Off-gas released from nuclear fuel reprocessing plants contains ^3H , ^{14}C , and $^{129/131}\text{I}$, and ^{85}Kr . In order to design a system which continuously monitors the concentrations of the former four nuclides with the coexistence of ^{85}Kr , the performance of elementary technologies was tested such as catalytic oxidation, gas separation by permeable membranes, adsorption of iodine, and radiation measurement. A combination of these technologies could be applied for detection of ^3H , ^{14}C , and $^{129/131}\text{I}$ with ^{85}Kr down to 1.0×10^{-3} , 3.7×10^{-4} , and 3.7×10^{-8} Bq/cm³, respectively.

1. Introduction

From the standpoint of radiation control for the public, it is desirable to monitor gaseous radioactivity in off-gas from nuclear facilities. In the off-gas from a nuclear fuel reprocessing plant, however, ^{85}Kr coexists at 10^2 - 10^3 times the concentrations of ^3H , ^{14}C , and $^{129/131}\text{I}$, and, in addition, these radionuclides have several chemical forms. This leads to the difficulty of continuous measurement of radioactivity. In this research, assuming the following basic flow for continuous monitoring, fundamental studies of elementary technologies were carried out.

2. Targeted discrimination factor (DF^{*1}) of separation for continuous monitoring

The targeted DFs of separation for continuous monitoring of ^3H , ^{14}C , and $^{129/131}\text{I}$ were calculated, based on a performance of radiation detectors and the estimated annual discharge of gaseous radioactivity released from a nuclear fuel

*1: DF means a ratio of gas concentration of feed to permeate.

reprocessing plant⁽¹⁾. In this study, the radioactivity detectors were selected as shown in the Table 1. More than 10^5 and 10^7 were obtained for the targeted DFs of ^{85}Kr to ^3H , ^{14}C , or $^{129}/^{131}\text{I}$ and that of for ^{14}C to ^3H , respectively.

Table 1. Detectors for ^3H , ^{14}C $^{129}/^{131}\text{I}$ monitoring.

nuclide	detectable limit Bq/cm ³	detector
^3H	6×10^{-4}	proportional counter with pulse-shape discriminator
^{14}C	4×10^{-4}	plastic scintillator
^{129}I	$3 \times 10^{-8*}$	N-type Ge semiconductor detector
^{131}I	$1 \times 10^{-8*}$	N-type Ge semiconductor detector

*:The values can be attained by adsorption of iodine in 14m³ off-gas

3. Unification of chemical forms

CH_4 is assumed to be the most difficult compound to oxidize among the chemical components containing radionuclides of ^3H and/or ^{14}C in off-gas. More than 95% of CH_4 could be converted into CO_2 by oxidation at 400 °C and at a space velocity of 10^4h^{-1} , using a Pd-alumina catalyst. In the case of iodine, it was revealed that the adsorption of iodine on Pd catalyst and piping makes it difficult to measure the correct concentration of iodine. Thus, it was determined that iodine should be separated from Kr by TEDA-impregnated charcoal which can capture both I_2 and CH_3I .

4. Gas separation by permeable membranes

An HTO monitoring system using vapor separation membranes was developed and the DF value for ^{85}Kr was reported to be 10^4 ⁽²⁾. Further, the ^{85}Kr separation from $^{14}\text{CO}_2$ or Ar by silicone membranes was also studied^(2,3). These methods have low DFs and require an appropriate system for applying to ^{85}Kr removal and HTO separation for off-gas from reprocessing plants.

4.1 Gas separation for ^3H monitoring

The permeability of H_2O , Kr, and CO_2 was investigated to determine a membrane suited to the selective permeation of H_2O . Commercially available hollow-fiber type modules such as perfluorocarboxylic acid membrane (FLEMION), perfluorosulfonic acid membrane (NAFION), and polyimide membrane (UPIREX) were used for the purpose. The gas permeation rates at 40 °C are shown in the Table 2. NAFION and FLEMION have a higher ratio of permeation rate for H_2O to for Kr. Of the two membranes, FLEMION indicated a more rapid response to H_2O permeation. FLEMION was selected as the HTO permeation membrane in view of

its high permeability and rapid response. The permeation rate of FLEMION depends on humidity and falls to less than 1/10 in dry air. However, the rate decrease could be prevented by controlling humidity to be 20 °C as dew point in the purge gas.

A separation system whose $DF(Kr/H_2O) = 5.0 \times 10^6$, $DF(CO_2/H_2O) = 3.0 \times 10^4$, and $C/C_0(H_2O)^{*2} = 0.77$ to 1 could be established by using two-stage of FLEMION hollow fiber modules and humidifying the permeate side. Combining this system with the proportional counter enables a continuous monitoring system to be established for 3H , which ensures a detectable 3H concentration limit of 1.0×10^{-3} Bq/cm³ when ^{85}Kr and ^{14}C exist with 1.0×10^4 and 60 Bq/cm³, respectively.

Table 2. Permeation rates of gases to be separated at 40 °C.

Membrane	Permeation rates at 40 °C (cm ³ /cm ² ·cmHg·s)		
	H ₂ O	CO ₂	Kr
NAFION	4×10^{-3}	2×10^{-6}	8×10^{-8}
FLEMION	1×10^{-2}	8×10^{-7}	1×10^{-7}
UPIREX	2×10^{-3}	5×10^{-5}	1×10^{-6}
SILICONE	5×10^{-4}	5×10^{-5}	3×10^{-5}

4.2 Gas separation for ^{14}C monitoring

UPIREX was selected for the separation of CO₂ from Kr because the DF of Kr is as high as 50, which is the highest among other membranes. To attain a DF for Kr higher than 10⁶, a multi-stage separation system and the high value of C/C₀ for CO₂ are required. This requirement could be satisfied by increasing the pressure difference between the feed side and the permeate side. Pressurization of feed gas is advantageous for making the system compact.

A separation system whose $DF(Kr) = 10^5$ and $C/C_0 = 1$ was established by adopting the four-stage separation of UPIREX in which the supply side is pressurized to 4 atm. By combining this system with the plastic scintillation detector, it is possible to design a continuous monitoring system whose ^{14}C detectable concentration limit can be 3.7×10^{-3} Bq/cm³ in the presence of ^{85}Kr of 3.7×10^7 Bq/cm³.

5. Design of monitoring system

A monitoring system based on the test results is shown in the Figure. In this system, $^{129}I/^{131}I$ in the off-gas is at first captured by the TEDA-impregnated charcoal cartridge. At the same time, $^{129}I/^{131}I$ is measured by an N-type Ge semiconductor detector, which enables monitoring at a level of 10^{-6} Hq/cm³. The charcoal cartridge is automatically replaced

*2: C/C₀ means a ratio of gas concentration of feed to permeate.

at intervals of four hours, and then additional measurements for other four hours are performed to detect down to a level of 3.7×10^{-8} Bq/cm³ by holding the charcoal cartridge between two N-type Ge semiconductor detectors. After iodine is captured, ¹⁴C and ³H are oxidized in order to unify their chemical forms into CO₂ and H₂O respectively by Pd-alumina catalyst. Then, ¹⁴CO₂ and HTO are separated from interfering nuclides by the above-mentioned membrane separation systems and measured by the plastic scintillation detector and the proportional counter, respectively, which are shown in table 1.

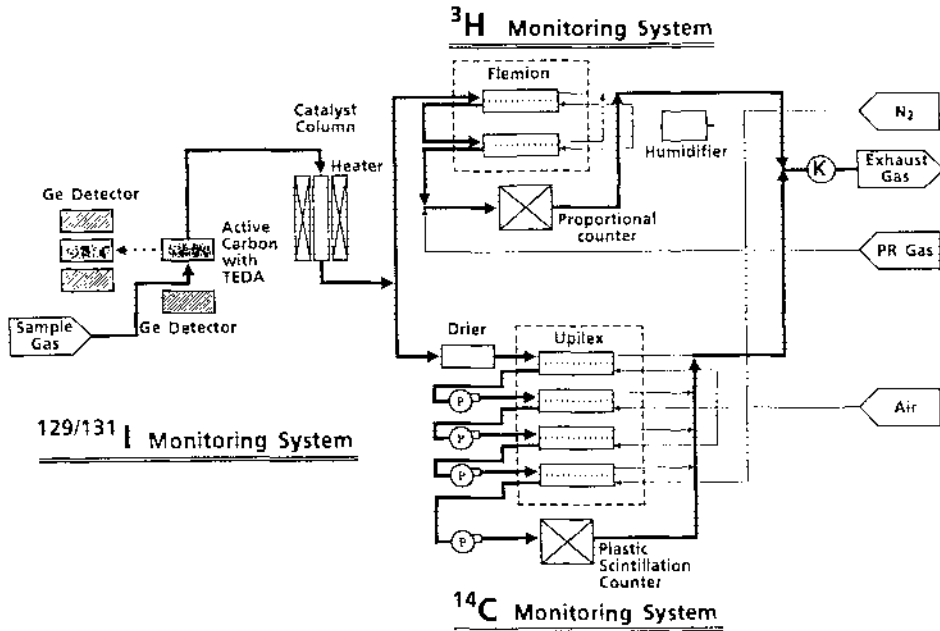

Fig. Process Flow of ^{129/131}I, ¹⁴C and ³H Monitoring System

6. Conclusion

A system was established for continuously monitoring the ³H, ¹⁴C, and ^{129/131}I concentrations in off-gas released from reprocessing plants in the presence of ⁸⁵Kr.

ABSTRACT

In order to elucidate the fluctuations of the exposure rate, classification of monitoring sites based on various variational patterns of monthly exposure rate was attempted. To obtain various variational patterns, seasonal adjustment method and period analysis method were used. By comparing various variational patterns and correlation coefficients, classification of monitoring sites could be carried out. The classification of monitoring sites is an useful tool to get some information for estimating the reasons and the intensity of variation on exposure rates.

INTRODUCTION

The exposure rates due to environmental gamma-rays show roughly constant levels at respective monitoring sites. However, if examined in detail, the exposure rate varies periodically or occasionally from several to ten-several percent. It is important to make clear the reasons of the variation from the view points of monitoring of nuclear facilities and research of environmental radiation and radioactivity. In order to elucidate the fluctuations of the exposure rate due to environmental gamma-rays near nuclear power station, classification of monitoring sites was attempted. This paper briefly describes monitoring site classification method based on various variational patterns of monthly exposure rate. As an application of this method, classification of monitoring sites around TSURUGA Nuclear Power Station is also described.

MONITORING SITE CLASSIFICATION METHOD

To obtain various variational patterns of monthly exposure rate, time series analysis methods, that is, seasonal adjustment method and period analysis method, were used. Seasonal adjustment method calculates trend-circular exposure rate, seasonal factor and irregular factor by the moving average method. Trend-circular exposure rate represents the moving average of original data and the deviation of original data from trend-circular exposure rate represents

seasonal and irregular factors. The periodic component of this deviation is seasonal factor and the rest is irregular factor. Period analysis method, on the other hand, calculates periodgram by the finite fourier transformation. Periodgram represents the order of periods involved in original data. From the calculational results obtained, the interpretation of variational patterns is discussed.

Using time series analysis methods mentioned above, monitoring site classification based on various variational patterns of monthly exposure rate could be carried out as follows.

Step 1. Calculate correlation coefficients among monthly exposure rates at monitoring site,

Step 2. Calculate monthly trend-circular exposure rate, seasonal factor and irregular factor of monthly exposure rate at each monitoring site by seasonal adjustment method,

Step 3. Calculate correlation coefficients among monthly trend-circular exposure rates at monitoring site,

Step 4. Calculate periodgram of monthly exposure rates at each monitoring site by period analysis method,

Step 5. Calculate periodgram of trend-circular exposure rate at each monitoring site,

Step 6. Compare the various variational patterns and the correlation coefficients,

Step 7. Classify monitoring sites.

Flow chart of monitoring site classification method is shown in Fig.1.

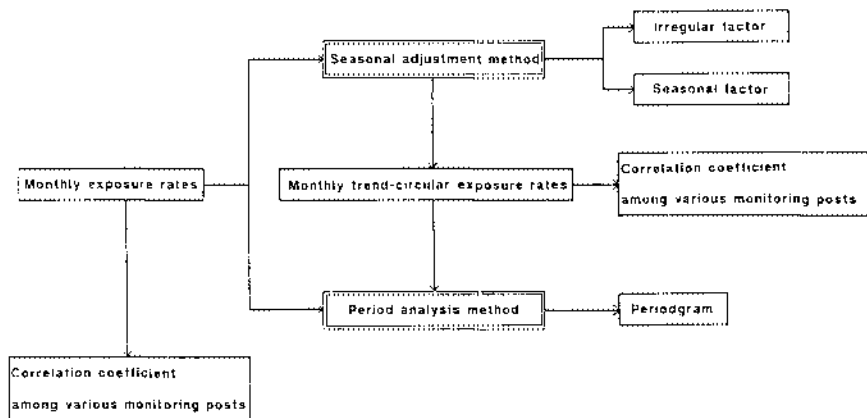

Fig.1 Monitoring site classification method based on various variational patterns of monthly exposure rates

Using this monitoring site classification method, the classification of monitoring sites around TSURUGA Nuclear Power Station was carried out. The area around TURUGA Nuclear Power Station is the area of higher exposure rates due to the terrestrial natural gamma-rays than the other

area in FUKUI Prefecture. Monthly exposure rates measured and evaluated at nine monitoring sites from April 1984 to March 1990 were used.

CLASSIFICATION RESULTS AND DISCUSSION

Several typical characteristics obtained from the calculational results and the classification of monitoring sites are listed below.

Considering seasonal factor obtained from seasonal adjustment method, there are three types of monitoring sites.

Type 1 : Monitoring site where low monthly exposure rate in winter has been measured because of shielding terrestrial gamma-rays by the snow.

Type 2 : Monitoring site where low monthly exposure rate in winter and rainy season has been measured because of shielding terrestrial gamma-rays by the snow and by the increase of water content in soil.

Type 3 : Monitoring site where no significant seasonal variation in monthly exposure rate has been measured.

Considering periodogram obtained from period analysis method, there are three types of monitoring sites.

Type 4 : Monitoring site where seasonal variation in monthly exposure rate has been measured because of the influence of the four seasons.

Type 5 : Monitoring site where trend variation in monthly exposure rate has been measured because of the gradual change of the topography.

Type 6 : Monitoring site where zigzag variation in monthly exposure rate has been measured.

Considering correlation coefficients, there are two types of monitoring sites.

Type 7 : Monitoring site where similar variation in monthly exposure rate to that at the other monitoring site has been measured because of the similar influence of environmental conditions.

Type 8 : Monitoring site where similar variation in trend-circular exposure rate to that at the other monitoring site has been measured because of the similar influence of environmental conditions without the effect of the four seasons.

From the classification results obtained, the reason of spatial and time dependent variation on exposure rate could be estimated by investigating in detail at the other monitoring site which has the similar classified characteristics, if low or high exposure rate were temporarily measured at some monitoring sites. Accordingly, the classification of monitoring sites is an useful tool to get some information for estimating the reasons and the intensity of varia-

tion on exposure rate.

CONCLUSION

In order to elucidate the fluctuations of the exposure rate due to environmental gamma-rays near nuclear power stations, classification of monitoring sites based on various variational patterns of monthly exposure rate was attempted. To obtain various variational patterns, time series analysis methods, that is, seasonal adjustment method and period analysis method, were used. By comparing various variational patterns and correlation coefficients among monthly exposure rates at monitoring site, classification of monitoring sites could be carried out.

Using this monitoring site classification method, the classification of monitoring sites around TSURUGA Nuclear Power Station, where is the area of higher exposure rate due to the terrestrial natural gamma-rays than the other are in FUKUI Prefecture, was carried out. As a results, it is found that there are eight types of monitoring sites which have typical similar characteristics around TSURUGA Nuclear Power Station.

From the classification of monitoring sites, the reason of spatial and time dependent variation on exposure rates could be estimated by investigating in detail at the other monitoring site which has the classified similar characteristics. Accordingly, the classification of monitoring sites is an useful tool to get some information for estimating the reasons and the intensity of variation on exposure rates.

Introduction

The Republic of the Marshall Islands (RMI) is located in the central Pacific Ocean about 3,500 km southwest of Hawaii and 4,500 km east of Manila, Philippines. It consists of 34 atolls and 2 coral islands, having a total land area of about 180 km², distributed over more than 2.5×10^6 km² of ocean. Between 1946 and 1958 the United States conducted nuclear tests there: 43 at Enewetak and 23 at Bikini. Thirty-three years after the cessation of nuclear testing in the RMI, the impact of these operations on the health and radiological safety of the people living in or planning to return to their contaminated homelands is still an important concern⁽¹⁾⁽²⁾.

The present Brookhaven National Laboratory (BNL) Marshall Islands Radiological Safety Program (MIRSP) began in 1987 with funding from the U.S. Department of Energy (DOE). The objectives of the MIRSP are to determine the radionuclides present in the bodies of those people potentially exposed to residual radionuclide from weapon tests and fallout, and to assess their present and lifetime dose from external and internal sources. Field bioassay missions involving whole-body counting (WBC) and urine sample collection have, therefore, been important components of the program. WBC is used to measure γ -emitters, such as ⁴⁰K, ⁶⁰Co and ¹³⁷Cs, present in individuals. Urine samples are used to measure α and β -emitting nuclides, such as ²³⁹Pu and ⁹⁰Sr, that are undetectable by WBC routine methods.

Whole-Body Counting Program

Whole-body counting measurements are conducted on a voluntary basis. Two complete counting systems are operated simultaneously and independently during daily WBC operations. The counting time is 15 minutes per measurement. About 50 to 60 measurements could be completed in a working day. A total of 916 persons were counted in 1989. This group included 216 the people of (dri-) Enewetak, 258 dri-Rongelap, and 414 dri-Utirik. Also included were 28 visitors, workers, and DOE personnel, listed as "Others". A total of 1,051 persons participated in the WBC in 1991; 311 dri-Enewetak, 272 dri-Utirik, 427 dri-Rongelap, and 41 Others. Since 1985, when

^a This work was supported by the US DOE under contract #DE-AC02-76CH00016

dri-Rongelap self-exiled to Mejatto Island, all Rongelap measurements were obtained at Mejatto.

^{137}Cs is the only fallout nuclide detected in the WBC measurements. The highest value from any of the three missions was 14 kBq. Except at Enewetak, all measurements showed a decrease from 1989 to 1991. Dose calculations from the ^{137}Cs body counts were based on an ICRP-56 tabulation of conversion factors⁽³⁾ used to compute the committed effective dose equivalents (CEDE) following acute exposures to cesium at different ages. The conversion factor of 1.4×10^{-8} Sv/Bq for 15 year old individuals was used for conservative reasons. The ICRP-30 retention function⁽⁴⁾ indicates that 90% of the CEDE is received within the first year of exposure, and that a 2.8 ratio exists if a constant level of ^{137}Cs is maintained as opposed to its being eliminated from the body in one year. Therefore, the annual effective dose equivalents (AEDE) were calculated by multiplying the CEDE by factors of 0.9 and 2.8. Table 1 shows the AEDE that an individual would receive due to uniform chronic exposure throughout an entire year.

Population	1989	1991
Enewetak	11 ± 3	22 ± 4
Rongelap	3 ± 2	2 ± 2
Utirik	39 ± 2	35 ± 3

Plutonium Measurements and Urinalysis Program

In 1983, a Photon Electron Rejection Alpha Liquid Scintillation (PERALS) system was used for ^{239}Pu urinalysis for the Marshallese. Unexpectedly high apparent ^{239}Pu activities (130 μBq) in samples collected from a location that should not have been affected by the Bravo fallout were obtained. It was subsequently shown that most of the measured ^{239}Pu was actually ^{210}Po which could not be differentiated by the PERALS system. These findings prompted development of a fission track analytical (FTA) technique⁽⁵⁾ that would be capable of detecting very low-levels of ^{239}Pu without interference from ^{210}Po . By 1987, FTA could be used to detect values as low as 4 μBq per sample of ^{239}Pu . With further improvements, a sensitivity of about 2 μBq was achieved in 1989.

As of December 1988, a total of 195 Rongelap and 300 Utirik urine samples were analyzed at BNL. These 495 samples were collected from volunteers during field missions conducted between 1981 to 1984. The frequency distribution for the ^{239}Pu values from the Marshallese urine were log-normal with the 50 percentile (geometric mean) at about 9 μBq per sample for Rongelap and 4 μBq for Utirik. The 95% of the results were below 37 μBq for both populations. The highest value measured was 174 μBq .

Among the 195 Rongelap FTA results, 22 cases were found with inconsistent results from individuals who participated in the urine program more than once during the 1981-1984 missions. Three potential causes for these disparities were investigated: (1) was it possible that small amounts of contaminated soil were getting into the urine samples and thereby resulting in false estimates of plutonium excreted by the individual? (2) were the 24-h urine volumes used in the calculations appropriate and did each sample contain the entire 24 hour urine output as required for a proper systemic burden estimate? (3) were the other metabolic parameters used in this calculation appropriate for the Marshall Islanders?

In September 1988, urine samples were collected from individuals residing on Mejatto, Utirik, and Majuro. FTA values from the 146 urine measurements (67 Rongelap and 79 Utirik) and urine-blanks (26 synthetic and 76 composite human urine from a BNL employee) are shown in Table 2. For dri-Utirik, the values of mean (μ) and standard deviation (σ) were higher than those of Rongelap because of one sample containing 742 tracks (about 50 μBq of ^{239}Pu). Since samples collected from this same person in 1981 and 1989 were both less than the minimum detection limit (MDL), we concluded that the 1988 reading was due to contamination.

	n	μ	σ	median
Dri-Rongelap	67	59	34	56
Dri-Utirik	79	64	82	54
BNL-Employee	76	54	29	49
Synthetic-Urine	44	37	15	43

The MDL ($\mu + 3\sigma$) derived from the synthetic urine data was 82 tracks. All samples greater than 82 tracks are considered to have statistically significant levels of ^{239}Pu activity. Otherwise, less than MDL was reported.

In 1989, a new urine collection protocol was developed which approximates the precision and accuracy obtainable in a hospital. Collection bottles were no longer distributed to participants for use at their homes. Instead, all samples were taken on the mission vessel over a controlled 24-h period, and were acidified (16N HNO_3 , 10% by volume) within 24 hours of the collection period. A group of 32 individuals who previously had ^{239}Pu readings greater than 11 μBq were resampled in 1989. Only two of these samples were above the MDL of 2 μBq (i.e., 2.8 and 2.4 μBq). These data lead to the conclusion that soil contamination was the cause of earlier abnormally high readings, and provided confidence in the new urine collection protocol. The 2.8 μBq is equivalent to a CEDE of 0.4 mSv.

Interlaboratory Comparison of ^{137}Cs and ^{239}Pu Data

For ^{137}Cs , BNL whole-body counts yielded an average of 3.7 kBq in 1984; Lawrence Livermore National Laboratory (LLNL) estimated 5.9 kBq could be expected using their environmental sample measurements and availability of imported foods. For ^{239}Pu , BNL estimated an CEDE of 0.40 mSv from the interpretation of Rongelap urine data; and LLNL estimated 0.46 mSv from dietary assumptions, intake pathway analysis, and Pu activities measured in foods, dust and soil⁽⁶⁾.

Waste Engineering Department
Atmospheric Dispersion and Radioecology
Munich, Germany

ABSTRACT

Dispersion conditions are often inhomogenous and instationary because of the local presence of disturbing influences. Experimental investigations in a wind tunnel allow the analysis of these disturbed dispersion conditions. Thus a realistic calculation of the atmospheric diffusion of emitted radioactive substances is possible.

INTRODUCTION

The method of calculation of the atmospheric dispersion of emitted radioactive materials is according to German regulations based on the so called Gaussian plume model. The parameters used for this model are valid for homogeneous stationary dispersion conditions especially for emissions from elevated point sources respectively. Basic assumptions of this model are not met if the dispersion of the exhaust is disturbed by emissions of cooling towers of a power plant or by building structures or marked orographic situations. A Gaussian plume model cannot reasonably be used without modified model parameters under such conditions. Often dramatic differences are seen between the undisturbed dispersion conditions over plane areas and the aerodynamic conditions under actual site specific orographic and geometric situations. Important aerodynamic effects are changes of the mean wind profile, the structure of turbulence (zones of displacement, recirculations and channelling effects). These effects occur inhomogeneously in space and instationary with time.

EVALUATION OF DISPERSION CONDITIONS

The transport and the dilution of emitted radioactive substances in the atmosphere occurs by turbulent diffusion. Under the assumption of a quasi-continuous emission of these substances during normal operation of the power plant according to generally accepted models plumes are formed. Its spatial and temporal behaviour is heavily influenced by the dispersion situations at the site. These dispersion situations depend on

the meteorological conditions at the site, the emission heights and the influence of the surrounding area, the nearby buildings and cooling towers. The calculations of the atmospheric dispersion are based besides on the technical emission data mainly on the temporal average of dispersion conditions as well as on the meteorological conditions.

In accordance with the German regulations it is necessary to determine the most important parameters which influence the dispersion of the plume by experimental investigations at a properly scaled model in a wind tunnel.

INHOMOGENEOUS AND INSTATIONARY DISPERSION CONDITIONS

Often significant differences are seen between the flow patterns of undisturbed dispersion conditions over a plane area and those of an actual site with a specific orographic and/or geometric situation.

If a homogeneous atmospheric flow hits an obstacle complex aerodynamical effects occur like:

- changes of the mean wind profile,
- changes of the flow pattern,
 - . bent flow lines,
 - . abrupt changes of velocity,
- change of turbulence structure e.g.,
 - . zones of displacement,
 - . zones of recirculation,
- aerodynamical effects of buildings or cooling towers,
- channeling effects,
- thermally caused circulation effects.

Wind tunnel experiments were conducted by Technical Inspection Agency of Bavaria for sites with different conditions like

- complex industrial areas with complicated building structures and sources with low emission heights,
- power plants in special orographic situations (sites in a valley, steep slopes in the nearby vicinity, channelling effects by a curved valley),
- influence of cooling towers of different design,
- influence of different surface structures in the vicinity.

WIND TUNNEL EXPERIMENTS FOR DETERMINATION OF DISPERSION CONDITION AT A SITE

It is the purpose of the wind tunnel experiments to simulate and quantitatively evaluate the dispersion conditions controlled by site specific aerodynamical effects using a model true to nature and properly scaled in a way that modified model parameters also of non-straight trajectories as well as

spatial dispersion factors result for the calculation of radiation exposure.

Very important is the concept of the experiments concerning the validity of the results of the experiments in the nature /1/. The wind tunnel experiments must be planned and conducted in a way that based on the valid relations of similarity statements can be made for the total relevant range of wind velocities.

- A: In a first step smoke gas visualisation experiments are carried out. They are recorded by a video tape recorder. Laser sheet images are a good tool for collecting informations of the mean relative concentrations and their standard deviation using digital image processing.
- B: For obtaining quantitative results tracer gas experiments are conducted.
- C: The measurement of the tracer gas close to ground reveals directly the spatial dispersion factors (χ -value in s/m^3).
- D: From A: to C: a trajectory is chosen for each drift sector and wind velocity.
- E: Vertical concentration profiles are measured at selected points on each trajectory.
- F: Horizontal concentration profiles are measured perpendicular to each trajectory at the height of the maximum of the respective vertical concentration profile.
- G: From E: and F: the model parameters H_{eff} , Σ_y and Σ_z are calculated for each pair of profiles along the trajectories using a curve fitting methode.

CONCLUSION

The wind tunnel experiments allow the visualisation of influences of different parameters and the results of its tracer gas measurements enable the evaluation of the dispersion conditions of emitted radioactive substances quantitatively. They also allow to introduce suitable corrections for Gaussian type calculations in the course of licensing and surveillance procedures of nuclear sites as well as for their online remote monitoring systems.

P. SPEZZANO

ENEA, AREA AMBIENTE, DIPARTIMENTO ANALISI E MONITORAGGIO
MASAL CRE SALUGGIA - ITALY

SUMMARY

This paper describes the design criteria, which were used for the realization of an automatic system for the real time monitoring of the artificial radioactivity in the air.

Special attention was paid to minimize particulate losses along device ducts.

Particulate losses showed to be lower than 10%. The minimum detectable activities and the particulate-collection showed, in every respect, to be equivalent to the traditional system.

DESCRIPTION OF THE AIR MONITORING SYSTEM

The automatic monitoring system allow perform gamma spectrometry at the same time of the filtering operation. Therefore, if the verification of the acquired counts is performed immediately, the air radioactivity values can be obtained almost instantaneously.

The air monitoring system includes:

- air sampler;
- spectra acquisition system;
- computer and various peripheral units.

The air sampler is formed by a filter holder and a suction unit.

The (patented) filter holder is directly mounted on the gamma radiation detector, and was designed so as to optimize both the flow rates of filtered water and the detection geometry of the radiations emitted by the radionuclides eventually present.

The air suction unit includes a centrifugal electric pump with graphite blades, a volumetric counter, and the regulation and protection devices for such components.

The suction unit is interfaced with a computer, by which it is possible to perform the setting and the remote control of every sampling parameter.

The system used for the acquisition of the gamma radiation spectra is formed by a high-purity germanium detector, located in a lead well, and connected to the multichannel.

The fully automatic operation of the monitoring system is managed by a computer, which is interfaced with the analyzing system, the flow meter, the alarm unit, and, finally, the eventual modem for data transmission to the national monitoring center.

Concerning the recognition of the alarm conditions, two different types of warning systems were arranged to distinguish between the malfunction of the devices and the detected air contamination.

DESCRIPTION OF FILTER HOLDER AND SUCTION DUCT

The filter holder (fig. 1) is formed by a cylindrical receptacle with a round opening at the bottom, so that it can be inserted on the detector.

A seal ring prevents air from passing between the detector and the filter holder.

The detector, by penetrating within the filter holder, forms a wall of the toroidal distribution manifold.

The toroidal manifold surrounds the cylindrical surface of the detector, and is connected with the filtering portion by a continuous ring slot.

The distance between detector and filter surface is approx. 1 mm.

The filter support is formed by a metal net, able to withstand 1-atm pressure without creating resistances to air flow.

The collection manifold is formed by a cylindrical-geometry chamber, located downstream of the filter and designed so as to convey the flow of filtered air towards the outlet duct.

The filter holder is kept in the correct position by the pressure generated by the depression of the suction pump.

The filter, with related support, can be reached from the upper side of the filter holder directly.

Every component of the filter holder is realized by electroconductive materials, in order to reduce the deposit of air particulate on the walls of the device itself due to the accumulation of electrostatic charges.

The operating principle of the filter holder is the following (with reference to figure 1):

- the air, coming from the sampling point located out of the laboratory through a properly sized duct, enters the toroidal distribution manifold A;
- due to the vacuum created by the suction pump in the collection manifold B, the air crosses the filter;
- the radioactivity, present in the particulate which is collected on the filter, is continuously measured by the high-purity germanium detector;
- from the collection manifold, the air passes the outlet duct and is sent out by the suction pump again.

Substantially, the device allows to perform the filtration operation on the flat filter directly facing the detection surface.

In addition, the use of the toroidal manifold allows to minimize the distances between filter and detector, and the loss of pressure, necessary to maintain the air flow.

Therefore, such a manifold allows to make the detection efficiency and the quantity of filtered air as high as possible.

The suction duct was designed by the use of some technical solutions so as to minimize the losses of air particulate [1].

The conduit was realized as short as possible. In detail, to reduce the settling, which is not depending upon the whole path of the aerosol in the conduit, but only upon the length of the projection on the horizontal plane of the conduit itself, we try to minimize the horizontal development [2].

Furthermore, the fluid mechanics in the conduit was chosen so as to reduce to a minimum the losses due to settling, diffusion, and impact for the particles having granulometry range of 0.2 to 2 μm [3].

EXPERIMENTAL MEASUREMENTS

To estimate the losses of particulate along the suction duct experimentally, some measurements of gross-alpha, gross-beta, and gamma spectrometry were carried out on the particulate, which collected on pairs of filters (type of filter: SCHLEICHER & SCHUELL-498/1) [4]; the measurements were obtained by contemporary filtering of the air both by

Figure 1 - Conventional representation of the filter holder

traditional system (without conduit upstream of the filter) and by automatic system.

At first, the measurements of gamma spectrometry were carried out; they allowed to estimate the content of Pb-212 for each filter. The losses showed to be lower than 6%.

Then, the measurements of gross-alpha and gross-beta radioactive emission were carried out.

The losses showed to be lower than 4%, if estimated as gross alpha, and lower than 6% as gross beta.

The analysis of the percentage differences obtained for the three types of measurements showed that, in the worst hypothesis, the loss of particulate can be estimated to be lower than 10%.

Furthermore, the minimum detectable activities and the detection efficiency were estimated; they showed, in every respect, to be equivalent to the traditional system.

CONCLUSIONS

The designed automatic monitoring system allows to carry out the monitoring of air radioactivity complying with the same operating parameters, which are used in the traditional manual procedure. In addition, it allows to reduce, even to few minutes, the time intervals between different measurements and, therefore, a continuous alarm system is available.

RADON EXPOSURES IN THE UK

TO BE READ AT
INRA 8 MAY 1992

M C O'Riordan

National Radiological Protection Board,
Chilton, Didcot, Oxon OX11 0RQ, UK

ABSTRACT

Public and occupational health protection against radon is provided in the UK. Protection is advised where geological conditions cause high concentrations in domestic and commercial buildings. These circumstances are described and the resulting exposures reviewed. An account is given of the limitation scheme for radon in the home and the regulatory scheme for radon at work, the manner in which they are implemented, and the degree to which they are successful.

INTRODUCTION

Radon is the dominant source of human exposure to ionising radiation in every country of the world. It is dominant in most circumstances - at home and at work, for individual persons and for whole populations. The worst characteristic of radon, apart from its carcinogenicity, is its ubiquity: one of its few redeeming properties is lack of smell. We might also say in its favour that it is unlikely to reach such high concentrations as to cause acute clinical effects, although the doses to lung tissue in perfectly ordinary circumstances can indeed be considerable.

BACKGROUND

Virtually all of the 21 million dwellings in the UK are made of masonry and do not have basements. About one half are detached or semi-detached houses, about one third are terraced or row houses, and the remainder are flats or apartment buildings with multiple occupancy. Half of the housing stock has been renewed since the second World War. Commercial buildings vary from small converted houses to tall office blocks and large warehouses.

It is also necessary to describe the geological setting. There is a clear division between the igneous and metamorphic areas of the north and west and the sedimentary areas of the south and east that is most of England. Intrusive rocks often imply high radon levels, metamorphic and sedimentary rocks range from high to low, and extrusive rocks usually mean low levels.

CONTROLS

As in other countries, we in the UK have different approaches to the control of radon exposure in homes and places of work; our modus operandi is shown in Table 1. For householders, the commitment to measure and take action against radon is completely voluntary. Employers, on the contrary, are obliged to comply with statutory controls on occupational exposure in all places of work - schools, offices, factories and so on. Government employs encouragement in the first circumstance and enforcement in the second.

The Action Level for existing dwellings is 200 Bq m⁻³ of radon in air averaged throughout the year. New dwellings are to be designed so that levels are as low as reasonably practicable and not, of course, above the Action Level. The dose limit for workers is still 50 mSv a year, but employers are required by occupational legislation to prevent doses continually approaching it, and we have adopted a constraint of

15 mSv a year, on the average, in anticipation of the new ICRP recommendations. When the annual effective dose equivalent from radon is less than 5 mSv (which corresponds to an average 400 Bq m³ when temporal occupancy is considered) the enforcement agency does not require action by the employer.

DWELLINGS

By early 1992, around 110,000 dwellings in the UK had been surveyed for radon. As can be seen from Table 2, these measurements are mostly made at the request of householders. Virtually all are at public expense, the major source of funds being central Government. At an early stage in the radon programme, a positive decision was made to provide free measurements for householders who might have cause for concern about radon.

An initial survey by NRPB had two purposes, one to determine the distribution of indoor radon concentrations in a systematic manner and the other to discover the most radon-prone regions of the UK guided by limited radiological and geological information. The exercise was successful in that subsequent surveys have not confounded the initial findings.

Once the overall picture was clear, it was possible to adopt an intervention policy with known - and acceptable - implications. The key element was the delineation of so-called Affected Areas, where the probability of finding a dwelling above the chosen Action Level was one per cent. Within such areas, two significant steps would be taken: first, a campaign would be mounted to persuade householders to apply for free measurements; second, the building authorities would delimit localities within which new dwellings would require preventive measures. The latter requirement was not to apply to non-residential buildings.

So far, two administrative counties in the southwest of the country have been formally designated. Over three-quarters of the demand for measurements have arisen there, mostly as a result of the direct mailing of a radon leaflet to all householders. Nevertheless, the response was only one in eight, so more persuasive tactics will need to be tried. Government has indicated that similar plans will be carried through in other affected areas when these are defined.

Table 3 has a summary of the most significant results. In the first Affected Area, the average indoor concentration of radon is about five times the population-weighted value for the UK as a whole. In round terms, about 100,000 dwellings in the UK, or 0.5% of the housing stock, are estimated to be above the Action Level. So far, some 12,000 of these have been discovered, mostly in the first Affected Area. The radon-prone parts of the country are rural and much less densely populated than average: an appreciable fraction of the land area may eventually be designated.

WORKPLACES

There are, of course, far fewer workplaces than dwellings: Table 4 has the important statistics. Surveys of radon in places of work, initially funded by the Health and Safety Executive, now arise mainly from direct requests by employers. Not surprisingly, much of the demand comes from those regions of the country where raised radon levels occur in dwellings.

We estimate, again in round terms, that there may be about 50,000 places of work in the likely Affected Areas throughout the UK of which

one tenth may have radon levels above 400 Bq m^{-3} ; perhaps as many as 75,000 workers may therefore receive annual doses greater than 5 mSv. These estimates are based on surveys in 3000 premises, some 10% being found subject to the regulations. The maximum dose discovered to date is 45 mSv in a year, and only a few per cent of workers receive more than 15 mSv in a year. Radon levels in house-like places of work are similar to houses: levels in large industrial buildings are generally much lower.

INTERVENTION

Employers have a considerable incentive to reduce radon levels because by doing so they can avoid the necessity of mounting radiological surveillance in their premises and of complying with other regulatory requirements. About half of the workplaces initially found subject to the regulations, 150 or so, have subsequently had satisfactory remedial measures, mostly by sub-floor suction. Very few new commercial buildings have had preventive measures built in, however, because developers are not required to do so by law.

Householders, on the other hand, have some disincentive: if they decide to take remedial action, it is likely that they will have to pay since Government grants are restricted to those who do not have the means. This may explain why only 250 or so dwellings above the Action Level have been remedied so far. Various techniques such as floor sealing and positive pressure have been tried, but the most effective method is sub-floor suction especially for appreciable reductions. Since anti-radon measures become mandatory for new dwellings in certain localities, some 4000 have been built in line with developing technical guidance issued by Government which has proved to be quite effective.

DISCUSSION

This brief paper scarcely does justice to the radon programme in the UK which also embraces mining, geology, dosimetry, epidemiology, and metrology. Attention has rather been focussed on the determination and limitation of indoor exposure: some degree of success can be claimed for the few years in which the programme has been running. We have a coherent and judicious system of controls. We know what the general exposure levels are at home and at work and where raised values are most likely to be found. Our Government provides free measurements on a generous scale to householders in radon-prone areas so as to push the programme forward.

As a result, we have discovered about one tenth of the dwellings and workplaces throughout the UK that we believe to be adversely affected by radon. National policy is directed towards the goal of identifying most radon-affected homes by the end of the decade: to eliminate excessive exposures, it will therefore be necessary to redouble our efforts in the coming years. Many more householders and employers must be persuaded to make radon measurements, and having made them, to take whatever action is required to minimise the risk from radon. We are sanguine about the prospects.

ACKNOWLEDGEMENTS

The work described in this paper was variously supported by the Department of the Environment, Welsh Office, Scottish Office, Northern Ireland Office, the Health and Safety Executive, and the Commission of the European Communities. It was performed by various members of staff of the National Radiological Protection Board including R A Algar, K D Cliff, D W Dixon, B M R Green, T D Gooding, P R Lomas, J C H Miles, K Whysall. A list of staff publications on radon is available.

RADON IN THE ENVIRONMENT AND THE DWELLINGS - A REVIEW OF
MEASUREMENTS CARRIED OUT IN FRANCE BY IPSN

ABSTRACT

Over the last decade, the monitoring of radon gas in various natural environments and regions of France has allowed the IPSN to construct a radon data base. In holes drilled in soils and in underground cavities, radon concentrations between a few hundred $\text{Bq}\cdot\text{m}^{-3}$ and many thousands $\text{Bq}\cdot\text{m}^{-3}$ were measured. Exhalation rates between 10^{-3} and $50 \text{ mBq}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$ were measured in different regions and for different types of soil. In the open air, mean levels were observed in the range of a few $\text{Bq}\cdot\text{m}^{-3}$ to several hundred $\text{Bq}\cdot\text{m}^{-3}$ and concentrations as high as one thousand $\text{Bq}\cdot\text{m}^{-3}$ were measured over short periods.

INTRODUCTION

Le radon est aujourd'hui reconnu comme la source principale d'exposition aux rayonnements pour l'homme. Les travaux effectués en France par l'Institut de Protection et de Sécurité Nucléaire (IPSN) au cours des dix dernières années nous permettent d'apprécier la variabilité des niveaux de radon dans différents milieux, selon les lieux géographiques et les circonstances. Différentes techniques de mesure sont utilisées: ponctuelles, en continu et intégrées. Nous présentons une revue des données concernant la mesure de ^{222}Rn dans les sols, à l'interface entre le sol et l'air, dans l'atmosphère extérieure et dans l'atmosphère des milieux souterrains. Les résultats sont présentés par départements regroupés en régions géologiques, en distinguant les terrains sédimentaires et granitiques.

ACTIVITE VOLUMIQUE DU ^{222}Rn DANS LES SOLS

Des mesures ponctuelles ont été effectuées à l'aide de ballons scintillants dans l'air du sol, de 0,50 à 1 m de profondeur environ (1). Elles indiquent des activités volumiques comprises entre 2 et $420 \text{ kBq}\cdot\text{m}^{-3}$, les valeurs étant en moyenne 5 à 10 fois plus importantes en terrain granitique qu'en terrain sédimentaire (figure 1). Les enregistrements en continu à l'aide de sondes Barasol révèlent en outre des variations temporelles d'un facteur 2 à 3 en un même point, quelle que soit la nature du terrain (1).

FLUX D'EMISSION DU ^{222}Rn à LA SURFACE DU SOL

Les mesures instantanées du flux d'émission de ^{222}Rn (quantité arrivant à l'air libre par unité de surface et par unité de temps) sont faites selon la technique d'accumulation.

En France, les flux observés dans les régions granitiques varient sur 4 ordres de grandeurs (de 1 à 8316 mBq.m⁻².s⁻¹) et peuvent atteindre localement des valeurs très élevées (jusqu'à 50000 mBq.m⁻².s⁻¹ en zone minéralisée) (figure 2). Dans les régions sédimentaires, les flux sont comparables à la valeur de 16 mBq.m⁻².s⁻¹ considérée par le Comité Scientifique des Nations Unies comme représentative du flux moyen à la surface de la terre (2).

ACTIVITE VOLUMIQUE DU ²²²Rn DANS L'AIR EXTERIEUR

Une fois dans l'air extérieur, le radon se dilue en fonction des conditions de diffusion atmosphérique liées à la météorologie et au relief. On observe généralement un gradient de concentration vertical, et des variations temporelles selon un cycle journalier. Le jour, la diffusion atmosphérique est bonne: les concentrations en radon sont relativement faibles. La nuit, se produisent fréquemment des inversions de température: le radon stagne au niveau du sol et sa concentration dans l'air augmente ainsi jusqu'à un facteur 10 à 100 (figure 3a).

Des mesures effectuées en continu pendant 3 années à l'aide d'une chambre d'ionisation ont révélé des moyennes horaires variant sur plusieurs ordres de grandeur en un même lieu (figure 3b). Des écarts significatifs apparaissent entre le jour et la nuit et d'un mois à un autre. Les moyennes annuelles s'avèrent par contre relativement stables sur les 3 années étudiées.

Dans les régions granitiques, les moyennes sur quelques jours (toutes conditions météorologiques confondues) s'échelonnent entre 25 et 210 Bq.m⁻³. Elles sont inférieures à 60 Bq.m⁻³ dans les régions sédimentaires.

ACTIVITE VOLUMIQUE DU ²²²Rn DANS LES CAVITES SOUTERRAINES

Les activités volumiques rencontrées en terrain sédimentaire varient sur plusieurs ordres de grandeur, aussi bien dans les cavités naturelles (de 101 Bq.m⁻³ dans un gouffre du département de la Dordogne à 10876 Bq.m⁻³ dans une grotte de ce même département) que dans les cavités artificielles (moins de 37 Bq.m⁻³ dans le Métro Parisien à 5070 Bq.m⁻³ dans les Catacombes à Paris).

Les niveaux mesurés en terrain granitique sont plus élevés en moyenne: de 942 à 1592 Bq.m⁻³ dans un gouffre en Corrèze et de 400 à 1600 Bq.m⁻³ dans un musée souterrain installé dans une ancienne mine d'argent du département des Deux-Sèvres.

DISCUSSION ET CONCLUSION

Les mesures de ²²²Rn effectuées en France montrent la présence de ce gaz dans tous les milieux de notre environnement. Les 4 paramètres étudiés, c'est-à-dire radon dans le sol, à l'interface entre le sol et l'air, dans l'air extérieur et dans les milieux souterrains, varient très fortement selon les lieux géographiques et le moment.

Figure 1- Activité volumique du ^{222}Rn dans les sols de différents départements français.

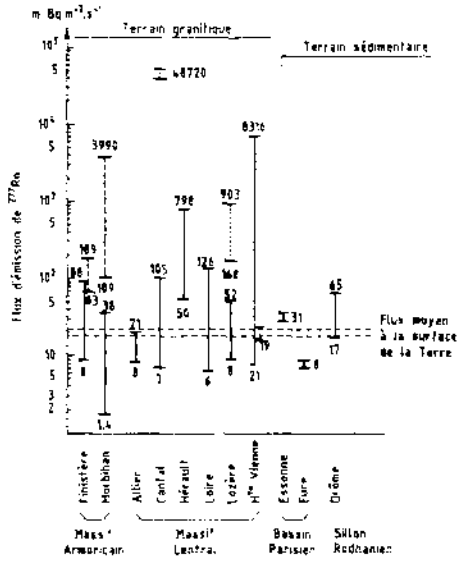

Figure 2- Flux d'émission de ^{222}Rn à la surface du sol dans différents départements français.

Figure 3 - Activité volumique du ^{222}Rn dans l'air extérieur à Saint-Priest-la-Prugne (département de la Loire):
 a) enregistrement en continu au mois de juillet 1983
 b) valeurs moyennes pendant différentes périodes d'observation, d'après une mesure en continu en 1983, 1984 et 1985.

Les différents résultats obtenus dans une région donnée forment cependant un ensemble de données cohérentes et représentatives de la région (tableau 1).

	Granitique			Sédimentaire
	Finistère	Morbihan	Haute-Vienne	Région Parisienne
Débit de dose γ dans l'air ($n\text{Gy}\cdot\text{h}^{-1}$) (a)	75	90	120	49
^{226}Ra dans les sols ($\text{Bq}\cdot\text{m}^{-3}$)	52-137	83-214	134-292	35
^{222}Rn dans les sols ($\text{Bq}\cdot\text{m}^{-3}$)	36-300	33-420	18-290	2-46
flux d'émission par le sol ($\text{mBq}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$)	8,4-88,2	1,4-37,8	21-8316	7,7-31,5
^{222}Rn dans l'air extérieur ($\text{Bq}\cdot\text{m}^{-3}$)	8-300	10-370	20-1000	8-120
^{222}Rn dans les maisons ($\text{Bq}\cdot\text{m}^{-3}$) (b)	99	87	123	25

(a) moyenne arithmétique

(b) moyenne géométrique (mesures intégrées)

Tableau 1. Activité massique du ^{226}Ra dans les sols, débit de dose γ dans l'air et différents paramètres liés au ^{222}Rn dans 3 départements français granitiques et la région Parisienne sédimentaire.

En toute logique, les activités volumiques moyennes en ^{222}Rn dans les habitations sont conformes à cet ensemble de données. Elles sont plus élevées dans les régions granitiques que celles sédimentaires, d'un facteur 4 à 5 environ, comme pour chacun des paramètres mesurés dans les autres milieux. C'est sur ces multiples données que peuvent s'appuyer les diagnostics radon⁽³⁾ et les études sur la potentialité des sols en radon.

Measurement of new operational quantities with radiation protection
instruments designed for working area monitoring and for
individual monitoring

The ICRP recommended a dose limitation system based on numerical evaluation of the dose equivalent to organs or tissues, H_T , which are used to calculate the effective dose, H_E , by weighting. The ICRU proposed new operational quantities accessible to measurement which are conservative with respect to these recommendations. The objective of this paper is to recall briefly the basic recommendations and to find out if radiation protection instruments presently used calibrated in terms of the previous quantities are capable to measure these new quantities. A dozen of practical cases are presented.

RESUME

L'ICRP a recommandé un système de limitation des doses basé sur l'évaluation numérique de l'équivalent de dose dans certains organes ou tissus, H_T , pour accéder, après pondération à l'équivalent de dose efficace, H_E . Le but de cette communication est d'une part de rappeler brièvement les recommandations de base et d'autre part d'examiner si les appareils de radioprotection actuellement utilisés en France et étalonnés dans d'anciennes grandeurs sont aptes à mesurer ces nouvelles grandeurs. Une douzaine de cas pratiques sont traités.

I. INTRODUCTION

L'International Commission on Radiation Units and measurements dans son rapport ICRU de 1985 n° 39 intitulé "Détermination des équivalents de dose dus aux sources externes de rayonnements" donne les définitions des grandeurs à employer pour le contrôle des rayonnements ionisants, grandeurs qui servent de base à la radioprotection opérationnelle pour mettre en place dans la pratique les recommandations de l'ICRU (rapports 25 et 33). Ce même rapport expose ensuite dans son introduction son but qu'il est bon de rappeler :

- lorsque des personnes sont exposées aux rayonnements ionisants, il est généralement nécessaire de spécifier le niveau d'exposition externe en termes numériques. Ceci est exigé pour assurer une radioprotection réelle et pour montrer que les limites réglementaires sont respectées. La Commission Internationale de Protection Radiologique (CIPR) a recommandé un système de spécifications numériques fondé sur la somme pondérée des équivalents de dose reçus dans divers organes : l'équivalent de dose efficace, H_E . Ces équivalents de dose ne peuvent, dans la plupart des cas, être directement mesurés et, par conséquent, doivent être évalués à partir de ce que l'on sait mesurer.

(*) IPSN / DPEI / Fontenay-aux-Roses - (**) SFR / Grenoble

S'agissant du contrôle pratique de l'irradiation externe par des appareils de surveillance des zones de travail et par des appareils de surveillance individuelle, des grandeurs directement mesurables appelées "grandeurs opérationnelles" (H^* (10), H' (0,07) pour la surveillance des zones de travail et H_p (10), H_s (0,07) pour la surveillance individuelle) seront utilisées pour évaluer de façon la plus correcte possible (sans sous-évaluation ou surestimation excessive) l'équivalent de dose efficace.

II. CARACTERISTIQUES SOUHAITABLES DES INSTRUMENTS UTILISES POUR LA SURVEILLANCE DES ZONES DE TRAVAIL (AMBIANCE)

II.1 Equivalent de dose ambient H^* (10)

Les instruments destinés à la mesure de H^* doivent présenter une réponse isotrope. Ces appareils qui ont une réponse isotrope et qui sont étalonnés en terme de H^* mesureront H^* dans n'importe quel champ de rayonnement uniforme dans un volume au moins égal à celui qui est occupé par l'appareil. La définition de H^* implique que l'appareil soit conçu de telle façon qu'il tienne compte du rayonnement rétrodiffusé dans la sphère de référence.

II.2 Equivalent de dose directionnel H' (0,07)

Les instruments destinés à la mesure de H' sont conçus pour des rayonnements faiblement pénétrants provenant d'un angle solide 2π stéradians. Ils doivent donc répondre correctement, non seulement aux rayonnements d'incidence normale à la face d'entrée de l'instrument, mais aussi aux rayonnements d'incidence oblique (les normes CEI spécifiques définissent les limites de variations tolérées pour leurs caractéristiques principales).

III. CARACTERISTIQUES SOUHAITABLES DES INSTRUMENTS UTILISES POUR LA SURVEILLANCE INDIVIDUELLE

III.1 Equivalent de dose individuel en profondeur H_p (10)

Les instruments destinés à la mesure de H_p sont conçus pour des rayonnements fortement pénétrants provenant d'un angle solide 2π stéradians.

III.2 Equivalent de dose individuel en surface H_s (0,07)

Les instruments destinés à la mesure de H_s sont conçus pour des rayonnements faiblement pénétrants provenant d'un angle solide 2π stéradians.

Les instruments destinés à la mesure de H_p et H_s sont conçus pour être portés à la surface du corps. Celui-ci assure donc la production du rayonnement rétrodiffusé. Ils doivent répondre correctement aux rayonnements d'incidence normale à la face d'entrée de l'instrument, mais aussi aux rayonnements d'incidence oblique (les normes CEI spécifiques définissent les limites de variations tolérées pour leurs caractéristiques principales).

IV. ETALONNAGE DES INSTRUMENTS

- les instruments destinés à la mesure de H^* (10) et H' (0,07) sont étalonnés dans l'air. Les coefficients de conversion du kerma dans l'air aux grandeurs H^* (10) et H' (0,07) sont donnés dans (1).

- les instruments destinés à la mesure de H_p (10) et H_s (0,07)

sont étalonnés sur un fantôme approprié :

- soit une sphère de 30 cm de diamètre constituée d'un matériau équivalent tissu (2).

- soit une plaque de dimensions 30 cm x 30 cm x 15 cm d'épaisseur d'un matériau équivalent tissu (3)

Suivant le fantôme utilisé, on appliquera les coefficients de conversion spécifiques (3).

V. RESULTATS D'ESSAIS SUR PLUSIEURS APPAREILS DE RADIOPROTECTION DESTINES A LA MESURE DES RAYONNEMENTS γ (ETALONNAGE, REPONSE EN FONCTION DE L'ENERGIE, REPONSE ANGULAIRE)

La présentation "poster" porte sur une douzaine d'appareils équipés de détecteurs différents (chambre d'ionisation de différentes épaisseurs, tube Geiger-Muller, détecteur en silicium) à partir de graphes dont les résultats seront comparés aux normes existantes de la CEI.

Les étalonnages de ces appareils ont été effectués de façon systématique dans les anciennes et nouvelles grandeurs afin de connaître leur comportement et principalement leur réponse en fonction de l'énergie et leur réponse angulaire. Ces essais ont permis de connaître l'aptitude des appareils actuels à effectuer des mesures dans les nouvelles grandeurs et d'envisager les actions correctives à apporter pour les mettre en conformité ou à la limite ne pas les recommander s'il s'avère qu'ils ne peuvent pas être adaptés.

Par ancienne grandeur nous entendons pour la France la dose absorbée $D_{(3)}$ dans les tissus mous sous 300mg.cm^{-2} . Dans un domaine d'énergie de 10 keV à 3 MeV elle peut être déduite du kerma dans l'air à l'air libre, K_a , si l'on néglige le rayonnement de freinage. Cette grandeur avait été retenue en prenant le cristallin comme organe critique pour le risque.

Jusqu'à présent les appareils français destinés à la surveillance des zones de travail ou à la surveillance individuelle étaient étalonnés dans l'air et leur réponse devait être isotrope dans les 4π steradians.

Ce document ne présente que deux exemples :

- un appareil de surveillance des zones de travail dont le détecteur est une chambre d'ionisation (figure 1),
- un appareil de surveillance individuelle équipé d'un détecteur au silicium (figure 2).

VI - CONCLUSION

La conclusion générale est que la plupart des appareils actuellement en service peuvent être utilisés pour mesurer les grandeurs opérationnelles au prix le plus souvent d'un simple changement d'échelle et plus rarement d'une adaptation des écrans de correction entourant le détecteur en se satisfaisant de leur réponse angulaire actuelle.

POTENTIAL RISK OF THORON AND ITS PROGENIES IN THE AIR OF TRADITIONAL JAPANESE WOODEN HOUSES

Masahiro Doi, Sadayoshi Kobayashi and Kenzo Fujimoto
Safety Analysis Unit, National Institute of Radiological Sciences
9-1, Anagawa-4, Chiba 260, JAPAN

Abstract

A new type of passive dosimeter has been developed, which can measure radon and thoron concentrations separately. Detailed measurement using the radon-thoron differential detectors thus developed revealed that thoron concentration indoors in some selected houses has a distribution to decrease significantly as the distance from the interior soil wall increases. Interim measurements on Hiroshima houses ascertained that some Japanese wooden houses with traditional Japanese interior soil walls may have enhanced thoron concentration indoors.

Introduction

A national survey of indoor radon concentration in Japan was commenced in 1985, and covered 6,300 houses throughout Japan¹⁾. Karlsruhe passive radon detectors²⁾ were used in the survey, in view of the fact that it had already been used in many countries at the time when the project was initiated and hence international comparison was possible. The indoor radon concentration showed a median value of 23 Bq/m³ whose distribution was log-normal with a geometric standard deviation of 1.6¹⁾. Statistical analysis on the type of buildings and indoor radon concentration revealed that the extreme values of high concentration were found mostly in wooden houses especially of traditional Japanese style. It should be noted that the dosimeter employed in the survey registers α -tracks from thoron (²²⁰Rn) as well as radon (²²²Rn), if they exist in the same ambient air. Since traditional Japanese houses have interior soil walls, one of the causes of apparently higher concentration was suspected to be due to thoron concentration from the building materials. In order to carry out an analysis on indoor thoron concentration as well as radon's, a new type of passive dosimeter was developed which can estimate radon and thoron concentrations differentially³⁾. The results of interim measurement on some houses with elevated radon and thoron concentration are presented.

Method of the measurement

An illustration of the passive radon-thoron differential detector²⁾ is shown in **Figure 1**. The

Figure 1 Schematic Figure of the passive radon-thoron differential detector

placed in each of the two hemispheric chambers. One polycarbonate film faces the inside of the large chamber, and another the inside of small chamber. Eight air inlets are provided on the stainless disk, which are covered by glass fiber filters in order to prevent decay products from entering the detector housing. Since the air exchange rate of these air inlets is 15.89 times per hour, 99% of gaseous radon and 26% of gaseous thoron are able to intrude into the large chamber. Gaseous radon and thoron in the large chamber diffuse into the small chamber through a pinhole inlet (1mm ϕ) on a inner stainless disk at the air exchange rate of 0.38 times per hour. Because of its short half life (55 sec), only 0.2% of thoron gas diffuse into the small chamber.

After the exposure to the atmosphere for 2 months, the polycarbonate film placed in the large chamber is subjected to preliminary chemical etching for 3 hrs which is performed at 30 °C with a blend of 8.0N KOH solution (80% by volume) and C₂H₅OH (20%) and following electrochemical etching for 3 hrs under AC800V, 2kHz. The radius of the hemisphere is large (60mm), and the duration of preliminary chemical etching is long (3hrs) enough to discriminate low energy α -particles whose ranges in polycarbonate film are so short that they can not reach the depth of electrochemical etching layer. In this condition, α -particles emitted by thoron and thoron daughters are registered as electrochemical etch pits dominantly. In contrast, the polycarbonate film in the small chamber is subjected to preliminary chemical etching for only 0.5 hrs and following electrochemical etching for 3 hrs. The radius of the hemisphere is small (37.5mm), and the duration of preliminary chemical etching is short (0.5 hrs) enough to discriminate high energy α -particles whose ranges in polycarbonate film are so long that they overstep the depth of the electrochemical etching layer. In this condition, α -particles emitted by radon and radon daughters are registered as electrochemical etch pits mainly.

detector housing is made of stainless steel, which has two hemispherical chambers, whose diameters are 120 mm and 75 mm respectively. Two hemispheric chambers cover the detector holder from the up and down sides, being combined into a shape of a flying saucer. One sheet of disk-shaped polycarbonate film (Iupilon S-2000, Mitsubishi Gas Chemical Co., Ltd., Japan, 50 mm in diameter, 300 μ m in thickness) is

Films	Conversion factor Tracks cm ⁻² /(Bqm ⁻³ day)	
	Radon	Thoron
PC film in 120mm chamber	0.0299 \pm 0.0017	0.0127 \pm 0.0022
PC film in 75 mm chamber	0.0395 \pm 0.0053	0.0000 \pm 0.0000

Table 1 Summary of conversion factors (Tracks cm⁻²/(Bqm⁻³day)) for radon and thoron exposures determined by calibration exercises.

Conversion factors from etch pit density into radon and thoron concentration are shown in **Table 1**. Calibration exercises were performed using a standard ra-

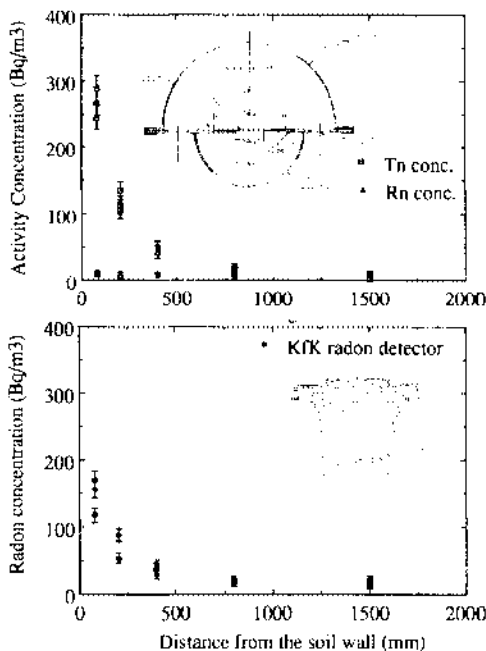

Figure 2 Distributions of indoor radon and thoron concentration in a traditional wooden house in Kyoto Prefecture by radon-thoron differential detector (upper figure) and that of "radon" concentration by Karlsruhe radon detector (lower), for the period from June to August, 1991.

contrast, thoron concentration distributes in a wide range: it decreased significantly as the distance from the soil wall increased. Since thoron concentration varies so significantly according to the place in the room, the point of the measurement must be taken into account to estimate the thoron concentration indoors. Distribution of radon concentration estimated by Karlsruhe radon detector²⁾ is also shown in **Figure 2** (lower figure). It is ascertained that the Karlsruhe radon detector²⁾ responded to thoron contribution.

An interim survey using passive radon-thoron differential detectors was performed on 42 rooms of 21 houses in Hiroshima Prefecture. These houses were regarded as high radon risk houses by previous national survey¹⁾. Each detector was posi-

tioned in a radon chamber of the U.S. Environmental Protection Agency and a standard thoron chamber of Waseda University, Japan. Detailed specification of the detector was presented elsewhere³⁾.

Results and discussions

Detailed measurements were performed using radon-thoron differential detectors at some traditional Japanese wooden houses with interior soil wall in Kyoto Prefecture. Detectors were placed at five different distances, three at each distance in total of 15, from the surface of soil wall. Each detector was coupled with a Karlsruhe passive radon detector²⁾. Distributions of radon and thoron concentrations are shown in **Figure 2** (upper figure). Radon concentration was $8.8 \pm 1.6 \text{ Bq/m}^3$, whose distribution is almost uniform. In con-

Figure 3 Radon and thoron concentration in 42 rooms in 21 houses in Hiroshima Prefecture, estimated by passive radon-thoron differential detectors. Measurement period was June-August, 1991.

tioned at the same place where Karlsruhe radon detector²⁾ was placed in the previous survey¹⁾. Therefore, the distance from the soil wall to the detector differed by each house from 40mm to 800mm. Results of the measurement are shown in **Figure 3**. Radon concentration ranges from 7.80 Bq/m³ to 33.3 Bq/m³, and thoron concentration from N.D. to 587 Bq/m³. There is no correlation between radon and thoron concentration. The median value of indoor radon concentrations in the Hiroshima houses was estimated as 56.7 Bq/m³ (median) by Karlsruhe radon detector²⁾ from April to September, 1991. Whereas it was shown by use of the radon-thoron differential detector³⁾ that they have radon concentration of 18.3 Bq/m³ (median), plus thoron concentration of 57.4 Bq/m³ (median). Since about 70 % of Japanese houses are wooden house according to the national statistics⁴⁾, indoor thoron concentration needs to be investigated in detail especially on wooden houses with traditional interior soil walls in order to identify potential risk of thoron and its progenies indoors as well as radon's.

Conclusion

A new type of passive dosimeter has been developed, by which radon and thoron concentrations can be measured separately at a same time. Thoron indoors in some selected Japanese houses with interior soil walls showed a gradient distribution of concentration in such a way as it decreases significantly as the distance from the interior soil wall increases. Interim measurements on Hiroshima houses ascertained that some Japanese wooden houses with traditional interior soil walls may have extremely enhanced thoron concentration indoors.

Acknowledgments

Authors would like to express their hearty appreciation of the assistance given by Prof. Kurosawa of Waseda University, Japan who kindly made available the use of thoron chamber for calibration exercise. They also wish to thank Mr. Sensintaffar and his staffs of U.S. EPA and Mr. George of U.S.DOE for their kind help in carrying out the radon calibration exercise.

THE LEGAL SITUATION OF RADON IN SWEDEN

Lars Persson

Swedish Radiation Protection Institute
Box 60204, S-10401 Stockholm, Sweden

ABSTRACT

The Swedish Local Authorities are responsible for decreasing the radon concentration in homes. The National Board of Health and Welfare regulates and supervises this programme. The National Board of Occupational Safety and Health regulates the radon levels in mines. The National Board of Housing, Building, and Planning regulates the upper level of radon indoor in newly built houses. The Swedish Radiation Protection Institute is responsible for measuring techniques and risk assessments of radon.

INTRODUCTION

Due to the natural conditions (U-rich ground, Ra-rich building materials, and the cold climate), there often exists high levels of radon and its decay products in the air of houses, mines and other working places in Sweden. The work to reduce the levels of radon started with the improvement of the ventilation of the mines in the late 1960's. During the 1970's the interest was focussed on houses and indoor air.

PUBLIC INVESTIGATIONS

In 1979 the Swedish Government authorized the Minister of Agriculture to appoint an investigator to study the question of countermeasures against radiation risks in buildings. The investigation was carried out by The Radon Commission. The Commission submitted its final report to the Swedish Government in January 1983 (1).

Most of the Commission's work was devoted to practical issues connected with radon in housing. The radon problem in Sweden was originally considered to derive from building materials containing radium. The measuring activities performed by the Local Authorities and a nationwide investigation of the occurrence of radon in housing by the Swedish Radiation Protection Institute indicated the ground as the principle source of radon. The number of buildings, in which the radon daughter concentration exceeded 400 Bq/m^3 , was estimated to be about 40 000. In Sweden the limits are given as annual averages of the Equilibrium Equivalent Concentration of Radon (EER), also called the radon daughter level.

The Commission proposed a radon daughter action level of 400 Bq/m^3 , and that homeowners be provided with possibilities of obtaining special loans for financing countermeasures if the radon levels exceeded this figure. The Commission also proposed that the National Board of Health and Welfare and the National Board of Housing, Building and Planning, in collaboration with the Swedish Institute of

Radiation Protection, should undertake the responsibility that the Local Authorities receive information and directives concerning radiation in buildings. The Commission proposed that research in the radon protection field should be carried out or supported by the Swedish Institute of Radiation Protection and the National Council for Building Research.

The Swedish Government decided in 1985 to follow the main recommendations of the Radon Commission. The Government's decision was now also based on the proposals and risk estimates of the Swedish Cancer Committee, which in 1984 submitted its report (2) to the Government.

The Swedish Committee for Revision of the Radiation Protection Legislation submitted in 1985 its report (3) to the Government. The Committee proposed that the new law should cover also natural radiation sources such as radon. The tasks of the Swedish Radiation Protection Institute with respect to natural radiation should be the development and standardization of measuring techniques and methods and the risk assessment of radon. It was also proposed that the law should grant authorization to the Radiation Protection Institute to impose directives with respect to measuring and protective equipment as well as testing, supervision or inspection of natural radiation. The Swedish Parliament accepted these proposals in 1988 (4).

NORDIC CO-OPERATION IN THE RADON FIELD

There exists a close cooperation in the radiation protection field between the five Nordic countries and its radiation protection authorities (5). A working group with the aim of developing radiation protection recommendations for natural radiation in the Nordic countries was set up by the radiation protection institutes in Denmark, Finland, Iceland, Norway, and Sweden. The working group reported in 1986 its recommendations (6). The main recommendation of the working group was that the action level for existing houses should not be higher than 400 Bq/m³ radon daughters. If the radon daughter concentration exceeded this value in a house, remedial action to bring the concentration down to a level as low as reasonably achievable should generally be an obligation. The possibilities for remedial action with financial support from the authorities should also be considered, if the radon daughter concentration exceeded 100 Bq/m³.

PRESENT RISK ASSESSMENT AND LEGAL SITUATION

The risk assessment for radon made by the Swedish Radiation Protection Institute (7) is based upon ICRP's principles for limiting exposure to natural radiation sources (8). The recent Swedish experience in radon control has been reviewed by Swedjemark and Maekitalo (9) and the Swedish view on radon control by Mjoenes (10).

Several authorities and different laws are involved in the field of radon protection in Sweden as follows:

* The Swedish Local Authorities are responsible for decreasing the radon daughter concentration in the homes and working places other than mines in each municipality. These authorities act according to the Health Protection Legislation. In 1990 the action level for remedial measures of existing buildings and working places has been decreased to 200 Bq/m³ radon daughters by the National Board of Health and Welfare according to an authorization by the Government (11). For houses with radon daughter levels between 70 and 200 Bq/m³ simple remedial actions should be carried out. The Board of Health and Welfare supervises the indoor radon gas remedial programme.

* The National Board of Occupational Safety and Health in 1986 issued a regulation on rock work (underground work) with an upper exposure limit of 2 MBqh per m² and year for the radon daughter exposition (12).

* The National Board of Housing, Building and Planning has issued a regulation on the permitted upper level of radon indoor in newly built houses based on the Act on Planning and Building (13). The radon daughter level must be lower than 70 Bq/m³. The health risk from radon must be taken into account in the building planning process. The Board has thus recommended that the Local Authorities and builders ensure that they take into account the risk of radon from the ground, when planning for building and the use of land (14). For planning purposes the ground should be classified into high, normal and low risk areas. This classification should be based on geological criteria but it must also be related to building structure. For details see ref. (9).

* The Radiation Protection Law (4) also covers natural radiation including radon. According to this act the Swedish Radiation Protection Institute is responsible for target-oriented research and monitoring of international developments, risk assessment and principles of risk management, recommendations concerning limits on activities and doses for the implementation of certain measures, development and standardization of measuring techniques and methods, requirements concerning testing and inspection of measuring techniques and equipment, and consultation and provision of information on injuries that may be caused by radon.

**INDOOR RADON CONCENTRATIONS IN
SOUTH AFRICAN HOMES**
A H Leuschner, A Steyn, R Strydom, G P de Beer
Atomic Energy Corporation of South Africa Limited
P O Box 582, Pretoria 0001, South Africa

ABSTRACT

Radon concentrations have been measured in about 2 000 South African houses during a phased study. The winter-month average was 63 Bq/m³ and the geoemetric mean 45 Bq/m³. Parameters correlating with high indoor radon concentrations were floor type and uranium content of geological formation.

INTRODUCTION

The radiation dose from inhaled decay products of radon seems to be the dominant component of radiation exposure of the world population. Although much can be learnt from overseas experience, local differences warrant an investigation of the South African situation. On the one hand the South African climate may favour better ventilation conditions which may result in lower indoor radon concentrations. On the other hand the cold Highveld winters and lack of central heating may promote stagnant indoor conditions for certain months of the year. Furthermore, the densely populated areas on the Witwatersrand are surrounded by waste dumps from gold/uranium mines. These contain enhanced ²²⁶Rn concentrations. The Department of National Health and Population Development and various town and city councils provided financial and logistic support for this study.

OBJECTIVES AND PHASES OF THE STUDY

The main objective was to assess the magnitude of the public exposure to indoor radon concentrations through nationwide surveys as extensive as possible, in accordance with requirements and resources available.

The study was conducted in three phases. The first phase was conducted in 1988 in a few areas to obtain initial logistic and sampling experience and to evaluate the techniques. The second phase during the winter of 1989 evaluated randomly selected houses of AEC employees and areas selected from an airborne radiometric survey, granitic areas, and an area that showed a geological fault and high indoor radon concentrations. In the third phase the study was expanded to other areas, including an area where indoor burning of coal might contribute to high indoor radon levels.

METHOD AND PROCEDURES

In order to obtain representative concentrations for average conditions, it is necessary to perform integrated measurements over days or preferably even months. No consideration is given to diurnal patterns or the equilibrium factor of the radon. These factors should be the subject matter of later studies.

SAMPLING TECHNIQUES

All the studies were performed primarily during the winter months. Time-integrating passive samplers were used. Charcoal canisters (Cohen *et al*, 1986) were used in some early investigations but this method of sampling was discontinued. Nuclear-track (or track-etch) detectors (Urban *et al*, 1981) were used for sampling. These monitors were normally exposed for three months. After electrochemical etching of the films the tracks were counted using a computer-automated technique.

DATA COLLECTION

Together with each measurement a one-page questionnaire was administered to obtain information about the house. This information was finally combined with that of the area characteristics and the radon concentrations in a computer data base.

DATA ANALYSIS

Data analysis was aimed at determining the relationship between indoor radon concentrations and house characteristics and the area characteristics. Analyses of variance (ANOVA) were determined for four effects, namely ventilation, sub-floor type, floor type and geographical type.

Poor ventilation is represented by a level 0 and high ventilation by level 5. Sub-floor level of 0 indicated normal soil, level 1 filling with rubble with large pores, level 2 a basement or crawl space and level 3 filling with mine tailings. Floor type level 0 indicated wooden floor or no floor covering and 1 concrete slab. Geographical types were assigned level 0, 1 or 2, where 0 indicated geological type with relatively low uranium concentrations, 1 indicated uncertain or variable uranium concentrations and 2 relatively high uranium concentrations. This evaluation indicated that the areas selected were not significantly biased towards high-uranium geological types.

RESULTS

The sample size was 1 801 houses, the total averaging was 63 Bq/m^3 , the median 52 Bq/m^3 , the mode 39 Bq/m^3 and the geometric mean 45 Bq/m^3 .

The measured indoor radon concentrations are shown in Figure 1.

Figure 1: Log-normal distribution of Indoor Radon Concentrations in South Africa

It should, however, be noted that the measured values do not represent seasonally-, construction- and locality-averaged values. Outdoor measurements indicated a winter- to annually-averaged ratio of 1,5. (This approximates ratios reported for the USA [Borak, *et al*, 1989].) Dividing the winter-measured values by 1,5 gives the lower curve in Fig. 1.

Table 1 gives the indoor radon concentrations for the various areas.

Sub-floor/uranium	5 472	3	1 824	,050	,9851

935 missing values have been excluded.

DISCUSSION

Measurements in about 2 000 residential homes in South Africa indicate an approximate log-normal distribution of indoor radon concentrations. An average concentration of about 63 Bq/m³ was measured during the winter months of three consecutive years. If corrected for seasonal variations an average closer to 42 Bq/m³ is expected.

Table 2 shows that geological type (containing uranium) and floor type played significant roles as well as the combination of these factors.

The results from Table 1 show that coal burning (Soweto) did not result in higher radon concentrations in the typical residences where coal is burnt.

Detailed discussions are given in a separate report (AEK-0036/90).

CONCLUSIONS

The average indoor radon concentration found in about 2 000 South African residences averaged about 63 Bq/m³. The seasonally-averaged value is estimated to be closer to 42 Bq/m³. Although the former value ranges high among international values, the percentage of houses with concentrations above 200 Bq/m³ coincide closer with the international average. In less than 1 % of the houses monitored, concentrations about 400 Bq/m³ were recorded while between 3 and 4 % recorded values above 200 Bq/m³. With the seasonal correction these percentages decrease to 0,5 % and between 1 and 2 % respectively.

ABSTRACT

More than one hundred materials, containing natural radioactive nuclides, are being investigated due to radiation exposure to people. This paper deals with thoriated gas mantles and shows that the radiation exposure by inhalation of radionuclides released while burning and exchange is not negligible.

INTRODUCTION

As a consequence of the restrictive limitation of radiation exposure in the Federal Republic of Germany, caused by artificial radionuclides, the radiation exposure by natural nuclides has become more importance. By human work some natural materials are changed in such a way, that natural radionuclides are enriched. Therefore remarkable exposures are possible in some cases. These exposures are especially relevant, when radioactive aerosols are generated, which result in radiation exposure by inhalation.

Within a research programme of the Bavarian government, more than 100 man-modified materials (raw materials, residual materials and consumer products) were found with a relevant amount of natural radionuclides.

Objective of our research was to examine the radiation exposure of workmen and other people handling with such materials. By means of a literature study and own calculations we found relevant subjects for further investigations. The most interesting sources we have identified are:

- thoriated gas mantles
- thoriated tungsten welding rods
- dental products containing uranium
- phosphate fertilizers
- zircon sand
- radon therapy
- mines and caves for visitors
- water purification plants

In the following we will present a special part of our investigation, dealing with the "thoriated gas mantles".

NUCLIDES AND ACTIVITIES OF GAS MANTLES

The gas mantles used for gastechnical illumination are impregnated with natural thorium to produce incandescence. Thorium is extracted from ores by separation. In practise only Th-232 with daughters and Th-230 is relevant for radiation exposure.

We determined the activity of 39 gas mantles bought in normal storehouses. The time since thorium was separated from the ore was mathematically evaluated from activity values. Here some results in extracts.

37	2	20,9	2	22,5	1,2	8,3	1,8	169,8
38	5634	0,5	14086	25,0	0,4	25,0	2,7	2,4
39	7003	0,4	14005	20,0	0,5	20,0	6,2	2,7

In a number of samples also the Th-230 activity was determined. The average specific activity was 207 Bq/g and the average Th-232/Th-230 ratio was found to 0,3.

RADIOACTIVITY EMITTED FROM BURNING GAS MANTLES

During the initial burn and during burning, a part of radioactivity is released from the gas mantle. The results of a study are shown in the following figures. They represent the relation of the specific activity of the burning mantle to the unused mantle as a function of burning time.

From these results, it is possible to assess the radiation exposures by inhalation of nuclides released from burning mantles. For example we will give a conservative assessment.

Assumptions for the calculation: room closed, no ventilation rate, breath rate: $1,2 \text{ m}^3/\text{h}$, dose conversion factor (ICRP 30) for AMAD = $0,1 \mu\text{m}$, highest retention class, time of exposure: 1 h, number of burning mantles: 1, activity of unused mantle: values of sample number 18, no attachment of radionuclides on objects, volume of space:

- a) 2 m^3
- b) 10 m^3
- c) 50 m^3

Effective committed dose equivalent H_{50} :

- a, $H_{50} = 0,43 \text{ mSv}$
- b, $H_{50} = 0,13 \text{ mSv}$
- c, $H_{50} = 0,03 \text{ mSv}$

INHALATION OF RADIONUCLIDES BY THE EXCHANGE OF GAS MANTLES

After the initial burn, gas mantles are very unstable against mechanical influence. For that reason, mantles have to be exchanged from time to time. Because the material is very brittle radioactive aerosols are generated and inhaled by the handling people.

We investigated the above mentioned problem with a cascade impactor. All conditions of the experiments were in that manner, that the human respiration was simulated by the measuring equipment. The following figures are showing results for Th-232.

The effective committed dose equivalent H_{50} was calculated with three methods:

- first assessment: no consideration of the activity size distribution, Dose Conversion Factor (ICRP 30) for AMAD = 1 μm , the same activity for each nuclide (on an average)
- second assessment: like a₁, but with consideration of the different activities of the nuclides
- third assessment: consideration of the activity size distribution.

Effective committed dose equivalent H_{50} for one exchange, lasting four minutes:

- a, $H_{50} = 0,33 \text{ mSv}$ b, $H_{50} = 0,48 \text{ mSv}$ c, $H_{50} = 0,27 \text{ mSv}$

FINAL REMARKS

Although the use of gas mantles in the public illumination for streets and squares is decreasing, there is a high increase for camping lanterns, so that radiation exposure by inhalation of radioactive nuclides is not negligible.

INDOOR RADON CONCENTRATION IN A TEST CHAMBER: EXPERIMENTAL DATA AND THEORETICAL EVALUATIONS

D. Capra*, C. Silibello*, G. Queirazza'

* Cise SpA - Via Reggio Emilia, 39 - 20090 Segrate (MI)
+ ENEL/CRTN - Via Rubattino, 54 - 20134 Milano

ABSTRACT

This paper reviews the preliminary work performed to evaluate the influence of building materials on Radon concentration. Experiments were carried out under various conditions in order to examine data variability in a test chamber built in Milan. A mathematical model, based on the Jacobi-Pörstendorfer theory, was developed to predict Radon and daughters concentrations in the chamber. The model yields Radon concentration estimates that agree with experimental data and permits Radon progeny concentrations and doses in the chamber to be evaluated.

INTRODUCTION

The Italian National Electricity Board (ENEL) has set up, in cooperation with CISE, an investigation program for the purpose of assessing the hazards connected with coal ashes being used as partial substitutes for cement and other building materials in civil applications. This program refers specifically to Radon emanation characteristics, since Radon is the major natural radiological hazard for the community. Preliminary laboratory tests on the exhalation rate of powdered samples had shown a slight contribution of fly ashes to indoor Radon concentrations⁽¹⁾. In order to confirm these evaluations, two identical rooms (3.4 x 3.8 x 2.15 m) were built using conventional and fly ash-containing building materials. The two rooms were separated from the ground by a 40 cm high crawl-space. A sandy underlying soil with a high porosity level and sidewise diffusion and a shallow foundation were used to obtain the lowest possible Radon concentration in the crawl-space in order to enhance the Radon emanation of the rooms' building materials.

The principal objectives of this work were to develop a mathematical model for estimating Radon levels in a test chamber, and to verify the accuracy of the model output by a comparison with experimental data.

METHODS

The study site was a test chamber, located near Milan, made of conventional building materials. Facilities were provided to produce any desired temperature, humidity and air-change conditions within the room. The following parameters were continuously monitored: Radon concentration inside the room, in the open air and in the crawl space; meteorological parameters (outdoor and indoor temperatures, differential atmospheric pressure, humidity). The air change rate was controlled by an SF₆ measurement system (see Appendix).

Experimental conditions were continuously changed, during the period November 1990 - August 1991, to evaluate the influence of various parameters (air-conditioning system, ventilation, humidity, differential pressure, differential temperature, Radon levels in the crawl space) on indoor Radon concentration. Mean values for all parameters are given in Table 1.

In order to evaluate the indoor Radon concentration which is not related to that outside by ventilation, hourly Radon entry rates were determined by using a general mass balance equation:

$$\frac{dC^{INDOOR}}{dt} = E_s \frac{S}{V} + \lambda_v C^{OUTDOOR} - (\lambda_v + \lambda_{Rn}) C^{INDOOR} \quad (1)$$

where C^{INDOOR} = indoor Radon concentration [$Bq\ m^{-3}$], $C^{OUTDOOR}$ = outdoor Radon concentration [$Bq\ m^{-3}$], E_s = Radon exhalation rate from walls [$Bq\ m^{-2}\ h^{-1}$], S = room surface area [m^2], V = room volume [m^3], λ_v = ventilation rate [h^{-1}], λ_{Rn} = Radon decay constant [h^{-1}]. Assuming $\beta = E_s S / V + \lambda_v C^{OUTDOOR}$ and $\alpha = \lambda_v + \lambda_{Rn}$, the general solution of this equation, over a particular time step $\Delta t = t - t_0$, is:

$$C^{INDOOR}(t) = \frac{\beta}{\alpha} [1 - \exp(-\alpha \Delta t)] + C^{INDOOR}(t_0) \exp(-\alpha \Delta t) \quad (2)$$

Using measurement data to supply hourly values of indoor Radon concentration and air change rates, Effective Radon Entry Rates (ERER = [$Bq\ m^{-3}\ h^{-1}$]) were calculated for each hour of the period using the following relation⁽²⁾:

$$ERER(t) = \alpha \left[\frac{C^{INDOOR}_{measured}(t) - (C^{INDOOR}_{measured}(t_0) \exp(-\alpha \Delta t))}{1 - \exp(-\alpha \Delta t)} \right] - \beta \quad (3)$$

Seasonal averages of the measured and calculated parameters are shown in Table 2 (the ventilation rate is derived using mass balance formula in Appendix and ERER is calculated considering that Radon exhalation rate from walls is quite constant with an average value of about $2\ Bq\ m^{-2}\ h^{-1}$).

In order to predict Radon and daughters concentrations in the chamber, a general mass balance model was developed. This model, called RADBOX, represents a dynamic version of Jacobi-Pörstendorfer one and it is stated as a system of differential equations reflecting the mass balance among Radon (equation 1) and its progeny in the three forms: free, attached and deposited⁽³⁾⁽⁴⁾⁽⁵⁾.

Using available data for attachment, deposition and desorption rate constants, it is possible to estimate Radon and its progeny concentrations, equilibrium factor and Potential Alpha Energy Concentration (PAEC) inside the chamber.

RESULTS AND DISCUSSION

As shown in Table 1 and 2, measurements carried out inside the test chamber indicate the dependence of Radon concentration with ventilation and stack effect (variation of differential pressure with height across a vertical wall separating air masses of different temperatures). An increase in ventilation causes a diminution of the differential pressure ($P_{outdoor} - P_{indoor}$), due to the inlet of outdoor air. Both the lower Radon concentration in the outdoor air and the suppression of the upward airflow from the crawl-space (more contaminated) determine a lowering of indoor Radon concentrations (see Table 1 experimental conditions 2, 3 and 8). From Table 2, seasonal variations of indoor Radon concentrations and Radon entry rates (ERER) are related to stack effect action on upward airflow in the chamber. Higher Radon concentrations ($40-50\ Bq\ m^{-3}$) and higher entry rates ($5-7\ Bq\ m^{-3}\ h^{-1}$) in autumn and winter were consistent with lower differential

temperature ($T_{\text{outdoor}} - T_{\text{indoor}}$) and higher differential pressure (about to 1.8 Pa). During spring and summer both the differential temperature and differential pressure were mostly close to zero. This means that the stack effect was suppressed and Radon entry rates were low. The aspiration of air from the crawl space (see table 1 experimental condition 16) does not show a great influence on the indoor Radon levels because of the low residual Radon concentration in the crawl-space.

A comparison of model results with observations shows that hourly average predictions for indoor Radon concentrations ($>10 \text{ Bq m}^{-3}$) are within 14 % agreement of the corresponding experimental data. Calculated and observed hourly ^{222}Rn concentrations for two different ventilation conditions ($\lambda_v = 2.1$ and 0.69 h^{-1}) are compared in Figs 1 and 2 respectively. Calculated values for ^{222}Rn are in close agreement with observations, but a model-observation discrepancy occurs for low values ($3 \pm 10 \text{ Bq/m}^3$).

APPENDIX: TWO WAYS TO ESTIMATE VENTILATION IN THE TEST CHAMBER

Since ventilation measurements using SF_6 techniques are only possible in some representative situations, two different approaches are being used for continuous ventilation monitoring.

The first one estimates ventilation using a power law expression $\lambda_v = VD\Delta P^n$ where D =permeability of building envelope [$\text{h}^{-1} \text{ Pa}^{-n}$], ΔP = pressure drop across the building envelope [Pa] and n =flow exponent [dimensionless]. In this study we used $n=0.65^{(6)}$ and a value of $D=0.76 \text{ h}^{-1} \text{ Pa}^{-0.65}$, calculated according to previous formula, when both ventilation rate and pressure drop were available.

The second approach is derived from the mass balance equation (1) assuming steady state conditions and neglecting λ_{Rn} ; so that λ_v can be evaluated from measurements of Radon emanation and indoor and outdoor Radon concentrations using this formula:

$$\lambda_v = (E_0 S / V) / (C^{\text{INDOOR}} - C^{\text{OUTDOOR}})$$

Figure shows the comparison between measured (SF_6 technique) and calculated ventilation rates (Power law and mass balance formula)

ABSTRACT

Infiltration of radon from the ground is usually the primary source of indoor radon pollution. A uniform method for radon risk classification of foundation soils based on soil-gas radon concentration measurements and on the determination of soil porosity, permeability and structure was proposed in 1990. Results of assessment of some areas in Czechoslovakia, containing more than 5 000 radon concentration measurements, demonstrate the utility of the technique and confirm the link between geology and radon potential of the soil.

INTRODUCTION

The Czech Republic /CR/, the western part of Czechoslovakia, is situated mostly on the eastern end of the Central European Platform with a higher than normal content of uranium in rocks. These geological conditions cause higher risk of radon penetration into buildings from the ground. Since the acceptance of the Decree of the Ministry of Health of the CR concerning the Requirements for Limiting the Irradiation from Radon and Other Natural Radionuclides /1/ in 1991, the detailed radon measurements are obligatory for all areas of urban planning.

RADON corporation, a private radon monitoring firm, was established in 1990. During one year it has realised a radon survey at about 70 areas of different size /from 400 to 200 000 sq.m./, especially in Prague and in Northern Bohemia but also in other regions of the CR. Some results of this work, containing more than 5 000 radon concentration measurements, are presented in this paper.

RADON RISK CLASSIFICATION OF FOUNDATION SOILS

The uniform method for radon risk classification of foundation soils, proposed by Geological Survey Prague in cooperation with the Ministry of Health of the CR and other authorities /2/, is based on soil-gas radon concentration measurements at each measured point of the area investigated /grid 10 x 10 m/ and on permeability classification of foundation soils, which respect the Czechoslovak National Standard 731001 /three groups of foundation soils - low, medium and high permeability soil classes - see Table 1/. The other parameters including vertical and horizontal changes in soil

and rock profile are also taken into consideration /geological description and laboratory analysis - the documentation of 4 - 6 drillings for each 10 000 sq. m. of the area/. In practice, the radon classification is usually done in connection with the engineering geological investigation.

Table 1 - Radon risk classification of foundation soils

classification of risk /categories/	radon concentration /222-Rn/ in the soil gas /kBq.m-3/		
	low	medium soil permeability	high
low risk area	< 30	< 20	< 10
medium risk area	30 - 100	20 - 70	10 - 30
high risk area	> 100	> 70	> 30

Note : A special category of extremely high risk has been established for anomalies more than ten times higher than those at the high risk areas.

SOIL-GAS RADON CONCENTRATION MEASUREMENTS

The soil-gas sample collection method has been described recently /3/, similar sampling technique was used by Reimer /4/. The sampling system consists of a small-diameter hollow probe pounded into the ground to a depth of 0,60 - 0,80 m. Samples of about 100 cm³ are collected by a syringe and introduced into evacuated Lucas cells. The cells are transported into the laboratory and counting begins usually from 5 to 15 hours after injection. The radon concentration is determined with analytical sensitivity of about 0,3 kBq.m⁻³.

Both the method and its calibration have been verified in the Reference laboratory /Ministry of Health of the CR/. In September 1991 RADON corporation took part in the international intercomparison and intercalibration exercise /Badgastein, Austria/.

SURVEY RESULTS

It is known, that soil characteristics do vary over a small area, both large scale and the small scale parameters have to be considered. The first effort is to gather general data appropriate for radon assessment on the large scale - lithology, soil and bedrock structure, structural geo - mechanical deformation of rocks. The second approach is to investigate factors influencing the production and migration of radon in soils. In brief, it is necessary to determine local soil conditions - in particular the permeability and changes in the soil profile.

Experiences based on the large number of survey data are shown in the following summary.

1. It is possible to collect a large number of samples in a short time period. Sample collection must be made very carefully. Perfect sealing of all parts of the equipment is especially important. There are no problems with sample collection even when very high soil-moisture contents or fine clays are encountered. Some difficulties may appear when the sampling depth is below the ground water level.

2. Tectonic zones determine the potential for more serious radon problems to exist. Measurements in some regions in the north-western part of Bohemia confirmed this fact. Values of soil-gas radon concentration observed in the area situated on a tectonic zone /Hrob area/, where longitudinal and transverse faults form a fault belt /called Krušnohorský/, were about four times higher than those in the near-by areas with similar geological conditions /Litvínov and Dubí areas/. Average soil-gas radon concentration in the Hrob area was 300 kBq . m⁻³ /standard deviation 261 kBq . m⁻³; number of samples 36/, while in the Litvínov area it was 69,7 kBq . m⁻³ /27,8 kBq . m⁻³; 36/ and in the Dubí area 84,9 kBq . m⁻³ /34,1 kBq . m⁻³; 36/. Similar results were obtained in Chaby, Prague, where RADON corporation had realised a detailed radon survey for the projected housing estate /3/ - about 1 700 soil-gas radon concentration measurements.

3. Radon risk mapping on large scales is first of all based on the evaluation of bedrock. In many measured areas, soil-gas radon concentrations really correspond to the expected radon potential of bedrock with different stratigraphical and petrographical character /3/. On the other hand, some results of detailed in situ measurements / for example at the locality north of Prague/ illustrate the significant role of various soil layers. Two reference areas /Veltěž, Ďáblice/ are situated in the Tertiary /Pliocene/ sandy gravel fluvial and lacustrine sediments. Owing to the granite pebble content in these sediments, higher radon concentrations were assumed. In the Ďáblice area, loess eolian deposits /average thickness of about 5 m/ cover underlying fluvial and lacustrine sediments. Homogenous and relatively less permeable loess and loess loam cause homogenous and relatively not so high soil-gas radon concentrations ranging from 29,5 to 58,4 kBq . m⁻³ /average value 41,8 kBq . m⁻³; standard deviation 7,2 kBq . m⁻³; number of samples 36/. Different situation was found in the second area /Veltěž/, where the thickness of loess eolian deposits varies from 0 to 1m. Soil-gas samples were thus collected in the layer of high permeable sandy gravel sediments. Presence of overlying less permeable layer at majority of the measuring points resulted in higher radon concentrations /with the highest value 158 kBq . m⁻³/and in inhomogenous distribution /average value 78,4 kBq . m⁻³; standard deviation 45,4 kBq . m⁻³; number of samples 36/. These results confirm the important role of air permeability of soils. The permeabilities have much larger range than the values for other parameters and local differences in them may be very significant in determining radon infiltration risk /5/.

4. Radon risk classification of foundation soils may be difficult in areas, where excavations or other human interventions occurred in the past, because of frequently observed anomalies.

5. Investigations concerning seasonal and meteorological variations of soil-gas radon concentrations have not been finished yet. Because it is evident that these variations differ in different geological conditions, further data are needed.

CONCLUSIONS

The applications presented in this paper demonstrate how geology /including lithology, structure and soil permeability/ and soil-gas radon measurements can be combined in a reconnaissance of the radon infiltration risk from the ground. Survey results improve understanding of factors controlling the radon generation and migration pathways. It is possible to divide the areas reserved for building activities into different groups of potential risk. When the locations of building areas or separate houses are known, the radon risk prevention technology for buildings can be chosen and proposed.

RADON IN HOUSES - IDENTIFICATION OF SOURCES AND PATHWAYS OF TRANSFER

The Institut de Protection et de Sécurité Nucléaire (IPSN) is studying the remedial actions to reduce high concentration of radon in houses. The first step to know how to modify houses is to identify radon sources and pathways of transfer to upper floors.

A pilot study in Brittany was designed to develop a simple method of diagnosis. This investigation was based on indoor and outdoor measurements of ^{222}Rn activity concentration in the air and ^{222}Rn area exhalation rate from the soils and walls, measurements of the potential alpha energy concentration of ^{222}Rn daughters and the ventilation rate.

The structural characteristics of houses and the influence of the life style of the inhabitants were examined. Analysis of the results showed that a limited number of parameters can be selected for use in a rapid radon diagnosis.

INTRODUCTION

Dans le cadre du programme national d'évaluation de l'exposition du public aux rayonnements naturels à l'intérieur des locaux d'habitations, un certain nombre de maisons étudiées s'est avéré présenter de fortes concentrations en radon, susceptibles d'entraîner une exposition significative pour les occupants.

En vue de proposer des solutions appropriées de réduction des concentrations en radon, l'objectif recherché dans cette étude consiste à élaborer une méthodologie rapide et simplifiée de diagnostic. Cette méthodologie est établie à partir d'une série d'études plus complètes portant sur cinq maisons de Bretagne choisies selon les critères suivants :

- une activité volumique en radon 222 supérieure à 400 Bq.m^3 (limite recommandée pour les habitations existantes par la Commission des Communautés Européennes),
- une concentration en énergie alpha potentielle volumique (EAPv) supérieure à 10^{-6} J.m^{-3} (*),

(*) à l'équilibre radioactif entre les descendants à vie courte et le radon,
 $10^{-6} \text{ J.m}^{-3} = 180 \text{ Bq.m}^{-3}$

- les caractéristiques architecturales du bâtiment,
- le volontariat des occupants.

Nous présentons l'étude complète, d'une durée de 48 heures, ayant porté sur l'une de ces cinq maisons.

CARACTÉRISTIQUE DU BATIMENT

L'analyse des caractéristiques du bâtiment conduit à l'établissement d'un plan schématique d'agencement (figure 1). Il s'agit d'une maison construite en 1962 en parpaings, revêtue extérieurement de granit, possédant une cave dont le plancher est constitué de terre battue.

On note au rez-de-chaussée la présence de deux pièces, situées au-dessus de la cave, et dont le plancher est constitué par du travertin. Ce plancher n'est traversé par aucune canalisation provenant du sous-sol. Par contre, il existe une porte de communication entre cave et rez-de-chaussée.

Cette maison est assez représentative de l'habitat individuel en Bretagne.

PARAMETRES MESURÉS ET RÉSULTATS

On a procédé à un ensemble de mesures à l'intérieur et à l'extérieur de la maison (tableau 1).

	PARAMETRES mesurés	Lieu de mesure
radon 222	concentration dans l'air ambiant	simultanément dans la cave (pièce A) et le rez-de-chaussée (pièces B et C)
	concentration dans les sols (profondeur à 0,30 m)	cave jardin
	taux d'émanation surfacique	cave : plancher et murs rez-de-chaussée : plancher, jardin, perron
descendants à vie courte du radon	concentration en énergie alpha potentielle	cave, rez-de-chaussée, étage
radium 226	activité massique	sol de la cave
irradiation externe	débit de flux gamma	matériau de construction cave et jardin
ventilation	taux de renouvellement de l'air	rez-de-chaussée
paramètre météorologique	pression, température, humidité, vitesse et direction du vent, pluviométrie	environnement

Tableau 1 - Ensemble des paramètres mesurés à l'intérieur de la maison

L'ensemble des résultats est donné sur la figure 1.

On note dans la cave des flux d'émanation radon très importants (environ 100 fois le flux moyen à la surface du globe), rarement observés même en terrain granitique. Ceci entraîne, dans ce local peu ventilé, des concentrations en radon et en descendants à vie courte également très élevées.

Les mesures de concentration radon après un confinement de quelques heures au rez-de-chaussée révèlent des niveaux de l'ordre de $10\ 000\ \text{Bq}/\text{m}^3$.

A partir de l'ensemble de ces mesures il apparaît que la source est constituée par le plancher en terre battue de la cave et secondairement par les murs de celle-ci.

Le transfert de radon entre le sous-sol et le rez-de-chaussée s'effectue principalement par la porte de séparation, et secondairement au travers du plancher et dans les murs.

Ce diagnostic est confirmé par des mesures intégrées de l'énergie alpha potentielle volumique des descendants du radon sur une période de 15 jours. Elles mettent en évidence des niveaux de $25\ \mu\text{J}\cdot\text{m}^{-3}$ ($4500\ \text{Bq}\cdot\text{m}^{-3}$ de concentration équivalente radon à l'équilibre) dans la cave, entre 4 et $5\ \mu\text{J}\cdot\text{m}^{-3}$ (720 et $900\ \text{Bq}\cdot\text{m}^{-3}$) au rez-de-chaussée et de l'ordre de 1 à $3\ \mu\text{J}\cdot\text{m}^{-3}$ au premier étage (180 à $540\ \text{Bq}\cdot\text{m}^{-3}$).

Durant l'étude, les mesures montrent que l'ouverture des portes et des fenêtres conduit en quelques minutes à une chute d'activité de $7\ 000\ \text{Bq}\cdot\text{m}^{-3}$ à $1\ 000\ \text{Bq}\cdot\text{m}^{-3}$ tandis que leur fermeture entraîne un retour au niveau initial en l'espace de quelques heures.

CONCLUSION

Au cours de cette étude, comme dans les quatre autres maisons, les moyens mis en oeuvre étaient importants et parfois même redondants. Il faut noter une bonne cohérence entre les résultats des différents paramètres mesurés.

Ceci nous permet de proposer l'établissement d'un diagnostic rapide, avec des moyens réduits, en préconisant tout d'abord la localisation de la (ou les) pièce(s) où est (sont) située(s) la (ou les) source(s) de radon par :

- un examen visuel du soubassement et des matériaux de construction,
- des mesures instantanées et ponctuelles de la concentration du radon ou de ses descendants après une période de confinement de quelques heures.

Dans le cas d'une maison à plusieurs niveaux où des voies de transfert doivent être recherchées, des mesures instantanées de la concentration du radon ou de ses descendants doivent être effectuées aux différents niveaux après une période de confinement de quelques heures.

Si elle s'avère indispensable, l'identification plus précise de la source passe par des mesures de flux d'émission. Cette étape peut être facilitée dans certains cas par l'utilisation d'un scintillomètre portatif de prospection donnant des indications sur le débit de flux gsmma.

L'ensemble de ces étapes successives doit conduire, en moins d'une journée, à un diagnostic radon avec des moyens réduits.

THE RADIOLOGICAL IMPACT OF A RADIUM RICH
BY-PRODUCTS DEPOSIT : METHODOLOGY OF ASSESSMENT

Radiological impact due to the deposit of radium rich by-products can be assessed by:

- the characterization of the source-term based on the measurement of ^{226}Ra content and ^{226}Ra activity concentration in soil, area exhalation rate of ^{222}Rn from the deposit and external dose rate in air,
- the measurement of the activity concentration of ^{222}Rn in air above the ground,
- the study of the transfer of ^{222}Rn in the neighbourhood of the deposit with the same measurements as above.

The assessment can be followed by the radiological monitoring of the environment over more or less long periods of time consisting of the potential α energy at several stations, according to the protocole designed on the former results.

INTRODUCTION

L'exploitation de certains minerais, pour la production de matières premières comme l'uranium, les terres rares ou encore les phosphates, aboutit en fin de traitement à l'obtention, en grandes quantités, de matériaux de faible activité massique et de longue période. Ces matériaux sont désignés généralement par le terme de résidus. Parmi les radioéléments contenus dans ceux-ci se trouve généralement du radium 226.

La radioactivité de ces matériaux est, bien entendu, d'origine naturelle mais elle nécessite de prendre des dispositions afin de ne pas accroître de façon significative les risques pour les populations présentes et futures. Différentes possibilités existent pour les gérer soit sur le lieu d'extraction ou le lieu de traitement des minerais, soit sur un centre de stockage.

Il s'agit dans les deux premiers cas de dépôts de produits radifères de plus ou moins grandes étendues, pouvant être situés à des distances plus ou moins grandes de zones d'habitations.

Nous développons ci-après une méthodologie d'évaluation de l'impact radiologique de tels sites vis-à-vis du radon issu des produits radifères.

METHODOLOGIE D'EVALUATION

L'évaluation a pour but dans un premier temps de caractériser le site et son environnement plus éloigné ("bruit de fond régional") puis de définir un protocole de surveillance radiologique à plus ou moins long terme.

Cette évaluation, basée sur un ensemble de mesures, est réalisée en quelques jours.

La caractérisation du site et de son environnement se déroule principalement en 3 phases :

- caractérisation du terme source,
- étude du transfert dans l'environnement,
- mesure du bruit de fond régional.

La caractérisation du terme source (phase 1) comprend essentiellement des mesures ponctuelles de flux d'émission de ^{222}Rn à la surface du sol.

Les mesures sont effectuées selon une technique d'accumulation. Celle-ci consiste à déterminer, à un instant donné, l'activité volumique du radon collecté dans un conteneur, dont une face ouverte est appliquée sur le sol. La manipulation du dispositif nécessite une surface de sol débroussaillée d'au moins un mètre carré.

Pour la détermination de l'activité volumique du radon, deux prélèvements d'air sont effectués dans des fioles scintillantes mises préalablement sous vide.

Pour chaque point de mesure de flux, une fois les deux prélèvements d'air par fioles scintillantes réalisés, un échantillon de matériau superficiel est prélevé sous le conteneur, afin de déterminer l'humidité pondérale du sol au moment de l'analyse. En effet, les flux d'émission radon varient en fonction de l'humidité du sol. C'est pour cette raison que la mesure du flux ne peut pas avoir lieu par temps de pluie ou de neige.

De plus, en chaque point de mesure de flux radon, le débit de flux gamma est relevé au moyen d'un scintillomètre portatif.

Le nombre de points de mesure est choisi en fonction de la superficie du dépôt, sachant que l'investigation est poursuivie si nécessaire au vu des résultats.

Cette caractérisation du terme-source peut être complétée par des mesures instantanées d'activité volumique de ^{222}Rn dans le sol et des analyses en ^{226}Ra d'échantillons de matériaux.

L'étude du transfert du ^{222}Rn dans l'environnement (phase 2) se fait, parallèlement, au moyen d'un laboratoire mobile. Il est équipé :

- d'un système de génération électrique fournissant une autonomie de mesure de 24 heures,
- d'un système de repérage cartographique,
- d'un ensemble d'acquisition et traitement de données,
- de chambres d'ionisation permettant la mesure en continu du débit de dose gamma, à 2 m du sol environ, et de l'activité volumique radon 222. Le prélèvement d'air nécessaire se fait à une hauteur de 1,50 m du sol environ.

Afin de mettre en évidence les variations temporelles et spatiales les mesures ont lieu :

- à poste fixe, en quelques points du site, pendant des périodes de quelques heures à quelques jours, sous différentes conditions de diffusion atmosphérique (variations temporelles liées par exemple aux inversions de température pendant la nuit),
- en déplacement, selon des trajectoires fonction des caractéristiques du site (infrastructure routière, groupe d'habitations, orographie, ...) et des conditions météorologiques sous différentes conditions de diffusion atmosphérique.

Cette méthodologie est également appliquée dans l'environnement proche du dépôt. Quelques mesures de flux d'émission ^{222}Rn sont faites, le cas échéant, afin de déterminer si le ^{222}Rn observé dans l'atmosphère a une origine locale ou s'il est dû à un transfert à partir du dépôt des produits radifères.

Enfin dans un environnement plus éloigné du site de dépôt (à quelques kilomètres, hors d'influence du dépôt mais sur un terrain de caractéristiques géologiques comparables) on applique cette même méthodologie, afin de connaître les gammes de niveaux naturels de flux d'émission ^{222}Rn et d'activités volumiques dans la région (phase 3).

Les limites de la zone d'influence du dépôt peuvent être ainsi évaluées par rapport à ces niveaux de référence.

SURVEILLANCE RADIOLOGIQUE A PLUS OU MOINS LONG TERME

A partir de cette évaluation, une surveillance radiologique peut être exercée rationnellement pour évaluer l'éventuel supplément d'exposition pour des personnes résidant ou travaillant dans cette zone d'influence ("groupe critique"). Elle consiste en des mesures mensuelles de l'Energie Alpha Potentielle volumique (EAP_v) des descendants à vie courte du radon, représentatives du "groupe critique" et du niveau naturel. Cette surveillance radiologique peut être effectuée sur plusieurs mois ou années. De plus, elle permet de vérifier régulièrement que cette situation n'évolue pas.

CONCLUSION

La méthodologie d'évaluation décrite apporte très rapidement des informations utiles sur différents plans, tant pour l'exploitant que pour les autorités compétentes et la population.

D'une part, elle permet de caractériser, du point de vue radiologique, le site de dépôt de produits radifères et de déterminer sa zone d'influence dans l'environnement, compte tenu du niveau du bruit de fond régional.

D'autre part, si des groupes critiques de la population sont identifiés, cette étude permet de proposer l'implantation rationnelle d'un réseau de surveillance à plus ou moins long terme.

Cette méthodologie d'évaluation peut être appliquée sur un site en cours d'exploitation ou en fin d'exploitation ainsi qu'après qu'il ait été reconstitué.

Elle constitue alors une base de données pour aider à la gestion du site de dépôt.

**THE NATURAL RADIOACTIVITY OF NONURANIFEROUS
MINES FROM ROMANIA**

ABSTRACT

Between 1970 - 1980 were investigated 267 mining and exploration non-uranium units at 104 (39.0%) being exceeded the maximum permissible radon concentration (MPC) for public (110 Bq/m^3) and at 15 (5.6%) the MPC for occupational exposure (1100 Bq/m^3), so being necessary the recommendation of limiting measures.

Were clarified the causes of appearance and accumulation of radioactive gases, the main source being the natural radioactive elements from rocks and minerals and the cause of accumulation the inefficiency of ventilation.

INTRODUCTION

In 1974 by a governmental programme, initiated by the Department of Mines and Geology, on the basis of measurements previously carried out by our laboratory², has been started the investigation of non-uranium mining and exploration units from the point of view of natural radioactivity.

The aim of this programme was to clarify the causes of appearance and accumulation of radioactive gases in the underground atmosphere and to estimate the workers' exposure.

The implied investigation methods have been those presented in Table 1.

TABLE 1. Investigation methods

Nature of samples Radioelement	Method	Sensitivity	
<u>Solid</u>			
U natural	Fluorimetry	0.05	g/t
Th natural	Spectrophotometry	0.2	g/t
Ra-226	Scintillation	$0.1 \cdot 10^{-6}$	g/t
<u>Water</u>			
U natural	Fluorimetry	$0.1 \cdot 10^{-6}$	g/t
Ra-226	Scintillation	0.004	Bq/L
Rn-222	Scintillation	0.4	Bq/L
<u>Air</u>			
Rn-222	Scintillation	200	Bq/m ³
Rn daughters	modified Kusnetz	40	Bq/m ³

To clarify the causes of appearance and accumulation were determined the concentrations of natural uranium and thorium and of Ra-226 in rocks, minerals and mine waters and those of Rn-222 in waters. The geological environment, the mining methods and the ventilating conditions were also investigated.

As thoron was found only in two mines, this paper will refer only to Rn-222.

The exposure to radiation was estimated by measuring the gamma dose rates and the concentrations of radon and its daughters.

EXPERIMENTAL RESULTS

Between 1970 and 1990 were investigated 267 underground non-uranium units. Were collected over 5,000 geological samples and were made determinations of gamma dose rate, radon and its daughters at over 7,000 underground sites.

In Table 2 are given some results of natural uranium and thorium content of geological samples analysed by our laboratory.³

TABLE 2. Uranium and thorium content of rocks (mean values)

Rock type	No. of samples	U	Th	Th:U
		g/t	g/t	
Igneous rocks	416	2.2	9.2	4.1
Metamorphic rocks	89	2.2	11.1	5.0
Sedimentary rocks	107	1.5	-	-

From the igneous rocks the highest radioactive element content is presented by the acid ones, from the metamorphic rocks by porphyrogenic schists and from sedimentary rocks by clays. The geological samples have an uranium and thorium content comparable to the mean content of upper lithosphere. The mean values for Ra-226 content vary from $1.4 \cdot 10^6$ g/t in acid igneous rocks to under $0.1 \cdot 10^8$ g/t in ultrabasic igneous ones.

The mean uranium and Ra-226 contents of mine waters are shown in Table 3.

TABLE 3. Uranium and radium 226 content of mine waters

Water source	No. of samples	U	Ra-226
		10^6 g/L	mBq/L
Infiltration waters	102	12.94	32
Drainage channel waters	233	13.10	58

The radon content of mine waters is frequently between 15 and 110 Bq/L and in some cases over 550 Bq/L.

The gamma dose rates varied between 0.02 μ Sv/h and 7 μ Sv/h, with mean values of 0.04 μ Sv/h in salt mines and 0.33 μ Sv/h in iron mines.

It can be said that the external radiation by gamma rays is not important for the exposure of workers from non-uranium mines.

The most important factor that contributes to the radiation exposure of workers in non-uranium mines is radon and its short-lived daughters. The results of determinations of equilibrium equivalent radon concentrations are given in Table 4.⁴

It can be seen from Table 4 that in 104 (39.0%) from the investigated units was exceeded the MPC for public and in 15 (5.6%) ones the MPC for occupational exposure.

The limiting measures concerned first of all the improvement of ventilation, primary and/or secondary, by increasing of air changes/min, distribution of air, maintenance of tubing and continuous operation of fans. The increasing of air

changes/min, can be obtained either by increasing of air flow rates or by reducing the volume of underground workings necessary to ventilate. For an underground working or a mine area it was used the following formula⁵:

$$Q = \left(\frac{C}{MPC} \right)^{0.55} \cdot Q_1 \quad (\text{m}^3/\text{min}) \quad (1)$$

where

- Q - required air flow rate (m³/min)
- Q₁ - provided air flow rate (m³/min)
- C - equilibrium equivalent concentration of radon in that environment (Bq/m³)
- MPC - 110 Bq/m³ - maximum permissible concentration for public.

For the general ventilation it was used the formula⁶:

$$Q = \frac{D}{MPC} = \frac{Q_1 \cdot C}{MPC} \quad (\text{m}^3/\text{min}) \quad (2)$$

where Q, Q₁, C and MPC have the meaning from (1) and D is the radon flow rate (Bq/m³). As it can be seen, relation (2) is more restrictive than relation (1), the resistance of the whole mine being higher than that of a working or a mine area. Both relations were used with success.

TABLE 4. Equilibrium equivalent concentration of radon vs. useful mineral
(mean values)

Mining and exploration units	No. of units	Equilibrium equivalent concentration Bq/m ³		
		<110	110-1100	>1100
Iron	26	13 (50.0%)	10 (38.5%)	3 (11.5%)
Non-ferrous	98	57 (58.2%)	34 (34.7%)	7 (7.1%)
Gold-silver	22	10 (45.5%)	12 (54.5%)	-
Bauxite	8	1 (12.5%)	7 (87.5%)	-
Pegmatite	9	5 (55.6%)	4 (44.4%)	-
Talc, clay, opalin or bentonite	15	10 (66.7%)	5 (33.3%)	-
Barytine	4	1 (25.0%)	1 (25.0%)	2 (50.0%)
Salt	8	8 (100.0%)	-	-
Coal	67	36 (53.7%)	28 (41.8%)	3 (4.5%)
Bituminous shale	6	3 (50.0%)	3 (50.0%)	-
Total	267	143 (53.5%)	104 (39.0%)	15 (5.6%)

An epidemiological study⁷ proved that, in a gold mine having a mean cumulative exposure to radon of over 60 WLM, the frequency of death by respiratory cancer, in the period 1960-1985, was 1.9 times greater for miners than for the public from the same region, supposing the same smoking habits.

CONCLUSIONS

Responsible for the appearance of radon 222 in the atmosphere of underground non-uranium mines is the presence of Ra-226 in rocks, minerals and mine waters.

There is no linear relationship between the level of the radon and the natural radioelement content of geological environment, respectively the gamma dose rate, but it strongly depends upon the ventilating conditions.

From the 267 investigated units in 113 (44.8%) ones was necessary the application of limiting measures, concerning first of all the improvement of ventilation.

Responsible for the cumulative exposure of non-uranium workers are radon and its daughters, the contribution of external dose by gamma radiation being insignificant.

RADIOLOGICAL IMPLICATIONS OF NATURALLY OCCURRING
RADIOACTIVITY IN AN ELEMENTAL PHOSPHORUS REFINERY

Leo M. Lowe, D.B. Chambers
SENES Consultants Limited
52 West Beaver Creek Road
Richmond Hill, Ontario
Canada L4B 1L9

ABSTRACT

Phosphate ore mined in central Florida contains small amounts of naturally occurring uranium. This ore is the feed for a plant in Quebec that produces elemental phosphorus by the electrothermal method. Calcium silicate ("phosphate slag"), a by-product of the refining process, has excellent properties as an aggregate material. This paper reviews the radiation exposures of the plant workers and some potential uses of the by-product silicates.

INTRODUCTION

Phosphate ore can be refined to produce phosphoric acid or elemental phosphorus. Ore from the State of Florida in the United States contains up to 100 to 200 ppm of naturally occurring uranium, or up to 60 times the 3 ppm of uranium found in typical rocks and soils. In a Quebec plant, elemental phosphorus is produced by the electrothermal method whereby the ore, after first being calcined and formed into nodules, is fed to an electric furnace with silica and coke. The high temperature reaction produces gaseous elemental phosphorus which is collected and distilled. The reaction also produces a by-product calcium silicate (sometimes called "slag"), a hard ceramic-like material, which retains most of the uranium and associated decay products.

The silicates have excellent properties as aggregate material and had been used in Canada, the United States, and elsewhere for road construction and other purposes for many years. However, because of concerns related to the radioactivity of the silicates, many such uses were prohibited by a number of jurisdictions, including the Province of Quebec which issued a ban on further selling of the silicates. Because this ban, and the associated requirements for disposal of the silicates, potentially affected the viability of the phosphorus producer, SENES Consultants Limited was asked to make an assessment of the potential radiation exposures that might result from various proposed uses of the silicates. In addition, as part of a separate comprehensive industrial hygiene survey of the plant, radiation exposures to the workers at the plant were also assessed. This paper reports on both the worker exposure estimates, and the estimated potential exposures to members of critical groups associated with various proposed applications of the silicates.

POTENTIAL EXPOSURE PATHWAYS

Occupational Exposure

The workers are exposed to direct gamma radiation, to airborne particulates, and to radon-222. Because of the high temperature process, essentially all the radon and more than 95% of the relatively volatile radionuclides, lead-210 and polonium-210, are released to the process air (1). As shown in Table 1 which gives the radiological analysis of five silicate samples, the remaining radionuclides report to the silicates. Thorium-230 and radium-226 were in approximate equilibrium with the uranium while lead-210 and polonium-210 were much below equilibrium. The increase in the concentrations of lead-210 (and its decay product polonium-210) with age of the silicates is evident. The average uranium concentration in the silicates was equal to that measured in the phosphate ore.

The radon release fraction shown in Table 1 is defined as the ratio of the measured radon release rate of the sample to the theoretical maximum release rate calculated from the radium-226 concentration. The average release fraction of 0.0028 is about a factor of 60 below the 0.2 fraction often quoted for typical soils. The average release fraction from three ore samples was measured as 0.026. These results are consistent with results reported elsewhere (e.g. 2,3). Apparently, the dense ceramic matrix of the silicates greatly inhibits the release of radon. Additionally, track-etch radon detectors placed in the refinery did not measure any above-background levels of radon. Radon was therefore not considered in the exposure assessment. The worker monitoring program was based on the use of portable personal respirable air samplers to measure airborne radioactivity in potentially elevated areas (two week program) and thermoluminescent dosimeters (TLDs) (three month program). Standard breathing rates and inhalation dose conversion factors (4) were used with the exception that the polonium-210 and lead-210 particles were assumed to have an AMAD of 0.3 μm rather than the standard default value of 1 μm (1). The new 1990 ICRP recommendations (5) would produce somewhat lower dose estimates.

Exposure of the Public

Based on the good aggregate properties of the silicates and on experience with previous uses, a number of potential applications for the silicates were proposed by the phosphorus producer. These included uses such as base for railroads and highways, massive fill for large industrial areas, and massive fill for highway overpasses. Because of the very low radon emanation and the measured low leachability of the silicates, the only significant exposure pathway was gamma exposure. Exposures were based on the product of assumed exposure time, and exposure rate derived from the exposure rate measured on top of massive, uncovered silicates (up to 150 $\mu\text{R/h}$) and attenuation of any cover used in the various applications.

RESULTS

Worker Exposures

The estimated inhalation exposures for four workers in the distillation area of the refinery averaged 2.5 mSv/y (range 2.1 to 3.3 mSv/y); exposures in other areas of the plant were lower. Doses from uranium, thorium-230, radium-226, lead-210 and polonium-210 averaged 0.1, 0.1, <0.1, 0.6 and 1.6 mSv/y, respectively. The results show the relative importance of lead-210 and polonium-210, the more volatile radionuclides. The "residue" remaining after distillation of the phosphorus contained concentrated levels of these two radionuclides, greater than 500 Bq/g. For this reason, careful handling and disposal of the residue was recommended. Estimated gamma exposures ranged from 0.2 to 2.4 mSv/y, with an average of 0.8 mSv/y. Unlike inhalation exposures, the highest gamma exposures were recorded by workers who spent most of their workday near the ore or silicate storage piles. Total exposures were estimated at less than 5 mSv/y for all workers.

Exposure from Proposed Uses of Silicates

The maximum exposure rate of 150 uR/h for uncovered, massive silicates was used as a starting point in all the exposure estimates. The results shown in Table 2 for some proposed uses, assuming $1 R = 0.007 Sv$, are dependent on the assumed exposure times e.g. 2 h/day for use of roads. All estimates were less than 1 mSv/y for the exposure assumptions used.

CONCLUSIONS

Exposures to phosphorus refinery workers ranged up to about 5 mSv/y, with inhalation of polonium-210 and lead-210 being major contributors to the exposures. Public exposures to various proposed uses of the by-product silicates were estimated as being less than 1 mSv/y for the assumed exposure times.

THE PRACTICAL IMPLICATIONS OF THE NEW ICRP
ANNUAL DOSE LIMIT AT OLYMPIC DAM OPERATIONS

Jim Hondros
Olympic Dam Operations
Box 150, Roxby Downs
S.A. 5725

ABSTRACT

The radiation protection mechanisms in place at Olympic Dam Operations have been proven to be adequate for the control of employee radiation doses. The introduction of the new ICRP average annual dose limit of 20 mSv per year resulted in a review of the existing radiation protection mechanisms to ensure that their adequacy was sufficient. This paper will overview the existing radiation protection mechanisms and present the practical implications of the new ICRP limit as they apply to operations at Olympic Dam.

APPROACH TO RADIATION SAFETY

Olympic Dam Operations is a copper, uranium, gold and silver producer located approximately 600 km north of Adelaide in South Australia. The Operations consist of an underground mine and a multifunction metallurgical processing plant. The Operations have been in production since 1988 and employs approximately 800 people.

The company approach to radiation safety has revolved around designing the workplace to control employee exposure to radiation. Initial design criteria for the underground mine was that average doses to employees would be less than one quarter of the 50 mSv annual limit. Similarly, the use of good design and procedures are used for the control of radiation in metallurgical processing plant.

It must also be recognised that in the mining and processing of radioactive ores, radiation is only one of a number of hazards that is required to be managed and controlled. Radiation is a chronic exposure hazard and when compared to the more traditional mining and processing hazards such as; rock falls, chemicals and manual handling, it is relatively minor. However, an active managerial approach to radiation safety ensures that radiation is controlled and that employee exposures remain low.

RADIATION PROTECTION MECHANISMS

The major employee exposure pathways in the mining and processing of radioactive materials are; irradiation by gamma radiation, inhalation of radon daughters and inhalation of radioactive dust. The following radiation protection mechanisms are used in the control of radiation in the underground mine and metallurgical plant.

i) Mine

The control of gamma radiation in practice, is by selecting the mining method, such that there is no entry into the actual mineralised area. All access to the ore is from outside the ore body. This effectively shields employees from the gamma radiation. In the event that entry into the ore body is required, for exploratory reasons for example, then maximum exposure times are calculated from the measured gamma dose rates.

The underground ventilation system is designed to provide at least a fixed quantity of fresh air to each workplace, based on theoretical calculations prior to underground development. Experience at Olympic Dam has shown that the ventilation capacity required to control the radon daughter hazard is sufficient to control the other airborne hazards including radioactive dust.

To ensure that the ventilation system remains in optimum operating condition, it is necessary that it be maintained. This includes routine maintenance of the physical components of the ventilation system and the quick repair of any damages that occur during operations.

Formalised written procedures exist for work areas that may be inadequately ventilated as determined by the monitoring. Access to these areas is restricted to authorised personnel with appropriate personal protective equipment. Access is usually for ventilation maintenance and monitoring purposes. Prior to any change in the ventilation system, the ventilation officers and radiation safety officers are consulted to determine any possible effects on other workplaces.

Major ventilation installations are expensive and must be planned well ahead of their intended time of use. Experience to date has proven the need to properly schedule mining work in different areas. Non planned work may affect the operation of the whole ventilation system resulting in inadequate capacity in some areas. Therefore, the aim is to adhere to the established work schedules thereby ensuring adequate ventilation. If changes in schedules are necessary then considerable thought needs to be given to the specific ventilation requirements. Active management of the planning of the ventilation capacity is an integral part of the production and development of the mine.

Control of radioactive dust in the design stage initially involves the identification of potential dust sources. Physical control mechanisms and good work procedures for the control of dust include;

- flow through dilution ventilation in work areas,
- water sprays in ore handling areas,
- extraction ventilation in ore handling areas where the use of water is inappropriate,
- the watering down of roadways to prevent the resuspension of road dust,
- the use of water for all drilling operations to suppress dust,
- the use of water on all newly broken rock to suppress dust.

The use of personal protection, usually respirators, for the control of airborne radiation exposure is the least preferred control option, however it is useful in the pursuit of maintaining exposures as low as possible. Personal protection acts as a fallback control mechanism, but is not relied upon as a long term option.

ii) Metallurgical Processing Plant

Most of the total dose to employees at the metallurgical plant is delivered via the inhalation of radioactive dust. The control of radiation therefore primarily revolves around the control of potential dust sources. Specific design criteria for the packaging of uranium oxide involved installation of an isolation booth operating under negative pressure. Other potential dust sources arise from spillages of process material. Consequently, the processing plant was designed for ease of clean-up of any spillages. Areas beneath potential spillage points, for example; tanks and grinding mills, are fully concreted with bunding and sumps. Water outlets are abundant for hosing up of spillages. Strict operating clean-up procedures are enforced, with the aim being, not to let spillages dry and become dust sources.

Extraction ventilation systems are used to control identified dust sources and these systems receive routine maintenance. The use of personal protective equipment, usually respiratory protection, is mandatory for a number of tasks including; uranium packaging and clean-up of dried spillages.

IMPLICATIONS OF NEW ICRP LIMIT

Total radiation doses to mine and metallurgical plant workers show that the existing radiation protection mechanisms outlined in this paper are adequate and effective in controlling the doses to employees. For the period July 1990 to June 1991, annual doses, on average, were one quarter of the new ICRP average annual dose limit and the maximum doses were less than 70 percent of the new limit.

At the beginning of 1991, a series of discussions with the South Australian state regulatory authorities occurred in an attempt to determine the implications of the new ICRP annual dose limit on operations at Olympic Dam. As a result of these discussions, a number of agreed objectives were established. These were as follows;

i) To maintain and improve existing radiation protection mechanisms.

As stated, existing radiation protection mechanisms are adequate for maintaining employee doses below the new ICRP average annual dose limit. However, on-going review of existing mechanisms, and formalisation of existing and new procedures will be actively pursued to ensure that doses remain low.

ii) To more accurately assess employee doses by reducing random errors and reducing systematic errors.

The reduction of the margin between assessed doses and the new ICRP limit, compared to the old ICRP limit, implies that there is a need to ensure that the magnitude of the error in dose assessment is low enough to maintain compliance.

The magnitude of the random error in dose assessment is primarily a function of the statistical significance of the physical measurements used for dose estimation.

Systematic errors in dose assessment are biased due to deliberate over estimates for conservative dose assessment. Replacement of default parameters in the ICRP dose assessment methodology, with actual workplace measurements, reduces the magnitude of the systematic error and increases accuracy. Systematic errors will be reduced with the use of particle size measurements and radionuclide in dust analyses.

iii) To pursue personal dosimetry.

Another way to increase the accuracy of dose assessment is to use personal dosimetry. A number of systems are commercially available for radon daughters, however, their adequacy for the conditions and environment must be assessed. At Olympic Dam, the use of passive radon monitors and workplace equilibrium factors are being investigated. To complement the passive devices, it is planned to use active radon daughter dosimeters to monitor critical workgroups. Prototype monitors are currently being tested at Olympic Dam.

iv) To develop better reporting of doses.

To complement the monthly report on monitoring results, a quarterly report is now being generated which presents the assessed doses for individuals for the three months. The timely reporting of employee doses to managers results in closer control of the overall annual doses. Also contained in the report are the dose parameter monitoring results used to reduce the systematic error in dose assessment.

CONCLUSION

Existing radiation protection mechanisms at Olympic Dam Operations are adequate to ensure compliance with the new average annual ICRP dose limit. However, a number of specific requirements have been identified to ensure that employee radiation dose will continue to remain low and well controlled.

ABSTRACT

Theoretical models and experimental methods are described for the determination of parameters used in the analysis of Radon adsorption and diffusion in porous media.

INTRODUCTION

Adsorption on activated charcoal is a phenomenon widely used for the measurement of Radon concentration in air.¹ Following exposure to an unknown atmosphere, the Radon content in a charcoal canister is derived from the γ -emission of its decay products, at radioactive equilibrium. Radon concentration in the air is then usually inferred by comparing the above mentioned γ -activity to the activity resulting from exposure to a known Radon concentration.

The Nuclear Instrumentation and Measurements Laboratory of DCMN is involved in the definition of the Italian standard for Radon measurement by means of activated charcoal. Among the goals of this effort is the identification of simple and accurate procedures for the determination of two fundamental parameters governing Radon permeation in porous media: adsorption and diffusion coefficients.

THEORETICAL MODELS AND EXPERIMENTAL MEASUREMENTS

Adsorption coefficient. This coefficient is found by injecting a gas pulse into a charcoal column open at both ends and analyzing the temporal evolution of the gas concentration at the outlet.^{2,3}

A mathematical description of the pulse shape through the porous medium is given by the "theoretical plate model," borrowed from the analysis of plate distillation columns, which treats adsorption as a discrete process. The adsorbing column is regarded as a series of N chambers of height H where immediate equilibrium is reached between mobile and stationary phases. The pulse shape through the filter can be deduced, at any time t , from a mass balance, setting an initial condition of zero concentration in all the plates but the first one, where the input pulse is assumed as uniformly distributed. This yields:

$$C_N(t) = A \cdot \frac{N^N \cdot Q^{N-1} \cdot t^{N-1}}{(N-1)! \cdot (k \cdot m)^N} \cdot e^{-(N \cdot Q \cdot t / k \cdot m)}$$

The gas concentration at the outlet, calculated from this expression, is:

$$C_N(t) = \left(\frac{N \cdot Q \cdot t}{k \cdot m} \right)^{N-1} \cdot e^{-(N \cdot Q \cdot t / k \cdot m)}$$

The time t_{MAX} , at which the output concentration is maximum, and the time interval $\Delta t_{1/2}$, (FWHM), may be easily derived from experimental elution curves (Figure 1). The number N of the theoretical plates may be then deduced from the relation between $\Delta t_{1/2}/t_{MAX}$ and N , reported in Figure 2. The relation between t_{MAX} and the average retention time, \bar{t} , is: $t_{MAX} = \bar{t} \cdot (N-1)/N$.

Finally, the adsorption coefficient K , relative to a column containing a charcoal mass m and crossed by an air flow Q , may be calculated from the expression: $K = (\bar{t} \cdot Q / m)$.

Figure 1. Elution curve

Figure 2. $\Delta t_{1/2} / t_{max}$ as a function of N

Effective diffusion coefficient. In order to measure the coefficient D_e , a charcoal column with one open end is exposed to a Radon atmosphere until a uniform concentration C_0 is reached throughout its height, a . A continuous flow of air then sets at zero the upper free surface concentration, while the γ -emission from Rn daughters is monitored with time. With these initial and boundary conditions, integration of the set of differential equations describing the process of combined elution and decay

$$\frac{\partial C}{\partial x} = D_e \frac{\partial^2 C}{\partial t^2} - \lambda C$$

$$C(0, x) = 0$$

$$C(t, a) = 0$$

$$\left[\frac{\partial C}{\partial x} \right]_{t, x=0} = 0$$

yields a concentration profile along the column axis which approaches a single sinusoid when $t > \frac{1}{2 D_e} \left(\frac{a}{\pi} \right)^2$.

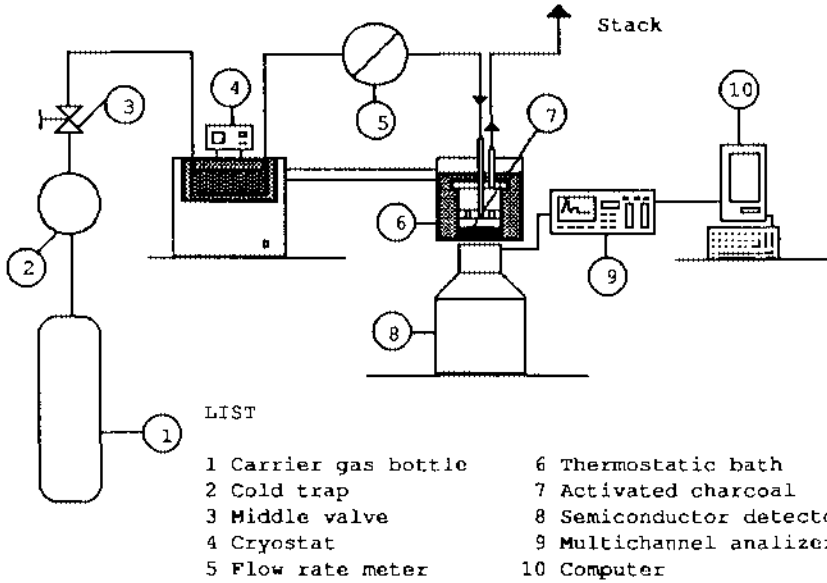

Figure 3. Test-rig

In this case, the distribution of radioactive isotopes inside the charcoal column does not vary with time, therefore, the geometric efficiency of a γ -detector placed near the column is constant. This allows for the measurement of the decrease of activity:⁴

$$A(t) = \frac{8 C_0 a}{\pi^2} e^{-\left[D_e \left(\frac{\pi}{2a} \right)^2 + \lambda \right] t} \quad t > \frac{1}{2 \cdot D_e} \left(\frac{a}{\pi} \right)^2$$

The value of the constant $\left[D_e \left(\frac{\pi}{2a} \right)^2 + \lambda \right]$, where the diffusion coefficient D_e is the only unknown quantity, may be calculated through exponential interpolation of the experimental data, as shown in Figure 4.

Figure 4. Temporal evolution of the γ -activity of the three most pronounced peaks of the Radon daughters spectrum.

CONCLUSIONS

At DCMN we can measure all the quantities that characterize the response of an activated charcoal canister exposed to constant conditions until equilibrium is reached with both environmental humidity and Radon. Based on these data, we are developing the analysis of the canister response when conditions of exposure undergo dynamic transients.

INTERCOMPARISON OF RADON EMANATION IN MOROCCAN AND TUNISIAN PHOSPHATE ROCKS

ABSTRACT

We suggested a method for measuring the emanation of radon gas of phosphates mineral from different origins using solid state track nuclear detectors (CR39 and LR115) with the aim to demonstrate radioactivity effects on the human.

1- INTRODUCTION

Les phosphates sédimentaires, de part leur mode de formation géologique contiennent les isotopes ^{238}U et ^{235}U de l'uranium, à l'état de traces, ainsi que leurs descendants. Parmi ceux-ci le radon, élément radioactif gazeux, émane de ces minerais et se retrouve dans l'air avoisinant. On conçoit donc qu'en détectant ce gaz et en le mesurant, on puisse l'employer comme traceur pour le suivi de la radioactivité dans les sites d'extraction et d'exploitation des phosphates.

En vue de cela, une méthode simple est proposée pour mesurer l'émanation du gaz radon: il s'agit d'une approche par détecteurs solides de traces nucléaires (DSTN)

Toutes les mesures sont effectuées en laboratoire, sur des échantillons de phosphates prélevés sur différents gisements (Maroc, Tunisie). Dans le cadre de cette étude préliminaire, nous avons comparé les émanations en radon issu de ces minerais afin d'évaluer l'activité volumique due à ce gaz.

2- LE RADON

Gaz radioactif, le radon existe dans la nature sous forme de trois isotopes: l'Actinon ^{219}Rn de la famille de ^{235}U , le Thoron ^{220}Rn de la famille de ^{232}Th et le Radon ^{222}Rn issus de la famille de ^{238}U . A cause de leurs périodes respective (3,9 s ; 55 s et 3,8 j), seul le ^{222}Rn peut être utilisé comme traceur pour le suivi de la radioactivité dans les gisements de phosphate.

Le radon 222, résulte du radium 226 par désintégration alpha. La mesure et le suivi de la concentration du radon 222 présente également un intérêt majeur en radioprotection, ce gaz étant le principal composant de la radioactivité atmosphérique. Ce gaz présente donc un risque radioactif dans et autour des gisements de phosphates qui présentent des teneurs non négligeables en éléments radioactifs (de l'ordre de la centaine de ppm) et c'est une raison supplémentaire pour réaliser la mesure du potentiel d'émanation en radon.

3- MESURES DE L'EMANATION EN RADON 222

3.1- Détecteurs Solides des Traces Nucléaires (DSTN)

3.1.1- Caractéristiques

Le passage d'une particule (ici particule alpha) chargée dans un diélectrique minéral ou organique, entraîne l'apparition d'une zone de dépôt appelée "trace latente". Un traitement chimique approprié permet de développer ces traces latentes pour les rendre visibles et mesurable en microscopie optique. Dans notre étude nous avons utilisé deux types de DSTN : un polycarbonate d'allyl diglycol (CR39) et un nitrate de cellulose (LR115)

DSTN	Nom commercial	Plage de détection en énergie (MeV)	Révélation par voie chimique
Nitrate cellulose	LR115 (Kodak)	1,5-4,5	2,5N (NaOH) 60°C - 1h30
Carbonate d'allyl	CR39 (Tastrak)	0,1->20	7N (NaOH) 70°C-3 à 6h

Tableau: Caractéristiques des détecteurs solides de traces nucléaires utilisés

3.1.2- Réponses des DSTN (CR39 et LR115)

Une étude de la réponse des DSTN (CR39 et LR115) en fonction du temps a été réalisée, sur une période de 20 jours (Fig.1). On observe que la réponse des deux DSTN est proportionnelle au temps. Par ailleurs, dans cette expérience, et avec les conditions de développements employés, on constate une sensibilité 7,5 fois plus grande de CR39 par rapport au LR115. Ceci peut s'expliquer par des plages de détection en énergie différentes (cf. tab.1) et par des types de traces développées dissemblables.

Fig.1: Evolution de la densité de traces avec le temps

Fig.2: Schéma de principe d'un dosimètre

3-2. Détermination des conditions expérimentales

Une étude préliminaire est réalisée pour déterminer les conditions optimales pour mesurer l'émanation en gaz Radon. Ces mesures sont réalisées pendant 30 jours en laboratoire avec des dosimètres (fig.2) contenant 15 g de phosphates.

Les échantillons de phosphates sont tamisés pour séparer les grains de phosphates de différentes tailles, la mesure de l'émanation en gaz radon est réalisée sur dix fractions granulométriques de 80 à 1000 μ . On a mis ainsi en évidence que l'émanation est la plus importante pour la fraction comprise entre 315 et 500 μ (fig.3). Nous avons donc adopté cette fraction granulométrique, pour la suite de notre travail.

3.2.2- Détermination de la distance DSTN-surface de phosphate

Nous avons comparé les densités de traces alpha enregistrées par les DSTN en fonction de la distance DSTN-surface de phosphate (fig.4); on observe sur celle-ci qu'à partir d'une distance de 7,5 cm il existe un palier. On peut en déduire qu'à partir de cette hauteur, seules les désintégrations alpha du radon 222 sont enregistrées.

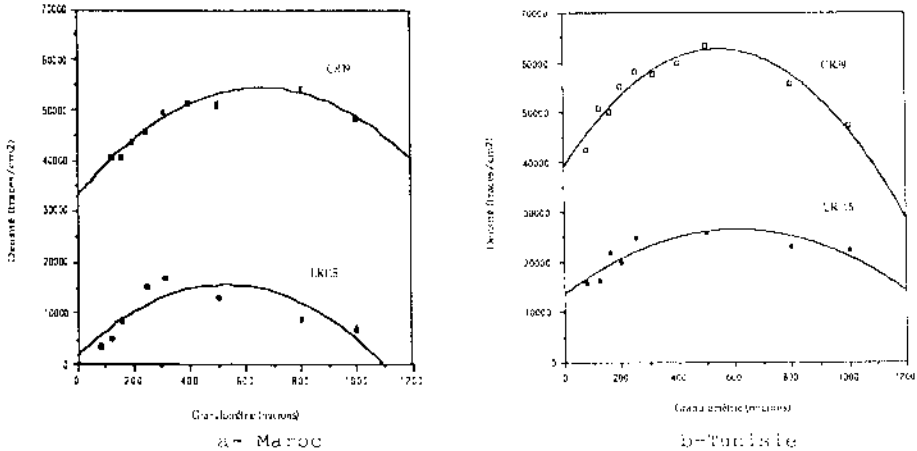

Fig.2: Evolution de l'émanation en radon en fonction de la granulométrie

Fig.3: Evolution de la densité de traces en fonction de la hauteur

3.3- Détermination du potentiel d'émanation en radon 222

3.3.1- Choix des phosphates

3.3.1- Choix des phosphates

Nous avons effectué des mesures sur des échantillons de phosphates prélevés sur les gisements de Gafsa en Tunisie et de la région de Gantour au Maroc.

3.3.2- Résultats

Au Laboratoire, une source de radon et des appareils de mesures en continu nous ont permis d'étalonner la réponse en radon des DSTN utilisés. D'après cet étalonnage, nous avons pu déterminer l'activité en radon 222 dans les phosphates.

Phosphates	Densité (traces/cm ²)	Activité volumique (Bq/m ³)	Activité volumique/heure (Bq/m ³ /h)
Gantour (Maroc)	CR39 21500	16348,09	22,7
	LR115 5460	18357,78	25,49
Gafsa (Tunisie)	CR39 10654	8022,94	11,142
	LR115 3756	12215,032	16,96

Une étude comparative a été réalisée en spectrométrie gamma à partir d'un détecteur Ge(hp) pour évaluer la concentration en uranium dans ces phosphates. Les résultats sont cohérents avec ceux obtenus par la méthode des DSTN.

4- CONCLUSION

Cette étude préliminaire a montré qu'il est possible d'effectuer la mesure du potentiel radon des phosphates par DSTN. Cette grandeur est en effet primordiale pour, d'une part estimer les tonneaux en radioéléments dans ces phosphates et d'autre part évaluer leur risque radiologique.

MEASUREMENTS OF REGIONAL DISTRIBUTION OF ^{222}Rn CONCENTRATION
and ANALYSIS ON OPTIMAL ALLOCATION OF MONITORING STATIONS

Hirokuni YAMANISHI¹, Yukitaka TKEBE and Takao IIDA

Department of Nuclear Engineering, Faculty of Engineering,
Nagoya University, Chikusa-ku, Nagoya 464 01, Japan

ABSTRACT

Outdoor ^{222}Rn concentrations were measured with electrostatic integrating radon monitors (EIRM) at 40 points around Nagoya, in which fifteen sets of 2-month-exposure data over 2.5 years were obtained. Seasonal variation of ^{222}Rn concentration showed a clear pattern which had a spring to summer minimum and an autumn to winter maximum. Annual mean ^{222}Rn concentration ranged from 3.5 to 11.7 Bq m⁻³ depending on locations. From the obtained regional distribution of ^{222}Rn concentration, optimal allocation of measuring instruments was analysed. As a result, it was expected that the same concentration distribution could be obtained with less instruments.

INTRODUCTION

Measurements of regional distribution of ^{222}Rn (radon) concentration have been rare due to lack of proper detectors which enable us to conduct simultaneous measurements at many points for a long time. Information on the regional distribution of ^{222}Rn concentration and its time variation is important to study radon in relation to geological features, ^{222}Rn exhalation, and its behaviour in the atmosphere. Such information is also important to evaluate lung dose precisely. Based on such a background, measurements of outdoor ^{222}Rn concentration were implemented in an area around Nagoya to obtain its regional distribution and time variation.

INSTRUMENT

To measure the regional distribution in large area, monitors should be cheap and maintenance free for a long time. To meet such demands, the most appropriate device will be passive monitors. In this study, we used electrostatic integrating radon monitor (EIRM) developed by Iida et al.⁽¹⁾. It is simple and easy to handle, and can measure low level

¹Present address ; National Institute for Fusion Science,
Chikusa ku, Nagoya 464 01, Japan

outdoor ^{222}Rn concentration as its sensitivity is 20 times higher than cup methods.

The EIRM is a passive ^{222}Rn monitor, which accommodates a cellulose nitrate film and has electrostatic field in its interior to collect charged ^{218}Po . Tracks recorded on the CN films are enlarged by etching for 180 min at 60°C in 2.5 N NaOH solution, and are counted through a microfiche reader. The lowest detectable concentration is 1.2 Bq m^{-3} for a 2-month-exposure.

MEASUREMENTS

The measurements were done in an area within 100 km from Nagoya University. Figure 1 shows the map of the area. The total number of monitoring stations was 40. EIRMs were settled at about 60 cm above the ground. In Nagoya City, the EIRMs were distributed in particular densely so that we could check the data consistency among nearby stations. The period of measurements was from August 1985 to January 1988 at half of the 40 stations, and from December 1985 to March 1987 at the other half. Results were obtained as an average of 2 month interval.

RESULTS

The annual mean ^{222}Rn concentrations are shown in Figure 1. They scatter uniformly between 3 and 12 Bq m^{-3} . The areas of high and low levels correspond to mountainous regions and plains near the sea, respectively. The distribution patterns were nearly the same among the 15 periods while their levels differed largely. The ^{222}Rn concentration at each station was low from spring to summer,

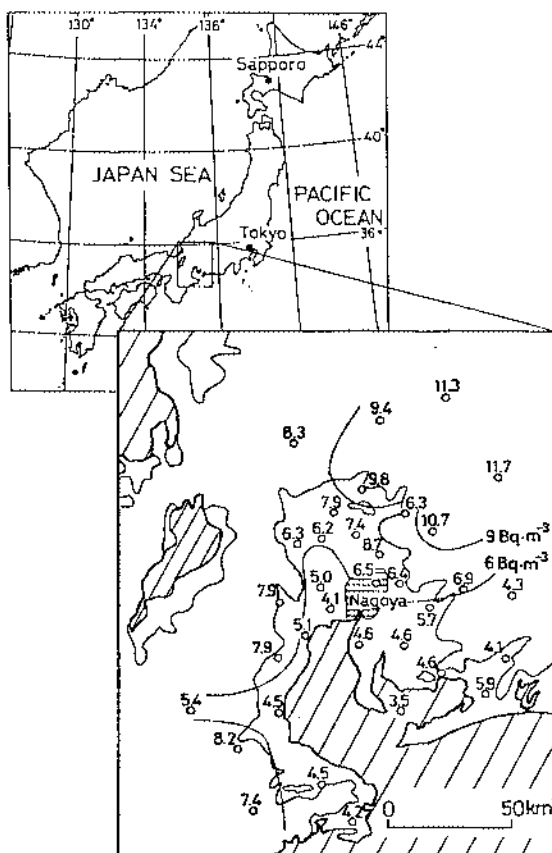

Fig. 1 Map of ^{222}Rn measurement points around Nagoya and annual mean concentrations

and high from autumn to winter. Amplitude of seasonal variations were between factors 1.2 and 2.8. In the mountainous regions, the mean ^{222}Rn concentration was high and fluctuated widely between 6 and 11 Bq m^{-3} . Near the sea, on the contrary, it was low ranging from 3 to 6 Bq m^{-3} .

In Nagoya City, the differences among stations fell within experimental uncertainty. This indicates that the concentration would be almost uniform within an about 10 km scale⁽²⁾, if it is a plain with uniform geology.

OPTIMAL ALLOCATION OF MONITORING STATIONS

When we measure a regional distribution of atmospheric radon concentration, we must solve a problem how monitoring stations allocate. Methods of optimal allocation of monitoring stations have been developed in the field of air pollution monitoring. In the present study we looked for optimal allocation of monitoring stations with the view of measuring a regional distribution as precise as possible with limited measuring instruments.

For simplification of calculation, total area was segmented to "cell" that was a square of 6 km x 6 km. A concentration in one cell was regarded as uniform. A concentration of every cell was estimated with measured value of ^{222}Rn concentration by simple interpolation method.

It was regarded that a certain cell "x" represented cells which were within 25 km from it, and whose concentration differed from that of cell "x" within 1 Bq m^{-3} . Figure 2 shows reset stations and their representative areas. Each monitoring station is indicated by small circle, and its represented cells are marked the same alphabet as the station. If a cell belongs to several

Fig.2 Allocation of monitoring stations and their representative area

representative area. It is put in alphabetical order of stations which occupy it. Summary process of the allocation is described as follows⁽³⁾. In the beginning, representative area was estimated for every cell respectively. The cell whose representative area had the most cells was chosen as the first station. The second station or subsequences was set at a cell which had the largest representative area as a result of subtracting overlap cells with the representative areas of the station set before. In consequence, imaginary monitoring stations were set alphabetically as shown in Figure 2. Fifteen sets of representative area cover 92 % area of all cells.

CONCLUSION

Regional distribution of ^{222}Rn concentration around Nagoya was measured with AIRMs. The concentration had a seasonal variation that it was low in spring to summer and high in autumn to winter. The level ranged from 1.9 to 11.7 Bq m^{-3} in spring, and from 2.3 to 18.9 Bq m^{-3} in autumn. Besides, the concentration was high and fluctuated widely in mountainous regions while it was low and varied to less extent near the sea.

Optimal allocation of monitoring stations was analysed with measured ^{222}Rn concentrations. By selecting new stations whose have large representative area, it was expected that the same distribution of concentration could be obtained with the half stations than existing stations.

INVESTIGATION ON FOOD RADIOACTIVITY AND ESTIMATION OF INTERNAL DOSE BY INGESTION IN CHINA

H. Zhu, J. Zhang, P. Fan, X. Huang and S. Wang

Institute of Radiation Medicine, Chinese Academy of Medical Sciences, P.O. Box 71, Tianjin 300192, China

ABSTRACT

Activity concentrations of ^{40}K , ^{87}Rb , U , Th , ^{226}Ra , ^{228}Ra , ^{210}Pb , ^{210}Po , ^{227}Ac , ^{14}C , ^3H , ^{90}Sr , ^{137}Cs , ^{144}Ce and ^{106}Ru in 14 categories of Chinese food were determined in 1982-1986. The food samples were collected from normal radiation background area and two elevated natural radiation areas. Based on typical Chinese diet composition, our determined results of the food and reported available typical contents in water, Annual Intake and Committed Dose Equivalent of these radionuclides by ingestion for Chinese male adult were estimated. The total Committed Dose Equivalent is about 0.77 mSv/a. Relative contributions of different categories of food and radionuclides to the total are discussed.

INTRODUCTION

Internal dose of the public from environmental radiation by ingestion depends on radionuclide concentrations in different categories of food (including drinking water) and local dietary habits. Asian dietary habits are quite different from those in other parts of the world. Purposes of this paper are presentation of current levels of important radionuclides in Chinese food and drinking water and estimation of resulting Annual Intake (AI) and Committed Dose Equivalent (CDE).

MATERIALS AND METHOD

Activity concentrations of ^{40}K , ^{87}Rb , U , Th , ^{226}Ra , ^{228}Ra , ^{210}Pb , ^{210}Po , ^{227}Ac , ^{14}C , ^3H , ^{90}Sr , ^{137}Cs , ^{144}Ce and ^{106}Ru in 14 categories of Chinese food were determined in cooperation with 30 radiation protection units during 1982-1986. The samples were collected from 14 provinces, one normal radiation background area and two elevated natural radiation areas. Almost all of the samples were got from lately harvested products. A given radionuclide in all samples was analysed in the same laboratory and measured with calibrated instruments by use of the same standard solution to ensure analytical quality. Almost in the same period as our survey, two other nationwide surveys on contents of some radionuclides in water were accomplished too and some available data have been published recently (1-3).

Based on typical composition of Chinese diet (4), our determined concentrations, reported mean contents of the nu-

clides in water and accepting 1.65 liter/day as mean consumption⁽⁵⁾, AI and CDE of these radionuclides by ingestion for Chinese male adult were estimated.

RESULTS AND DISCUSSION

1. Radionuclide contents in Chinese food and water

The results showed in Table 1 indicate that in normal radiation background area the concentrations of natural radionuclides in food and water were generally higher than those of artificial ones, ⁴⁰K is the highest in food, followed by ¹⁴C, ³H, ⁶⁷Pb, while ³H is the highest in water, followed by ⁴⁰K. In addition, some findings are of significance: quite high concentrations were noticed in certain kinds of food for particular nuclides, for example, tea and kelp for cesium nuclides, pork for ³H, ¹⁴C, ¹³⁷Cs and ⁹⁰Sr, egg for Ra. It was found that the contents of ¹³⁷Cs and ⁹⁰Sr nuclides in samples collected from Yangling high background area were higher than those from normal area, while around the Tsiming area, only contents of H-series nuclides showed to be obviously high.

Table 1. Average concentration range of radionuclides in various food and water

Radionuclides	Concentration range in food, Bq/g or Bq/l	Average concentration in water, Bq/l
⁴⁰ K	2.2-3.4x10 ¹	3.1
⁶⁷ Pb	0.53-1.9x10 ⁻¹	/
³ H	4.4x10 ⁻³ -4.9x10 ⁻¹	7.7x10 ⁻¹
²²⁶ Ra	1.4x10 ⁻² -1.0	1.1x10 ⁻²
²¹⁰ Pb	9.1x10 ⁻² -4.0	6.7x10 ⁻²
²¹⁰ Po	4.0x10 ⁻¹ -4.0	0.8x10 ⁻²
²²⁸ Rn	1.2x10 ⁻³ -0.2	0.1x10 ⁻²

¹⁰⁶ Ru	9.5x10 ⁻³ -5.2x10 ⁻¹	/

* including both artificial and natural sources

2. Public AI of the radionuclides by ingestion in normal radiation background area of China.

The estimation results showed in Table 2 indicate that ^{40}K , ^{14}C , ^3H and ^{87}Rb are the nuclides with more contribution to the total than the others. Most of these AI come from food, while only the AI for tritium and U come from drinking water.

Table 2. Public AI by ingestion for Chinese male adult ($\mu\text{Sv/a}$)

Radionuclide	Food		Water		Total
	AI	%	AI	%	
U Series: U	10.4	34.3	19.9	65.7	30.3
^{226}Ra	22.1	77.0	6.6	23.0	28.7
^{210}Pb	69.1	94.3	4.2	5.7	73.3
^{210}Po	69.8	95.2	3.0	4.8	62.8
Th Series: Th	5.5	89.8	0.6	10.2	5.9
^{228}Ra	30.2	89.3	3.6	10.7	33.8
Others: ^{227}Ac	0.3		/		
^{40}K	2.3×10^4	99.2	1.8×10^2	0.8	2.3×10^4
^{87}Rb	1.3×10^3		/		
^{14}C	1.6×10^4	97.5	4.0×10^2	2.5	1.6×10^4
^3H	2.1×10^3	31.3	4.6×10^3	68.7	6.7×10^3
4 Artificial nuclides	1.1×10^2	92.7	8.6	7.3	1.2×10^2

3. Public CDE of the radionuclides by ingestion in normal radiation background area of China

Based on above mentioned AI, public CDE of these nuclides were estimated and are showed in Table 3. Because

^{40}K in the body is under close homeostatic control, the CDE here is quoted from the world average⁽⁶⁾. It can be seen from the Table that the total CDE was estimated to be about 0.35 mSv, the part contributed by natural nuclides accounted 99.4% of the total, the most important contributors were ^{40}K , ^{210}Pb and ^{210}Po . The estimated value is quite consistent with the world average published in UNSCEAR 1986 Report⁽⁶⁾. The food with the biggest contribution to the total are vegetable, yam, flour, rice and water. In addition, It was found that the total CDE for U Series and Th Series nuclides in Yan jiang high background area were about 2.5 and 6.7 times those in normal area respectively, while in the U mining area, only the CDE of U Series nuclides was 6.4 times that in normal area and the value of Th Series was almost the same as that in normal area.

Table 3. Estimated CDB by ingestion for Chinese male adult

Radionuclide	Food (Sv)	Water (Sv)	Total (Sv)	Relative contribution(%)
U Series: U	6.7×10^{-7}	1.28×10^{-6}	1.95×10^{-6}	0.5
226Ra	6.9×10^{-6}	2.06×10^{-6}	8.96×10^{-6}	2.5
210Pb	9.7×10^{-5}	5.90×10^{-6}	1.03×10^{-4}	28.9

**DETERMINATION OF THE FACTORS THAT CONTROL MIGRATION
AND ENTRY OF RADON INTO BASEMENTS***

T.B. Borak, M.S. Gadd, D.C. Ward, M.S. Barry
Department of Radiological Health Sciences
Colorado State University
Ft. Collins, CO 80523, USA

Elevated concentrations of radon gas indoors are the result of a complicated combination of factors. This report describes results from a facility designed to test and verify theories of radon migration into underground structures. The buildings resemble miniature basements using conventional construction methods, but eliminate other confounding factors introduced by the activities of occupants. Sensors accumulate data on soil properties such as temperature, moisture, pressure differentials, and permeability, as well as outdoor meteorological conditions and indoor environment. Results indicate that indoor radon concentrations do not correlate with changes in the adjacent soil gas concentration or the rate that radon enters the structure. When no attempt is made to control the indoor environment, periods of highest indoor concentration occur when the rate of entry is low. Methods to identify the driving mechanisms and implication for mitigation and control will be described.

*Centre d'Etude sur l'Evaluation de la Protection
dans le domaine nucléaire (CEPN)
F-92263 Fontenay-aux-Roses, France

ABSTRACT

The dismantling project of the Belgian nuclear testing reactor BR3, which constitutes the object of a CEC research contract, requires the implementation of the ALARA principle on certain important operations. The major operations of the first phase consist of the decontamination of the primary circuit and the cutting of the thermal shield which are now practically terminated. The radiological optimization study is being carried out in collaboration with CEPN (Centre d'Etude de l'Evaluation de la Protection dans le domaine nucléaire, Fontenay-aux-Roses, France).

A general working sheme was developed, consisting of

- the elaboration of an evaluation methodology for the prediction of doses ;
- the identification and comparison of standard and alternative procedures ;
- the follow-up of the doses during the operation(s) and the feed-back to the predictions.

Aiming at the dose predictions, the operations fore-mentioned were subdivided into unitary or elementary tasks, each of them being characterized by its localization, dose rate, work volume or exposure time and an exposure coefficient.

Concerning the decontamination of the primary circuit, certain measures for dose reduction were identified and their influence on the dose predictions evaluated. As a result of the application of these measures and of the experience from the feed-back of early dose measurements, a reduction of 30 % in dose predictions was calculated. The collective doses observed during the execution of the operations differed from the predicted values by less than 20 %.

As far as the cutting of the thermal shield is concerned a special problem will be formed by the generation of secondary wastes (aerosol, scrap...).

INTRODUCTION

The BR3 reactor is a Pressurized Water Reactor with a

capacity of 11 MWe and had been operated from 1962 to 1987. Actually the SCK/CEN is dismantling or decontaminating certain parts of the reactor. The Commission of the European Communities selected BR3 as a pilot dismantling project for the 1989-93 R&D programme on the decommissioning of nuclear installations. The phases of dismantling/decontamination envisaged or completed until now, include :

- the decontamination of the primary circuit
- the cutting and elimination of the thermal shield (phase 1)
- the segmentation of the lower and upper core support assemblies and of the reactor vessel collar (phase 2)

The total contamination distributed on the inner surface of the primary circuit was estimated at 7 to 11 TBq before decontamination. The main contributors were Co-60 ($\approx 80\%$), Cr-51 (10%), Mn-54 (5%) and Co-58 (4%). Specific β γ activities were comprised between 200 and 1000 kBq/cm². Concerning the reactor vessel (Fig. 1) the neutron-induced activity of the lower and upper core support plates and the thermal shield is very high. For the thermal shield it amounted to 32-87 MBq Co-60/g and 1.0-3.6 MBq Mn-54/g at mid 1989. The activation of the reactor collar is very low due to its great distance from the reactor core.

ORGANIZING RADIOLOGICAL OPTIMIZATION (ALARA)

In recent years the SCK/CEN has done much effort in the field of radiological optimization (ALARA). The effective dose constraint at the SCK installations has been set at 20 mSv.y⁻¹ following international trends of reducing professional dose limits. Evaluations are being made of the feasibility to lower dose constraints still to 10 mSv.y⁻¹.

A project has been set up, including formation of staff members of SCK in ALARA procedures and radiological optimization studies in specific fields. Objects of such studies have been selected in the field of nuclear site restoration and in the field of the dismantling operations at BR3. However not the dismantling as a whole will be envisaged ; only specific parts of it will constitute the objects of the optimization.

Until now radiological optimization has been mainly involved in some large stereotype projects in the field of maintenance at nuclear power stations such as the replacement of steam generators. A dismantling project shows special features while all operations are only executed once. The CEPN (Centre d'étude sur l'évaluation de la protection dans le domaine nucléaire) has been contracted to execute the formation task and to support the radiological optimization of some specific dismantling operations.

DECONTAMINATION OF THE PRIMARY CIRCUIT

In the framework of the decontamination of the primary circuit of BR3 the tasks executed in collaboration with CEPN concerned :

- the choice of the decontamination process from a radio-

logical optimization point of view

- the application of an evaluation methodology for the prediction and analysis of doses
- the organization of follow-up of job-related doses during the operations
- the feed-back from observations to predictions and the drawing of lessons from the experience.

In this stage, the optimization know-how being limited and the procedure of decontamination being nearly determined, based upon the experience of the 1975 decontamination, the identification and comparison of standard and alternative procedures for optimization purposes has not been worked out.

Concerning the choice of the decontamination process, technical requirements already reduced potential processes to LOMI (Low State Transition Metal-ion reagents) and CORD (Chemical Oxidizing Reducing Decontamination). From the point of view of radiation protection and efficiency the two processes were very similar. Nevertheless CORD was designed as the better one since it yielded lower waste volumes. During this evaluation it was also pointed out that irrespective of the decontamination process the potential for workers' exposure is more important during the preparatory phase, when checking the installation and verifying valves, pumps ... (several years after the last outage !), than during the decontamination itself.

The methodology for the prediction and analysis of doses was based upon the principle of dividing the operations into elementary tasks, each of which being characterized by the geographical zone, the dose rate and the volume of work (man.h). The persons required for each elementary task were to be characterized by their speciality (expertise), working conditions and exposure coefficient (the ratio between his individual exposure dose rate and the representative value for the zone). For the calculation and analysis of dose values in this way, the computing programme DOSI ANA of CEPN was applied.

The decontamination of the primary circuit has been divided into approximately 100 elementary tasks, 90 of them being preparatory operations. A first prediction of the total collective dose amounted to 0.199 man Sv, 0.195 man Sv being due to the preparatory phase. From the analysis of the predicted dose some important conclusions could be drawn. Considering an annual individual dose limit of 20 mSv and the different types of expertise required, a total number of 14 technicians were to be provided for, 9 persons of which could reach the annual dose limit within a period of 3 to 4 months. The individual reference level of 2 mSv month⁻¹ was foreseen to be exceeded or attained for a number of 20 elementary tasks.

During execution of the tasks the following-up of doses was carried out applying job-related dosimetry. In that time the dosimeters used were stylo-type ones ; it was recommended that more precise, electronic devices should be applied manageable with processor and PC. With one third of the

elementary tasks executed, the comparison between predicted and measured doses showed an O/P ratio of 0.85. However differences between predictions and observations were considerably higher for some elementary tasks.

At that time it was decided to undertake some dose reduction measures such as the use of biological shielding (lead, wool) on the reactor cover, the filling of some components of the circuits with water and the reduction of the number of bolts to be applied on the reactor cover, which lowered dose predictions with 25 %. Especially the last measure was very effective in this respect.

From the following-up of the job-related doses so far it was also learnt that for rather immobile positions on the operating deck, dose rates had been underestimated and for rather mobile tasks on the pool-bottom the influence of near-by sources overestimated. The correction of these erroneous assumptions yielded another net decrease in predicted doses of 5 %.

A new prediction of doses was then made and a collective dose of 0.142 man Sv was calculated.

The predicted and observed doses are graphically depicted on Fig. 2. As may be noticed the difference between the second prediction and the observations is very small (observed dose: 0.140 man Sv). Decontamination factors between 2 and 16 at various reference points on the primary circuit have been obtained.

CUTTING OF THE THERMAL SHIELD

The cutting of the thermal shield of the reactor has been executed with three techniques in order to gain experience for further segmentation operations. These operations are : electro erosion (in-situ) ; mechanical sawing (in-situ) ; plasma torch (in separate chamber).

Some characteristics of these techniques with respect to the cutting of the thermal shield are indicated in the following table.

	time for cutting 1 m	width of the cut	waste produced for cutting 1 m
electro erosion	29 h	7 mm	4.2 kg
mechanical sawing	2.5 h	4 mm	2.4 kg
plasma torch	3.3 min	11 mm	6.5 kg

Also for these operations a real optimization study could not be started, because of the requirements for technical experimentations which reduced the number of options that could be taken into account considerably, and because of the late introduction of optimization considerations in the planning. It was then decided that experiences from phase 1 and phase 2 operations be used to develop and improve equipment and procedures needed for optimization purposes.

One of the items which had to be improved concerned the

follow-up of job-related doses. Therefore an electronic computerized dosimetric system (GAMMA COM) was put into service. With this system, indications about residence times at different ambient levels of radiation can be obtained.

However in the optimization process for the cutting operations not only external dose rates are important. Other radiological factors such as exposure through other pathways and the generation of waste are very important. During the cutting operations important quantities of solid and liquid waste are generated. These include not only the cutted segments but also secondary waste such as aerosols, ions dissolved in the water, scrap, dross, etc... The finer forms of waste can give rise to internal contamination of the operators if not adequately filtered. The whole package of secondary waste (including filters and resins used for purifying air and water) pose a problem of collection, transport and disposal. The way of solving this problem may also be subjected to an optimization study. Potentials for exposure due to accidental releases have also to be taken into account.

The follow-up of the cutting operations revealed some elementary potentials for dose reduction :

- the unnecessarily high number of personnel present at the working place during certain operations
- the additional number of manipulations which were necessary because of the unavailability of the transport container for the waste in due time
- the obstruction of the working place with equipment and waste offering potentials for accidents and increasing working times

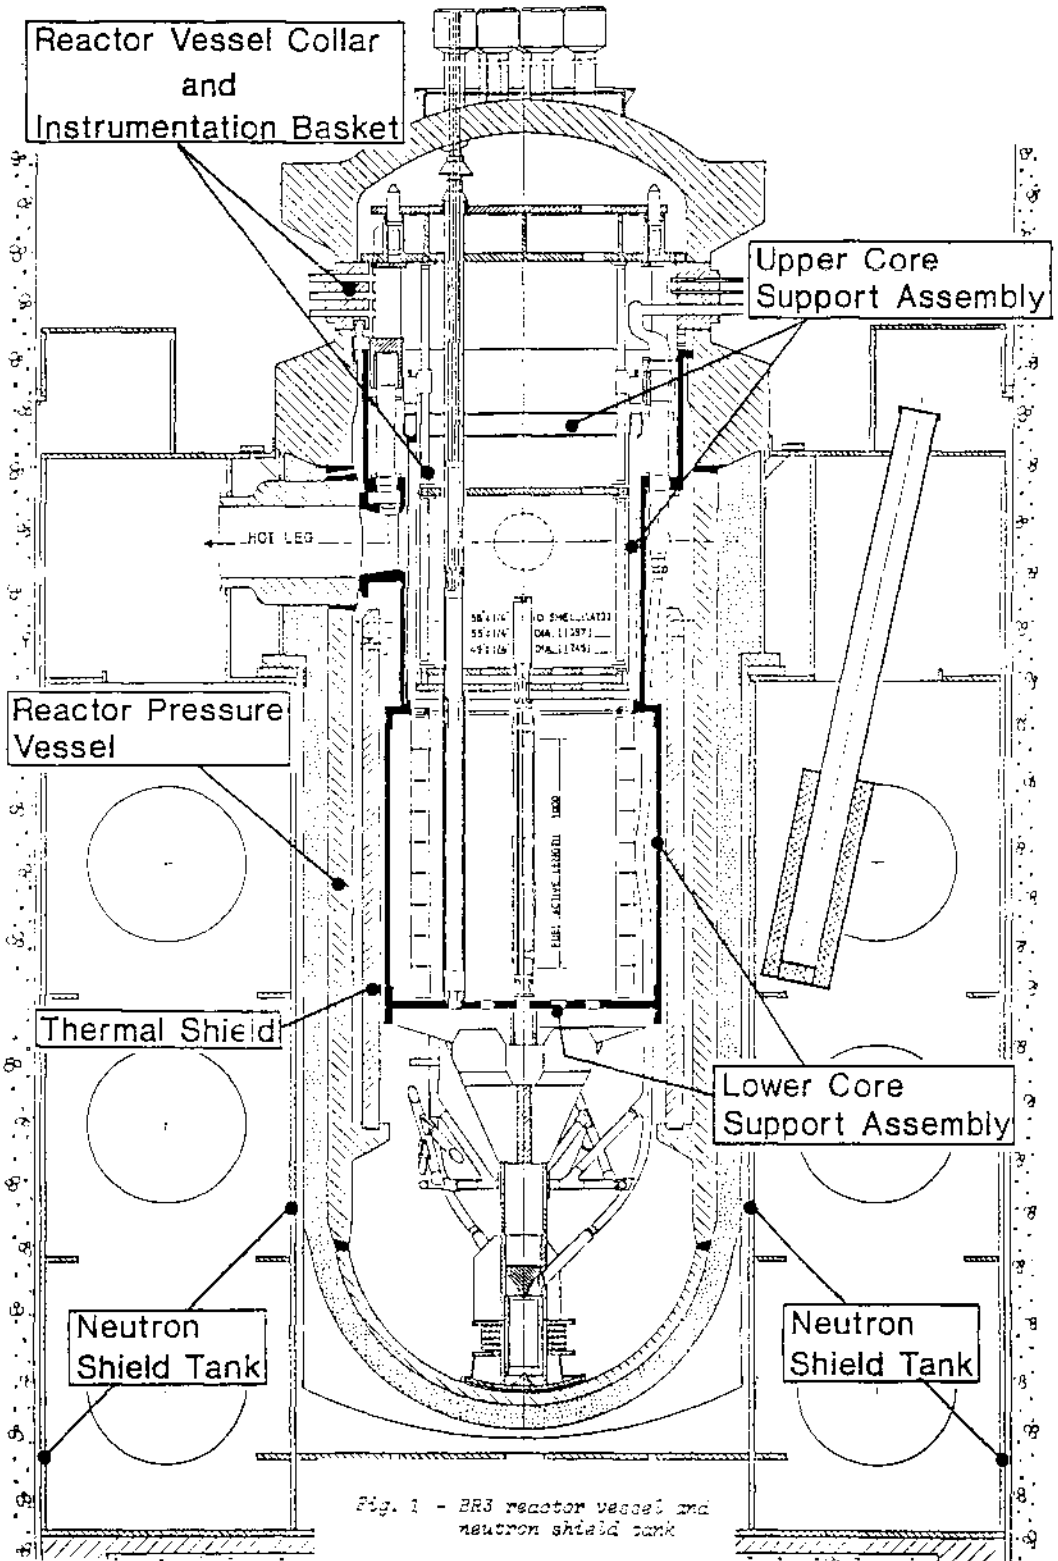

CONCLUSIONS

- For all phases of the dismantling operations at BR3 executed so far, the radiological optimization considerations have been introduced too late. In order to be able to conduct the optimization in an efficient way it must be taken into account from the very beginning.
- Although an efficient optimization has not been possible some interesting experience was gained and important conclusions were derived from the dose prediction and analyses for some operations (e.g. with respect to the number of operators-technicians being necessary).
- The necessity or desirability of the presence of an ALARA coordinator at the site was experienced.
- Radiological factors other than external doses are also to be allowed for in the optimization process (internal contamination, quantities of waste, potentials for exposure).

ACKNOWLEDGEMENTS

This work has been performed in the framework of contract n° F12D-0003-B(TT) with the Commission of the European Communities. The collaboration of the BR3 dismantling project team and of the health physics team of the SCK/CEN,

respectively coordinated by F. Motte and J.P. Deworm, was highly appreciated.

ELECTRICITE DE FRANCE
SERVICE DE LA PRODUCTION THERMIQUE
PARIS - LA DEFENSE

CHINON A2 DISMANTLING

Application of the principles retained by EDF for its global decommissioning strategy resulted in the achievement of an IAEA-level 2 on the Chinon A2 installation.

This decision has been taken after the analysis of the safety parameters, radiological characteristics of the installation, in function of the techno-economic consequences of the radioactive waste management and the conditions of radioprotection.

Containment and in-situ intermediate storage of the own wastes of the installation were the main operations carried out. The global dosimetric cost is estimated at roughly 2.1 man-SV.

INTRODUCTION

La centrale de CHINON A2 fait partie du site nucléaire de CHINON, situé sur la rive gauche de la Loire et qui comprend deux types d'installations :

- 3 tranches (A1, A2 et A3) de la filière à uranium naturel, graphite-gaz (UNGG) respectivement mises en service en 1963, 1965 et 1966 et arrêtées en 1973, 1985 et 1990.
- 4 tranches (B1 à B4) de la filière à eau pressurisée (REP) respectivement mises en service en 1982, 1983, 1986 et 1987.

1 - CARACTERISTIQUES DE L'INSTALLATION

La tranche de CHINON A2 dont le circuit de refroidissement (4 boucles distinctes) est situé à l'extérieur du caisson du réacteur appartient à la première génération de centrales de la filière UNGG. D'une puissance électrique de 210 MW, elle a été couplée au réseau national en 1965 et a été arrêtée en juin 1985 après 132 000 heures de fonctionnement soit une disponibilité moyenne d'environ 70 % (86 % pour les cinq dernières années) et une production de 23,6 milliards de Kwh correspondant à l'utilisation de plus de 133 000 éléments combustibles.

Le combustible a été déchargé entre septembre 1985 et mai 1986 et son évacuation vers le Centre de Retraitement de MARCOULE s'est déroulée de janvier 1986 à avril 1987.

2 - BILANS MATIERE ET RADIOLOGIQUE

Le rayonnement gamma à l'intérieur du caisson est actuellement de l'ordre de 4 Gy/h et est essentiellement dû au Co 60.

Le tableau ci-dessous mentionne la masse et l'activité calculée au 1.1.1988 des principaux composants.

	Nature du composant	Masse (t)	Activité (GBq)
Coeur	Caisson	980	2000.10^3
	Structures internes	1490	14700.10^3
	Empilement graphite	1730	210.10^3
Hors Coeur	Echangeurs de chaleur	2760	1500
	Circuit primaire et soufflantes	855	115
	Circuits annexes	370	155

On peut relever un facteur 10^3 à 10^4 entre l'activité due à l'activation des composants internes du coeur et celle due à la contamination exclusivement sur leurs faces intérieures des composants situés à l'extérieur du réacteur.

L'activité massique la plus élevée est rencontrée sur les circuits de détection de rupture de gaine (1640 Bq/g). Le niveau de contamination surfacique des circuits est situé entre 1500 et 4000 Bq/cm². L'aspect radiologique caractérisant les éléments de circuits extérieurs au coeur, révèle un spectre de radio-éléments peu contraignant car les incidents sur le combustible sont restés rares, de faible importance et rapidement détectés et qui se traduit par l'absence d'émetteur alpha ; le spectre type déterminé à la date de l'arrêt de l'installation est le suivant :

Co 60 : 94,5 %
Mn 54 : 5,5 %
Cs 137 : quelques traces sur quelques prélèvements

3 - STRATEGIE DE DÉCLASSEMENT RETENUE

Conformément à la politique générale d'Electricité de France en matière de déclasserment des installations nucléaires, il a été décidé, sur la base d'études technico-économiques, prenant en compte en particulier l'état radiologique et physique de l'installation, de réaliser un déclasserment de niveau 2 AIEA suivi d'une période d'attente avant démantèlement total de quelques dizaines d'années. Pour parvenir à cet état intermédiaire, il a été nécessaire de réaliser les travaux suivants :

- isolement et confinement du réacteur avec obturation des traversées au plus près du caisson,
- confinement des 4 échangeurs de chaleur non démontés dans leurs locaux,
- démantèlement des circuits annexes,
- découpe du circuit primaire en tronçons de 1,4 m de longueur,

- conditionnement des circuits annexes dans les tronçons du circuit primaire ainsi obtenus, obturés aux deux extrémités et entreposés dans les quatre locaux des échangeurs,
- assainissement des locaux ayant comportés des circuits démantelés,
- maintien en dépression du réacteur et des échangeurs permettant ainsi un contrôle de l'intégrité du confinement.

Il est à souligner que l'entreposage intermédiaire in-situ des déchets métalliques, volumineux et peu actifs a été préféré au stockage définitif sur un centre agréé toujours très coûteux.

4 - DISPOSITIONS PARTICULIERES ADOPTEES POUR LES TRAVAUX

Les techniques mises en oeuvre dans les travaux de démantèlement étant tout à fait classiques, et n'ayant recours ni à l'utilisation de robots, ni à la téléopération, il a été nécessaire, afin de limiter la dosimétrie du personnel et d'éviter la sortie de zone contrôlée de tout élément radiologiquement non sain, de mettre en oeuvre certaines dispositions particulières suivantes :

- établissement de cartographies précises des débits d'exposition dans les locaux d'intervention,
- création d'une entrée-sortie de zone contrôlée unique pour les personnels et d'une sortie unique avec contrôle obligatoire pour les matériels supposés inactifs,
- adoption d'un système dosimétrique individuelle automatique complémentaire au film dosimétrique réglementaire et permettant d'affecter les doses par nature de travaux,
- installation dans la zone contrôlée d'un atelier de décontamination équipé d'un nettoyeur haute pression pour les pièces susceptibles d'être décontaminées et d'un atelier de traitement des matériaux pour la fabrication des colis de démantèlement,
- création dans la zone contrôlée de diverses zones délimitées et protégées d'entreposage temporaire de produits particuliers en attente de traitement.

5 - BILAN DOSIMETRIQUE

Les travaux de post-exploitation et de confinement menés depuis 1986 jusqu'à fin août 1991 par un effectif de l'ordre de 50 personnes (20 agents EDF - 30 agents d'entreprises) ont abouti à un total en dose intégrée de 1,94 h.Sv. Compte-tenu des travaux restant à effectuer, le niveau 2 devrait conduire à une dose intégrée globale d'environ 2,1 h.Sv.

Le diagramme ci-dessous illustre ce bilan et la répartition des doses en fonction des principaux chantiers effectués (exprimées en h.Sv).

On note que ces doses ont été supportées à 14 % (0,28 Sv) par le personnel EDF et 86 % (1,66 Sv) par les entreprises extérieures intervenantes. Par ailleurs, la dose prise par le personnel EDF, essentiellement affecté à des tâches très diversifiées dans l'installation représente près du tiers de celle de la rubrique "divers" et est tout à fait insignifiante dans les autres chantiers.

6 - CONCLUSION

Le déclassement au niveau 2 de l'installation CHINON A2 tel que défini par l'exploitant a conduit à des travaux de démantèlement importants liés à l'architecture de la tranche et qui ont pu être réalisés à un coût dosimétrique tout à fait acceptable grâce à :

- des choix de solution simples facilités par la parfaite connaissance des installations par le personnel chargé des études et des travaux,
- une organisation rigoureuse et une préparation des travaux dans l'esprit des travaux de maintenance habituels (assurance de la qualité, procédures de consignation et de travail, radioprotection, etc.),
- des données radiologiques de l'installation relativement peu contraignantes comparativement au niveau de la contamination rencontrée dans les réacteurs REP.

Radiological Hazards from Deposits of Tin-Smelting Slag and the Problems of Site Clearance and Disposal

J C Gilmore and R G Jackson

Wigshaw Lane, Culcheth,
Warrington, Cheshire, WA3 4NE
ENGLAND

ABSTRACT

High background dose rates from tin smelting slag used as sea defences led to the identification of our client's site as one of a number with a potential external and airborne radiological hazard. Surveys showed that access to the affected area should be restricted as a precaution. Samples taken for analysis fell just below the level of activity which would require the material to be disposed of as radioactive waste. To ensure safe disposal a scheme is being developed to dilute the slag with general building rubble before disposal to an appropriate landfill tip.

INTRODUCTION

From the end of the nineteenth century until the early 1970's tin smelting was carried out in Bootle and surrounding areas near Liverpool and the river Mersey in the UK. The tin bearing ore contains significant quantities of the naturally occurring radioactive isotopes ^{238}U and ^{232}Th and their daughters. The specific activity is enhanced in the slag during the smelting process and in large quantities the slag can present a significant radiation hazard.

The collapse of the industry in a depressed area of the country means that the problem arises on derelict or semi-derelict land. In addition the owners of the land are often not familiar with radiation protection legislation and its implementation.

This paper describes the provision of advice and assistance in radiation protection to the owners of a trading estate part of which had once been part of a tin smelting works. Operations included advice on immediate protection measures, identifying and contacting the relevant authorities and the arrangements for clearing the site and disposing of the material.

DISCOVERY OF PROBLEM

The first indication of the existence of a radiological hazard came during a routine survey being carried out for Sefton Metropolitan Borough Council. Radiation levels over 10 times the normal background were traced to rocks in the river estuary put in place as part of sea defences. The rocks turned out to be made up of waste slag taken from local smelting works.

An assessment of the hazard to members of the public using the area concluded that the critical group were likely to be dog owners out exercising their animals (the area is away from

beaches which are likely to be frequented during the summer). It was estimated that an individual would need to be exposed for 70 hours for doses to exceed 500 μSv which was thought to be considerably more than would occur annually. The council therefore decided that no further action was required with respect to the sea defences.

However, Her Majesty's Inspectorate of Pollution (HMIP), which is responsible, *inter alia*, for administration of the Radioactive Substances Act (ref 1), were informed. HMIP compiled a list of sites where a hazard may exist and notified the owners. Following a visit to an industrial estate, part of which had once been part of a tin smelting works, the owners of the site asked us for advice on immediate precautions which were likely to be necessary and long term measures to remove the problem.

NATURE OF THE HAZARD

The tin bearing ore contains ^{238}U and ^{232}Th and their daughters. The thorium decay series includes ^{208}Tl with a 2.6 MeV gamma emission. This means that although the specific activity is low large quantities can exhibit significant external dose rates because of the build up of radiation from within the bulk material. Each decay chain includes an isotope of radon gas which could result in significant radiation doses if it diffused into buildings constructed over the slag without proper precautions.

From the point of view of the site owners the problem is therefore one of controlling the hazard from external radiation before any development takes place and taking steps to control the additional hazard from airborne activity in any buildings on the site. One such site in the area had been developed for housing and all the slag had had to be removed before building could commence to ensure that there would be no abnormal radon hazard.

In formulating a proposal for the disposal of the smelting slag a major consideration must be that the problem is not simply transferred to another site.

SURVEY RESULTS

The survey of the site carried out by HMIP had shown areas with dose rates up to 6.5 $\mu\text{Sv h}^{-1}$. While this is not particularly high in a nuclear establishment it is high for an area where there are no restrictions on access. An initial survey at the start of the contract confirmed the results and further defined the high dose rate areas as being associated with a particular type of material and a sample was taken for analysis.

A more detailed survey was carried out during which a number of samples of various types of material were taken for analysis from different depths with the aid of a mini-excavator. In areas previously inaccessible due to brambles dose rates up to 10 $\mu\text{Sv h}^{-1}$ existed at 1m above the surface. A plan of the site with associated dose rates is shown in fig 1.

Table 1 shows some results of the samples taken from the locations shown in fig 1. Only representative nuclides below and above the radon isotopes need be measured equilibrium levels soon become established after the processing. Values in brackets have been inferred from other measurements; samples were analysed by different laboratories but there was good agreement between them. The slag (samples 2, 3, B(2) and C(2)) is hard vitreous material but around 30% of the ^{220}Rn is lost before it decays to ^{216}Po and around 60% of ^{222}Rn diffuses out.

It was found that the area was covered with slag and rubble to a depth of approximately 1.5m. About 1000m² was found to consist of the more active 'black slag' with about 2500m² of less active 'grey slag' weighing approximately 1900 and 3200 tonnes respectively. The remainder of the material is building rubble.

The total activity has been estimated to be 11.3 GBq ^{238}U and 26.9 GBq ^{232}Th .

REMEDIAL MEASURES

Following the initial site visit and discussions with the Factory Inspector from the Health and Safety Executive (HSE) the owners were advised to fence off the affected area. Strictly speaking as no operations were being carried out in the area it does not come within the category of work with ionising radiations but it was considered prudent to restrict access.

Normally before radioactive waste may be accumulated the operator must register under the Radioactive Substances Act. However, as the activity is naturally occurring an exemption order under the act (ref 2) applies and registration is not required. Similarly a licence is normally needed for the disposal of radioactive material with a specific activity exceeding very low limits (e.g. Thorium: 2.6 Bq m⁻³). The exemption order allows disposal of waste containing natural activity up to 15 Bq m⁻³.

As can be seen from Table 1 the levels of activity just fall below the limit and could therefore be disposed of without reference to HMIP. However, this would only transfer the problem from one location to another and it could resurface at a later date. The solution which has been proposed is to 'dilute' the active material with general building rubble. This has been used successfully on waste from other sites in the locality. In the current recession the site owner has no plans at present to develop the affected area and currently only requires a disposal route to be identified and an outline of arrangements to ensure the protection of workers during removal operations. These will be prepared in the near future in consultation with HMIP and the HSE and put on hold until such time as they are required.

ABSTRACT

The JPDR decommissioning program was begun in 1986, by the end of March 1991 most of activated and contaminated equipments were removed. The cumulative collective dose equivalent since initiation of the program is about 0.28 man-Sv. Dose distribution of workers engaged in dismantling of the reactor internals and the RPV showed hybrid log-normal distribution. Radioactive aerosol generation with mechanical cutting tools was higher than that with thermal cutting tools.

INTRODUCTION

Japan Power Demonstration Reactor (JPDR) is a BWR-type experimental power plant (12.5MWe) that begun to generate electricity for the first time in Japan in 1963. The plant was shut down permanently in 1976. The JPDR decommissioning program was begun in 1986. By the end of March 1991, reactor internals and a reactor pressure vessel (RPV) were dismantled using an underwater plasma arc cutting system and an underwater arc saw cutting system, respectively, in order to reduce exposure to workers and aerosol generation. This report describes radiation control experience during the decommissioning.

EXTERNAL EXPOSURE CONTROL

During the dismantling work, dose reduction measures for workers were taken, such as remote dismantling techniques, installation of shield. The cumulative collective dose equivalent since initiation of the JPDR decommissioning program is about 0.28 man-Sv. The collective dose equivalent for the removal of the reactor internals and the RPV was 0.073 man-Sv and 0.11 man-Sv, respectively. Figure 1 shows management data of JPDR decommissioning. Most of the exposure resulted from the removal of dross in fuel pool produced by underwater plasma arc cutting and the installation of a water tank which allowed the RPV to be submerged in water when it was cut.

Dose distribution models of workers are important in evaluation of collective dose in the planing stage. The distributions of cumulative dose of workers who engaged in the dismantling of the reactor internals and the RPV showed hybrid log-normal distribution¹. Figure 2 shows hybrid log-normal plots

This work performed by the JAERI under contract from the Science and Technology Agency Japan.

Figure 1 Management data of the JPDR decommissioning

of cumulative doses of the two groups. These dismantling work continued more than one fiscal year during which individual dose was restricted below the dose limit. The scattering of cumulative dose of the several workers who received the highest dose in FY 1989 decreased compared with that of total period of dismantling. This implied the effort of dose reduction and leveling off the dose of the workers to prevent the dose of small part of the worker becoming much higher compared with others.

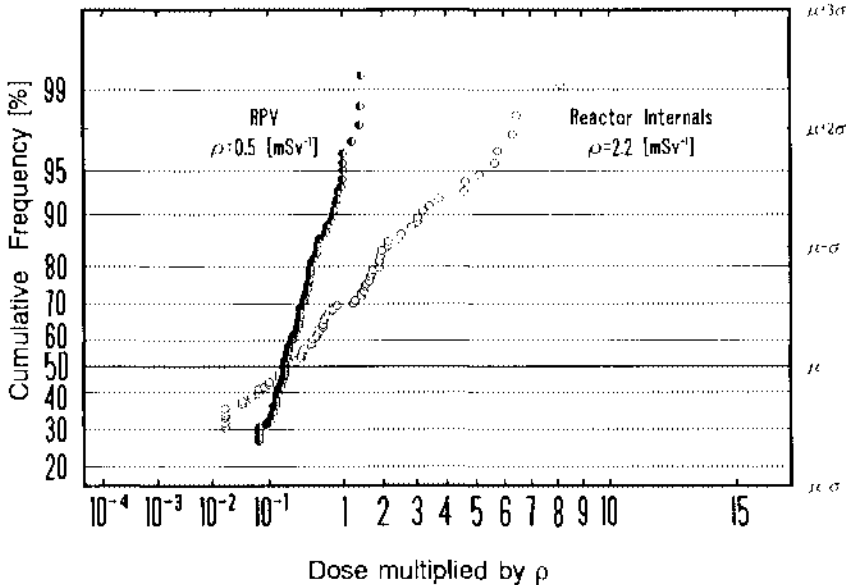

Figure 2 HLN probability plots of cumulative dose of workers engaged in removal of the reactor internals and the RPV

Various newly developed dismantling methods were adopted in the decommissioning to demonstrate their technical feasibility. In the dismantling of the forced recirculation outlet pipe connected to the RPV and penetrated biological shield, rotary disk knife cutting technique which could cut the pipe from outside of the biological shield remotely was adopted². Surface concentration of radioactivity inside the pipe was 1000 Bq/cm² and dose rate around the RPV where the pipes were connected was a few hundred μ Sv/h. Table 2 shows the man-power and collective dose equivalent for the dismantling of the forced recirculation pipes with the rotary disk knife and an oxy-acetylene torch. Total man-power of the rotary disk knife cutting was 3 times higher than that of the oxy-acetylene torch and 75% of the man-power was due to installation of the cutting equipment. Collective dose equivalent in the rotary disk knife cutting was very low compared with the oxy-acetylene torch, because the workers didn't need to access the RPV to cut the pipe. 40% of collective dose equivalent of the oxy-acetylene torch was due to installation of shield around the RPV.

Table 1 Total manpower and collective dose equivalent for dismantling of forced circulation pipes

Method	Object	Man-Power (man-day)	Collective dose equivalent (man-mSv)
Rotary disk knife	outlet pipe	354	0.2
Oxy-acetylene torch	inlet & outlet pipes	110	11.5

INTERNAL EXPOSURE CONTROL

To prevent the spread of air contamination, temporary containment enclosures equipped with ventilation system were built and it was possible to reduce effectively the radioactivity concentration in air of working places. During the dismantling work, to select the most suitable measures for reduction of internal exposure, the radioactive concentration in air of working areas must be evaluated in advance. But little data is available for radioactive aerosols from dismantling work for quantitative evaluation^{3,4}. Based on the measured aerosol radioactive concentration or mass concentration, normalized aerosol generation ratios, termed as immigration ratios (defined as : radioactivity in aerosols generated / radioactivity in kerf, and mass of aerosol generated / mass of kerf), were evaluated which will be used for evaluation of radioactive concentration or mass concentration in air during dismantling work.

Table 2 shows the immigration ratio for the radioactively contaminated stainless steel pipes segmentation with various

Table 2 Immigration ratios for stainless steel pipe segmentation

Cutting tool	Pipe size (inch)	Radioactivity immigration ratio (%)		Mass immigration ratio (%)	
		Range	Mean	Range	Mean
Band saw	2	5.8 - 37	13	---	$< 10^{-2}$
Band saw	6	10 - 58	19	---	$< 10^{-2}$
Reciprocating saw	12	7.0 - 24	9.9	---	$< 10^{-2}$
Plasma torch	12	0.23 - 0.78	0.44	0.53 - 0.82	0.66

cutting tools⁵. Because of the high radioactivity immigration ratio of the reciprocating saw, the radioactivity in aerosol generated per cut of the 12-inch pipe was about 30 times greater than that with the plasma torch. The size distribution with the plasma torch contained higher ratio of sub-micron aerosols than that with the reciprocating saw and showed bimodal distribution. The immigration ratios ranged from the order of $10^{-3}\%$ to $10^{-2}\%$ for underwater plasma arc cutting of the reactor internals and underwater arc saw cutting of the RPV.

During the reactor internals segmentation, besides the temporary containment enclosure, an air curtain was installed over the water surface of the pool to further enclose radioactive aerosols. Supply air flow rate was 40 m³/min and exhaust air flow rate was 140 m³/min. The ratio of the radioactive concentration of the lower side of the air stream to the upper side during the internals cutting ranged from 10 to 1000 and average ratio was 45.

LA REGLEMENTATION FRANCAISE EN MATIERE DE LIMITATION DES RISQUES RADIOLOGIQUES DES SITES MINIERES URANIFERES

par J. PRADEL, ingénieur conseil
27, rue Chanez - 75016 PARIS
(document préparé avec P. ZETTWOOD, CERTAC, CEN/FAR
92265 FONTENAY-aux-ROSES CEDEX, France)

RESUME

Marked anomalies in uranium concentration of the geological medium characterize regional natural radioactivity, which is significantly altered by mining and milling of uranium ore and the resulting generation of solid wastes. In consequence, additional exposure to ionising radiation may occur via various potential transfert pathways. A system for limitation of the associated radiological risks has been applied in France for more than 20 years, and formed the basis of French regulations adopted in March 1990. These regulations specify the conditions to be applied in monitoring of mining sites. In addition, they detail the management restrictions required to ensure that the limits of individual cumulated exposure of the population are not exceeded and that the radiological impact is minimised.

INTRODUCTION

Les opérations d'extraction et de traitement de minerais perturbent toujours de façon plus ou moins importante les sites concernés. Le milieu géologique est modifié par rapport à son état initial et des dépôts de produits solides provenant de l'extraction ou du traitement des minerais sont créés en surface. Il en résulte, dans le cas des mines d'uranium, une modification des niveaux de radioactivité naturelle et de l'exposition correspondante.

Les nuisances liées à l'extraction et au traitement des minerais d'uranium :

Les travaux miniers provoquent une déstabilisation du milieu géologique initial perturbant le comportement mécanique des formations géologiques, l'hydrogéologie locale et la géochimie des eaux de percolation.

L'exploitation entraîne aussi la création en surface de dépôts de déchets solides d'extraction constitués par les roches encaissantes qu'il faut extraire pour accéder au minerai et par les résidus du traitement destiné à obtenir les concentrés uranifères.

Des envois de poussières et des transferts de matières solides peuvent se produire à partir de ces dépôts ou des anciens travaux. Des transferts d'éléments solubles lixivifiés et des dégagements de radon 222 provenant du radium 226 peuvent aussi avoir lieu surtout dans le cas des résidus de traitement. Il faut aussi prendre en considération deux nuisances à caractère aléatoire : le risque d'instabilité des dépôts et le risque d'intrusion humaine avec construction d'habitation sur le dépôt ou utilisation des déchets comme matériaux de construction. A l'ensemble de ces nuisances potentielles, il faut aussi ajouter celle due au fait même de l'existence de tels dépôts avec les contraintes associées quant à l'utilisation ultérieure des emplacements correspondants.

La protection contre les nuisances potentielles

Il existe heureusement des technologies efficaces pour maîtriser ces nuisances potentielles. Elles reposent sur la mise en place de barrières de confinement comprenant notamment :

- des barrières d'étanchéité vis-à-vis des eaux de percolation, constituées de préférence d'une couche épaisse de matériaux géologiques naturels placée dans le soubassement du stockage,
- une couverture de surface pour limiter à la fois le débit de dose gamma en surface, les dégagements de radon, les infiltrations d'eau, les entrées d'oxygène dans le cas de minerais contenant de la pyrite, la pénétration des animaux et les intrusions humaines.

Il est ensuite possible de procéder à une réhabilitation du territoire, adaptée à chaque cas, qui peut comprendre un remodelage des formes paysagères, une modification du tracé des cours d'eau et une remise en végétation appropriée.

L'état des connaissances sur les mécanismes fondamentaux régissant les transferts vers l'homme des radionucléides présents sur les sites miniers ainsi que l'expérience acquise in situ dans de nombreux pays depuis deux ou trois décennies, permettent d'atteindre les objectifs actuels de limitation de l'exposition des populations avoisinantes tels qu'ils sont précisés dans la réglementation nationale française actuelle.

Les bases de la réglementation

La réglementation est nécessairement spécifique des déchets miniers contenant des radionucléides naturels de la durée de l'uranium pour les raisons suivantes :

- Les radionucléides principaux concernés sont l'uranium naturel, le thorium 230 et le radium 226. Ils ont tous des périodes extrêmement longues : $4,510^9$ ans pour l'uranium et $7,7.10^4$ ans pour le thorium 230. Quant au radium 226, sa période est de 1600 ans, mais sa décroissance est régie par le thorium 230 lorsqu'il lui est associé dans les résidus de traitement. Aussi, à la différence des stockages de surface des déchets de faible activité provenant des réacteurs nucléaires, la banalisation des sites au bout de 3 ou 4 siècles ne peut pas se justifier puisqu'il n'y a pas décroissance de l'activité. En effet, en vertu du principe qui veut que l'on admette pour l'exposition des générations futures, même très éloignées, les limitations actuelles, toute banalisation ne peut dans ce cas, être qu'immédiate. Il doit donc être instauré des contraintes illimitées dans le temps, ce qui amène à utiliser des ouvrages de stabilisation dont l'entretien et la surveillance soient relativement aisés et ne constituent pas des charges inacceptables pour les générations futures.

- Il s'agit de radionucléides naturels dont les activités spécifiques sont dans le stockage de l'ordre de cent fois celles rencontrées dans l'environnement non perturbé. Dans le cas des déchets contenant des radionucléides artificiels, l'absence de bruit de fond naturel à un niveau facilement mesurable rend la détection de ces radionucléides possible à très longue distance des points d'émission, voire à l'échelle planétaire, alors que l'on ne peut observer le marquage radioactif d'un stockage de déchets miniers qu'à de faibles distances, de l'ordre du kilomètre. Il en résulte qu'en raison des fluctuations temporaires et spatiales du bruit de fond naturel, l'impact des installations minières ne peut être correctement évalué qu'après plusieurs années d'observation avec un réseau de stations de mesure fonctionnant en continu.

- Les populations dans ces régions subissent des expositions naturelles, non liées à l'exploitation, dues au rayonnement alpha, au radon domestique et aux eaux radifères d'origine locale souvent très supérieures aux valeurs exigées pour les centres de stockage de surface des déchets radioactifs artificiels. Il en résulte que pour que la mesure de l'impact radioactif soit possible

au milieu du bruit de fond d'origine naturelle, et pour que les contraintes liées au respect des limites imposées pour cet impact soient justifiées, on ne peut pas raisonnablement exiger que la valeur tolérée pour l'exposition ajoutée soit tout-à-fait négligeable par rapport aux valeurs de bruit de fond et de ses fluctuations locales et temporaires.

- Les scénarios d'intrusion humaine dans les stockages conduisent par contre à des expositions qui dépassent celles considérées comme acceptables. Ces expositions ne peuvent être évitées, comme d'ailleurs des exposition identiques sur de nombreux sites uranifères non exploités, que grâce à l'établissement de servitudes liées au site et réglementant certaines pratiques.

La réglementation française :

L'ensemble de ces considérations a été pris en compte pour l'élaboration de la réglementation française de 1990 pour les sites miniers, dont on peut retenir les points suivants :

- fixation d'une limite inférieure pour les déchets solides devant faire l'objet d'un plan de gestion : teneur en U = 0,03%.
- fourniture d'une étude d'impact préalable
- limitation de l'exposition individuelle ajoutée à 5 mSv/an avec pour l'énergie alpha potentielle pour les descendants du radon 222, la correspondance 5 mSv → 2 mJ,
- fixation de limites en radium 226 pour les rejets liquides :
 - . Concentration inférieure à 740 Bq/m³ : rejet sans condition
 - . Concentration inférieure à 740 et supérieur à 3 700 Bq/m³ avec facteur de dilution du rejet pour les cours d'eau supérieur à 5 : rejet sans condition.
 - . Dans les autres cas, mise en place d'une station de traitement qui doit abaisser la concentration en dessous de 370 Bq/m³, en application du principe d'optimisation.
- Calcul de l'exposition ajoutée des groupes critiques déterminée pour chaque phase d'exploitation ou d'aménagement, à partir de mesures de l'activité d'échantillons d'eau et d'aliments divers et aussi grâce aux résultats fournis par un réseau de surveillance à base de stations fixes judicieusement implantées et comprenant un dosimètre TL pour la mesure de l'exposition alpha, un dosimètre de site pour la mesure de l'énergie potentielle alpha (comprenant un filtre de prélèvement, un collimateur sélecteur de particules à 4 plages d'énergie, un film de nitrate de cellulose où sont comptées les traces de particules alpha de différentes énergies), un dispositif de prélèvement de poussières permettant la mesure en laboratoire de leur activité alpha à vie longue.

Application de la CIPR 60

La publication 60 et la CIPR ne modifient pas les recommandations antérieures pour la gestion du risque radon qui est la source principale d'exposition dans le cas des sites miniers. Mais il est certain qu'un abaissement important des limites concernant le radon et ses descendants poserait des problèmes difficiles de différentes natures :

- difficultés pour mesurer les niveaux des expositions apportées compte tenu des incertitudes quant à l'origine du radon et apparition de problèmes juridiques associés,

- incohérence évidente entre les exigences pour limiter le radon provenant des travaux miniers et des dépôts de résidus associés, à des concentrations très inférieures à celles du radon préexistant localement. Cette incohérence est illustrée par les données suivantes :

- . bruit de fond radon sous forme gaz dans l'atmosphère libre : 1 à 30 Bq/m³, pouvant atteindre quelques centaines de Bq/m³ dans les régions uranifères et situations de ventilation atmosphériques défavorables,
- . recommandation CIPR pour le radon sous forme gaz dans les habitations : 200 ou 800 Bq/m³,
- . limitation pour la contribution des sites miniers (radon sous forme gaz avec un facteur d'équilibre des descendants de 0,5) :
 - 30 Bq/m³ si la limite d'exposition est fixée à 1 mSv/an
 - 3 Bq/m³ si la limite d'exposition est fixée à 0,1 mSv pour tenir compte des autres pratiques donnant lieu à l'exposition des groupes critiques.

CONCLUSIONS

L'environnement des installations minières et des usines de traitement de minerai est obligatoirement perturbé, ce qui ne constitue pas une affirmation nouvelle puisqu'à l'époque d'Agricola dans les années 1550, les détracteurs des activités minières, ancêtre des Ecologistes modernes, affirmaient que les exploitations minières causent plus de détriments qu'elles ne procurent de bénéfices. Mais dans le cas des minerais d'uranium, la connaissance des modalités d'exposition des populations et les performances des techniques de confinement permettent de limiter les expositions des populations concernées à des valeurs tout-à-fait acceptables, voire inférieures à ce qu'elles étaient avant exploitation. Des réglementations conformes aux recommandations de la CIPR peuvent être établies et l'ont été récemment en France en 1990. Les objectifs définis par ces réglementations pour assainir les sites miniers sont accessibles dès maintenant et pourraient être maintenus sans limitation dans le temps à condition que des servitudes restent attachées aux sites de façon permanente. Ces servitudes sont acceptables et ne correspondent qu'à ce qu'il conviendrait en toute logique, d'imposer aux nombreuses régions présentant des anomalies naturelles de concentration en uranium et probablement à de nombreuses mines considérées comme non uranifères. La CIPR qui doit traiter de la gestion du risque radon doit prendre en compte les problèmes qui risquent de se poser pour maintenir la cohérence entre les différentes recommandations tout en conservant l'ensemble de son système de gestion de risques.

Fusion of metallic wastes slightly contaminated with
radioactive substances

The increasing of metal waste volume contaminated by radioactive substances coming from nuclear facilities, led the Commissariat à l'Energie Atomique (Research Center of Saclay) to study the possibilities brought by melting processing of such a type of waste.

This report describes both the realized facility and the remedies brought to the problem arising due to the presence of radioactive contaminants (filtering, operator protection, etc). It deals with the results obtained after processing of some 30 tons of metallic waste coming from the dismantling of the primary circuit of a research reactor laid out on Saclay's site, as well as the outlooks expected through the process.

1 - INTRODUCTION

Les mesures de la contamination résiduelle des déchets métalliques issus de démantèlement sont fastidieuses et entachées d'erreurs et ne permettent pas le plus souvent de répondre aux exigences des autorités de sûreté en matière d'évacuation des déchets.

A défaut de certitude la pratique courante conduit à surclasser ces déchets en les considérant comme justifiables d'un stockage en site spécialisé avec pour conséquence des coûts importants entraînés par leur conditionnement, leur transport et leur prise en charge.

Parmi les méthodes envisagées pour pallier ces inconvénients, le traitement par fusion est apparu de nature à répondre aux objectifs suivants :

- Réduction significative des volumes
- Décontamination partielle
- Caractérisation précise du lingot obtenu
- Répartition homogène et immobilisation dans la matrice de la contamination résiduelle
- Optimisation du conditionnement.

2 - DEFINITION DE L'INSTALLATION

2.1. Caractéristiques des déchets à fondre

Ce sont des tuyauteries, vannes, capacités en acier et en moindre quantité en alliages d'aluminium et de cuivre. Ils sont contaminés, à des degrés divers, par des radionucléides émetteurs bêta, gamma avec en faible quantité des émetteurs alpha. Ces déchets, aux formes multiples, ne sont pas exempts de matières organiques, (caoutchouc, matières plastiques, huile...) et de peinture. Enfin plusieurs métaux et alliages peuvent être associés.

2.2. Choix du four

Après étude comparative, le choix s'est porté, compte tenu des quantités à traiter, sur un four à induction (mise en oeuvre facile, brassage vigoureux du bain) d'une capacité de 700 kg d'acier, alimenté par un générateur délivrant 400 kW sous 800 volts à 1000 Hertz. Le creuset est réalisé en pisé alumineux (93,8% Al_2O_3 , 3% Cr_2O_3 , 3,2% autres liants), son diamètre utile est de 400 mm, sa hauteur de 1040 mm.

2.3. Implantation

Le four a été installé dans une cellule ventilée, maintenue en dépression par l'intermédiaire d'un circuit d'extraction et de filtration d'air raccordé à la cheminée de l'installation. Cette cellule (volume 200 m³) est desservie par deux sas, (accès personnel, accès matériel). Le four a été placé dans une fosse de rétention, en cas de vidange accidentelle.

2.4. Le circuit d'épuration des effluents gazeux

La figure 1 montre le dispositif mis en place à l'issue d'une étude effectuée en 1985 [1] Il se compose d'une hotte reliée à un préfiltre électrostatique lui-même relié à la cheminée par l'intermédiaire de filtres à très haute efficacité. L'étude entreprise a permis de déterminer le diamètre médian et les débits d'aérosols produits lors des fusions (diamètres : inférieurs au micron et débits compris entre 0,05 et 3 grammes par kilogramme de métal fondu).

Des essais comparatifs effectués sur des préfiltres [2], tels que électrocyclone, filtres à manches, filtres électrostatiques ont montré l'intérêt de ces derniers qui présentent un rendement de filtration voisin de 99% tout en ne produisant qu'une très faible quantité de déchets secondaires.

2.5. Protection des opérateurs

Les agents travaillant à proximité du four sont équipés de vêtements ventilés réalisés en tissu aluminisé à l'intérieur desquels est distribué l'air respirable qui est également utilisé pour le refroidissement du corps et pour assurer la surpression constituant l'étanchéité dynamique vis à vis de la contamination. Les opérateurs communiquent entre'eux et avec l'agent de surveillance par liaison phonique.

3 - DESCRIPTION SOMMAIRE DU PROCEDE

Les déchets métalliques sont placés sur le chantier de démantèlement dans des bacs métalliques. Avant chargement dans le four, ils sont découpés à l'aide d'une cisaille hydraulique, en fragments de 15 cm de côté.

Le remplissage initial du Creuset est complété au fur et à mesure de la fusion. Après ajustage de la température de coulée, on procède à l'ajout d'entraîneurs favorisant le décrassage du bain et la formation des laitiers. Après écrémage des scories surnageantes, la coulée est opérée par basculement du four, dans une lingotière.

3.1. Les prélèvements d'échantillons, les mesures de radioactivité

Six prélèvements sont effectués à chaque coulée : deux échantillons de métal, deux échantillons de scories, deux prélèvements de poussières et aérosols en amont et en aval du préfiltre électrostatique. Après mise en solution des échantillons, les caractéristiques radioactives sont déterminées par spectrométrie gamma et alpha, par comptage et par scintillation liquide.

4 - RESULTATS OBTENUS

A l'issue du traitement d'environ 30 tonnes de déchets métalliques issus du démantèlement du circuit primaire du réacteur de recherche EL3, on peut résumer comme suit les résultats obtenus :

- Facteur de réduction du volume au moins égal à 10, comparé au volume d'un colis de déchets standard
- Répartition très homogène de la contamination résiduelle dans le lingot due essentiellement au phénomène de brassage du bain
- Excellente caractérisation des lingots permettant d'optimiser leur destination finale
- Qualité exceptionnelle du conditionnement de la radioactivité résiduelle.
- Décontamination quasi totale pour le tritium (98%), importante (90%) pour le césium, par entraînement dans les scories, les fumées et aérosols.

5 - PERSPECTIVES OFFERTES PAR LE PROCÉDE

Cette installation, de taille modeste, est cependant bien adaptée au traitement des quelques 100 tonnes de déchets métalliques produits annuellement dans un centre de recherche tel que Saclay. Ce procédé permet de valoriser les métaux récupérés en envisageant pour les lingots de très faible activité résiduelle une réutilisation de la matière première soit en milieu nucléaire (fabrication d'écrans, de conteneurs à déchets...) soit en milieu industriel surveillé, voire leur banalisation lorsque la radioactivité résiduelle se situe au niveau des traces. Il permet par voie de conséquences d'éviter l'engorgement des sites de stockage par "des pseudo-déchets". Son application est facilement extrapolable à des installations de tailles beaucoup plus importantes .

THE UTILIZATION OF A PRESSURIZED-GRAPHITE/WATER/OXYGEN
MIXTURE FOR IRRADIATED GRAPHITE INCINERATION

The authors demonstrate the interest of the utilization of a pressurized-graphite/water/oxygen mixture in the incineration of irradiated graphite. The aqueous phase comes in the form of a three-dimensional system that traps pressurized oxygen, the pulverulent solid being dispersed at the liquid/gas interfaces. These three-phasic formulations give the following advantages :

- reduction of the apparent viscosity of the mixture in comparison with a solid/liquid mixture at the same solid concentration;
- reduction of the solid/liquid interactions;
- self-pulverizability, thus promoting reduction of the flame length ;
- utilization of conventional burners;
- reduction of the flue gas flow rate ;
- complete thermal destruction of graphite.

INTRODUCTION

Dans le cadre du démantèlement de réacteurs nucléaires UNGG, les auteurs proposent un nouveau procédé visant la destruction complète du graphite irradié par incinération directe à haute température, d'un mélange triphasique graphite/eau/oxygène (PG-WOM pressurized/graphite/water/oxygène mixture).

Le transport en conduit de solides divisés en vue de l'alimentation d'enceintes de réaction est classiquement réalisé grâce à deux vecteurs :

- le transport pneumatique, par lequel le solide divisé est convoyé en conduite sous forme d'une dispersion gaz/solide pseudo-homogène, ou bien sous forme d'un lit mobile aux plus faibles vitesses;
- le transport dense en phase " slurry " dans lequel le solide divisé est convoyé en conduite sous forme d'une suspension solide/liquide se comportant comme un fluide pseudo-homogène visqueux.

Les auteurs ont choisi une troisième voie qui consiste à utiliser une solution intermédiaire, à savoir le transport du graphite divisé sous forme d'une dispersion gaz/solide/liquide. Le mélange triphasique en question consiste en une mousse chargée, pressurisée présentant des caractéristiques rhéologiques intermédiaires entre un liquide et un gaz compressible. La phase liquide se présente sous forme d'un réseau cellulaire tridimensionnel, structuré, emprisonnant le gaz sous pression, et dans lequel le solide divisé se répartit aux interfaces liquide/gaz.

LES "MOUSSES CHARGÉES" - MISES EN OEUVRE - PROPRIÉTÉS

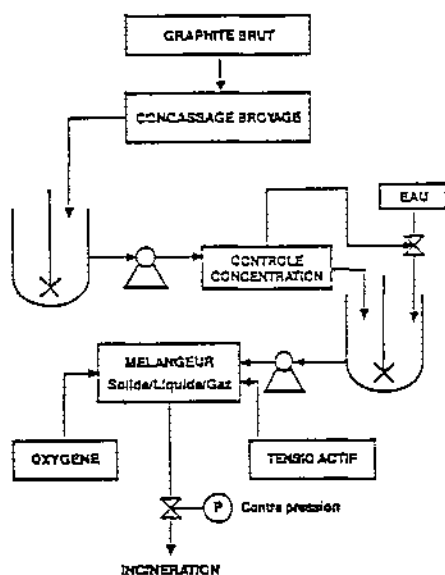

Schéma de principe de création de la mousse

La première étape consiste à concasser puis à broyer les chemises ou empilements de graphite. Afin d'obtenir un "slurry" ayant une granulométrie telle que 80% des grains obtenus soient inférieurs à 200 μm .

Comme l'indique le schéma ci-contre le mélange est obtenu par dispersion en continu du slurry obtenu dans une mousse pressurisée (foisonnement gaz/liquide en enceinte sous pression). Naturellement une étape de laboratoire permet de fixer le choix des agents tensio-actifs et stabilisants nécessaires au foisonnement et à la stabilité de la mousse.

Le mélange obtenu (mousse chargée) est compressible et les variations de sa masse volumique en fonction de la pression sont bien décrites par une équation d'état analogue à celle de Van Der Waals, dans laquelle le co-volume est le volume de la phase incompressible du mélange (solide à l'empilement compact plus eau interstitielle).

Ainsi le mélange triphasique, pressurisé lors de la phase de préparation est susceptible de transport en conduite par auto-détente par simple ouverture de vanne, ce qui permet par exemple, de supprimer les pompes de transport (fuites, érosion...), mais aussi de bénéficier des propriétés d'auto-pulvérisation du mélange lors de son introduction en enceinte de réaction.

De plus, cette formulation triphasique, permet de minimiser les contacts solide/solide, par aération du produit, abaissant ainsi sa viscosité apparente par rapport à la viscosité qu'aurait le produit en mélange solide/liquide à même concentration massique en solide. Autrement dit, la teneur massique en solide peut atteindre 80 à 85% dans la mousse pressurisée, alors qu'elle ne peut guère dépasser 60 à 65% dans un "slurry", et ce avec une relative indépendance à :

- la nature du solide (physico-chimie de l'interface solide/liquide), ce qui permet de limiter le choix des agents tensio-actifs à des molécules banales (agent moussant) et donc peu coûteuses ;
- la répartition granulométrique du solide divisé, ce qui permet de s'affranchir de la recherche de répartition multimodale en fluidification de mélanges solide/liquide.

La présence de liquide dans le mélange, par exemple ici l'eau, permet, malgré sa faible teneur, de supprimer les risques d'explosion dans les étapes de préparation et de manutention. De plus, ceci permet d'envisager l'utilisation de broyages en phase humide à l'amont de la préparation, et donc de minimiser les risques d'explosion ou d'envol dans les étapes de broyage.

Le produit fini peut être aisément chassé des conduites de transport ou d'injection par utilisation de gaz comprimés en cas d'indisponibilité du procédé aval (arrêt d'incinération par exemple). Le mélange peut être ainsi transféré dans un réservoir de confinement où la mousse chargée peut être "cassée" par dispersion d'agents anti-mousse, autorisant la minimisation du volume de l'enceinte de repos.

LE FOUR CYCLONE

Schéma de principe de fonctionnement du foyer cyclone

Le choix d'un foyer cyclone a constitué une alternative très intéressante pour la destruction du graphite, matériau difficile à incinérer parce que ne renfermant aucune matière volatile. Comme l'indique la figure ci-contre, le foyer utilise les mêmes principes aérodynamiques qu'un séparateur solide/gaz fonctionnant à froid.

L'entrée tangentielle du combustible/comburant (mélange gaz et particules solides) à très haute vitesse permet la centrifugation des particules vers les parois qui a pour effet de les désolidariser de la veine gazeuse ; de ce fait, elles séjournent plus longtemps dans le foyer et leur combustion s'en trouve améliorée ; ceci d'autant plus que l'effet cyclone provoquant une forte turbulence, les contacts combustible/comburant sont améliorés.

Le rôle de séparateur gaz/solide permet en outre aux cendres ou imbrûlés d'être évacués par le cendrier situé à la base du four.

INTERET DE L'OXYGENE

Le choix de l'oxygène comme gaz de formulation et combustion permet :

Comparaison de la cinétique de combustion d'un grain de graphite de 200 µm pour différentes compositions d'atmosphères comburantes

- l'amélioration de la cinétique de combustion des particules solides (voir courbe ci-contre)
- l'augmentation de la température adiabatique de flamme;
- la suppression des oxydes d'azote dans les produits de combustion;
- la réduction du volume d'effluents gazeux à traiter. Ainsi pour un même débit massique de graphite incinéré soit 150 kg/h et une même température d'incinération (1200°C), le débit volumique des fumées produit avec le procédé PG-WOM est de 1080 Nm³/h (dont 48% d'eau) alors qu'il serait de 2250 Nm³/h dans le cas d'un lit fluidisé.

CONCLUSION

L'intérêt de ce procédé réside dans sa sûreté liée à l'utilisation des "mousses chargées" en graphite, dans la qualité de la combustion grâce à l'auto-pulvérisation des mousses et à l'utilisation d'un four cyclone et dans l'écologie du procédé limitant le volume des fumées à traiter et évitant le dégagement d'oxydes d'azote.

TRAITEMENT DES ACIERS CONTAMINES
EN PROVENANCE DES REACTEURS UNGG G2 et G3
EN VUE D'UNE REUTILISATION DANS LE DOMAINE INDUSTRIEL

J.L. Decitre UDIN CEN Valrho
CEA - DCC/DERD/UDIN/RHO/CP
BP. 171 30200 - BAGNOLS SUR CEZE
FRANCE

Treatment of contaminated steel
from dismantling of G2 and G3 reactors,
for industrial reuse.

La limite d'activité pour la remise dans le domaine industriel des aciers en provenance du démantèlement des réacteurs G2 et G3 a été prise à :

- 1Bq/g en fonction du radionucléide principal se trouvant dans ces aciers (Co 60 à 95%),
- 1 Bq/cm²,
- contamination labile nulle.

L'objectif pris par UDIN est de remettre 90% des aciers extérieurs au caisson réacteur dans le domaine industriel.

La méthode adoptée pour atteindre cette objectif consiste en une caractérisation radiologique des morceaux de tuyauteries après découpe suivie d'un lavage permettant d'enlever la plus grande partie de la contamination labile puis d'une fusion dans un four à arc de grande dimension.

1 - NATURE DES INSTALLATIONS

- Réacteurs UNGG (Uranium Naturel Graphite Gaz) plutonigène et électrogène (250 MW T./40 MW E)

Le gaz calo-porteur était du dioxyde de carbone à la pression de 15 bars.

L'ensemble des tuyauteries était en acier ordinaire.

Le coeur du réacteur était contenu dans un cylindre à axe horizontal en béton, d'épaisseur 3 mètres.

2 - DATES REPERES

	<u>G2</u>	<u>G3</u>
- Mise en service	07/1958	06/1959
- Mise à l'arrêt	02/1980	06/1984
- Prise en charge UDIN	02/1982	01/1986
- Achèvement prévu du démantèlement pour les 2 réacteurs :		
Niveau 2 - fin 1993		
Niveau 3 - décision en cours d'étude, après construction d'un pilote d'incinération de graphite.		

3 - MAITRISE D'OEUVRE DU DECLASSEMENT

- La maîtrise d'oeuvre du déclassement est assurée par l'Unité de Déclassement des Installations Nucléaires du Commissariat à l'Energie Atomique, CEA/DCC/UDIN. Cette unité spécialisée dans le déclassement et le démantèlement des installations nucléaires (réacteurs de tous types, laboratoires chauds ...) travaille dans la France entière sur tous les sites du CEA et de la COGEMA (3 sites dans la zone de Paris, La Hague, Brennilis, Grenoble, Pierrelatte, Marcoule, Cadarache).

4 - STRATEGIE

La stratégie repose sur deux axes principaux:

- A) Quantifier le plus précisément possible tous les éléments du réacteur et des circuits associés.
- B) Traiter les produits du démantèlement pour remise dans le domaine industriel de la plus grande partie aux coûts économique et radiologique les plus faibles.

Dans ce domaine, et après avoir étudié les résultats de la quantification des circuits annexes (4000 tonnes de tuyaux servant à véhiculer le CO₂, fluide de refroidissement), UDIN a décidé de fondre l'ensemble des aciers en provenance de ces circuits après un lavage sommaire à l'eau sous haute pression. Les résultats des mesures d'activité entreprises sur les premières 1000 tonnes, montraient que 90 % de ces aciers pouvaient être remis dans le domaine public (contamination labile nulle, contamination surfacique très largement inférieure à 1 Bq/cm² et contamination massique de l'ordre de 1 Bq/g).

Le dimensionnement des installations de fusion construit dans les bâtiments de l'un des réacteurs a été calculé pour permettre de fondre 5.000 à 10.000 tonnes d'acier contaminé par an, avec une contamination moyenne massique maximum de 250 Bq/g.

Caractérisation des installations

La caractérisation a été réalisée par mesures directes (frottis, sondes), et par carottage vertical, sur toute la hauteur du réacteur.

A l'intérieur des coeurs des réacteurs, l'activité des aciers varie de $10E+3$ à $10E+6$ Bq/g, la contamination est de l'ordre de 200 Bq/cm² (95% due au Co60, 5% due au Cs137).

A l'extérieur, les aciers sont uniquement contaminés, entre 40 et 200 Bq/cm².

Traitement

Les aciers internes seront lavés pour diminuer leur contamination, puis découpés pour être stockés sur un site de surface.

Les aciers extérieurs seront lavés sous haute pression et fondus. Les corps creux qui n'ont pas besoin d'être découpés en fonction de la dimension du four choisi seront nettoyés par mousse (procédé développé par le CEA/UDIN).

Le four choisi est un four à arc de capacité 15 tonnes (8 MVA) possédant une ouverture de 2,5 m. ; il est installé dans un bâtiment confiné et ventilé, à l'intérieur du hall du réacteur G3. La première fusion a été réalisée début octobre 1991.

Contrôle

Les pièces démantelées sont transportées en containers après découpe (dimensions < 1,7 m. x 1,7 m. x 1,3 m.), à proximité du four et introduites à travers un sas dans l'aciérie. La gestion radiologique est basée sur un suivi complet des morceaux découpés. Après un contrôle à l'entrée de la salle de préparation (contrôle à la sonde d'un container entier après étalonnage et établissement d'une fonction de transfert), les pièces sont chargées dans des paniers en les triant de façon à obtenir des charges de coulée < 1 Bq/g.

Les déchets de fusion seront traités pour être stockés sur un site de surface.

Les lingots obtenus seront orientés dans 3 directions principales :

- si l'activité est < 1 Bq/g , remise dans le domaine public,
- si l'activité est comprise entre 1 et 100 Bq/g, recyclage dans le domaine nucléaire,
- si l'activité est > 100 Bq/g , stockage sur un site de surface ou décroissance sur le site des réacteurs.

La coulée sera caractérisée par l'analyse fine d'un échantillon recueilli dans le four avant coulée ; un contrôle statistique de 5 lingots par coulée permettra une dernière vérification.

STUDY OF A MICROSAMPLING SYSTEM BY LASER IMPACT FOR ANALYSIS OF CONTAMINATED SURFACES

ABSTRACT

A method of microsampling by laser YAG is described. The aim is to take a very small amount in surface of contaminated materials (nuclear or chemical contamination). The use of an Electric Aerosol Analyser allowed to distinguish two different phenomenous of interaction between a power laser and a target: ablation (hole formation of the target less than 0,5 mm of diameter) and desorption (invisible surface sampling). The rate of desorbed material is estimated by regression. Some perspectives are also discussed.

INTRODUCTION

Nous présentons une méthode de prélèvement de matière par impact laser qui se caractérise par:

- un dégât petit à la surface d'une cible (diamètre du cratère formé inférieur à 0,5 mm)
- un produit prélevé facilement analysable par différentes méthodes physico-chimiques.

L'interaction entre un faisceau laser et une cible peut se manifester sous deux formes très différentes selon l'énergie, l'angle d'incidence, la défocalisation du faisceau laser et les propriétés physico-chimiques du matériau cible (coefficient de réflexion, paramètres thermodynamiques,...). La première possibilité est une ablation avec formation d'un impact et production de microgouttelettes de liquide et d'un plasma. Ce dernier, composé de particules partiellement ionisées, se refroidit très rapidement. Les clusters créés condensent et forment un aérosol composé de microbilles dont la particularité réside dans une distribution en taille relativement monodispersé (Voir Fig.1)[1]. La seconde consiste en une description [2] à la surface de la cible. L'unique produit résultant de l'interaction est un aérosol. Dans ce cas, la surface irradiée ne montre pas de dommages "visibles". L'aérosol formé est facilement récupérable.

APPAREILLAGE

- *Système de prélèvement*

Le prélèvement de matière est effectué dans une cellule en duralumin (voir Fig.2), comprenant une entrée et une sortie du gaz vecteur. Une fenêtre en saphir permet le passage du faisceau laser, celui-ci interagissant avec la surface à analyser avec un angle d'incidence nul. Les paramètres du faisceau sont regroupés dans le tableau 1:

Laser Longueur d'onde	Energie faisceau	Duree d'impulsion	Puissance crête	Densité de puissance surfaccique	Distance focale de la lentille de focalisation
Nd-YAG 1,06 μm	0,1-0,3 J	100-150 μs	1000-3000 kW	$10^6 - 10^7$ W.cm^{-2}	40 ou 100 mm

Tableau 1: Paramètres du faisceau laser utilisé

- Récupération de la matière expulsée

Lors de l'interaction laser-matière, il est nécessaire d'éviter les projections de gouttelettes difficilement récupérables et contaminant les parois de la cellule.

A l'opposé, l'aérosol (voir Fig.1) possède des propriétés bien différentes du liquide projeté dans le cas d'une ablation laser. Les microbilles formés lors du refroidissement brutal du plasma sont très bien localisées laissant l'enceinte de prélèvement propre. En effet, les particules obtenues sont submicroniques, ce qui rend leur transport très aisé au moyen d'un gaz vecteur.

Grâce à cette facilité de déplacement, l'aérosol peut être récupéré sur un filtre Millipore. Au moyen d'un diaphragme, une très petite quantité de matière est concentrée sur une très petite surface du filtre. L'analyse du dépôt par des techniques de microanalyses telles que la spectrométrie LAMMA (Laser Microprobe Mass Analyser) [3] et la microsonde d'analyse X (Fig.3) est rendue possible.

COMPARAISON ENTRE ABLATION ET DESORPTION PAR ANALYSE DE L'AEROSOL FORME

Dans l'étude qui suit, la chambre d'échantillonnage est couplée à un Analyseur Electrique d'Aérosol de la firme Thermo System Inc. (Fig.2). Ce compteur de particules permet de déterminer le nombre et les dimensions des microbilles formées. Les Fig.4 et 5 (respectivement pour une défocalisation de 0 mm et +10 mm par rapport à la surface de la cible) montrent les différentes allures pour les deux phénomènes résultant de l'interaction laser-cible métallique (or 14 carats). Pour une focalisation non nulle (sans formation de cratère), la décroissance du nombre d'aérosols en fonction du temps d'irradiation est continue pour tendre asymptotiquement vers une valeur limite: nous sommes en présence d'une désorption. En revanche, une focalisation du faisceau laser à la surface de la cible engendre une densité d'énergie très élevée générant un cratère sur le matériau. La concentration en aerosol varie de manière importante et le phénomène de décroissance dans le cas d'une désorption est stoppé: il y a ablation.

Par régression, nous avons exprimé le volume de matière ablaté en fonction du temps d'irradiation.

La modélisation proposée est schématisée à la Fig.6, le volume V prélevé étant donné par la relation (1):

$$V = \frac{D}{\alpha} \left[\frac{1}{\beta} - \frac{1}{\alpha t + \beta} \right] \quad (1)$$

avec D: débit du gaz vecteur

t: temps d'irradiation

α et β : coefficients provenant de l'expression de la régression

(2) entre v, volume d'aérosol prélevé par unité de temps, et t.

$$\frac{1}{v_{0,5}} = \alpha \cdot t + \beta \quad r = 0,990 \quad (2)$$

(avec $\alpha = 9,70 \cdot 10^{-5}$ et $\beta = 22,46 \cdot 10^{-4}$).

On en déduit la profondeur ablatée z (3):

$$z = \frac{4V}{\Delta \pi} \quad (3)$$

avec Δ : diamètre du trou créé (supposé être un cylindre de profondeur z).

Dans le cas de l'or 14 carats, avec $\Delta = 3000 \mu\text{m}$, on obtient un volume V de matière prélevée égal à $3 \cdot 10^7 \mu\text{m}^3$ avec une profondeur z = 2,4 μm .

DEVELOPPEMENTS ET PERSPECTIVES

Les expériences présentées ci-dessus confirment les options choisies lors de la conception de la cellule de prélèvement:

- l'aérosol produit peut être transporté au moyen d'un gaz vecteur
- une gamme de défocalisation importante est possible permettant une ablation ou une désorption.

Nous avons également montré la possibilité de vaporiser des matériaux sans créer des dégâts apparents, ceci peut s'avérer important pour des applications de cette technique dans le cadre d'authentification d'oeuvres d'art (statuettes, bijoux, peintures,...) ou de contrôles non destructifs.

La méthode présentée est intéressante dans le cas de surfaces contaminées par voie radioactive ou chimique. Ainsi, le prélèvement à l'intérieur de sites irradiés (réacteur nucléaires, circuits primaires,...) peut être envisagé grâce à l'utilisation d'une part de fibres optiques en couplant le laser et la cellule et d'autre part de la robotique.

**GUIDE FOR DECONTAMINATION
IN P.W.R. POWER PLANTS**

J. HERISSON
C. GLORENNEC

Electricité de France
Service de la Production Thermique
Paris - La Défense

Nuclear power plant components or equipment often need to be more or less decontaminated before maintenance. In order to coordinate the activities of the various maintenance specialists belonging to the Corporate or Site Organizations, the Management of EDF/Nuclear and Fossil Division has created a "Decontamination Task Force". The first objective of this Task Force was to prepare this "Decontamination Guide for Nuclear Power Plants".

This document is the result of a close collaboration, within a specific working group, between representatives of Nuclear & Fossil Division (from Nuclear Power Plants & Corporate Departments) and EDF Project & Construction Group. It will provide assistance to Nuclear Plants Operators in the very specific field of decontamination.

INTRODUCTION

Human external exposures and contamination risks increase over the years, with nuclear plant operation time. This applies essentially to maintenance personnel. In order to reduce dose rate, conventional radioprotection measures can be efficiently improved by equipment decontamination.

However, decontamination should not be considered as a panacea and should only be used after an in-depth and critical evaluation of the technical, dosimetric and economical aspects (ALARA).

The objective of this Guide is to provide the operators with methods and techniques which will help them to take decisions in the decontamination field.

This Guide describes essentially decontamination techniques available for the maintenance of Pressurized Water Reactors. Some of these techniques might be applied, after evaluation, to other types of reactors.

It is not only useful to those in charge of implementing these techniques, but also to planners having to integrate decontamination techniques in maintenance and working procedures.

The Guide is divided into two parts :

- part I contains general information about decontamination techniques, and gives the basics for obtaining an acceptable level in this discipline,

- part II describes the decontamination methods and techniques available to Power Plants. It is to be considered as prescriptive ; in fact, all decontamination techniques not included in this book have to be implemented very carefully, after consulting with Company specialists.

It is an evolving Guide, as far as the prescriptive part is concerned. It depends essentially on experience feedback from all the users.

DECONTAMINATION GUIDE

PART I : PRESENTATION AND GENERAL INFORMATION

The first chapter describes the technical aspects of equipment decontamination and covers the following topics :

- Radioactive contamination cases in a PWR NPP
- Thresholds - Contamination measurement
- Contamination prevention
- The equipment to be decontaminated
- Decontamination objectives
- Description of the main decontamination methods
- Decision criteria
- Decontamination liquid treatment and waste processing
- Safety - Health Physics - Environment

The second chapter covers EDF quality organization in the decontamination field :

- Policy :
- Decontamination activities
- How to attain quality
- Who is suppose to do what
- Qualification of decontamination personnel
- Acceptance and qualification of a decontamination process

- Implementation :
- When planning a decontamination :
 - Responsibility of the initiator
 - Responsibility of the planner
 - Responsibility of the decontamination crew leader

Part I (and essentially chapter II) are related to the French regulations applicable to operators and contractors.

PART II : METHODS AND TECHNIQUES

This part is essentially technical and addresses the personnel actually involved in equipment decontamination. It provides a list of applicable methods, depending on the type of contamination and the basic material of the component.

The optimum method can be sought in two ways :

- by nuclear power plant component : the guide proposes 14 logical search flowcharts for the following component types :

- M1 Steam Generator
- M2 Reactor cavity and spent fuel pit walls
- M3 Reactor coolant pump
- M4 Charging pump
- M5 Residual Heat Removal (RHR) pump
- M6 CVCS regenerative heat exchanger
- M7 CVCS non-regenerative heat exchanger and RHR heat exchanger
- M8 RCS pipes
- M9 CVCS/RHR pipes
- M10 RCS valve
- M11 RHR/CVCS valves
- M12 Spent fuel element shipping cask
- M13 Electrical/electronic/optical equipment
- M14 RCS Pressurizer

- by basic material : the guide proposes 11 logical search flowcharts :

- L1 Stainless steel (high temperature contamination)
- L2 Stainless steel (low temperature contamination)
- L3 Nickel based alloys (Inconel..) (high temperature contamination)
- L4 Carbon steel
- L5 Cobalt based alloys (stellites)
- L6 Copper based alloys
- L7 Aluminium and zinc based alloys
- L8 Lead
- L9 Concrete
- L10 Plastic - Rubber
- L11 Liners - Paints

These logical flowcharts indicate a certain number of decontamination methods applicable to the relevant equipment. The methods are described in technical files indicating :

- Qualification of the process : the EDF specialists in the different fields involved (metallurgy, chemistry, etc...) have collected sufficient information and test results and can thus authorize the use of this process on the relevant equipment, as described in the file. This authorization does not necessarily cover all specific requirements prescribed by the Regulatory Bodies, since adherence to the rules is the users's responsibility.

- Applicability : a list of the materials and equipment that can be treated by the corresponding process. It also lists the materials and equipment on which it should not be used.

- Operating instructions and procedures : it describes the various chemical phases and the necessary equipment.

- Operating instructions and procedures : it describes the various chemical phases and the necessary equipment.

- Expected results : it indicates the results usually obtained by using the process, and more specifically the expected dose rate reduction factor.

- Waste processing methods : it indicates the various methods for processing the resulting effluents. These methods are in accordance with the French regulations related to environmental protection.

- Advantages and drawbacks : it indicates the strong points of the process and also its shortcomings.

- Historical aspect : it indicates some worldwide results of previous use of the process.

- Basic diagram : it shows basic set-up and installation drawings of the process.

- List of accepted and similar commercial products : it enables a Nuclear Operator to implement the process himself, providing these products or the process are not patent protected.

- List of EDF qualified vendors and contractors : it gives the list of those contractors that have satisfied the EDF Quality Assurance requirements and are authorized to work on EDF equipment.

The guide contains 40 technical files concerning about decontamination methods.

Data and information are extracted from technical publications and EDF guarantees neither the efficiency of the methods nor the expected results. It is however now being satisfactorily used by the EDF nuclear sites.

The guide is now available in its French version. An English version could be published in 1992, depending on the results of an ongoing market survey.

DECOMMISSIONING OF NUCLEAR FACILITIES IN GERMANY
RADIATION EXPOSURE CAUSED BY THE UNHARMFUL REUSE OF
RADIOACTIVE RESIDUAL MATERIALS

P. Guglhör, K.-H. Lehmann, B. Jähnert
Technical Inspection Agency of Bavaria (TÜV Bayern)
Munich, Germany

ABSTRACT

The decommissioning of nuclear facilities causes the release of radioactive material. The radiation exposure of the public was calculated and contamination limits for the un-harmful reuse of residual material were derived.

INTRODUCTION

As a consequence of the strong requirements of the German Atomic Energy Act radioactive residual material or dismantled radioactive components from nuclear facilities must be reused in an un-harmful way.

As an independent expert organisation TÜV Bayern checked how these requirements had been met in the nuclear licensing procedure for the NPP

- Kahl (25 MW_e, BWR),
- Niederaichbach (100 MW_e D₂O-moderated, CO₂-cooled),
- Gundremmingen (250 MW_e, BWR).

LIMITS FOR UNHARMFUL REUSE

After 2 years of reactor-operating time the NPP Niederaichbach was shut down in 1974. It was the first nuclear facility in Germany which was applied for decommissioning. Therefore TÜV Bayern get most experience in the valuation of the radioactive material of this plant.

Especially for concrete, steel and some other materials (e. g. insulation material) the radiation exposure of the public was calculated by using appropriate exposition scenarios. Contamination limits for the un-harmful reuse were derived. These limits depend on the nuclide mixture as well as the procedure for the clearance measurements.

The nuclide mixture depends on the material. In the activated steel there is mainly Fe 55, Co 60, and Ni 63, in the activated concrete there is mainly Ba 133, Co 60, Eu 152, and H 3.

At the time TÜV Bayern carried out the assessment on

the decommissioning of the NPP Niederaichbach no regulations for the release of radioactive material for unarmful reuse did exist. TÜV Bayern proposed such regulations by calculating the radiation exposure of the public. The radiation exposure caused by the release of radioactive material should be small compared with the range of the variation of the natural radiation.

As a result of our assessment of the release of former contaminated material it was not allowed to exceed the following two limits:

- mass specific activity,
(10^{-5} times the allowances per gramm as specified in the German Radiological Protection Ordinance (GRPO), e. g. for 100% Co 60 it would be 0.37 Bq/g),
- surface contamination,
(0.37 Bq/cm², required by the German Radiological Protection Ordinance)

The first limit restricts the amount of activity released and should be measured in an easy way (e. g. gamma-spectroscopy) using a reference nuclide composition. The second limit is a requirement of the GRPO and is to prove for every material released from the controlled area. For more than one radionuclide or a mixture of radionuclides of known composition the allowance shall be determined as the sum of the nuclide portions. In the licence for the decommissioning of the NPP Niederaichbach a nuclide mixture for the release of radioactive material was determined by the licensing authority. These nuclides are H 3, Mn 54, Fe 55, Co 58, Co 60, Ni 59, Ni 63, Nb 94, Cs 134, Ba 133, Eu 152, and Eu 154. For the mass specific activity of the NPP Niederaichbach you get the following condition:

$$\sum_{i=1}^m \frac{A_i}{F_i} + \sum_{j=1}^n \frac{B_j}{F_j} < 10^{-5}/g$$

- A_i : measured specific activity of the nuclide i
- B_j : detection limit of the nuclide j
- $F_{i,j}$: allowance of the nuclide i,j according to the GRPO
- m : number of nuclides with measureable activity
- n : number of nuclides with detection limit

The amount of radioactivity of some nuclides, e. g. Fe 55, Ni 59, and Ni 63, was measured separately in laboratory because they are emitting no gamma-rays. Because of the low amount of these nuclides in the material the radioactivity was not measureable. According to the licence it was necessary for these nuclides to use the detection limits

when proving that the clearance levels are met. The sum of the measured activity and the detection limits for all layed down nuclides shall not exceed the mass specific clearance level. Up to now a mass of about 740 Mg was released with a mean radioactivity of about 0.2 Bq/g. Considering the amount of the activity due to detection limits, one gets about 0.2 Bq/g. So the real activity of the material is only a part of it and will be significantly lower than 0.1 Bq/g.

With the materials and activities released up to now the theoretical exposition scenarios have been checked. It turned out that the actual radiation exposure of individuals of the public is significantly lower than the values calculated for the licensing procedure.

In 1987 the National Commission of Radiological Protection (SSK) made a recommendation for the unharmed reuse of radioactive steel released by a NPP. In this recommendation a value of 0.1 Bq/g for the mass specific activity should be adequate for an unrestricted release.

Because of the conservative procedures for the release of radioactive material one can state that the succeeding recommendation of the SSK is met in practice at NPP Niederaichbach.

VALDEC-F PROJECT FOR THE TREATMENT OF LOW ACTIVITY SCRAP STEEL

By Henri GODARD - SOCODEI - France

----*

Abstract

Maintaining -or dismantling- nuclear plants involves the issue of more or less contaminated scrap steel. Those scraps are today usually either stored on the plants or disposed of as nuclear wastes.

The VALDEC-F project consists in transforming the scraps at a specific facility in order to produce moulded items that are used in the nuclear field.

Basically the facility includes sorting equipments (according to the activity, iron or steel, ...), preparatory operations to melting, and casting.

Tonnages exceeding the orders of moulded items will be turned into ingots and temporary stored.

The VALDEC-F project (1 500 t/year) contributes in France to mastering the risks due to low level wastes as well as the economy of their treatment.

Résumé

L'entretien ou le démantèlement des installations nucléaires génère des ferrailles plus ou moins contaminées qui sont habituellement, soit conditionnées en vue de leur stockage définitif, soit accumulées sur les sites de production.

Le projet VALDEC-F consiste à transformer ces ferrailles dans une usine spécifique pour en faire des produits moulés, notamment des blindages utilisés dans le domaine nucléaire.

Les matériels principaux concernent le tri des ferrailles, leur préparation à la fusion et la réalisation de produits moulés. Les tonnages de ferrailles qui excèdent les commandes en produits moulés seront lingotés pour en réduire le volume.

Le projet VALDEC-F (1 500 t/an) est, en France, un élément nécessaire à la maîtrise des déchets de faible activité, tant au plan économique qu'au plan de la prévention de la dissémination de la contamination.

Brève histoire du projet VALDEC-F

Les essais de fusion de ferrailles faiblement contaminées, notamment ceux réalisés par EDF en 1985-1986, ont laissé entrevoir l'intérêt d'un tel traitement de ce type de déchets de faible activité :

- pour les ferrailles dont l'activité va de quelques Bq/g à 1 kBq/g, possibilité de réaliser des produits moulés pour l'industrie nucléaire, notamment des blindages entrant dans les colis de déchets irradiants des centrales ;
- pour les activités de l'ordre du Bq/g, mise sous une géométrie (lingots homogènes) permettant de mesurer par une méthode industrielle simple une radioactivité qui n'émerge guère du bruit de fond ;
- pour les activités supérieures à 1 kBq/g, réduction maximale du volume en vue du stockage définitif en centre de stockage de surface.

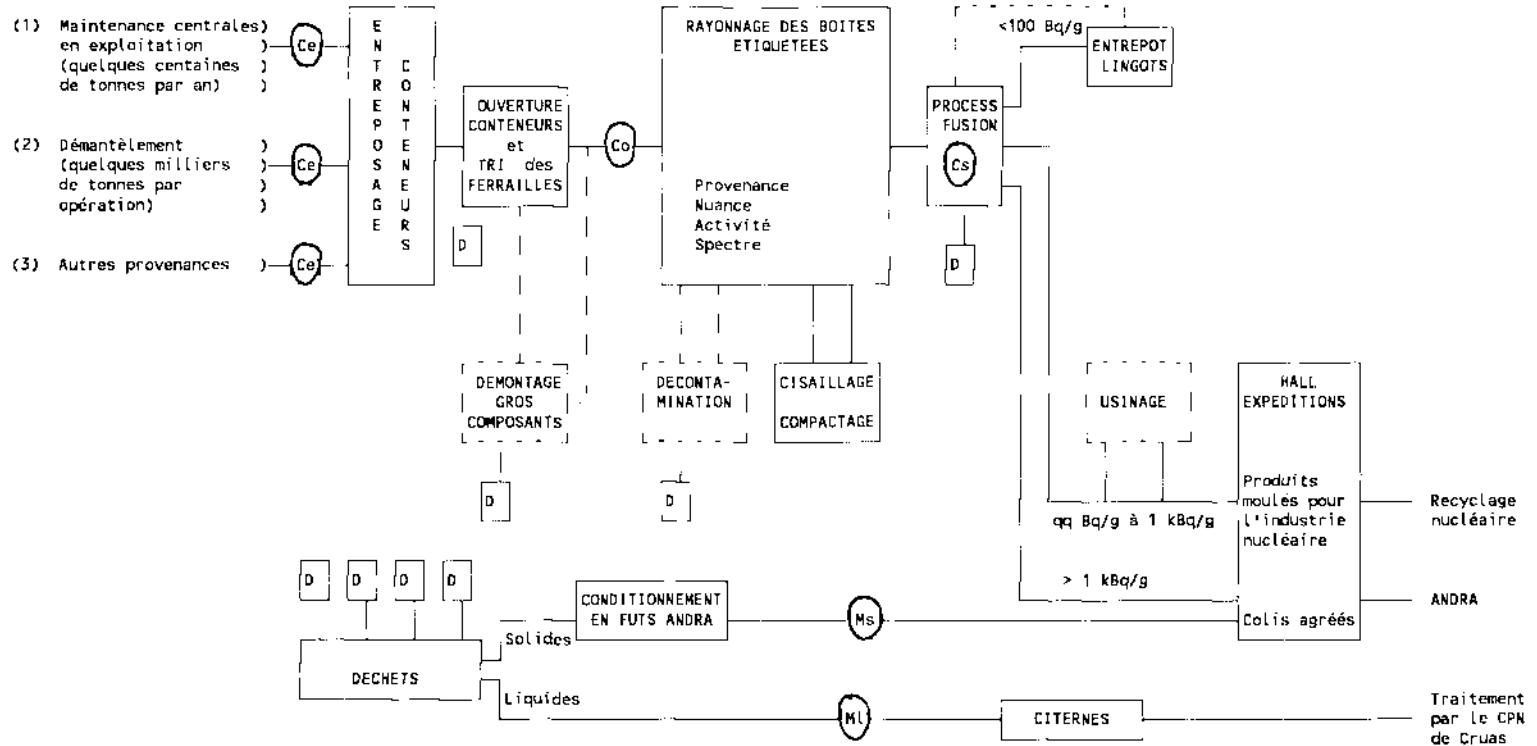

Il fallait dès la conception d'une installation, l'envisager en tant qu'usine qui permette de gérer à l'optimum économique des matières et des activités, la fusion n'étant qu'une phase de la transformation.

Les études technico-économiques conduites par EDF de 1988 à 1990 ont débouché sur un cahier des charges qui définit notamment :

- la capacité de réception : dimensions, masse, activité des colis à traiter ;
- la capacité de traitement : tonnages annuels pouvant être triés, découpés, fondus ;
- la capacité de production : tonnages de produits moulés, d'acier recyclable, de déchets.

Sur la base d'un avant projet suffisamment détaillé, étaient enfin définis les principes de surveillance, les mesures et contrôles qui seront mis en oeuvre lors de l'exploitation : SOCODEI a déposé en fin d'année 1991 les études d'impact et des dangers qui font partie de la procédure d'autorisation d'exploiter une telle installation en France.

Ms Mesure sur les déchets solides conformément aux prescriptions de l'ANDRA

Principales caractéristiques du projet VALDEC-F

Les ferrailles de faible activité proviennent de la maintenance des centrales nucléaires en exploitation, du démantèlement des centrales plus anciennes, ou encore d'autres installations, pour autant que leurs caractéristiques soient compatibles avec les installations.

Le traitement consiste principalement en la gestion des ferrailles (nuances, masse, radioactivité) et leur fusion, en vue, soit de leur revalorisation, soit de la réduction de leur volume.

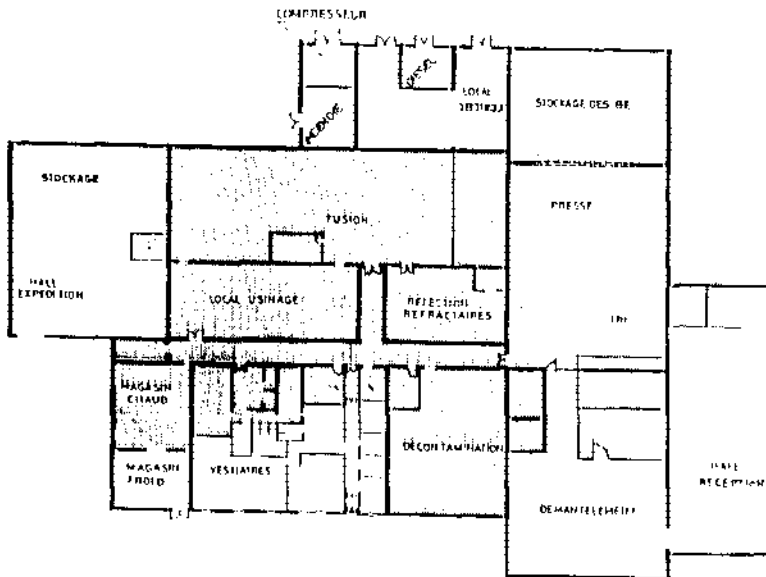

L'usine peut traiter 1 500 tonnes de ferrailles par an en travaillant en un poste.

Elle peut recevoir des colis jusqu'à une masse de 40 tonnes, et de dimensions jusqu'à 8' x 8'6" x 40 pieds.

Peuvent être traitées sans adaptation des installations, des pièces dont la masse est inférieure à 15 tonnes et dont l'activité sur 2 tonnes est nulle part supérieure à 15 000 Bq/g.

Les ferrailles livrées dans des conteneurs mis à disposition par SOCODEI et d'activité ne dépassant par 1 kBq/g, bénéficient de conditions particulières.

Des prestations auxiliaires telles que la décontamination d'une pièce en alliage à haute valeur marchande, ou l'usinage de produits moulés peuvent être réalisées.

FRENCH EXPERIENCE WITH ELECTROPOLISHING

P. SAURIN - C. WEBER - N. ENGLER (FRAMATOME) - B. LANTES -
A. BRISSAUD - P. RIDOUX (EDF) - P. BESLU - S. ANTHONI (CEA)
J.P. CIZEL (STMI)

ABSTRACT :

Following the results obtained in CHINON B1 comparing deposited activity observed on different surface finishes EDF decided to electropolish steam generator channel heads (S.G.C.H.) in order to reduce operator dose during plant maintenance. The qualification tests were performed on steam generator materials (Inconel 600 and S.S. 308 L) with the full on site operational equipment (i.e. a sealed sucker). In 1988 the 4 SGCH of NOGENT 2 were electropolished. In 1990 we observed a dose rate reduction of 45 % at NOGENT 2 compared to NOGENT 1.

Other French experience is electropolishing of 27 S.G.CH, since 1988

1. INTRODUCTION

French attention has also been focused on surface finishing and tests carried out at CHINON B1 NPP to evaluate the efficiency of mechanical polishing, electropolishing and combination of both [1].

The results after exposure of steam generators manway covers for up to three reactor cycles indicated a reduction factor of 3 in the radiation field following the use of electropolishing compared to the as received surface finish [2].

Based on these attractive results and also cost considerations it was decided by EDF to electropolish the S.G.C.H. bowl and partition plate.

Following this decision feasibility and qualification programmes were developed to exclude unacceptable behavior and detrimental effects (i.e. material degradation) [2, 3].

2. INDUSTRIAL APPLICATION

2.1. FRAMATOME electropolishing experience

The French experience of S.G.C.H. electropolishing for SG channel head is summarized in table n° 1.

Table 1 : French experience of S.G.C.H electropolishing

Year	Month	Electropolishing % of total surface area	NPP	Number of S.G.
1988	February	60 %	NOGENT 2	4
1988	July	60 %	CATTENOM 3	4
1989	February	80 %	PENLY 1	4
1989	July	80 %	GOLFECH 1	4
1989	Oct.-Dec.	80 %	DAMPIERRE 1	3
1990	May	80 %	CATTENOM 4	4
1991	Jan.-Feb.	80 %	PENLY 2	4

2.2. Description of an electropolishing operation

A typical electropolishing operation takes approximately 5 Weeks for 8 channel heads, including all the initial and final inspections and quality controls :

- surface pH, conductivity of the final rinsing water,
- microscopic examination on base surfaces and replicas to perform microscopic and SEM examinations,
- surface profilometry (roughness curves).

Metallurgical inspections also takes place during the electropolishing operation.

The electrolyte is composed of a mixture of sulfuric and phosphoric acids.

Electropolishing tools support the electropolishing sucker (STMI patent) which contains the cathode (S.S. disk) [3].

Figure 1 : During "Mosquito" electropolishing

Figure 2 : Partial polished surface on the clad bowl (using "Mosquito" tool)

3. METALLURGICAL RESULTS

Two types of results are recorded as follows

* roughness results

- regular, uniform and extremely smooth surfaces are obtained.

Figure 3 shows examples of initial and final surface profilometry measurements. The micro-roughness has been eliminated after electropolishing.

Figure 3 : Roughness curves on SS 308 L Profiles in X direction μm - from CATTENOM 3

The profilometry measurements are made directly on the S.G.C.H. base surfaces and are statistically analysed by STMI.

* Metallographical results

- no pitting, no etching, or any other undesirable side effects of corrosion .
- only a slight intergranular grain boundary attack on Inconel 600 (i.e. the partition plate) and a very low selective dissolution of delta ferrite on SS 308 1 (the weld overlay).

All replica are immediately examined optically during the electropolishing operation by the metallurgical team, and then characterized at the UNIREC metallurgical laboratory by SEM examinations, occasionally with supplementary EDAX analyses.

Figure 4 provides examples of the initial and final surface finishes (obtained for SEM replicas).

Figure 4 : Microscopic examinations of initial and final surface made on replicas of In. 600 from DA 1 (replacement S.G.)

Before electropolishing (x195)

After electropolishing (x503)

4. CONTAMINATION RESULTS : field results at NOGENT 2

In July 1990 during the first refueling outage after one operating cycle deposited activity and dose rates measurements were made.

The in situ deposited activity measurements were carried out by the CEA CADARACHE directly inside the steam generator with the Emec equipment (measurements and studies of circuit's contamination). Gamma scanning spectra data were obtained on the hot leg of the S.G.C.H. n° 3. The results obtained after processing by a micro-computer are given on table 2 for Co⁵⁸ and Co⁶⁰.

Table 2 : Deposited activity measurements at NOGENT 2 (GBq/m²)

Surface	State	Co ⁵⁸	Co ⁶⁰
clad bowl	non electropolished	10	0.9
	electropolished	2	0.4
partition plate	non electropolished	6	0.5
	electropolished	0.9	/

The electropolishing of the steam generator channel head clearly leads to a considerable reduction of activity specially that due to Co⁶⁰.

The contributions from the partition plate and the bowl to the total dose rate have been calculated in case of a electropolished S.G.C.H. or a non electropolished S.G.C.H. Thus electropolishing leads to a reduction of 44 % of the total dose rate compare to a non-electropolished channel head.

This beneficial effect was confirmed by the dose rate measurements obtained during the latest refueling outage :

Total average : 21.8 mSV/hour

Taking into account the total average channel head dose rates at NOGENT 1 after one cycle (39.0 mSV/hour) at NOGENT 2 the approximate dose rate reduction should be about 45 %.

5. CONCLUSIONS

French electropolishing experience has been very satisfactory to date.

The improvement of the S.G.C.H. surface finish by electropolishing leads to a significant reduction of the dose rate level.

After one fuel cycle in one plant, a decrease of 45 % in the dose rate from the steam generator channel head was obtained.

These results have encouraged EDF to electropolish all new S.G.C.H. including steam generator replacements.

Electropolishing will also be realized on site and in FRAMATOME manufacturing facilities.

DEMANTELEMENT DE L'INSTALLATION DE RETRAITEMENT AT.1 DE
LA HAGUE

C. LAFFAILLE UDIN / LA HAGUE
CEA - DCC/DERD/UDIN/LA HAGUE

DISMANTLING OF AT1 REPROCESSING PLANT AT

LA HAGUE

1 - PREAMBULE

L'installation AT.1 était l'atelier pilote de retraitement des combustibles des réacteurs surgénérateurs (Rapsodie - Phénix). Elle a fonctionné 10 ans de 1969 à 1979 et a produit 1094kg de U/Pu.

L'atelier comportait initialement trois cycles de retraitement. Un quatrième cycle de séparation U.Pu et un stockage supplémentaire de produits de fission furent créés ensuite dans le bâtiment extension mis en actif en 1972. La mise à l'Arrêt Définitif en 1979 fut suivie :

- d'une période de rinçage d'un an qui permit de récupérer 600g de Pu et 1 700 g de U ;
- d'une période de décontamination de dix-huit mois.

L'UDIN prit en charge l'installation le 1er janvier 1982. Les études préliminaires avaient commencé en avril 1981 et le dossier de sûreté fut présenté aux Autorités le 30 juin 1982. Les éléments combustibles étaient retraités dans l'atelier AT.1 selon le procédé PUREX. Les différentes fonctions étaient réparties dans une succession de cellules (voir figure).

L'objectif des opérations dans l'atelier AT.1 est de réaliser un déclassement de niveau 3, hors génie civil, c'est-à-dire consistant à :

- démonter et évacuer tous les circuits et équipements contaminés
- assainir les locaux au niveau le plus bas possible pour permettre une réutilisation du bâtiment sans contrainte de surveillance permanente.

Le scénario de démantèlement a été établi en fonction des difficultés d'intervention dans les différentes cellules et des moyens à mettre en oeuvre en conséquence. Les principales étapes sont les suivantes (voir tableau) :

- 1 : démantèlement des cellules et boîtes à gants alpha et des cellules non irradiantes.
- 2 : démantèlement des cellules irradiantes aisément accessibles
- 3 : démantèlement des cellules Haute Activité en béton.
- 4 : démantèlement des cellules de stockage.
- 5 : assainissement final de tous les locaux.

2 - DEMANTELEMENT DES CELLULES ALPHA

Le démantèlement des cellules alpha et des boîtes à gants qui ne présentaient qu'un très faible niveau d'activité gamma a été effectué en intervention directe. Toutefois, on a recherché à atteindre les meilleures conditions d'étanchéité pour la protection des travailleurs et de l'environnement. Dans ce but un système d'atelier modulaire a été développé permettant de s'adapter aux formes des cellules et des locaux. Des panneaux en acier inox de dimensions standart sont assemblés entre eux pour constituer les murs et le toit. Un joint polymérisant classique assure l'étanchéité entre les éléments. La forme des panneaux est conçue pour présenter une face interne lisse de manière à ne pas retenir la contamination. Un ensemble de modules de ventilation complète le dispositif. Le premier a été réalisé pour le démantèlement de la cellule 906 (fin de procédé) et des boîtes à gants de laboratoire. A cette occasion un système de scaphandre personnel, ainsi qu'un dispositif d'évacuation étanche des déchets ont été expérimentés.

3 - DEMANTELEMENT DES CELLULES HAUTE ACTIVITE

La stratégie du démantèlement de ces cellules répond aux principes suivants :

- * intervention dans les cellules par le haut ;
- * machine de démantèlement mobile et disposant de son propre confinement et d'un poste de maintenance ;
- * système indépendant d'évacuation de déchets vers un atelier de conditionnement ;
- * toutes les opérations effectuées sans rupture du confinement ni de la protection biologique.

La machine de démantèlement ATENA a été conçue pour le démantèlement en téléopération des cellules d'AT.1. Elle se compose d'un porteur et d'un télémanipulateur (MA 23 M ou RD 500).

Le porteur comprend :

- une hotte de confinement,
- un chariot de transfert,
- un bras constitué d'une partie à déplacement vertical et d'une partie polyarticulée supportant le télémanipulateur.

La machine ATENA se déplace sur des rails au-dessus des cellules 904-905. La conduite s'effectue à distance en vidéo. Une nouvelle protection biologique mise en place au-dessus des cellules 904-905 comporte des ouvertures par lesquelles le bras porteur et son télémanipulateur peuvent être introduits en cellule sans rupture de confinement. L'étanchéité est assurée par un opercule de travail amené au poste de travail choisi. Un opercule de maintenance assure le confinement d'ATENA au poste de maintenance à l'extrémité sud de la zone de travail. Sous la protection biologique circule un chariot équipé de deux palans destinés à l'élingage des pièces lourdes et à l'évacuation des déchets vers un atelier de conditionnement.

L'outillage de démantèlement utilisé avec ATENA est intégré dans des boîtes à gants amovibles qui permettent l'introduction et le supportage des outils en cellule et également leur maintenance hors cellule.

Pour la cellule 903 (dissolution), il a été nécessaire d'effectuer une brèche dans le mur de séparation permettant le passage du polyarticulé d'ATENA. La découpe du béton a été réalisée à l'aide d'une scie à disque diamanté montée sur la machine ATENA. Le refroidissement était effectué par azote liquide.

4 - EVACUATION DES DECHETS

Tous les déchets issus du démantèlement d'AT.1 sont contaminés par des radioéléments émetteurs alpha provenant des composés du Pu. En outre, les déchets issus de la tête du procédé sont contaminés par des émetteurs bêta-gamma provenant des produits de fission.

En France les normes interdisent le stockage en surface ou à faible profondeur de déchets ayant une concentration en émetteurs alpha supérieure à 3,7 GBq/t (0,1 Ci/t). Toutefois la présence d'émetteurs bêta-gamma dans les déchets d'AT.1 ne risque pas d'être une contrainte vis-à-vis des normes de stockage. On doit seulement vérifier que les colis ne présentent pas des débits de dose supérieurs à 2 mSv au contact.

La plupart des déchets issus d'AT.1 font donc l'objet d'une mesure de concentration en émetteurs alpha à l'aide d'une station de comptage utilisant la méthode dite "globale" basée sur la détection des neutrons dus aux fissions spontanées et aux réactions alpha, n.

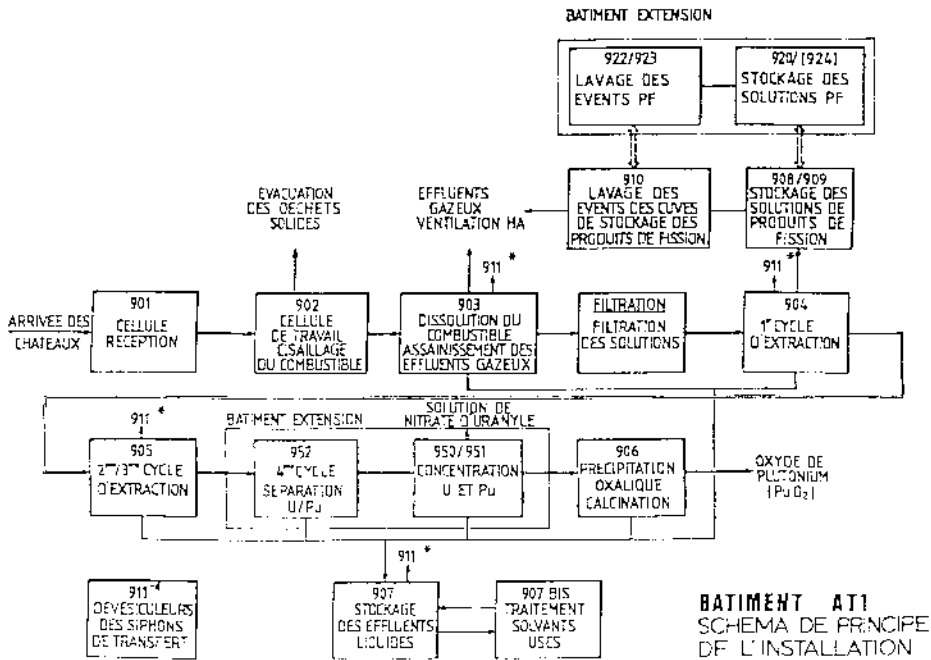

TABLEAU RECAPITULATIF DES OPERATIONS DE DEMANTELEMENT

	Cellule	Type	Risque radiologique dominant	Technique opératoire	Outillage principal	Dose Intégrée mSv	Masse (tonne) et Activité (GBq) des déchets

DECONTAMINATION PROCESSES APPLIED DURING DA1 S.G. REPLACEMENT

Authors : Y.M. BEISSIERE - B. LANTES - EDF
P. SAURIN - C. BRUN - FRAMATOME
P. BESLU - CEA

ABSTRACT

In support of the ALARA concept, applied to the DA1 SGR operation, EDF decided to decontaminate at least the primary pipes and elbows of each primary loop. For the 1st and the 2nd loops an electrodecontamination process was applied after steam generator removal. For the 3rd loop a soft chemical decontamination was also performed in the channel head using the LOMI process.

INTRODUCTION

The steam generators replacement on the DAMPIERRE 1 (DA1) nuclear power plant in 1990 (900 MWe with 3 loops PWR) was the first such operation performed in FRANCE.

- Decontamination had two purposes for DA1 (ALARA concept) :
- to lower the radiation level around the RCS elbows, thus to reduce overall radiation exposure,
 - to remove contamination from the RCS elbows surfaces, to allow easier working conditions in SG cubicles.

In order to achieve these goals the minimum DF demanded was 8 and no free remaining contamination was allowed.

PREPARATIONS AND QUALIFICATION OF THE PROCESSES

Preparative studies were carried out over three years before 1990 operation. Several processes were evaluated ; various soft chemical decontamination processes, electrodecontamination and sand blasting. Two processes were retained, the LOMI process as soft chemical decontamination and electrodecontamination method using phosphoric acid.

LOMI chemical decontamination

As shown on fig. 1, chemical decontamination was simultaneously applied in channel head and primary pipes. In order to avoid introducing chemicals into the reactor vessel, inflatable stoppers were developed to withstand the conditions required by the process. The LOMI process, for which FRAMATOME acquired the license in 1987, was finally chosen because, it was proved to be efficient, non-corrosive, compatible with the inflatable stoppers and less risky in terms of temperature and pressure required.

Electrodecontamination process

The preparation work consisted in the complete design of :

- The electrodecontamination process, mainly the selection of the electrolyte, and operation parameters such as time, temperature, current density, suckers velocity ...

- and, simultaneously, the tools required to apply the decontamination process on primary pipes ends (cast elbows and stainless steel primary pipes).

Electrodecontamination basic principle was derived from well mastered electropolishing of SG channel head, with suction cups as shown in fig. 2.

Figure 1 : Implementation of chemicals and stopper

Figure 2 : Tooling for electrodecontamination (Barras/Provence/STMI patented)

Tooling

Electrodecontamination of the pipe ends is applied after the steam generator has been removed. A specially designed carrier is mounted on the free end of primary pipes. It runs along a central rail fixed on the pipe end and is centered by a plug equipped with an inflatable ring located inside the primary pipe. This carrier supports a set of two leaktight suction cups applied on the RCS pipe walls and arranged symmetrically to decrease the force on the carrier.

The carrier drives both the continuous forward motion and rotation for the suction cups. Nominal displacement of the suckers comprised 2 passes (go and return) and rotation was achieved by a pitch equal to the diameter of cups. 15 stripes were planned to be performed by each cup.

DAMPIERRE 1 DECONTAMINATION OPERATIONS

The soft chemical decontamination was the first main steam generator replacement step. It started on march 8, 1990 on steam generator n° 3. Electrodecontamination started on march 26 for primary loop n° 1 since steam generators had to be first removed from their cubicles.

LOMI decontamination on SG n° 3

The main characteristics of the process used in DAMPIERRE were :

- 4 main steps O.R.O.R.
- Temperature 90° C

- Main steps duration O = 10 h - R = 8 h
- The oxidizing solution was stored temporarily in a buffer tank ready for reuse.
- 1st reducing step "decontaminated" by passing through cationic resins.
- Liquid effluents transported by trucks out of the plant for solidification.

Circulation and heating of solutions, resin treatment, chemical injection ... were performed by modular skid installed in the adjacent fuel building ; the reagents were routed through flexible hoses between the reactor building and fuel building. The tooling package consisted in two compact modules, two temporary storage tanks, and a laboratory skid.

The decontamination team was composed of 18 operators and 4 chemists for process control. The operation lasted the 8 days (3 shifts a day) scheduled. Total man-sievert dose to the deconteam was 0.055 man-sievert. Approximately 110 G.Bq were removed. Initial dose rates observed on DA1 RCS were very low (table 1) due to careful plant shut down and to purification of primary coolant.

Table 1 : Dose rates (arithmetic mean) m sievert/h
External contact of pipes

	INITIAL DOSE RATES (8 pts)	FINAL DOSE RATES (8 pts)	DRRF
Cold leg	0.413	0.027	15
Hot leg	0.253	0.022	11.2

The main results obtained were :

- Average dose rate reduction factor : 13.3 for 8 guaranteed.
- Decontamination factor (as ratio between initial surfacic contamination and final surfacic contamination measured by external γ probe collimated) :
 - Hot leg : DF = 30
 - Cold leg : DF = 70
- The average dose rate inside the cubicle was 0.05 m.sievert/h after steam generator removal.

Electrodecontamination on loops n° 1 and n° 2

The electrodecontamination tooling i.e, the carrier and its suction cups, the I and C cabinet and the electrolyte vats formed a self-contained unit installed in the reactor building at 4.6 m level for the vats, at 8 m level for the control cabinet in the containment annulus and at ground level for effluents storage. The electrodecontamination team was composed of 5 FRAMATOME supervisors and 27 operators and inspectors for STMI who operated the decontamination.

The decontamination operation lasted 100 h for loop n° 1 compared to 50 h scheduled and 70 h in the loop n° 2 for 50 h scheduled.

The decontamination team integrated dose after the decontamination of the two loops was 90 mSV (9 man-rem).

The average (arithmetic) dose reduction factors are shown in table 2 and 3 (m sievert/h)

Table 2 : DRRF before chamfer machining

Loop n° 1	Initial dose rate	Final dose rate	DRRF
Cold leg	0.457	0.030	
Hot leg	0.265	0.025	
Arithmetic mean	0.361	0.0275	13.1

Table 3 : DRRF after machining

Loop n° 1	Initial dose rate	Final dose rate	DRRF
Cold leg	0.457	0.027	
Hot leg	0.265	0.017	
Arithmetic mean	0.361	0.022	16.1

Loop n° 2	Initial dose rate	Final dose rate	DRRF
Cold leg	0.432	0.052	
Hot leg	0.252	0.020	
Arithmetic mean	0.342	0.036	9.5

4. CONCLUSION

Both decontamination processes were used in DAMPIERRE 1, because the first SGR operation was considered as a "bench test" for future similar operations.

- the goal was completely reached with soft chemical decontamination (dose rate reduction, working conditions in SG cubicles, experience)
- the goal was partially reached with electro-decontamination (dose rate reduction, experience) and improvement are already engaged to obtain clean working conditions.

The DRRF were similar (approx 13 in both cases) and this result was considered as successful, especially taking into account the low initial doses rates. The total man-SV saved by decontamination was estimated to be 0.5 man-sievert (50 man-rem) (i.e., 25 % of total integrated dose).

**La NORMALISATION INTERNATIONALE
un OUTIL pour la RADIOPROTECTION**

The international cooperation for standardization in the field of electrical industries was founded in 1904 to promote world wide compatibility and interchangeability of goods. Standardization is considered today as a suitable tool for radiation protection both nationally and internationally. To date more than 50 IEC and ISO standards are in use throughout the world and approximately 50 drafts standards are in the various phase of elaboration and publication. For the future, IEC and ISO have decided to have a close cooperation in order to harmonize and accelerate their work, for the benefit of the energy production and the environmental protection.

L.FITOUSSI

Président du CEI/TC45/SC45B "Instrumentation de
Radioprotection" et de l'ISO/TC85/SC2 "Radioprotection"

Origine et assise de la normalisation internationale

C'est au congrès international d'électricité qui se tenait en Septembre 1904 à Saint Louis (USA) que naquit l'idée de la normalisation internationale. Les savants et les industriels de l'époque souhaitaient une large coopération des sociétés techniques du monde en vue de créer une commission permanente pour servir de forum à une concertation et à une collaboration continue. Ils prévoyaient qu'ils pourraient, par l'entremise de cet organisme, élaborer des solutions communes, appelées depuis "normes internationales", à des problèmes qui, s'ils n'étaient pas résolus rapidement, pouvaient dans le futur conduire certainement à la confusion et créer des entraves et des barrières techniques!

Près de quatre vingt dix ans ont passé et l'esprit visionnaire de ces fondateurs se perpétue aujourd'hui au travers de deux grands organismes mondiaux de normalisation que sont d'une part la CEI (Commission Electrotechnique Internationale), et d'autre part l'ISO (Organisation Internationale de Normalisation) créées respectivement en 1906 et D'autres organismes ont une mission similaire sur le plan régional comme le CEN (Comité Européen de Normalisation) créé dans le cadre de la Commission des Communautés Européennes.

Les normes, outils d'intercomparaison et de décision

S'il n'est plus nécessaire de rappeler l'importance des normes techniques pour les marchés nationaux et internationaux, il est indispensable néanmoins de souligner le rôle primordial des normes internationales de radioprotection relatives à la surveillance de l'environnement. C'est le cas notamment de celles qui concernent les techniques de prélèvement et de mesure applicables, aux opérations de surveillance radiologique des rejets des effluents, aux vérifications des conteneurs de trans-

port de matières radioactives, et aux contrôles des produits de la chaîne alimentaire.

Cependant la normalisation internationale en radioprotection trouve plus particulièrement sa résonnance dans le cas de la gestion des situations de crises provoquées par les accidents nucléaires. En effet, seules des normes, largement adoptées par la communauté scientifique et technique mondiale, peuvent être un outil efficace d'intercomparaison, de dialogue et d'aide à la décision à la disposition des autorités réglementaires. De telles normes peuvent être, en outre, considérées comme un moyen efficace et incontournable de rassurer le public sur la qualité et la crédibilité des mesures et l'authenticité des informations diffusées.

Les domaines couverts par la normalisation en radioprotection

Les partenaires de la normalisation en radioprotection, chercheurs, concepteurs, fabricants, utilisateurs, ont depuis près de trente années œuvré, tant à l'ISO qu'à la CEI, pour publier plus d'une cinquantaine de normes techniques de radioprotection. A celles-ci il faut ajouter, à ce jour, plus d'une dizaine de normes en cours d'édition et une quarantaine de projets en cours d'élaboration.

Toutes ces normes représentent un ensemble cohérent de documents techniques portant sur:

- la terminologie (grandeurs, unités, symboles etc..)
- les rayonnements de référence pour les tests de qualification et l'étalonnage des appareils de mesure,
- la conception des matériels et des sources ainsi que les moyens de protection technique tels que les blindages, les revêtements, les filtres, les appareils respiratoires, etc...
- les méthodes et les appareils de surveillance:
 - . des expositions et des contaminations

individuelles,

- . des niveaux d'irradiation et de contamination aux postes de travail dans les installations,
- . des niveaux d'exposition et de contamination dans l'environnement en situation normale et en situation accidentelle et post-accidentelle.

Les approches et les choix de la normalisation

Le choix des sujets à normaliser ne s'est pas fait au hasard. Il a souvent répondu en priorité aux besoins des utilisateurs. C'est ainsi que l'abandon en radioprotection de la grandeur "exposition" c'est à dire de l'unité "roentgen" et l'adoption du concept de "dose absorbée" préconisé par la CIUR (Commission Internationale des Unités Radiologiques) et la CIPR (Commission Internationale de Protection Radiologique) a nécessité l'élaboration de nouvelles normes.

De même des événements marquants comme les accidents de TMI et de Tchernobyl ont conduit à concentrer les efforts sur la normalisation des techniques de surveillance du milieu et de la chaîne alimentaire. Aujourd'hui, alors que les problèmes liés à la radioactivité naturelle ont pris place sur le devant de la scène internationale, plusieurs normes relatives à la mesure du

radon et ses descendants sont en chantier pour répondre aux préoccupations des services sanitaires.

Aux premiers temps de la normalisation en radioprotection les partenaires concernés se sont entendus pour conforter et rendre cohérentes les options techniques relatives aux appareillages et aux méthodes existantes et déjà largement diffusés. De nos jours ces mêmes partenaires, confrontés à une technologie plus récente, souvent en évolution ou même en cours de développement, s'efforcent d'orienter les choix des spécifications techniques des appareillages vers des solutions communes et réalistes.

Cette nouvelle approche de la normalisation est aujourd'hui nécessaire pour éviter l'écueil de la dispersion des options techniques. Elle permet d'exiger un degré optimal de performance, de qualité et de fiabilité, tout à fait satisfaisant pour la grande majorité des utilisateurs, et par là, répond aux critères de base pour les appareillages devant être mis sur le marché international. Cette nouvelle attitude des "normalisateurs" n'est surtout pas contradictoire avec une certaine flexibilité ou liberté quand aux choix des procédés techniques de réalisation. C'est tout particulièrement le cas aujourd'hui des normes, en cours de préparation, sur les dosimètres électroniques de poche pour la mesure des doses individuelles dues aux rayonnements photoniques et neutroniques.

Le contenu des normes de radioprotection

Chacune des normes, établie à partir de spécifications précises et acceptées par tous les partenaires concernés, représente le meilleur compromis entre la qualité de la mesure, la conception et le coût de la méthode ou de l'appareil. Les textes rédigés en français et en anglais sont soigneusement examinés par un comité de rédaction afin d'obtenir des documents clairs, directement compréhensifs par tous et présentés suivant un format type de façon à couvrir tous les aspects relatifs à la conception, au fonctionnement, et à la sécurité.

En elles-mêmes les normes internationales contiennent donc tout ce qui paraît nécessaire pour assurer un niveau suffisant de performances et de qualité des méthodes et des appareillages. Par exemple, les normes techniques de radioprotection établies par la CEI traitent généralement des points suivants:

- domaines d'application et d'utilisation spécifiques de l'appareillage décrit dans la norme,
- terminologie adoptée pour la norme,
- caractéristiques conceptuelles et fonctionnelles,
- caractéristiques électriques et mécaniques,
- caractéristiques de sécurité et d'environnement,
- conditions normales d'utilisation et performances des mesures pour les rayonnements de référence,
- réponse de l'appareil aux grandeurs d'influence physiques (effet des variations de température, pression, humidité, champs électriques et magnétiques, chocs etc...) et radiologiques (effets dus à la nature et à l'énergie des rayonnements parasites...),

- description des méthodes d'essai pour vérifier les performances de mesure, et prescriptions minimales pour le respect de la norme.
- documentation technique liée à chaque appareil.

La normalisation aujourd'hui et demain

Aujourd'hui plus de 80 pays sont membres des organisations internationales de normalisation et plus de 20 pays participent plus ou moins activement à l'élaboration des normes de radioprotection. La plupart des pays engagés dans le développement de l'énergie nucléaire, la recherche et l'utilisation industrielle et médicale des rayonnements, ou de la radioactivité, s'appuient dans de nombreuses occasions sur les normes de l'ISO et de la CEI. Ainsi plusieurs pays se servent des spécifications techniques des normes comme prescriptions de base pour leurs documents commerciaux tels que les appels d'offres.

En France les normes de la CEI sont utilisées comme documents de référence pour les essais de qualification et d'homologation des appareillages de radioprotection mis en oeuvre dans les installations du Commissariat à l'Energie Atomique.

Même si la plupart des pays ne tirent, qu'à posteriori, largement profit des documents techniques, que sont les normes une fois publiées, il faut par surcroît faire ressortir le rôle des réunions internationales des comités, sous comités et des groupes de travail. Celles-ci sont aussi l'occasion d'échanges directs d'informations scientifiques et techniques. En effet les discussions qui se déroulent au cours de l'élaboration des normes contribuent certainement et activement aux transferts de technologie, ce que l'on peut considérer, à juste titre, comme un moyen international d'accroître la sécurité mondiale.

Pour l'avenir les organisations internationales de normalisation ISO et CEI ont fait part de leurs préoccupations majeures qui sont:

- d'une part l'estimation et la planification des besoins pour les travaux futurs de la normalisation internationale. Ceci en vue d'apporter une aide efficace au développement industriel dans des secteurs clés comme la production énergétique et la protection de l'environnement. A cet effet l'ISO et la CEI préconisent une accélération des travaux et insistent sur la production en temps voulu de documents normatifs courts mais précis, susceptibles le cas échéant d'être mis en révision peu après leur publication.

- d'autre part le développement d'une stratégie à long terme permettant d'associer plus étroitement les capacités et les compétences de ceux qui oeuvrent pour la normalisation internationale, et ce, en vue de répondre aux défis techniques et économiques de demain. C'est ainsi que les deux grands organismes ISO et CEI ont déjà définis leurs objectifs en créant des moyens permanents de concertation et en adoptant des procédures de travail communes et harmonisées. En outre des accords de coopération technique ont été conclus avec les organismes européens de normalisation. Tout ceci pour la mise en oeuvre de la devise:

" Faites-le une fois, faites-le bien, faites-le sur le plan international !"

THE ROLE OF THE IAEA ON THE CONTROL AND SAFE USE OF RADIATION SOURCES

J.U. Ahmed
Division of Nuclear Safety
International Atomic Energy Agency
Vienna

Abstract: Radiation sources are widely used all over the world with an increasing trend. Although safety records are claimed to be high, bad accidents with radiation sources have happened, resulting in injury or death to persons. Organized systems of safety and radiation protection for radiation sources are strikingly deficient both at national and international levels. The IAEA, in response to the demand from many Member States, has initiated a programme since 1988 on the control and safe use of radiation sources with the aim to develop and disseminate internationally harmonized regulatory and technical guidance for the control and safe use of radiation sources.

1. Introduction

Public concern about the safety and regulatory control of radiation sources has grown over the past few years particularly following some bad accidents that happened with both industrial and medical radiation sources. The most notable one is that of Goiania in Brazil in 1986 where an accident with medical irradiation source caused death of a number of innocent public including children (1). In Mexico, in 1983, a medical cobalt teletherapy source was declared as a scrap and was sold to a steel manufacturing company which melted this source together with tons of steel and manufactured furniture parts which were exported to the United States of America. There were no casualties in that accident but the logistical consequence was enormous (2).

Over the past 15 years there has been a number of accidents with industrial irradiation sources, for example, in Italy in 1975 (3). Norway 1982 (4), El Salvador in 1989 (5), and Israel in 1990 (6). High radiation exposures resulting from these industrial accidents caused severe radiation injuries which led to death of four operators and amputation of limbs of the fifth one. The question arises as to who were at fault, the designers, manufacturers, regulators or operators? Another question naturally arises as to what measures were missing which could have prevented such accidents?

2. Estimation about radiation sources

Some estimation made by the IAEA about radiation sources reveals large number in use throughout the world (Table). Also, estimates have been made of the magnitude of annual number of shipments of radioactive sources in 20 countries. These shipments cover all kinds of sources. The data are considered incomplete and inaccurate but it is believed that the actual number of shipments could be well over 10 million per year.

TABLE. SOME DATA ON RADIATION SOURCES

TABLE. SOME DATA ON RADIATION SOURCES

<u>SOURCE</u>	<u>NUMBER</u>	<u>WHEREABOUTS</u>	<u>SOURCE-STRENGTHS AVERAGE</u>	
Teletherapy sources	2600	worldwide	Co-60 Cs-137	220 TBq 40 TBq
Brachytherapy sources	30000 100000	USA worldwide	20 MBq - 4 GBq	
Radiography units	3500 25000	USA worldwide	Ir-192 Co-60	4-11 TBq 1.5 TBq
Commercial product irradiators	150	worldwide	Co-60 Cs-137	40000 TBq 400000 TBq
Industrial gauges	90000 500000	USA worldwide	--	--

3. Nature of the Problem

The IAEA operates through the national atomic energy organization in its Member States. However, radiation sources used in a country are not all procured through this organization. In most cases radiation sources used in industry, medicine, agriculture, and education are procured through the administrative channels of the relevant authorities. In other cases the user imports them directly from the supplier or the manufacturer (2). There are also cases where foreign companies operate industrial irradiation sources which are brought directly without channeling through the concerned national authorities (7). In many developing countries the national atomic energy organization, may not have any knowledge of all radiation sources or their locations of use. This is mainly because there are no established radiation protection infrastructures. The IAEA Radiation Protection Advisory Team missions revealed that 38 developing Member States have no radiation protection law in force and 50 Member States have inadequate radiation protection standards and/or infrastructures.

4. IAEA programme

4.1. Activities prior to 1988

By recognizing the radiation safety problems, the Agency in 1988 initiated a new programme on the control and safe use of radiation sources. This should not, however, imply that before 1988 the IAEA did not have any programme on the standards of safety and protection. The Agency since 1957 initiated a programme on radiation protection with the objective to ensure safe operation of radiation sources, nuclear installations and the protection of man and his environment from the harmful effects of radiation and radioactive releases. The major functions are the development of safety standards, safety guides, recommendations on practical procedures and also some operational service.

The IAEA Basic Safety Standards for Radiation Protection, issued in 1967 was revised jointly with WHO, ILO, and OECD/NEA in 1982 (Safety Series No.9). Following 1990 recommendations of the ICRP the IAEA initiated the revision of the Basic Safety Standards for Radiation Protection jointly with WHO, ILO, FAO, OECD/NEA and Pan American Health Organization, with a plan to publish it in 1993. Prior to 1988 the IAEA initiated two safety series documents related to the control of radiation sources: Safety Series No.101 on Operational Radiation Protection and Safety Series No.102 on the Recommendations for the Safe Use and Regulation of Radiation Sources in Industry, Medicine, Research and Agriculture, both published in 1990.

4.2. The programme initiated in 1988

There are three projects under this subprogramme namely, control and safe use of radiation sources, information on irradiation sources and application of the probabilistic safety criteria. The first task was the revision of the already existing Safety Series No.1 on Safe Handling of Radionuclides, by combining Safety Series No.20 on Safe Handling of Radioisotopes in Hydrology, Safety Series No.23 on Radiation Protection Standards for Radioluminized Time Pieces, and Safety Series No.40 on Safe Use of Radioactive Tracers in Industrial Processes. This combined document, now ready for publication, will serve as a parent document in the whole series of guides issued in the area of the control of radiation sources. One task initiated in 1989 is on regulatory guidance to assist and advise Member States on how to prepare the regulatory infrastructure and regulatory provisions for the control of radiation sources and a document will be published in the near future.

Radiation protection in hospitals is one important subject which was dealt with jointly by IAEA, WHO and ILO since many years. Five documents on this subject area were published jointly in 1970s. This time the Agency has taken the initiative to revise these documents jointly with ILO, WHO, FAO, OECD/NEA, and PAHO with a plan to publish the revised documents in 1993. Radiation safety aspects of specific uses of industrial and medical radiation sources is an important component of the activity under this programme. Six documents have been already prepared which are under publication and these are: Practical Radiation Safety Manuals on (1) Shielded Enclosures, (2) Gamma Radiography, (3) Nuclear Gauges, (4) High Energy Teletherapy, (5) Brachytherapy and (6) Therapeutic Uses of I-131.

Development of complementary resource materials for various technical documents, radiation protection principles for the handling and disposal of radiation sources no longer in use, development of guidance material for information of the public and standardization of international marketing system for sealed sources are the other on-going activities. Other activities are publication of a bulletin or news letter on the safe use of radiation sources, development of database on radiation sources and devices specifications, database on radiation accidents and publication of reports, exchange of practical regulatory information applicable to the control of radiation sources, co-ordinated research programme on the safety problems associated

with the design and CRP on radiation doses in diagnostic radiology and methods of reduction are two important activities.

Regional training courses have been organized in order to provide the Member States with the up to date knowledge on various regulatory and technical measures for the control of radiation sources. The organization of such training courses will remain as a continuing activity.

The project on the probabilistic safety assessment techniques to improve the safety of radiation sources has two components, one on identification of data requirements for PSA and means for data collection, and the other on the preparation of a manual on use of PSA in radiation source safety.

During 1993-1994 an activity will be initiated to develop an international register for radiation sources with significantly high activities, other than unsealed sources; simultaneously, competent authorities will be urged to develop national register for radiation sources, including data base on radiation source specification. Emphasis will be given to strengthen means of providing information to Member States on radiation accidents and lessons learned from such accidents. To assist Member States in providing high standards of training to workers, and regulatory and management staff, the Agency will develop appropriate training manuals and complementary resource material for such national and international training courses. Also, the Agency is going to place emphasis on the implementation of Radiation Protection Advisory Team recommendations to ensure establishment of regulatory infrastructure in those Member States where such infrastructures are non-existent at present.

UIR : ORGANISATION ET PROGRAMME

MYTTENAERE C.

PRESIDENT

U.I.R. Secretariat: Rue Cardinal Cardijn, 5 B-4680 Cupeye (Belgium)

IUR : ORGANIZATION AND PROGRAMME

I.U.R. is an International Association which aims to promote radioecology by exchange of scientific information, cooperation and the support of young scientists. The organizational chart involves a Board of Council which coordinates the various regional branches headed by a Bureau. Besides this vertical structure, it exists an horizontal one constituted by a series of Working Groups headed by a leader. The I.U.R. also cooperates to international programmes such as, i.e., VAMP (IAEA) and SCOPE-RADPATH.

L'Union Internationale de Radioécologie est une organisation non-gouvernementale qui a pour but majeur de promouvoir la radioécologie par le truchement d'une meilleure connaissance du transfert et des effets des radionucléides dispersés dans l'environnement.

L'IUR, association internationale de droit belge, a été fondée en 1978. Elle ne comptait à cette époque qu'une petite dizaine de membres; à l'heure actuelle l'IUR en compte 375 appartenant à 37 nationalités.

President	C. Myttenaere (Belgium)
Vice-Presidents	A.A. Cigna (Italy)
	G.G. Polikarpov (USSR)
Secretary-General	R. Kirchmann (Belgium)
Treasurer	J. Van den Hoek (Netherlands)
Officers	Cl. Bunnerberg (Germany)
	A. Grauby (France)
	B. Howard (UK)
	N. Pattenden (UK)
	Yu-Zao Qi (China)
	D. Reichle (USA)
	W. Schell (USA)
	J. Tveten (Norway)

Past Presidents:

1978-1982	P. Bovard, Honorary (France)
1982-1986	S.L. Auerbach (USA)
1986-1990	A. Aarkrog (Denmark)

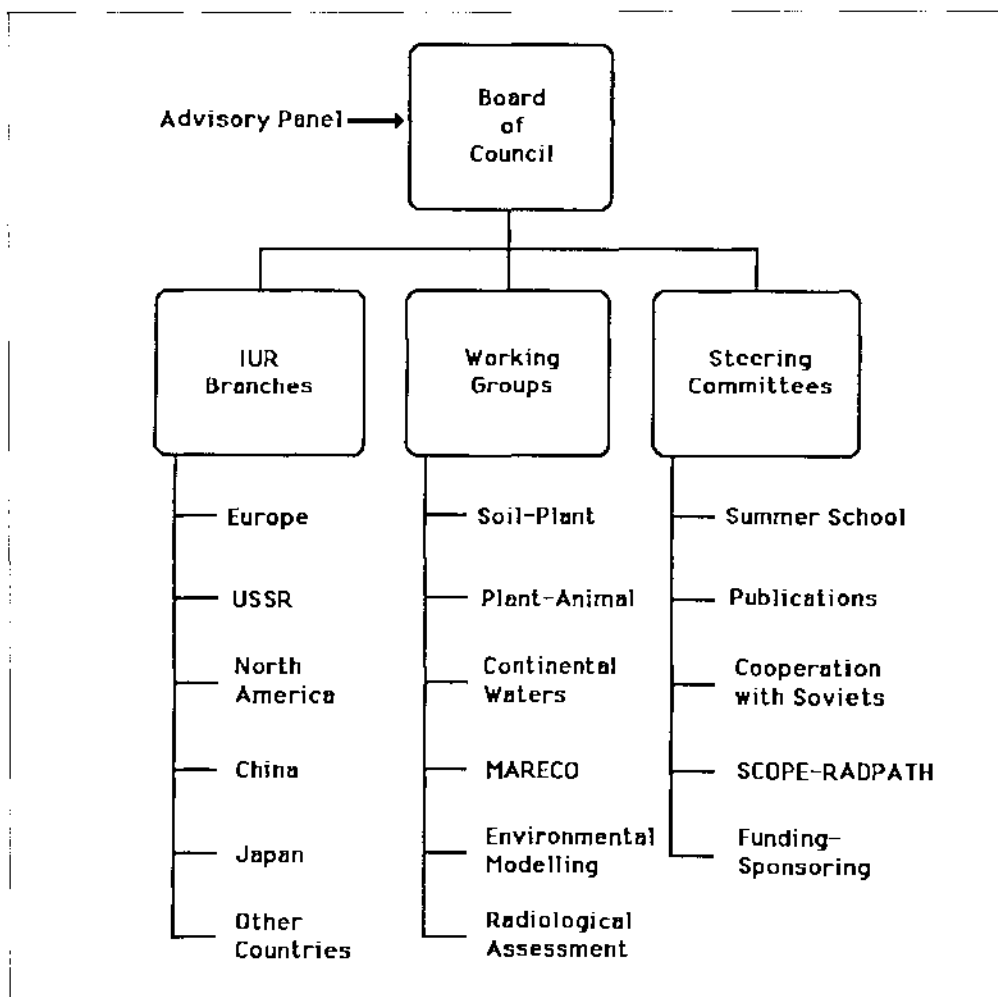

L'IUR est gérée par un Conseil d'Administration comprenant 8 membres en plus du Président, des deux Vice-Présidents, du Secrétaire Général et du Trésorier. Ces membres sont élus pour 4 ans en Assemblée Générale.

La croissance rapide de l'IUR a nécessité une décentralisation des responsabilités. Celle-ci s'est effectuée grâce à la création de Branches Nationales et Multinationales.

Les activités scientifiques de l'IUR sont soit gérées par des "Comités de Gestion", soit confiées aux divers groupes de travail. Les Comités de Gestion sont responsables des activités d'intérêt général (Ecole d'Eté, Publications,...).

Les six "groupes de travail" ont, par contre, la charge de faire le point en matière de radioécologie dans les différents domaines qui sont reprises à la figure ci-dessous.

En plus de ces différentes préoccupations l'UIR aide financièrement les jeunes chercheurs, leur permettant ainsi de travailler dans d'autres laboratoires et de participer aux discussions et réunions internationales. Cette aide aux jeunes chercheurs devrait assurer une relève qui s'avère urgente et nécessaire.

En conclusion, il faut espérer que, malgré un certain désintérêt pour le nucléaire, l'étude des conséquences des diverses applications du nucléaire sur l'environnement ne tombera pas dans l'oubli. L'UIR s'y emploie et souhaite que ces activités puissent se développer grâce à un "sponsoring" plus important.

En fin d'exposé je voudrais, au nom de l'UIR, remercier les Communautés Européennes qui ont compris l'importance de ces problèmes et qui nous ont assurés de leur soutien scientifique et financier.

OPTIMISATION OF RADIOLOGICAL PROTECTION IN COMPLEX SITUATIONS

F Phillips, R W Allott and H L Wilkinson

SRD, AEA Technology,
Wigshaw Lane, Culcheth, Warrington, WA3 4NE, UK

ABSTRACT

Optimisation in radiological protection is a complex process involving trading-off conflicting objectives. A seven-stage decision-process is outlined which helps the practical implementation of optimisation.

INTRODUCTION

In radiological protection, where doses are below Regulatory Limits, decisions about the level of protection are driven by the requirement to keep doses as low as reasonably achievable (ALARA). Judgements about whether this requirement is met have been largely concerned with comparing only the cost of increased protection and the averted health detriment, traditionally using cost-benefit analysis (CBA). However, in practice, decisions to implement further protection to reduce exposure are often made for other reasons not included in the formal analysis, but which nevertheless dominate the decision. More recently, for example in ICRP 55 (Ref. 1), attention has been focused on other decision-aiding techniques, such as multi-attribute utility analysis (MAUA) and multi-outranking criteria analysis (MCOA), which can take account of more facets of the decision directly in the analytical process. This paper outlines a general decision process (similar to that in ICRP 55 (Ref. 1)) to aid the practical implementation of ALARA. Neither the decision-process nor the analytical techniques are algorithms or machines for making decisions. No process or technique can capture all the facets of a decision and the ultimate responsibility for making the decision is always with the decision-maker. The decision-process does, however, help the decision-maker understand the problem more fully, discover which facets of the problem determine the preferred option, and helps communicate to others why, and under what circumstances, a particular course of action is preferred.

THE DECISION-PROCESS

A seven-stage decision-process is outlined below. It is described in further detail in Reference 2.

Define the Problem

Having recognised that a problem exists, the first step is to precisely define the problem. This step is important and should not be underestimated since it defines what the decision is, and conversely is not, meant to address. A simple example of a problem definition is: Annual individual doses to some workers on 'plant X' are higher than 15 mSv.

Define the Aim of the Decision

This step is closely linked to the definition of the problem and focuses the decision by defining the boundary of the problem and which aspects of it are (and are not) relevant to the decision process. This is important to avoid wasting resources on generating irrelevant options and performing unnecessary analysis, and provides a formal record for future use or further study. At this point it may be necessary or helpful to incorporate any constraints

which the chosen option must satisfy. For the problem defined above the aim may be: By the use of engineered means, reduce the maximum annual individual dose to workers on 'plant X' below 10 mSv. The requirement to use engineered means represents a constraint that, for example, operational measures such as dose sharing are not acceptable.

Objective hierarchies (Refs 3 & 4) may be used to help define the aim of the decision. Using these, the decision-maker provides an overall global objective under which a hierarchy of sub-objectives is defined. Iteration of this hierarchy provides an elegant means of closely defining the aim of the decision through the use of decision objectives.

Identify Options

At this stage options must be identified which, if implemented, would achieve the desired result. The identification of options is best undertaken in a two stage process that allows less obvious solutions to emerge. First, as many options as possible should be postulated; then in the second stage, those options that are clearly unacceptable or impractical are eliminated. To avoid wasting resources it is important to reduce the number of options to a minimum whilst at the same time making sure that options are not eliminated unnecessarily. Some initial formal analysis, such as cost-effectiveness analysis (Refs 1 & 2), may help. The effort associated with any analysis must be commensurate with its likely effectiveness and with the scale of the problem.

If a decision involves choosing between options which have a range of possible outcomes (e.g. probabilistic or potential events), then it is often helpful to illustrate the problem in terms of an event type decision tree (Refs 2, 4 & 5). These set out the options facing a decision-maker and map the consequences of choosing a particular option. The act of constructing the tree can in itself clarify the nature of the problem and may lead directly to a decision. However, in complex situations this is unlikely.

Identify Relevant Attributes

Attributes (or factors) are important characteristics of the problem. The process of identifying attributes could mimic the two stage procedure for identifying options described above: firstly, all attributes of conceivable importance to the decision are identified; then, secondly, only those attributes which discriminate between options are carried forward. For example, cost is always likely to be an important attribute but if the range of costs is such that it does not discriminate between options then it has no bearing on the decision and should not be included in the decision process. Techniques of particular use in this identification process include brainstorming and the construction of objective hierarchies (Refs 2 - 6).

The refinement and structuring of relevant attributes may be achieved by the use of multi-attribute decision trees. This type of tree, developed at SRD, explicitly reflects an attribute's relative importance to the decision-maker (Ref. 4). Whereas the problem structuring techniques described above present all the relevant information, multi-attribute decision trees also encapsulate the way in which the information is brought together to model the problem by representing the relative values of the attributes and the trade-offs which must be made to reach a decision, directly in the structure of the tree.

Characterise Options in Terms of Identified Attributes

Once options and attributes have been identified, each option must be characterised in terms of the relevant attributes. The particular manner in which this is done depends on

the specific analytical technique employed, but in general involves quantifying the value of attributes for each option and the relative importance of each attribute to the overall decision. For example, in CBA the attribute 'collective dose' will be quantified in terms of manSv and converted to an equivalent monetary value (Refs 1 & 2). While in other analytical decision aiding techniques, such as MAUA, a weighting factor would be defined to express the relative value of collective dose compared to cost (Ref. 1, 2 & 7). If potential events are integral to the decision problem then quantification of probabilities will also be required (Ref. 2).

It is not always possible or desirable to include all relevant attributes in the formal analysis. Two lists of attributes should be drawn-up: the first consisting of those to be included in the formal decision analysis technique; and the second listing those not included but which must nevertheless be taken into account once the analytical solution is known. This will ensure that all the relevant attributes contribute to the final decision. At this stage it may be necessary to re-formulate the multi-attribute decision tree to reflect the attributes which are to be considered in the formal analysis.

Analytical Decision

There are many analytical techniques available to aid decision-making, ranging from simple inspection of the available options to mathematically complex methods which combine all the facets of a problem into a single measure of its overall worth. Historically, CBA has been used almost exclusively for decisions in radiation protection. More recently, other techniques such as MAUA and MCOA, which can take more explicit account of the diverse nature of problems have been suggested (Ref. 1). Descriptions of these techniques can be found in standard texts (e.g. Ref. 1). While their application to potential exposures is under development (Ref. 2).

The application of a decision-aiding technique often brings new insights into the problem and its essential characteristics. Iteration of the whole decision process may then be desirable to refine work done at previous stages. The process of iteration recognises that it is naive to expect that all possible options will be identified and characterised in terms of all attributes at the outset. Even if this were possible, the data needed and the analysis undertaken would make it an enormous task. In general, decisions are made incrementally. Iteration should continue until the decision-maker is happy that he understands the problem and has characterised it well enough to make a decision.

The application of the analytical techniques generally requires a number of value judgements to be made. The results depend on both these judgements and the quality of the data which go into the analysis. For these reasons, a sensitivity study should be performed to determine how robust the analytical solution is to changes in the values assigned to attributes, uncertainty associated with their value, and changes in their relative importance. This often reveals that only a few of the attributes have a significant effect on the decision and that it is the relative importance attached to these that determines which option is preferred.

The Decision

Once the analytical solution is known, the final decision can then be made. This process cannot be completely separated from the previous stages since the way in which options are characterised in terms of the identified attributes, and the analytical solution, depends on the details of the particular analytical technique employed. The criteria defining the 'best' option are implicit in the mechanisms of the technique and the underlying philosophy

on which it is based. For example, in the case of CBA the 'best' alternative is that which maximises the net present monetary value since this is regarded as the measure of an options worth. If all relevant attributes were included in the formal analysis and the chosen technique models the decision-makers preferences fully, then the final decision will correspond to the analytical solution. However, this is unlikely, and at this stage those attributes not included in the formal analysis must be taken into account and the decision modified accordingly.

CONCLUSION

Optimisation in radiological protection is a complex process involving trading-off conflicting objectives. This paper has outlined a general decision-process and a number of decision-aiding techniques which can help the practical implementation of ALARA. The key to the whole process is to start with a simple model and iteratively refine it, simplifying where possible, and only if necessary developing a more detailed characterisation of the problem. Neither the decision-process nor the analytical techniques are algorithms or machines for making decisions. No process or technique can capture all the facets of a decision and the ultimate responsibility for making the decision is always with the decision-maker. The decision-process does, however, help the decision-maker understand his problem more fully, discover which facets of the problem determine the preferred option, and helps communicate to others why, and under what circumstances, a particular course of action is preferred.

DECISION-MAKING UNDER RISK IN THE OPTIMIZATION OF THE
RADIOLOGICAL PROTECTION APPLIED TO DESIGN

Daniel Germán Hernández

Comisión Nacional de Energía Atómica
Gerencia de Seguridad Radiológica y Nuclear
República Argentina

ABSTRACT

When applying optimization of the radiological protection to design, the corresponding data and parameters may present uncertainties. This paper presents a methodology which allows optimization to be kept under the field of decision-making under risk. This methodology involves the use of the Principle of Maximum Entropy, in order to generate a probability distribution from the available information, while the analytical solution may be assessed by applying the Monte Carlo Method.

INTRODUCTION

When applying optimization of protection procedure to design, lack of precise data on the performance of the protection options, uncertainties due to modeling, or the intrinsic uncertainties of random variables, often appears. If the probability distributions of these variables are unknown, it configures a case of decision-making under uncertainty.

The common way of dealing with this situation consists in assigning most likely values to the mentioned data and, consequently, considering it as a deterministic problem. In order to validate this solution, a sensitivity analysis is carried out.

As an alternative to the above mentioned procedure, another methodology is proposed, which allows to consider the situation as a decision-making under risk one. On doing this, information concerning the data may be recalled from experts, and by applying the Principle of Maximum Entropy to this information, its expert-related distribution is determined. Then, the analytical solution may be assessed by applying the Monte Carlo Method.

Optimization of radiation protection taken as a decision-making under risk problem consists in choosing some option a_i from the set of options A , without knowing in advance the exact state, s_j , that nature will adopt from the set of possible states, S . The probabilities of the states of nature may be denoted P_j ; therefore, the optimum action a_i^* consists in selecting the protection level i associated with action a_i , in such a way that:

$$E(U_i) = \sum_{j=1}^n U_{ij} P_j = \max \quad (1)$$

under the constraints:

$$y_r = f_r(X_1, X_2, \dots, X_k) \leq b_r \quad r = 1, 2, \dots, q \quad (2)$$

$$P [y_r = f_r(X_1, X_2, \dots, X_k) \leq c_r] \geq D_r \quad r = q+1, \dots, R \quad (3)$$

where $Y=f(x)$ denotes functional dependence, while U_{ij} represents the utility of option i , if state j occurs [1,2], and it depends upon design variables (X) through $U=f(X)$. Among these design

variables, collective dose S and costs C should be included, as well as individual dose (H) limitations should be established.

When probabilistic constraints occur, as in expressions (3), only a probability value of attaining a goal, (Dr), may be adopted. If such a goal consists in complying with the individual dose limitation, these limits should be expressed in a probabilistic form [1].

PRINCIPLE OF MAXIMUM ENTROPY OF THE INFORMATION

The probability distribution of any variable may be estimated from information given by experts [3], by applying the Principle of Maximum Entropy (PME). Given the states of nature, s, belonging to an interval R, and being f(s) a probability density function associated to R, a measure of the uncertainty is provided by the entropy of the information, H(f). The PME indicates that, in any case of decision-making under risk, the probability density function which maximizes entropy [4], should be applied.

$$\max \left\{ H(f) \right\} = \max \left\{ - \int_R f(s) \ln \left[f(s) \right] ds \right\} \quad (4)$$

subject to

$$\int_R f(s) ds = 1; \quad f(s) \geq 0 \quad (5)$$

and any constraint given by the available information, such as:

$$\int_R s f(s) ds = med; \quad \int_R (s-med)^2 f(s) ds = \sigma^2 \quad (6)$$

where, med and σ^2 represent values assessed by experts. As a final remark, the PME defines an unique probability distribution, which is the most dispersed one, compatible with the available information. The above mentioned concept justifies the conservatism of the results obtained from its application.

MONTE CARLO METHOD

This is a numerical technique, which allows the assessment of the probability distribution for a given non-linear function, by simulating random variables. For each one of them, a set of values is generated, with the same distribution corresponding to such a variable. These values are replaced in the mathematical model that characterizes the system, defining its response. The distribution of the dependant variable [5], which conceptually represents a hypothetical sampling of the system performance, may be obtained.

NUMERICAL EXAMPLE

As a demonstration, a simplified version of the optimization technique applied to the shielding thickness (t) of a container used for the transfer of burnt fuel elements at Embalse nuclear power plant is presented. This container is a cylindrical vessel, lead shielded and steel jacketed. Both, lead and steel thicknesses must be the same for the lateral surface, the basement and the top. The corresponding values for the calculation parameters are:

- Cost of unit of collective dose = 10 000 US\$/man Sv
- Cost of unit mass of lead = 10 US\$/kg
- Annual individual dose limit = 20 mSv/a

The container will be used throughout 2570 operations during 28 years. On performing the operations, workers identified as A, B, C, D and E will be exposed to radiation, as described below: Workers A and B will carry out tasks 25A and 25B, in an alternate chronogram. Workers C, D and E will deal with tasks 27, 28 y 30 in the same way. As a consequence of this working scheme, workers A and B will receive equal doses, as workers C, D and E will do [6].

Each task is characterized by the time required for its fulfillment (T), and by the distance between the workers and the container (WCD). Both values were obtained from the designers. The values were asked as a mean (MED), as a minimum (MIN) and as a maximum value (MAX). These values are presented at Table 1.

TASK	T (min.)					WCD (m)				
	MIN.	MED.	MAX.	c	μ	MIN.	MED.	MAX.	c	μ
25A	6.0	10.0	30.0	1.079	-0.246	0.2	1.0	5.0	1.577	-1.230
25B	6.0	10.0	30.0	1.079	-0.246	2.5	3.0	3.5	1.0	1.0
27	2.0	3.0	6.0	5.569	-0.898	0.2	1.0	1.5	0.278	1.001
28	2.0	5.0	7.0	0.062	0.246	0.5	1.0	1.3	0.196	1.950
30	0.7	1.0	3.0	33.97	-3.321	0.2	0.5	0.6	0.042	8.984

Table 1. Estimated time and distance for each task, and determined by the Principle of Maximum Entropy.

Equivalent doses (DC) for different distances and shielding thicknesses were calculated by using MERCURE-4 software [7,8]. Based upon experts opinion, it was estimated that the actual doses should be normally distributed with a mean value of 0.8 DC and a variance of 0.2 DC .

The mean values in Table 1 and the estimated doses (DC) were used in order to obtain the solution by applying the cost-benefit technique. The corresponding results are presented in Table 2.

t (cm Pb)	C (US\$)	S (Sv)	U=C+aS (US\$)	H(AB) (mSv/year)	H(CDE) (mSv/year)
7	38230	3.9307	77537	37.24	21.54
8	44590	2.0706	65296	19.57	11.33
9	51190	1.1503	62693*	10.81	6.33
10	58040	0.6193	64233	5.86	3.38
11	65130	0.3406	68536	3.23	1.85

Table 2. Results obtained by applying cost-benefit technique.

In order to obtain the solution by the proposed methodology, the principle of Maximum Entropy was applied to the available data. The corresponding distribution for each variable was assessed by using expressions (4) and (5), and constraint (6) as:

$$\int_{\text{MIN.}}^{\text{MAX.}} s f(s) ds = \text{MED} \quad (7)$$

Proper solutions were determined [4] by applying calculus of variations, resulting in $f(s)=ce^{\mu s}$, while constants c and μ were calculated by using constraints (5) and (7), and are presented in Table 1. The analytical solution was obtained by applying the Monte Carlo technique, which allowed the determination of the distribution of individual and collective doses (Table 3).

t (cm Pb)	C (US\$)	E(U) (US\$)	E[H(AB)] (mSv/y)	E[H(CDE)] (mSv/y)	P(1)	P(2)
7	38230	81525	46.27	30.49	0.2552	0.1439
8	44590	67456	24.42	16.11	0.5082	0.7892
9	51190	63929	13.58	9.02	0.7918	0.9943
10	58040	64712	7.11	4.75	0.9695	1.0
11	65130	68853	3.99	2.62	0.9968	1.0

Table 3. Results obtained by applying decision-making under risk. P(1) denotes $P[H(AB) \leq 20 \text{mSv/y}]$; while $P(2) = P[H(CDE) \leq 20 \text{mSv/y}]$.

According to the cost-benefit technique, the optimized thickness should be 9 cm lead, with a maximum individual dose of 11 mSv/a. The corresponding results for the proposed methodology should be an equal thickness, but a probability P(1) of only 79 % for individual limitation compliance should be accepted.

Cost-benefit techniques require a sensitivity analysis in order to evaluate the stability of its solutions. This analysis presents some problems, such as the lack of a proper methodology of input data selection or that, under certain circumstances, different results are obtained when changing the input data.

On the contrary, the proposed methodology emphasizes the probabilistic features found in most cases in optimization of protection, dealing with the available information accordingly with decision analysis axioms.

CONCLUSIONS

The proposed methodology has demonstrated to be a useful tool for decision-making applied to the optimization of radiation protection under uncertainties. These techniques are adequate in dealing with any kind of random variable, delivering non-contradictory results, with a high degree of coherency with the analyzed situation.

PRATIQUE DE L'OPTIMISATION DE LA RADIOPROTECTION
SUR LE CENTRE DE RETRAITEMENT DES COMBUSTIBLES IRRADIES
DE LA HAGUE DEPUIS 1976

J. BETIS, Chef du Service Prévention et Radioprotection de
l'Etablissement COGEMA LA HAGUE

OPTIMIZATION OF RADIATION PROTECTION
AT FUEL REPROCESSING PLANT
COGEMA LA HAGUE SINCE 1976

This paper presents the organisation of radiation protection service. The means and methods in connection with the technical measures applied into the facilities have permitted, since 1976, to divide the average annual dose per worker by ten and the activity of liquid radioactive waste by three. In the same time the amount of reprocessed spent fuel was multiplied by six. These figures result from the application of a global optimization approach.

INTRODUCTION

Une usine de retraitement est une usine chimique complexe comprenant de nombreux ateliers à risques potentiels très divers en relation avec l'activité, la nature et la forme physico-chimique des substances radioactives manipulées dans ces ateliers.

Une autre caractéristique est, depuis sa mise en service en 1966, l'évolution qualitative (nature) et quantitative (taux de combustion, tonnage annuel) des combustibles retraités. L'augmentation des risques, associée à cette évolution, a nécessité une adaptation des installations et une mise en oeuvre de moyens importants pour aboutir à une amélioration constante de la radioprotection des personnes.

Le but de cet exposé est de montrer comment COGEMA conçoit et exerce la radioprotection à La Hague, pour limiter l'exposition du personnel, conformément au principe ALARA.

ORGANISATION DE LA RADIOPROTECTION

Pour assumer sa responsabilité en matière de radioprotection, le Directeur de l'Etablissement est assisté d'un service de protection contre les rayonnements (aigle SPR) placé sous sa responsabilité, qui représente 10 % des effectifs (304 personnes), et dont les principales missions sont :

- assistance-conseil en matière de prévention auprès du Directeur et des chefs d'installations, responsables entièrement des installations dont ils ont la charge, y compris de la sécurité radiologique et non radiologique.

- contrôle et surveillance des nuisances radiologiques au niveau des installations (locaux et personnel) et de l'environnement dans toutes les configurations de cea installations (exploitation, maintenance, interventions d'urgence).

PREVENTION DES RISQUES RADIOLOGIQUES

Cette mission du SPR s'exerce à tous les stades de la vie de l'usine :

avant la mise en service par:

- l'aide au concepteur : analyse du risque radiologique, des méthodes d'intervention en maintenance, dépannage, des flux d'effluents et déchets, de l'organisation des postes de travail

- les essais et vérification des mesures de radioprotection des installations avant démarrage en actif

- la traduction opérationnelle de la réglementation en matière de radioprotection

- la formation du personnel au travail en milieu ionisant

au cours du fonctionnement

- le rôle préventif consiste à déclencher et à signaler le plus tôt possible toute dérive ou anomalie de "l'ambiance radiologique" des installations mise en évidence lors des nombreux contrôles continus ou périodiques portant sur les travailleurs, les locaux, les matériels, les déchets, les effluents, etc...

- tout travail présentant un risque radiologique doit être préparé et autorisé par un document appelé dossier d'intervention en milieu radioactif (DIMR).

Ce dossier comporte la description de l'intervention par l'exploitant, l'analyse du risque radiologique, une estimation du bilan dosimétrique et les conditions optimisées dans lesquelles doivent s'effectuer cette intervention, définies par le SPR.

Ensuite pendant l'intervention, s'exerce un suivi permettant de s'assurer que les conditions radiologiques du chantier restent dans les limites prévues par le DIMR et que le bilan dosimétrique est conforme aux prévisions (utilisation d'une dosimétrie opérationnelle automatisée par stylo-dosimètres).

SURVEILLANCE DES RISQUES RADIOLOGIQUES

La politique menée en matière de prévention ne peut être jugée et améliorée que par un suivi adapté des nuisances radiologiques :

- surveillance collective de l'état radiologique des locaux
- surveillance, contrôle et bilans de tous les rejets d'effluents

complétée par une mesure de l'impact de ces nuisances sur le personnel et la population :

- suivi de la dosimétrie du personnel

- surveillance de l'environnement.

Pour assurer tous ces suivis et surveillance, deux types de moyens sont toujours utilisés :

- des moyens de surveillance en temps réel qui assurent une fonction d'alarme permettant de détecter des évolutions rapides et importantes des paramètres surveillés et d'enclencher rapidement les mesures correctives qui s'imposent.

- des moyens de contrôles avec mesures en temps différé qui assurent une fonction de suivi fin, de détection d'évolution lente et de bilans précis des paramètres surveillés.

RESULTATS ET CONCLUSIONS

L'application des principes et la mise en oeuvre des moyens qui viennent d'être exposés a permis à COGEMA de maîtriser et de réduire au fil des années :

- l'exposition du personnel (cf figures 1 et 2)
- les rejets d'effluents (cf figure 3)

tout en augmentant sa production.

FRAMATOME, 10 Rue Juliette Récamier, 69006 - LYON

**RADIOPROTECTION OPTIMISATION DURING RCCA GUIDE TUBES PINS
REPLACEMENT IN A PRESSURIZED WATER REACTOR**

Initially due to incidental occurrences (Japan in 1978, France in 1982), pins replacement became a systematic and repetitive operation. Between 1983 and 1991, more than 4000 pins has been replaced in France and abroad. The average dose per replaced pin has been decreased with a ratio of approximately 8 (from 1,25 mSv/pin in 1982 to 0,14 mSv/pin in 1991). It is due, in a first step, to equipment modification and improvement and, in a second step, to highly skilled personnel, experience feed back and environmental conditions.

I - INTRODUCTION

Les problèmes rencontrés fin 1978 au Japon (fissures et ruptures) sur les broches de MIHAMA 3 ont incité FRAMATOME à prendre des mesures préventives de plusieurs types :

- Développement d'un dispositif de contrôle non destructif par ultra-sons.
- Etude d'une machine de changement de broches
- Recherches métallurgiques et mécaniques sur les broches elles-mêmes.

Lorsqu'en 1982 sont survenus des incidents sur Gravelines 1, Fessenheim 1 et Bugey 2, (incidents similaires à ceux rencontrés au Japon) il est apparu qu'ils avaient un caractère générique et qu'ils nécessitaient une action globale.

Dans un premier temps, il y a eu r eplacement pur et simple des tubes guide par des tubes guide neufs et parallèlement à cette action a été menée l'étude d'un dispositif de remplacement des broches.

L'objet du présent exposé est de montrer comment a évolué l'intervention depuis 1982 et quelles ont été les conséquences dosimétriques de cette évolution.

Nous précisons que ceci ne concerne que le changement de broches proprement dit et exclut les opérations amont et aval, à savoir les démontage, transfert et remontage des tubes guide sur site ou en atelier.

II - EVOLUTION DES MOYENS MIS EN OEUVRE

2.1. Remplacement d'une broche : procédure générale

Le remplacement d'une broche est réalisé en respectant la chronologie suivante :

Phase 1 - Désolidarisation de la goupille et de la rondelle d'arrêt par destruction de la soudure.

Phase 2 - Désolidarisation de l'écrou et de la broche.

Phase 3 - Retrait de la broche

Phase 4 - Retrait de l'écrou

Phase 5 - Nettoyage des lamages

Phase 6 - Mise en place écrou

Phase 7 - Mise en place et vissage de la broche

Phase 8 - Soudage goupille/rondelle d'arrêt.

NOTA : Les phases 1 et 2 sont maintenant réalisées en même temps (étincelage de la soudure et du filetage de la broche simultanément).

Présentation d'une broche montée sur un guide de groupe

2.2. Nuisances radiologiques

Les nuisances radiologiques sont dues :

- à l'activité massique des éléments constituant la partie basse du tube guide. Elle varie de 40 à 80 MBq/g (1 à 2 mCi/g) et induit un débit de dose de 5 cm de 2 à 4 Gy/h.
- à l'activité surfacique de l'ensemble du tube guide qui est de l'ordre de 1 MBq.cm⁻².

2.3. Evolution des moyens mis en oeuvre

FESSENHEIM (02/83)

Le délai très court pour la conception et la réalisation des stands chauds a fait que le stand est arrivé à Fessenheim alors qu'il n'en était qu'au stade d'un prototype en cours de mise au point. Après des essais infructueux de remplacement de broches ; il a été décidé de mettre en oeuvre le stand de secours EDF appelé communément "TOTEM".

Le TOTEM est constitué d'une cellule rotative en plomb sur laquelle vient s'appuyer la hotte de manutention des tubes guide.

Toutes les opérations de démontage et remontage des broches s'effectuent en manuel au travers de portes situées en regard des broches.

Tous ces travaux s'effectuent à l'intérieur d'une enceinte de confinement où les opérateurs travaillent en tenue confinée type MURUROA. L'opération de soudage de la barette d'arrêt est néanmoins réalisée sur le stand chaud.

STAND CHAUD

Le stand chaud est un confinement dans lequel sont installés six postes de travail. Le tube guide y est introduit et tourne pour être présenté successivement sur chacun des postes. Les opérateurs situés à l'extérieur du stand, sont protégés de l'irradiation et de la contamination dues au tube guide et peuvent visualiser chacune des opérations.

BUGEY (04/83)

Afin de remplacer les broches de Bugey, un stand chaud est installé dans un local sur le site. Le stand de secours (TOTEM) de Fessenheim est installé dans le Bâtiment combustible de BG 2. 21 tubes guide sont traités sur le TOTEM et stand chaud pour la soudure.

En parallèle à ces opérations, le stand chaud est rendu opérationnel et l'ensemble du reste des tubes guide sont traités sur le stand et l'utilisation du TOTEM est abandonné.

TRICASTIN (04 à 11/83)

Compte tenu des conditions difficiles d'environnement pour l'exploitation du stand à Bugey, EDF installe dans un local "chaud" de la Centrale de Tricastin, un atelier broche équipé de deux stands chauds simplifiés pour le remplacement total des broches et d'un stand de secours équipé d'un dispositif de meulage et de clef à sangle, de principe identique au TOTEM.

PIERRELATTE (12/83 à 12/87)

Afin de satisfaire les besoins industriels de remplacement des broches du parc électronucléaire français que ne peut satisfaire l'atelier de Tricastin, EDF confie à FRAMATOME l'ingénierie de définition et de conception de l'usine à broches de Pierrelatte sur le site de la COGEMA.

Cet atelier bénéficie du retour d'expérience de Bugey et Tricastin, tant sur le plan technique que sur le plan radioprotection.

Il est équipé de 4 stands chauds disposés en deux lignes de production pour le remplacement des broches, d'un stand de mesure d'entraxe des broches et d'un stand de remplacement des coupelles d'arrêt de la liaison des parties inférieure et supérieure des tubes guide.

BASE CHAUDE OPERATIONNELLE DE TRICASTIN

Afin d'effectuer la maintenance des outillages servant en centrale nucléaire, EDF met en exploitation en 1988 la BCOT. L'atelier de remplacement des broches de Pierrelatte est transféré à la BCOT.

STAND CHAUD EXPORT

Afin de satisfaire aux besoins spécifiques d'exploitant étrangers, FRAMATOME a mis au point une unité mobile (stand chaud et son environnement) permettant de remplacer les broches in situ sur n'importe quel site PWR.

III - BILAN

Plus de 4000 broches ont été remplacées à ce jour dont 10 % environ sur des sites étrangers (USA, Afrique du Sud, Suède) à l'aide du stand chaud mobile.

Les résultats dosimétriques sont résumés dans le tableau suivant :

SITES	FR	BG	TH	Pierre -latte	BCOT	EXPORT
Equivalent dose moyen par broche (mSv)	1,27	0,60	0,69	0,20	0,14	0,20

L'équivalent de dose moyen intégré pour la totalité des opérations de changement de broches est de 0,33 mSv par broche.

L'évolution constatée s'explique par :

- le retour d'expérience
- le changement de procédé après Fessenheim
- l'amélioration des stands après Tricastin
- les conditions d'environnement optimisées à la BCOT.
- l'expérience du personnel intervenant.

En ce qui concerne les opérations à l'export, l'unité mobile a bénéficié des dernières améliorations dues au retour d'expérience mais est tributaire des conditions radiologiques particulières de chaque site.

IV - CONCLUSION

Le produit "remplacement de broche" a démontré ses performances techniques, et paraît, à ce jour, difficilement améliorable sur le plan de la radioprotection dans le cadre du concept coût-efficacité.

LA POLITIQUE D'OPTIMISATION DE LA RADIOPROTECTION
A ELECTRICITE DE FRANCE

Lucien BERTRON - Laurent STRICKER
EDF - Direction Production Transport - Paris

ELECTRICITE DE FRANCE POLICY FOR OPTIMISATION
OF OCCUPATIONAL RADIATION PROTECTION

ABSTRACT

The ALARA concept is now applied widely throughout the nuclear industry and has helped significantly reduce doses. The new dose limits imposed by the CIPR - considerably below those used at present - should encourage nuclear plant managers to organize actions involving all their staff to ensure this concept is applied even more stringently. The increased expenditure required to apply these new standards will also incite managers to carry out research programs to assess the true effects of small doses.

INTRODUCTION

La radioprotection est, au même titre que la sûreté, une des composantes de l'acceptation des centrales nucléaires.

Le concept ALARA, qui figure dans les recommandations de la CIPR, s'est largement développé dans l'ensemble du monde nucléaire. Aller volontairement au-delà du simple respect des limites de la réglementation constitue un changement de comportement qui s'apparente, pour le monde industriel, à une petite révolution. Les raisons explicites qui ont poussé les responsables du nucléaire à agir de la sorte sont sans doute assez confuses et peuvent même cacher une crainte inavouée du nucléaire. Quoi qu'il en soit, les résultats sont positifs et nous devons tous nous en féliciter.

Reconnaissons cependant que l'application du concept ALARA s'est faite de façon assez inorganisée faute de référence. Il suffit pour s'en persuader de constater les écarts considérables qui existent dans les investissements que nous avons consentis pour économiser une fraction d'homme.sievert.

La CIPR, dans sa publication n° 60, a recommandé de nouvelles valeurs de limite de doses beaucoup plus sévères. Ceci pourrait laisser penser que notre personnel était jusqu'à maintenant mal protégé, ce que contredisent la plupart des enquêtes épidémiologiques faites dans différents pays sur les travailleurs des centrales nucléaires. Quoi que nous puissions penser de la légitimité scientifique des nouvelles limites, il est évident qu'elles seront reprises,

pour ce qui nous concerne, dans la réglementation européenne et prendront force de loi dans les réglementations nationales vers 1995/96.

Face à cette nouvelle réglementation, l'exploitant peut adopter deux attitudes :

- se contenter de veiller au respect des limites de doses,
- donner le maximum d'importance à l'application du concept ALARA.

La seule attitude possible et responsable est bien évidemment la deuxième pour, au moins, trois raisons :

- La première est que l'application stricte de la réglementation pourrait conduire à une augmentation significative des doses collectives par partage des doses, ce qui n'est pas le but recherché et ce qui, pour les médecins, aboutirait à tort ou à raison à augmenter le nombre de cancers attendus.
- La seconde est que par un souci extrême de prudence on considère qu'il n'y a pas de seuil pour les risques de cancers et d'anomalies génétiques ; il est donc raisonnable de vouloir diminuer les doses reçues par le personnel.
- La troisième est que les hommes de l'énergie nucléaire doivent être sans cesse à la recherche de la perfection dans tous les domaines : sûreté, disponibilité, maîtrise des coûts, communication, etc... Cela implique une culture, une façon de penser et d'agir qu'il sera nécessaire, si ce n'est déjà fait, d'inculquer à chaque travailleur.

L'application du principe ALARA relève fondamentalement de cette culture.

QUELLE DEMARCHE POUR DE VERITABLES PROGRES

La démarche ALARA est la seule démarche de progrès possible. Mais elle doit être décidée (les dirigeants doivent afficher clairement la volonté de s'engager dans cette démarche) et organisée selon un processus rationnel qui implique l'ensemble des corps de métiers. Quelques axes de cette démarche peuvent être identifiés :

- L'exploitation : il convient d'identifier et de mettre en oeuvre les méthodes d'exploitation visant à réduire la contamination des circuits. Ceci est particulièrement vrai dans la phase qui précède l'ouverture des circuits lors des arrêts de tranche.

- La décontamination des matériels : elle doit être effectuée dans un souci d'optimisation. Il convient de trouver le juste milieu entre la contamination génératrice de doses pour les travailleurs et la décontamination trop poussée qui expose inutilement les agents chargés de ce travail et génère des déchets.
- L'identification des postes de travail qui induisent les doses les plus importantes. Ceci doit permettre d'optimiser judicieusement les investissements à faire en matière de protection, d'outillage, de robot, pour réduire les doses individuelles ou collectives. Cette démarche passe nécessairement par un bilan coût/dose évitée qui suppose, pour la cohérence des actions engagées, une référence, au moins implicite, au coût de l'homme.sievert. C'est ce que nous essayons de faire à Electricité de France.
- L'organisation des chantiers, concrétisée par des "plans qualité, sûreté" établis à partir de l'analyse des risques, précisant notamment les protections, les moyens de confinement, le matériel de contrôle à utiliser, etc... et donnant une indication de la dose jugée raisonnable compte tenu des travaux à réaliser, qui servira de référence.
- Le retour d'expérience : l'organisation méthodique du travail doit s'appuyer sur le retour d'expérience. De ce point de vue, la nature standardisée du parc nucléaire français est un facteur très favorable. Un système de gestion des doses, couplé à une base de données, a été mis en place. Il permet au niveau de chaque site d'établir les prévisions de doses pour une intervention déterminée, d'en effectuer le suivi en cours d'opération et, enfin, de les analyser pour apporter les améliorations qui seront susceptibles de réduire encore les doses pour les prochaines interventions.
- La sensibilisation et la formation du personnel.

Indépendamment de la culture qualité qui doit animer chaque agent travaillant dans une centrale nucléaire, la réduction des doses passe par une prise de conscience des exigences liées à la radioprotection par les personnes chargées d'organiser et d'exécuter le travail. Il ne sert à rien de mettre en oeuvre des techniques d'intervention sophistiquées si le personnel n'a pas lui-même le souci de se soustraire du champ d'exposition chaque fois qu'il en a l'occasion.

Un des facteurs important de la réduction des doses est la réduction du temps d'intervention obtenue par l'entraînement du personnel. A cet effet, Electricité de France a construit en association avec FRAMATOME un centre technique où le personnel peut s'entraîner dans les conditions réelles d'intervention qu'il rencontrera in situ.

CONCLUSION

Tôt ou tard l'énergie nucléaire connaîtra un développement important. C'est en effet la meilleure façon de protéger l'environnement de notre planète tout en assurant aux hommes qui la peuplent l'énergie dont ils ont besoin et dont certains souffrent cruellement d'un très grand manque. L'opinion publique et nos dirigeants prendront un jour (et le plus tôt sera le mieux) conscience de cette réalité. Nous devons nous préparer à un revirement d'opinion en investissant dès aujourd'hui dans deux domaines :

- La sûreté : une large réflexion qui porte sur le concept des réacteurs du futur est déjà engagée au niveau international et devrait conduire à des réacteurs encore plus sûrs que ceux d'aujourd'hui, dans un large consensus international. Il serait bon d'intégrer dans cette réflexion l'aspect radioprotection qui doit être pris en compte dès le stade de la conception.
- La radioprotection.

Nous constatons depuis déjà de nombreuses années un désintérêt de la communauté nucléaire pour ce qui concerne la recherche fondamentale touchant la radioprotection. Des efforts importants devraient être consentis dans différents domaines, notamment sur les effets carcinogènes des faibles doses, sur la modélisation des risques, sur la dosimétrie biologique et les soins aux irradiés.

Nous acceptons aujourd'hui par facilité la loi linéaire dose/effet, associée à la non-existence de seuil pour les risques de cancers et d'anomalies génétiques, qui va certes dans le sens de la sécurité mais qui induit des investissements considérables dont on peut se demander s'ils ne seraient pas plus utiles ailleurs.

Les exploitants doivent être moteurs dans cette recherche en participant dans une large mesure aux orientations et au financement des programmes.

Une collaboration internationale dans ce domaine serait bien entendu extrêmement précieuse.

De même, nous devons poursuivre et intensifier nos efforts en matière d'études épidémiologiques pour confirmer que les personnels exposés professionnellement aux rayonnements ionisants ne sont pas soumis à des risques supérieurs. Ces études épidémiologiques n'auront de sens que si elles sont réalisées sur une grande échelle, c'est-à-dire au niveau international, ce qui suppose une harmonisation des méthodes de mesures et de comptabilisation des doses. Dans le domaine de la radioprotection, comme pour beaucoup d'autres domaines, les progrès que nous ferons dépendront largement de notre capacité à travailler ensemble. L'énergie nucléaire a besoin, pour se développer, d'un large consensus international.

A Practical Method for the Application of the As Low As Reasonably Practicable (ALARP) Principle in Facility Design

R G Jackson
SRD
AEA Technology
Wigshaw Lane, Culcheth,
Warrington, Cheshire, WA3 4NE
ENGLAND

ABSTRACT

A structured methodology has been prepared for the application of the ALARP principle throughout the design of a large nuclear facility based on design targets and design limits laid down in the company's radiological protection policy. ALARP reviews at each stage of the design process ensure that the final design will comply with the statutory requirement to restrict all exposures to ionising radiations as far as is reasonably practicable.

INTRODUCTION

In the UK the main radiological protection legislation requires that all exposures shall be restricted as far as is reasonably practicable. This is generally known as 'As Low As Reasonably Practicable (ALARP)' rather than the ICRP terminology 'As Low As Reasonably Achievable (ALARA)'. The term 'reasonably practicable' has been defined by English case law to require the reduction of risks so that the sacrifice required to reduce them further is grossly disproportionate in terms of time, effort or cost compared to the reduction in risk which would be achieved.

ALARP is generally considered to embrace ALARA and to be more restrictive rather than less. In order to demonstrate quantitatively that exposures will be ALARP it is not necessarily sufficient to balance costs and detriments but to err in favour of reducing detriments further.

This paper describes a scheme for the demonstrable application of the ALARP principle throughout the design process. The scheme uses Design Targets and Design Limits as a starting point in the application of ALARP. At each stage in the design process the design is reviewed to see whether exposures are likely to be ALARP. Where average doses are above or close to the Design Targets quantitative justification methods are required to be used. A simple method based on Cost Benefit Analysis which emphasises the importance of achieving the Design Targets is described.

INTERPRETATION OF ALARP

The Ionising Radiations Regulations 1985 (IRRs) (ref 1) require all reasonably practicable steps to be taken to restrict exposures to radiation. In UK case law this is taken to mean that there should be a gross disproportion between the amount that an employer would have to spend on reducing exposures and

the corresponding reduction in risk when expressed in monetary terms. The same process should also be applied to the risks from potential exposures from accidents where both the exposures as a consequence of the accident and the frequency with which the accident occurs will be made ALARP.

The Approved Code of Practice to the IRRs (ref 2) gives advice on the application of the ALARP principle.

In choosing between restricting dose to individuals and doses to groups priority should be given to keeping individual doses as far below dose limits as reasonably practicable. Dose sharing between individuals should not be used as the primary method of complying with dose limits.

It is unlikely that all reasonably practicable steps have been taken to restrict exposures of employees who do not normally work with radioactivity if they exceed one tenth of the annual dose limit to workers.

Engineering controls should almost invariably be provided to reduce exposures to persons from external radiation. Priority should be given to the containment of radioactive substances as a means of preventing dispersal or contamination rather than by applying ventilation.

THE ALARP PROCESS

The ALARP process in radiological protection is concerned with making decisions on the risks from routine and accidental exposures to radiation. Above a certain level risks become unacceptable; below a certain level risks may be accepted as being negligible. Between these two levels is the area in which the ALARP principle is important in determining the balance.

The application of the ALARP principle during the design stage of a large facility requires a structured approach. A sound radiological protection policy is required to provide a starting point for the design process. As the design progresses each design decision must then be considered with regard to the whether predicted exposures or risks from accidental exposures will be ALARP. In some cases it will be necessary to utilise quantitative methods to aid in decision making although the final decision must take into account any relevant non-quantifiable factors.

The final outcome must be a detailed demonstration that either doses and risks are negligible or that they have been justified as being ALARP based on an acceptable methodology.

RADIOLOGICAL PROTECTION POLICY

In developing the basis for the facility a policy statement on radiological protection has been prepared. In addition to the requirement to comply with all current legislation the policy provides a starting point for the application of the ALARP in the form of:

a) Design limits on individual dose and segregation distances for transport which the design must meet.

b) Design targets for average doses and risks from accidental exposures of different groups of workers and members of the public to radiation and the frequency of occurrence of accidents resulting in more than a defined radiation dose to the public which should be met unless it is impracticable or excessively expensive to do so.

c) The requirement that design limits and design targets for radiation and non-radiation workers shall not be achieved by artificial dose sharing.

Engineered safeguards in the facility will include shielding, containment (including that provided by the package construction) and ventilation. Radiological protection guidelines have been prepared for designers to assist in the implementation of the radiological protection policy.

IMPLEMENTATION OF THE ALARP PROCESS

The design process can be broken down into a number of individual stages. At each stage safety documentation is required and this will include demonstration that exposures will be ALARP. To determine that this is the case an ALARP review will be carried out to the level of detail appropriate to the particular stage of the design. Emphasis is placed on the use of engineered safeguards.

During the initial feasibility studies assumptions, calculations, experiments, measurements etc. will be made to determine the basic parameters affecting routine exposures and risks from accidental exposures of workers and members of the public as a basis for a conceptual design.

In preparing the conceptual design the specific requirements of radiological protection legislation and the radiological protection guidelines for designers will need to be taken into account.

As required by the IRRs (ref 1) and the ACOP (ref 2) the design should use good engineering practices to reduce radiation exposures. Unnecessary occupancy of any area with significant expected radiation or potential contamination levels should be avoided. Wherever reasonably practicable, radiological and accident protection should be provided by engineered means (such as shielding, remote handling, physical barriers to access, fail-safe systems, containment, ventilation and filtration) rather than by limiting working times in each area or by procedural means. In the more hazardous areas the dose rates will determine the allowable access (i.e. regular, occasional or exceptional) which will identify the reliability/recoverability which must be built in to any handling equipment.

The radiological information available at the conceptual design stage will enable initial estimates of doses and risks which may be incurred to be compared with the design targets and

design limits showing how they will be met or, in the case of the design targets, why they cannot be achieved. Initial estimates should be made of the differential costs of further reductions below the targets or savings from not meeting the targets.

The details of doses and risks to workers and members of the public and the associated differential costs will become more refined through the preliminary design to the detailed design. At each stage an ALARP review will be undertaken by suitably experienced personnel who will determine whether further increases in protection or any relaxations above the targets are justified.

A simple form of cost benefit analysis is recommended where doses/risks exceed some fraction of the design target to be determined by consideration of, inter alia, the uncertainties in the relevant calculations. The method is based on a band scheme where if the cost of any modification per man seivert saved is less than or equal to the value placed on the detriment the modification should be implemented; if the cost of the modification is more than 10 times the value of the detriment then it is probably not justified and in the intermediate band there is no clear decision and further factors must be considered. To emphasise the desirability of achieving the targets the collective dose cost bands for doses above the targets are a factor of 10 higher than for individual doses below the targets.

The review process continues through design changes during procurement and contract arrangements to the final design. The final ALARP review at the design stage must identify any areas of uncertainty which need to be assessed further during construction and commissioning.

CONCLUSION

The procedure developed will provide a structured methodology for the application of the ALARP principle throughout the design of the facility. Documentation prepared as part of the process will demonstrate that the radiological protection provided by the design, by engineered means wherever possible, is capable of meeting the statutory requirement to restrict all exposures to ionising radiation as far as reasonably practicable.

BILAN DOSIMETRIQUE DES REVISIONS DECENNALES DES
UNITES 2 - 4 et 5 REALISEES EN 1990-1991
AU CENTRE DE PRODUCTION NUCLEAIRE DU BUGEY

Jean FLUCHERE
EDF - Centre de Production Nucléaire du BUGEY

TOTAL DOSIMETRY FOR THE TEN YEAR OUTAGES OF
UNITS 2 - 4 AND 5 CARRIED OUT IN 1990-1991
AT THE BUGEY NUCLEAR GENERATING CENTRE

ABSTRACT :

The French regulation imposes a very important revision for pressurized water reactors which must be carried out every 10 years. Altogether, all the interventions on the primary and secondary circuits represented 800,000 hours of work for each unit. Total dosimetry varied from 3.45 Sv for Bugey 5 to 6.38 Sv for Bugey 2 - these results were very close to the previsions made according to the activity index of the primary circuit

1. PRESENTATION

La réglementation Française impose pour les réacteurs PWR une importante révision tous les 10 ans. Sur les unités du C.P.N. BUGEY, cette révision a été mise à profit pour réaliser les modifications permettant la mise à niveau avec les unités de 900 MW démarrées 10 ans plus tard. L'ensemble des interventions réalisées sur le primaire et le secondaire a représenté environ 800 000 heures de travail.

2. PREVISIONS DOSIMETRIQUES

Depuis le démarrage du palier 900 MW, EDF a corrélié la dosimétrie collective des révisions avec l'indice d'activité de l'installation. Cet indice est la moyenne arithmétique des mesures de débit de dose en mSv/h effectuées le premier jour de l'arrêt, 12 à 16 heures après la chute des grappes, sur les trois boucles du circuit primaire. En avril 1982, EDF estimait que la dose collective d'une révision décennale serait de 6,95 Sv pour un indice d'activité de 190

3. MESURES PRISES POUR REDUIRE LA DOSIMETRIE

3.1 REDUCTION DE L'ACTIVITE DUE AUX PRODUITS DE CORROSION

Les produits de corrosion activés sont responsables d'environ 90 % des doses reçues par le personnel. On estime qu'à l'équilibre, vers le 10e cycle, les isotopes 58 et 60 du Cobalt représentent respectivement 30 % et 50 % des doses.

Pour réduire l'activité induite par ces produits, il convient de surveiller très étroitement la chimie de l'eau du circuit primaire. EDF a mis en application depuis 1980 une procédure chimique à concentration en lithine décroissante, coordonnée à la concentration en bore, permettant de conserver un pH constant à chaud égal à 6,9. Si une très large unanimité s'est faite, au plan international, parmi les exploitants PWR pour reconnaître l'intérêt d'un pH constant à chaud, il existe encore des divergences sur sa valeur optimale (entre 7,0 et 7,5). EDF réalise actuellement un essai à pH = 7,1 sur quelques unités.

3.2. EPURATION CHIMIQUE LORS DU PASSAGE EN ARRET A FROID

La baisse de la température et du pH entraîne une augmentation de la solubilité des différentes espèces métalliques que l'on rencontre dans un PWR. Ceci permet de transférer l'activité déposée sur les structures du circuit primaire vers l'eau.

Ensuite l'épuration de l'eau primaire permet d'éliminer l'activité remise en solution. Depuis 1984, EDF utilise une procédure chimique très stricte lors du passage à l'état d'arrêt à froid pour intervention et ne commence l'oxygénation qu'à partir de 120° C.

3.3. PROTECTION DES CHANTIERS

Dans les centrales PWR le risque majeur est plus celui de l'irradiation que celui de la contamination volumique. Il convient donc dans la mesure du possible de limiter les durées d'exposition. Par exemple : les rajouts des protections de sols (buvards, vinyls) ont disparu compte tenu de la présence de peintures décontaminables. L'expérience a montré que, dans de nombreux cas, la construction de sas de confinement pouvait être remplacée par des dispositifs préfabriqués de confinement dynamique par aspiration d'air. Les feuilles de plomb, difficiles à mettre en place et en forme, ont été remplacées par des matelas de mousse de plomb souples et disposant de systèmes de fixation intégrés.

Par ailleurs, chaque fois que cela est possible, les interventions sont réalisées avec les circuits pleins d'eau.

Enfin dès la préparation des interventions, on cherche à réduire au maximum les durées d'exposition.

**3.4. ORGANISATION DE LA SECURITE RADIOPROTECTION PENDANT
LES REVISIONS DECENNALES**

Les révisions se succédant sans "temps mort", il a été nécessaire de construire une organisation particulière pour tirer rapidement le maximum de profit du retour d'expérience.

Cette organisation comprend une vingtaine de personnes conduite par un responsable directement rattaché à l'ingénieur chef de la Structure d'arrêt. Ce personnel travaille en 2 x 8 (ou en 3 x 8), conseille les intervenants et assure toutes les cartographies.

4. RESULTATS OBTENUS SUR BUGEY 2 - 4 - 5

UNITE	INDICE 90/91	PREVISION Sv 90/91	RESULTAT Sv	INDICE 82	PREVISION 82
BUGEY2	152	6,76	6,38	190	6,95
BUGEY4	91	4,14	5,72		
BUGEY5	52	3,68	3,45		

COMMENTAIRES

BUGEY2 a un indice élevé suite a des ruptures de gaines consécutives à des problèmes de jets de baffles.

BUGEY4 a connu des chantiers imprévus très lourds en dosimétrie.

5. CONCLUSIONS

Les décennales ont été plus "lourdes" en heures de travail que ce qui était prévu en 1982 notamment en raison de la réalisation des modifications et d'un volume très important de contrôles non destructifs. Mais les dispositions préventives prises montrent que la dosimétrie totale est tout de même inférieure : 6,38 Sv pour BUGEY2 contre 6,95.

Les résultats sont conformes aux prévisions (BUGEY2 et BUGEY5) quand les chantiers réalisés sont ceux qui étaient programmés.

UN CAS D'OPTIMISATION DE LA RADIOPROTECTION
LE PREMIER RGV FRANCAIS: DAMPIERRE 1990

R.Hochart, O.Jurion
Electricité de France

AN EXAMPLE OF OPTIMISATION IN RADIATION PROTECTION
THE FIRST FRENCH STEAM GENERATOR REPLACEMENT : DAMPIERRE
1990

2,13 man.sievert for replacing 3 steam generators with less than 10 RP technicians in the field; this outstanding result stems from a three-faced approach: extensively utilizing the complete set of actions on exposure constituents (sources, shielding, duration, distance), implementing a real radiation protection management thanks to the development of adequate tools and finally, reinforcing the individual radiation protection philosophy in practised in France.

INTRODUCTION

Le résultat dosimétrique remarquable de 2,13 homme.Siévert pour le remplacement de 3 générateurs de vapeur sous contrôle opérationnel de moins de 10 techniciens de radioprotection est le fruit d'une approche associant à la panoplie classique des actions pour réduire les doses, une gestion de la radioprotection collective et une philosophie de la radioprotection individuelle.

VERS UNE VERITABLE GESTION DE LA RADIOPROTECTION

La mise en oeuvre d'une véritable gestion de la radioprotection a été rendue possible par le développement d'outils adéquats, qui font par ailleurs l'objet d'autres présentations. Il s'agit, d'un système de suivi des doses en temps réel (FLEXIDOSE), d'une modélisation des tâches (nombre d'intervenants, durée, débit de dose) et de la base de données associée (DOSIANA) et enfin d'un outil de prévision des débits de doses (PANTHERE). Ces outils ont permis:

- une prévision analytique de la dosimétrie globale de l'opération, la définition d'objectifs et la mesure des écarts en temps réel pour actions correctives,
- des simulations pour évaluation des actions de protection donnant tout son sens au principe ALARA. Cependant ces simulations sont restées limitées à l'optimisation des mouvements d'eau, à la définition des protections biologiques à installer et à la validation du choix de décontamination des tuyauteries primaires.

Les options techniques de base de l'opération n'ont pas été prises en utilisant ces outils mais en évaluant les bilans dosimétriques de façon approchée.

L'ACTION SUR LES ELEMENTS CONSTITUTIFS DES DOSES

La panoplie classique mais complète des moyens d'actions sur les éléments constitutifs des doses (sources, écrans, durée et distance) a été utilisée :

La réduction des sources

L'analyse du niveau de contamination relativement faible des circuits de Dampierre 1 au moment de son arrêt fait l'objet du papier "Aspects contamination pour le RGV". En ce qui concerne la phase de mise à l'arrêt à froid, on peut noter que l'utilisation d'une filtration spécifique (ADF) et les vidanges du circuit primaire ont plus que compensé la recontamination importante apparue lors de la phase d'oxygénation.

Deux procédés différents de décontamination des tuyauteries primaires ont été mis en oeuvre au titre d'expérience pilote: la décontamination par chimie douce du fond de GV et des extrémités des tuyauteries primaires sur une boucle et l'électrodécontamination des extrémités de tuyauteries primaires sur les 2 autres boucles. Le gain dosimétrique net a été de 700 homme.mSiévert soit 25% de gain relatif et un coût de l'homme.rem évité qui, en supposant qu'un seul procédé ait été développé, aurait été d'environ 20000\$ c'est à dire supérieur à la valeur permettant de justifier l'opération.

Les protections biologiques

Il s'est avéré que le matériel existant n'était pas suffisamment adapté à l'opération de RGV. L'ensemble de 56 tonnes de matériels perfectionnés et de qualité qui ont été provisionnés et installés (matelas, paravents, murs, plaques de sol) a eu un impact non seulement sur la motivation des intervenants mais surtout sur le bilan dosimétrique. Le gain net a été de 484 homme.mSiévert (gain brut de 534 homme.mSiévert moins coût d'installation de 50 homme.mSiévert) soit un gain relatif de 20% et un coût de l'homme.rem évité d'environ 8000\$, qui diminuera avec la réutilisation du matériel. Ce gain aurait été supérieur en l'absence de décontamination des tuyauteries primaires.

La contribution des obturateurs hydrauliques mis en place dans les tuyauteries primaires pour les besoins de la décontamination est prise en compte dans le bilan dosimétrique correspondant.

La vidange de l'eau du secondaire des générateurs de vapeur au dernier moment avant leur évacuation a constitué un gain "gratuit" pouvant représenter jusqu'à 900 homme.mSiévert soit 30% de gain relatif s'il est calculé par rapport à une vidange en début d'arrêt.

Les outillages

Pour les 2 opérations les plus longues au contact des tuyauteries primaires, des outillages pilotés à distance ont été spécialement développés : machine à usiner le chanfrein de soudure et ensemble de soudage TIG orbital vidéo.

La préparation et l'organisation

Une optimisation du chantier sur le plan dosimétrique a été possible grâce aux actions de préparation suivantes:

- l'élaboration d'un ensemble de "Fiches Radioprotection" décrivant l'environnement participant à la dosimétrie de chaque tâche et le nombre d'intervenants prévu,
- une revue de projet de l'ensemble des tâches du RGV avec les entreprises concernées,
- un entraînement sur maquette des opérateurs spécialisés les plus exposés, en présence d'un spécialiste de radioprotection.

D'autre part l'absence d'alea de chantier, elle-même largement imputable au haut degré de préparation technique, a fortement contribué à la limitation des doses reçues.

UNE PHILOSOPHIE DE RADIOPROTECTION INDIVIDUELLE

Le type de formation donnée en France aux intervenants permet de limiter fortement le nombre de techniciens de radioprotection nécessaire sur les chantiers. Cette formation a été complétée par une information spécifique auprès des participants à l'opération de RGV (vidéo d'accueil, fascicule "ALARA", information spécifique de l'encadrement d'EDF et des entreprises, affichage des courbes dosimétriques prévisionnelles et réalisées). On a d'ailleurs pu observer une relation inverse entre dose individuelle et degré de formation/sensibilisation à partir d'interviews.

CONCLUSION

Même si on peut attribuer le bon résultat dosimétrique de l'opération de RGV de Dampierre 1 en partie à un état radiologique de la tranche meilleur que prévu, et qui explique par ailleurs 60% de l'écart entre le bilan prévisionnel avant arrêt (4,5 Homme.Siévert) et le résultat final (2,2 homme.Siévert), il n'en reste pas moins vrai que la contribution de l'ensemble des actions menées pour réduire la dose collective a été déterminante; les outils d'optimisation spécialement développés ont même permis de vérifier que les actions de protection ont eu l'impact prévu.

CONTAMINATION ASPECT FOR THE STEAM GENERATOR REPLACEMENT

The good dosimetry result of 2,13 men Sievert for the three steams generators replacement at DAMPIERRE is the result of an ensemble of dispositions choised for this occasion.

Among them are the contamination aspects of the system.

We can cite, particullary :

- design generally dispositions to permit a reduction politic of the activity of the systems (decreasing of the cobalt content from the steam generator tubes, using of zyrcaloy guid fuel assembly,...)
- the power operation parameters,
- an rigorous procedure for the refueling shut down;

ASPECTS CONTAMINATION POUR LES REMPLACEMENTS DE GENERATEUR DE VAPEUR

RESUME

Le résultat dosimétrique remarquable de 2,13 homme sievert pour le remplacement des 3 générateurs de vapeur de DAMPIERRE est le résultat d'un ensemble de dispositions adoptées à cette occasion.

Parmi elles figurent les aspects contamination des circuits. On peut citer plus particulièrement :

- des dispositions générales de conception permettant une politique de réduction de l'activité des circuits (diminution de la teneur en cobalt des tubes des générateurs de vapeur, utilisation de grille de maintien du combustible en zyrcaloy ...),
- les paramètres de fonctionnement,
- une procédure de mise en arrêt à froid rigoureuse.

CAS DE DAMPIERRE 1

DAMPIERRE 1 est une tranche présentant des niveaux de contamination intéressants, parce que relativement faibles par rapport aux autres tranches du parc, comme le montre la figure 1.

CONTAMINATION

Elle a fait l'objet de mesures spécifiques par le CEA/SECA à l'aide de l'appareil de spectrométrie EMECC (Ensemble de Mesures et d'Etudes pour la contamination des Circuits).

De leur analyse, il ressort que :

- * La conception des générateurs de vapeur (2 fabricants différents) favorise la déposition de produits de corrosion sur les faisceaux tubulaires, ce qui se traduit par une activité déposée sur les tuyauteries du circuit primaire plus faible.
- * L'introduction de grilles de maintien des éléments combustibles en zircaloy a été également un facteur favorable.
- * Le fonctionnement qui comportait, en cours de cycle, un arrêt à chaud de 12 jours, 40 jours avant l'arrêt fin de cycle, a fait l'objet d'un allongement de campagne d'environ 2 mois, avec 1 fonctionnement à 50 % de PN pendant 10 jours.

On peut retenir que la fin de cycle a été globalement bénéfique pour la contamination : on a estimé des gains de 5 à 35 % en activités, par rapport au début de l'allongement de campagne.

- * En ce qui concerne la chimie, un facteur intéressant supplémentaire à retenir : le fonctionnement un peu plus acide en fin de cycle, et 1 choc acide fin de cycle (ph = 6,6), qui favorise les déplacements d'activité hors flux vers les zones sous flux.
- * La mise en arrêt à froid a suivi la procédure habituelle avec quelques gestes particuliers :
 - utilisation d'une filtration adaptée combinant à la fois le piégeage des matières solubles et des particules,
 - globalement, le volume du circuit primaire a été renouvelé 2 fois.

Ces actions ont contribué à une bonne épuration du circuit primaire, bien que leur effet sur la contamination générale ne soit pas pleinement démontrée à ce jour. L'expérience acquise montre en effet que les mises en arrêt à froid sont plutôt des sources de contamination que de décontamination. Par exemple, l'oxygénation qui peut entraîner une redéposition (essentiellement du Co 58) si elle est réalisée à une température trop élevée.

RESULTATS

Par rapport au cycle précédent, on constate :

- une tendance à la baisse sur les activités Co 58 de 25 % sur les GV et 30 % sur les branches chaudes,
- une baisse de l'ordre de 20 % sur les branches chaudes pour le Co 60, au lieu de l'augmentation à laquelle on pouvait s'attendre.

Des mesures en continu ont été effectuées sur les GV 1 et 3 durant les phases de refroidissement, oxygénation et purification. On y constate une recontamination modérée (15 % en Co 58) et une solubilisation presque totale de l'Ag 110 m déposé (1350 GBq pour les 3 GV).

Une analyse est en cours pour déterminer si les parts relatives de la mise en arrêt à froid, de la borication en fin de cycle, ou de la chimie de l'eau sont responsables de cette baisse.

CONCLUSION

Il apparaît comme le démontre DAMPIERRE 1, qu'il faut compter sur un fort impact de la conception sur le niveau de débit de dose.

Néanmoins pour les prochaines opérations de remplacement de générateurs de vapeur, certaines actions peuvent être proposées afin de se placer dans la meilleure position possible :

- introduction de combustible avec des grilles de maintien en zircaloy,
- fonctionnement avec un pH primaire de 7.1, sous réserve des résultats des essais en cours,
- réaliser une bonne épuration de l'eau du circuit primaire pendant les phases d'arrêt,
- être vigilant pendant les phases d'oxygénation,
- utiliser des éléments d'épuration adaptés,
- être vigilants sur le problème des points chauds pouvant affecter des circuits auxiliaires proches du RGV ou éventuellement des boîtes à eau des GV.

DOSE RATE INDEX

FIGURE 1

Occupational exposure trend and the radiological protection optimization criteria in spanish nuclear power plants in operation:present and future.

O'Donnell, P.

NUCLEAR SAFETY COUNCIL STAFF

ABSTRACT

Occupational collective dose per reactor evolution in the operating nuclear power plants in Spain has shown in the last years a tendency to stability, within a range of values similar to the average of the OECD countries.

In this presentation the main indicators to assess the present development level of this criteria are reviewed and the basis to improve the effectiveness of the practical application of it is proposed.

INTRODUCTION

In this presentation the lecturer reviews the present situation in the application of the radiological protection optimization criteria in Spanish nuclear power plants and proposes the basis to improve the effectiveness of the practical implementation, within the framework of the role played by the regulatory body.

The terms in which this review is done are the following: first, the collective doses and the average individual doses as indicators of the occupational dose trends and, second, the basic components of an ALARA programme, i.e., commitment, organisation, tools and procedures.

OCCUPATIONAL DOSE CONTROL

Concerning dose control two main areas of interest are described within the international context: first, the control of sources of exposures, and second, the control of exposure duration.

A third approach to control doses is to introduce efficient work management programmes including work planning, training, optimization of work forces, etc.

COLLECTIVE DOSE

Occupational collective dose per reactor evolution in the operating nuclear power plants in Spain has shown in the last years a tendency to stability, within a range of values similar to the average of the OECD countries.

Surely, this tendency of the collective occupational dose for Spanish PWR's is far from reaching an ALARA plateau, which is not cost effective to reduce exposure with the current nuclear reactor design and technology.

Comparing the situation for PWR's within the international context, size and age taken into account, we can see according with the data of the table I that while collective occupational exposure in the last generation of spanish PWR's is in a very advantageous level, the behaviour of the second and first generation is different. In this sense,

the third generation incorporates in its designs more ALARA considerations than the others.

TABLE I.- AVERAGE ANNUAL COLLECTIVE DOSES OVER PLANT LIFETIMES AS A FUNCTION OF REACTOR SIZE AND AGE FOR PWR'S (man.mSv).

COUNTRY	OLD & SMALL PLANTS	INTERMEDIATE & MEDIUM	MODERN & MEDIUM
SPAIN (82-90)	5,190 (01)	2,790 (04)	750 (02)
INTERN.AVER. *	2,990 (18)	2,100 (34)	1,660 (22)

* Belgium, France, Finland, W. Germany, Holland, Japan, S. Africa, Spain, Sweden, Switzerland and USA PWR's > 400 Mwe gross output. During the period 1969-88 (Ref. 1).

NOTE: The values in parenthesis are the numbers of reactors in each class. The small plant of Spain is only 160 Mwe gross output.

Similar terms of comparison can be established for BWR's, but, in this case, with the supplier's country of origin. Again, the relative situation on occupational exposure is more advantageous for the new plant than for the old one (Table II).

TABLE II.- AVERAGE ANNUAL COLLECTIVE DOSES OVER PLANT LIFETIMES AS A FUNCTION OF REACTOR SIZE AND AGE FOR BWR'S (man.mSv).

COUNTRY / PERIOD	OLD & SMALL PLANTS	INTERMEDIATE & MEDIUM
SPAIN / 87-89	6,290 (1)	2,600 (1)
USA * / 87-89	5,430 (6)	4,710 (6)

* The lecturer has considered most similar plants in size and age to the Spanish ones (Source: Ref. 2).

NOTE: The values in parenthesis are the numbers of reactors in each class.

TASK RELATED COLLECTIVE DOSE

In order to homogenize dosimetric data, the CSN recommends in its safety guide nº 1.5 "Documentation on refuelling outage in LWR's", Appendix III, a codification system which is the one recognised by the CEC (Doc. nº 3650/90/ES MC/ae), and at the same time the one also included in the data base of the ILO, coordinated by the NEA/OECD.

Following the recolected data up to date, although with various codifications, some of the jobs involving higher average collective doses for PWRs are steam generators (45%), insulation/scaffold (15%), waste and decontamination (8%), open/close vessel(8%), RC pumps (4%), reactor components (2%), refuelling (1%) and others (17%).

INDIVIDUAL DOSES

In Spain this parameter is stabilized on the same order during last five years as the international medium (3 mSv). According to a study developed by the Radiation Protection Working Group of AMYS-UNESA, and the dosimetric data reported to the CSN, only about 5% of the workers were, at least once, over 20 mSv/year during the period of time 1985-89. The average being in the last five years about 2% of the workers

exceeding 20 mSv/year, i.e., between 100 and 170 workers each year. During the mentioned period only 0.25% of the workers were overpassed 100 mSv of cumulative dose, i.e., 42 workers.

IMPACT OF REDUCED EXPOSURE LIMITS AND ALARA IMPLEMENTATION

New ICRP's recommendations emphasize the need to focus the efforts in reducing the sources of exposure and the duration of exposure, by incorporating more means as crew for high dose work, restriction in use contractor's key worker, etc. not implying necessarily an increase in total collective occupational exposure, taking into account that both, individual doses and number of persons exposed, must be optimized.

The optimization criteria is implemented in Spain through "Dose Reduction" programs. The terms under which these programs are going to be reviewed are commitment, organization, tools and procedure.

A key factor then to a succesful ALARA programe is the commitment at all levels, but mainly at management level.

Although a strong commitment from management and the workforce can be enough, a specific management structure are very usefull to strengthen operating efficiency of ALARA program.

In my opinion, must be required the presence in the plants of a specific and permanent structure to cover the following roles and profiles:

- * Multidisciplinary structure at the management level
- * Expert group
- * The radiation protection manager in all plants has direct access to the plant manager and is independent of the operating organization.

On the other hand, the "Dose Reduction Programs" includes the guidelines of an ALARA job review, involving pre-job review, follow-up, post-job review and process review, in similar terms as the INPO considers as a good practice.

Nowadays, the CSN has started a process in order to homogenize the procedures that implement the ALARA program, in accordance with the last requirements related.

Examination of the evolution of exposures associated with routine or special maintenance operations in nuclear power plants normally shows a decreasing trend for collective doses throughout successive operations. This evolution is generally accompanied by a simultaneous reduction of the average individual doses for the various categories of workers involved.

One of the aspects that has an influence in this evolution is the "learning" effect which allows operator to integrate the lessons from previous operations. Studies have also shown that the dosimetric burden of the first operations can be substantially reduced if radiation protection considerations are present at the preparatory stages, as well as during work performance.

When carrying out ALARA assesments during plant operation it is essential to make the maximum use of operating experience. This can only be achieved if plant operator has all available information to estimate the consequences of their choices.

Computerised data base of collective doses and job related doses has been established by the CEC and the NEA/OECD is taking the last steps to set up an International Information System on Occupational Exposure (ISOE), which will process data from America, Europe and Japan utilities.

In Spain, utilities and the CSN will participate in the ISOE project. In addition, the CSN is supervising a historic study of recopilation of data in occupational exposures, job related doses and dose reduction techniques applied in order to provide the initial input to a similar data base on a national context, compatible with the CEC and ISOE data bases.

DOSE CONSTRAINTS

According to the ICRP-60 it may be necessary to establish dose constraints at the national level for operation, inspection and maintenance of nuclear power plants. From my personal point of view, the collaboration among the regulatory organization and utilities is essential to achieve the proper values.

CONCLUSIONS

ALARA must be regarded primarily as a "state of thinking" that should pervade the various levels of management and workforce.

The possibility of specifying valuation of detriment by the national authority is under consideration, but at the moment other actions, as mentioned above, to improve the framework in which the ALARA criteria is developing have been considered more urgent.

THE RESSAC PROGRAM: PROGRESS AND FUTURE WORK

The RESSAC program (Rehabilitation of Soils and Surfaces after a nuclear ACCident) was started in 1985. It has given since some improved answers to the problem of rehabilitation of radioactively contaminated land. With the involvement of the Commission of European Communities after 1987 and the implementation of collaboration programs with USSR it has an international dimension. In 1992 the scientific teams will be able to use new and important experimental facilities.

1 INTRODUCTION

Depuis les débuts de l'industrie nucléaire quelques accidents ont conduit à des rejets significatifs de radionucléides dans l'environnement. On peut citer les accidents nucléaires de Kyshtym et Windscale (1957), de Tchernobyl (1986) et l'accident radiologique de Goiânia (1987). En France, malgré les précautions prises lors de la conception, la construction et l'exploitation des installations nucléaires, l'analyse de sûreté montre que l'on ne peut pas exclure totalement la possibilité d'un accident grave. Pour gérer au mieux une telle éventualité des plans d'action ont été préparés; il s'agit du Plan d'Urgence Interne (PUI), spécifique à chaque installation nucléaire et sous la responsabilité du chef de l'installation, et du Plan Particulier d'Intervention (PPI), relatif à la phase réflexe de l'accident, et dirigé par le préfet du département concerné. Une fois l'installation remise en état sûr, les pouvoirs publics doivent mettre en application le Plan d'Action Post-Accidentel (PPA), dont les objectifs sont de permettre le retour à une vie normale dans les zones touchées par l'accident.

Au plan national, en cas de crise nucléaire l'Institut de Protection et de Sûreté Nucléaire intervient comme appui technique des autorités de Sûreté et des pouvoirs publics, notamment par l'intermédiaire du Centre Technique de Crise (CTC) implanté à Fontenay-aux-Roses.

Le but du programme RESSAC est d'établir un ensemble de données sur les transferts de la radioactivité dans l'environnement et les méthodes à mettre en oeuvre pour atteindre les objectifs définis ci-dessus. En 1987 la Commission des Communautés

Européennes a été associée au programme. Aujourd'hui l'Allemagne, la Belgique, l'Espagne, la Grande-Bretagne, et l'Italie ont une participation active. Des collaborations sont en cours avec l'URSS pour effectuer des études sur les zones contaminées de Tchernobyl et de l'Oural.

2 BILAN ACTUEL DU PROGRAMME RESSAC

2.1 Les études du terme source et le champ d'action du programme

Le terme source qui a servi à établir l'enveloppe du programme RESSAC (et par ailleurs le PPI et le PPA) a été défini à partir d'un scénario accidentel intervenant sur un réacteur à eau sous pression. Ce terme source, dénommé S3, correspond à une fusion du coeur avec défaillance des systèmes de sauvegarde et utilisation de la procédure ultime de décompression de l'enclaustrage de confinement à travers un filtre à sable. Les produits de fission les plus volatiles (non compris les gaz rares) seraient émis dans l'atmosphère à raison de quelques millièmes de l'inventaire du coeur et les quatre éléments dominants à moyen terme sont, par ordre d'importance décroissante, les césium, strontium, ruthénium et tellures, pour des raisons sanitaires. Des actions de réhabilitation des sols seraient nécessaires sur quelques km² et des restrictions temporaires de consommation de produits végétaux et animaux s'imposeraient sur quelques dizaines de km².

Compte-tenu des incertitudes sur les formes des radionucléides le premier objectif du programme devait être la simulation des conditions de formation du terme source. Le simulateur, appelé POLYR, est un four à induction capable de porter à 3000 °C un mélange de 16 corps représentant le combustible, les matériaux de structure de coeur et les produits de fission. Les aérosols dégagés sont recueillis dans une enceinte chauffée à 60 °C remplie de vapeur d'eau pour simuler les réactions possibles dans le bâtiment du réacteur accidenté. Les aérosols ainsi générés ont été caractérisés: granulométrie, aspect, composition chimique globale, espèces cristallisées et solubilité. On considère que l'objectif de similitude par rapport à un accident réel a été atteint de façon satisfaisante.

2.2 Les documents thématiques

Les distances d'intervention étant définies précédemment il fallait posséder des documents sur l'environnement proche (10 km) des sites électro-nucléaires. Des bases de données ont été constituées. Elles s'appuient sur trois éléments: des cartes d'occupation des sols élaborées à partir de fonds cartographiques existants (Institut Géographique National) des cartes pédologiques, et des cartes de vulnérabilité des nappes d'eau souterraine élaborées en coopération avec le Bureau des Recherches Géologiques et Minières (BRGM).

2.3 Le programme expérimental

Selon les niveaux de radioactivité des terrains contaminés trois types d'actions sont applicables, classées ici des plus

sévères aux plus douces: décontamination par enlèvement physique, contre-mesures chimiques agissant sur le comportement des radionucléides, mesures agronomiques (changement de pratiques) ou agro-alimentaires.

La décontamination par enlèvement physique concerne l'enlèvement de la végétation, le décapage des sols, le nettoyage des surfaces urbaines.

Des expérimentations non radioactives ont été conduites sur des terrains à CADARACHE pour déterminer quelle fraction d'un dépôt d'aérosols microniques serait fixée sur les cultures. Ils s'avère que dans de nombreux cas cette fraction est supérieure à 70, voire à 80 %. L'enlèvement de la végétation revient alors à emporter un pourcentage équivalent du dépôt. Un logiciel (CAPTATIO) a été écrit permettant de calculer ce pourcentage en fonction du type de culture et de sa maturité. Des expériences ont également été faites pour évaluer l'efficacité des techniques d'enlèvement et le taux de remise en suspension des poussières lors des opérations de réhabilitation.

Un logiciel (CATHY2) permettant de calculer la migration des radionucléides dans les sols a été écrit. Cela permet d'estimer l'épaisseur de la couche de sol qu'il conviendrait d'enlever après un dépôt. Les engins de travaux publics tels que profileurs, scrapers, bulldozers, ne sont pas adaptés à l'enlèvement d'épaisseurs inférieures à 5 cm alors que souvent le décapage de 1 ou 2 cm de sol suffirait. Pour cela l'utilisation de mousses polyuréthanes ou de peintures pelables a été testée. Ces produits liquides polymérisent une fois étendus sur le sol où ils forment une couche qui retient en général plus de 80 % du dépôt lors de l'arrachement. D'autres techniques faisant appel à un tapis végétal sont en cours d'étude. L'ensemencement peut se faire par hydrosemis à partir d'un véhicule ou d'un hélicoptère. L'enlèvement se fait à l'aide d'une déplaqueuse à gazon.

Les contre-mesures de nature chimique consistent à modifier le comportement des radionucléides pour diminuer leur transfert dans la chaîne alimentaire. Des expérimentations ont été faites pour établir des expressions analytiques des facteurs de transfert du césium et du strontium aux plantes en fonction de la plante, et de certaines caractéristiques du sol (capacité d'échange, pH, [K] pour le césium et [Ca] pour le strontium). Ce modèle permet de calculer les réductions de facteur de transfert pour Cs et Sr que l'on peut attendre d'un ajout de potassium ou de calcium.

Dans le cadre du programme et sous l'égide de la CCE les équipes de MOL en Belgique et de PIACENZA en Italie travaillent sur les facteurs de transfert fourrage-animaux. L'ajout de sels tels que le Bleu de Prusse à la ration alimentaire permet d'adsorber le césium dans le tractus gastro-intestinal et par là de réduire l'incorporation de ce radionucléide à la viande ou au lait d'un ordre de grandeur dans les meilleurs cas.

Les contre-mesures de nature agronomique et agro-alimentaires sont relativement peu étudiées à l'exception de la mise au point d'une charrue spéciale qui enfouit profondément (0.8 à 1 m) la couche superficielle de sol. Ce travail est fait par le centre de RISO.

3 PERSPECTIVES

3.1 Les documents thématiques

La mise à jour des documents existants par des méthodes traditionnelles est une tâche très lourde. Pour pallier cette difficulté l'équipe RESSAC travaille actuellement sur le traitement et l'interprétation des images obtenues par satellites (notamment par le satellite SPOT) ou aériennes. Cela permettra de planifier des opérations de réhabilitation dans des zones quelconques du territoire, d'évaluer au moment de l'accident l'état de développement du couvert végétal et enfin de réactualiser périodiquement les documents thématiques existants.

3.2 Le programme expérimental

Dans le futur, le programme expérimental se développera dans trois directions:

Sur le terrain on conduira essentiellement des études concernant le dépôt des aérosols par temps humide, comme cela a déjà été fait pour leur dépôt par temps sec.

Dans un bâtiment spécialement construit à cet effet on conduira les essais globaux, qui vont constituer une part prépondérante du programme. Le bâtiment comprendra 4 serres pouvant chacune abriter trois blocs de sols de dimensions $1.8 \times 1.8 \times 1.5 \text{ m}^3$ prélevés sans remaniement et appelés lysimètres. Un climat différent pourra être simulé dans chacune des serres. Les paramètres d'ambiance qui seront contrôlés sont: la température de l'air et des sols, l'humidité, la luminosité, les apports d'eau, le potentiel hydrique dans les sols. Il y aura 4 sites de prélèvements en FRANCE. De plus des lysimètres seront prélevés en Grande-Bretagne, Allemagne, Belgique et Espagne. La source de contamination sera obtenue à partir du four POLYR. Le but de ces expérimentations très réalistes sera de vérifier les modèles de transfert établis précédemment et de tester l'efficacité des contre-mesures envisagées.

En URSS des études sur les zones contaminées, entreprises en collaboration avec des organismes locaux, devraient permettre de tester les méthodes mises au point et de mieux définir les questions de stratégie de décontamination lorsque de vastes étendues sont touchées.

4 CONCLUSION

A l'aide des résultats du programme RESSAC il est déjà possible de proposer toute une variété d'actions de réhabilitation et de contre-mesures. La dimension internationale du programme et les moyens expérimentaux importants qui vont être mis à la disposition des équipes scientifiques devraient permettre une recherche d'un haut niveau de qualité pour optimiser les réponses aux situations de crise.

Enfin, une application de ce programme peut être trouvée dans la réhabilitation de sites industriels déjà contaminés, que ce soit par des radionucléides ou par d'autres polluants tels que des métaux lourds ou des produits organiques.

ON THE STATISTICAL MEANING OF ENVIRONMENTAL MODELS
USED IN DERIVING INTERVENTION REFERENCE LEVELS

ABSTRACT

A stochastic simulation of the (forage, cow milk, thyroid) exposure pathway shows, for a given peak concentration of ^{131}I in cow milk following an acute contamination, a lognormal distribution of the 60 days committed thyroid equivalent dose, with a geometric standard deviation of 2. The statistical variability of the values predicted by environmental models should thus be taken into account for a sound optimization of radiological protection in an emergency situation.

INTRODUCTION

Some important steps are required for environmental modelling (1) in the decisional process of banning milk consumption following an environmental contamination by a radionuclide (e.g. ^{131}I). Usually the adopted model is based on a set of coupled, distinguishable compartments, e.g. anatomical regions, metabolic phases, environmental segments, etc. Analytical solutions for the first order differential equations describing such a system are available but, as the model becomes more complex (but perhaps no more realistic for a given circumstance), numerical methods must be used. If information on the system is incomplete or inaccurate a detailed model is not warranted. The model structure and the form of the equations should be carefully tested and perhaps revised.

MODELLING THE (FORAGE, COW MILK, THYROID) EXPOSURE PATHWAY

Some complex models have been developed for this pathway, with up to twelve or more compartments inferred from the detailed iodine metabolism in cow and in man. The application in a given circumstance of a such very elaborate model, attractive by itself, seems to be justified only when accompanied by accurate and carefully verified values of the input parameters, owing to uncertainty in model predictions associated with uncertainty in the values of each new parameter included. The simplest model which can be acceptably validated is deemed thus more suitable than a more complex model. As an example (Figure 1) the simplified model simulating the (forage, cow milk, thyroid) exposure pathway can be used for estimating, in an emergency situation, the committed equivalent dose in thyroid starting from the measured peak concentration of ^{131}I in cow milk. The transfer constants in the model are simply related (proportional) to the "exposure parameters"

listed in Table 1, which are easy to be measured or estimated in a given exposure circumstance. In the cow model the transfer parameters between the compartments A and B, which should not be given a metabolic or anatomical meaning, have been adjusted to simulate the experimental time behavior of ^{131}I concentration in milk after a single intake, with a peak value between the second and the third day.

If the model adequately represents the situation being assessed, uncertainty analysis by stochastic simulation can be very useful to estimate the uncertainty in the model predictions and to rank the input parameters which more influence them. As a first approximation their values can be inferred from published data, usually in the form of a range into which the actual values distribute themselves as a random sample from an unknown population. An estimated frequency distribution of the values of the relevant parameters should be used to produce a frequency distribution of the model results, to be used together with the "deterministic" results computed from the values assumed for the parameters. Therefore numerical values predicted by the model should be processed as statistical values from an unknown distribution.

PRELIMINARY RESULTS AND CONCLUSIONS

For an effective reduction of the exposure consequences a decision about cow milk banning should be adopted early (within the first two or three days) after the beginning of environmental contamination by ^{131}I . The thyroid equivalent dose $H(60)$ committed over 60 days by the exposed adult member of the public consuming the milk can be computed as

$$H(60) = k_0 * IA(60) = k_0 * C(\text{peak}) * G(\text{peak}, 60)$$

where $IA(60)$ is integrated activity of ^{131}I in thyroid over 60 days, $C(\text{peak})$ is the measured peak concentration, $G(\text{peak}, 60)$ is a factor to be evaluated by means of the model of Figure 1 and k_0 is a suitable factor related to the "exposure parameters" of the model and to specific dosimetric aspects of thyroid irradiation by ^{131}I , as the value of the thyroid mass (Table 1). Owing to the propagation rules of statistics through multiplicative chain models the resulting values of $H(60)$, for a given value of $C(\text{peak})$, could be assumed to follow a probability distribution function related to the statistical distributions of the input parameters, i.e.

$$\text{var}(H(60)) = \text{var}(k_0) + \text{var}(G(\text{peak}, 60)).$$

The variance of k_0 and $G(\text{peak}, 60)$ has been estimated by a Monte Carlo simulation of the model in Figure 1, solving the associated differential equation system by means of a microcomputer program (2). In each simulation run (up to 200) the values of the input parameters are sorted from their statistical distribution around published values (Table 1)(3), assuming a correlation between some parameters (e.g. feeding habits and milk production) for avoiding a full random,

unrealistic sorting, which could produce an unacceptably wide range of predictions. For the transfer constants describing the iodine metabolism in the cow a uniform distribution in the range from 85% to 115% of the input values has been inferred on metabolic grounds to reproduce the observed geometric variance in the forage-milk transfer factor (SGD = 1.2).

Table 1
Standard geometric deviation (SGD) (3) for the model parameters

Weathering half-time for forage	1.4
Forage intake by the cow	2.0
Milk production rate by the cow	1.6
Cow milk intake	1.2
Biological half-time in thyroid	1.8
Iodine uptake by thyroid	1.4
Thyroid mass	1.6

Preliminary results for the probability distribution of the ratio of H(60) to the deterministic value (Figure 2) suggest a SGD value of about 2, with a value around 8 for the ratio of the 95th percentile to the 50th percentile (median). A comparison with previous simulations (2) for ^{137}Cs in cow milk and beef shows the effect of the short radioactive halftime of ^{131}I in reducing the variability of predicted committed equivalent doses. A lognormal distribution (SGD around 1.5) has also been found for the ratio between the ^{131}I peak concentration and the first day value, when sound results of environmental monitoring begin to be available.

The significant rank correlation found between H(60) and "exposure parameters" requires moreover circumstance specific values to be used for the feeding habits and milk consumption rate to avoid biased and misleading results. No such a strong correlation exists with the parameters in the cow model: widespread use of a generic model seems to be justified.

U.S. RECOMMENDATIONS FOR CONTROL OF ACCIDENTAL RADIOACTIVE CONTAMINATION OF HUMAN FOOD AND ANIMAL FEEDS

B. Burnett and M. Rosenstein

Center for Devices and Radiological Health
Food and Drug Administration
Rockville, Maryland (USA)

ABSTRACT

Recommendations for control of accidental radioactive contamination of human food and animal feeds issued in 1982 by the Food and Drug Administration (FDA)⁽¹⁾ are being revised to incorporate current scientific information and radiation protection philosophy, to include experience gained since 1982, and to take into account international guidance. The revised guidance will update the 1982 FDA recommendations regarding protective actions and will provide additional recommendations for limits on radioactive contamination permitted in foods distributed in commerce.

INTRODUCTION

The 1982 FDA recommendations for the control of accidental radioactive contamination of human food and animal feeds are under revision. The revised guidance will be designed to avert risk to the public, in the event of an accidental release of radioactive materials, through: (1) limits on the radioactive contamination permitted in foods distributed in commerce, and (2) preventive actions to mitigate the amount of radioactive contamination reaching the diet. The objective of the revision is to produce a consistent set of guides, applicable to accidental contamination of human food and animal feeds, for use by Federal, state and local agencies in the exercise of their respective authorities.

GENERAL PROVISIONS

The guidance will be for use in radiological emergency response planning and in the conduct of radiation protection activities associated with the production, processing, distribution, and use of human food and animal feeds accidentally contaminated with radioactivity.

An intervention level for radiation dose is included in the guidance and is called the Protective Action Guide (PAG). The recommended PAG in the current draft is 5 mSv (0.5 rem) committed effective dose equivalent with an overriding PAG of 50 mSv (5 rem) committed dose equivalent to an individual organ.

The recommended PAGs are consistent with the approach to the establishment of intervention levels recommended by the International Commission on Radiological Protection (ICRP) in ICRP Publication 40⁽²⁾. ICRP Publication 40 provides general

guidance on the selection of dose levels for the implementation of countermeasures, and indicates that the introduction of countermeasures for the control of foodstuffs would be appropriate within a range of 5 mSv to 50 mSv committed effective dose equivalent and an associated range for committed dose equivalent to individual organs of 50 mSv to 500 mSv . The recommended PAGs are also consistent with the intervention levels of dose selected as the basis for derived intervention levels for foodstuffs established independently by both the Commission of the European Communities and the Joint Food Standards Program of the Food and Agriculture Organization of the United Nations and the World Health Organization. The ICRP included updated concepts concerning intervention in Publication 60⁽³⁾. The application of the concepts in ICRP Publication 60 are currently under development by ICRP.

The revised FDA guidance will provide recommendations on limiting the radiation dose through: (1) limits on the concentration (in Bq/kg) of radionuclides permitted in foods distributed in commerce, called levels of concern, and (2) implementation of various types of protective actions.

The guidance will provide clear advice in advance of an accident, which can be immediately implemented at the onset of an accident. The guidance also will permit the flexibility necessary to respond to unanticipated or unique situations.

LEVELS OF CONCERN

The key feature of the guidance will be the establishment of levels of concern, the limits on the concentrations of radionuclides permitted in food after accidental contamination. The purpose of the levels of concern is to limit consumption of food confirmed as containing undesirable levels of radioactive contamination. Levels of concern are derived concentrations of radionuclides in food, which, if not exceeded, should assure that the PAGs would not be exceeded. In practice, when the levels of concern are not exceeded, the radiation doses to members of the public would be expected to be a small fraction of the PAGs. The levels of concern are being developed for application immediately following an accident; their application would not require early identification of all radionuclides present.

Food with concentrations of radionuclides below the levels of concern would be permitted to move in commerce without restriction. Food with concentrations of radionuclides at or above the levels of concern would normally not be permitted into commerce; however, flexibility would be permitted for special circumstances.

Levels of concern are based on typical quantities of food intake, the fraction of food intake that is assumed likely to be contaminated, and the relationship between radioactivity concentrations in food and radiation dose delivered to the individual per unit of radioactivity intake (i.e. the dose conversion factor).

The relationship between the levels of concern and the PAGs is given by:

$$\text{Level of Concern (Bq/kg)} = \frac{\text{PAG (mSv)}}{f \times \text{Food Intake (kg)} \times \text{DCF(mSv/Bq)}}$$

Where: DCF = the dose conversion factor; the radiation dose per unit of radioactivity ingested (mSv/Bq).

f = the fraction of the food intake that is assumed to be contaminated.

Food Intake = the total quantity of food intake in the time period of concern (kg).

Levels of concern were calculated for twenty three radionuclides and for six age groups using PAGs, DCFs and dietary intakes appropriate to each radionuclide and age group. Calculations were performed for the following age groups: 3 months, 1 year, 5 years, 10 years, 15 years and adult (>17 years). The DCFs used were from ICRP Publication 56⁽⁴⁾. The levels of concern were calculated based on the total annual dietary intake for each age group, not for individual foods or food groups. The calculation also included the assumption that contamination would occur in thirty percent of the total annual dietary intake or sixty day intake for I-131. The value of thirty percent is based on the expectation that less than ten percent of the total dietary intake would consist of contaminated food, and then applying an arbitrary additional safety factor of three. An exception was made for the case of I-131 in the infant diet where the entire sixty day intake was assumed to be contaminated.

The resulting levels of concern were evaluated to identify the radionuclides most likely to be the predominant contributors to dose through ingestion during the first year following an accident. Four radionuclide groups were identified as most likely to be the major contributors: Sr-90, I-131, Cs-134 + Cs-137, and Pu-238 + Pu-239 + Pu-240 + Am-241.

The final structure of the levels of concern to be recommended is still under review. The ease of implementation is a major consideration in the selection of the structure for the levels of concern. For example, one practical approach would be to group the six age groups to represent two population groups: infants (age groups 3 months and 1 year) and all others (age groups 5 years, 10 years, 15 years and adult). Recommended levels of concern for each radionuclide group would consist of two values, one to be applied to foods consumed by infants and the other to be applied to foods consumed by all other members of the population. Another practical approach would present a single level of concern for each radionuclide group which would be applicable to all foods and all members of the population. In either of these approaches, the most limiting level of concern for any of the age groups included in a population group would be selected (i.e. for each radionuclide group).

The guidance will recommend that the levels of concern be evaluated as soon as possible after an accident to insure that they are appropriate for the actual situation. In unique accidents, radionuclides for which levels of concern are not specified may contribute significant radiation doses. There may be other exceptions

or special conditions which could require additional or revised levels of concern. In these situations an evaluation would need to be performed to determine if the PAGs would be exceeded. The guidance will recommend that, when needed, the FDA be consulted for the development of additional or special purpose levels of concern.

The recommended levels of concern apply to the distribution and use in the U.S. of food grown, produced or manufactured in the U.S. Imported foods are currently controlled by existing guidance set out in FDA Compliance Policy. Foods exported from the U.S. are controlled by standards, regulations and guidance adopted by the importing country.

PROTECTIVE ACTIONS

The guidance will present recommendations for mitigating radionuclide contamination through protective actions taken to prevent or reduce the contamination of food and animal feeds or to delay the use of food and animal feeds suspected of being contaminated until the level of contamination can be determined. Many of the protective actions will be similar to those recommended in the 1982 FDA guidance, such as: sheltering livestock and placing them on stored feed, holding food to allow for decay of short half-life radionuclides, and removal of surface contamination. The draft will recommend that protective actions be selected as appropriate to the situation and once initiated, the action or actions continue until such time that, in the absence of the action, the affected food can be expected to meet the levels of concern.

STATUS OF REVISION

A draft of the revised guidance, including proposed values for the levels of concern and specific proposals on the application of protective actions has been circulated to the principal Federal agencies and the Conference of Radiation Control Program Directors for preliminary review and comment.

MEASUREMENT, ASSESSMENT, AND EVALUATION
WITHIN THE INTEGRATED MEASUREMENT AND INFORMATION SYSTEM FOR
SURVEILLANCE OF THE ENVIRONMENTAL RADIOACTIVITY (IMIS)

ABSTRACT

The Integrated Measurement and Information System for the Surveillance of the Environmental Radioactivity (IMIS) is currently being established. The field measurements involve existing Federal and State institutions and organisations. The measured radioactivity data as well as general data from the environment will constitute the foundation on which a series of assessment programs are built like contamination prognoses, models for assessment of radiation exposure, and models for precautionary measures. The data determined by measurement and calculation are so processed that in the case of an event a good evaluation is possible within a reasonable time.

INTRODUCTION

The Integrated Measurement and Information System for the Surveillance of the Environmental Radioactivity (IMIS) is currently being established. In the case of an event with radiological effects this system is determined to quickly supply comprehensive data which enable a rapid assessment of the situation. For this purpose all necessary steps, i.e. sampling, assessment, and representation of data, are coordinated and integrated in an optimal way.

MEASUREMENT

Basically, the Federal measurement networks and the State measurement institutions (Fig. 1) are included in the measurement programs. Those environmental areas showing the far-reaching distribution of radioactive substances (air, precipitation, gamma local dose rate, soil deposit, inland surface waters, North Sea and Baltic Sea) are controlled by the Federal measurement networks. The surveillance of the specific activity in other environmental areas, such as foodstuffs, drinking water, feedstuffs, etc., is carried out by State measurement institutions.

The measurement data determined by the Federal measurement networks are checked for their plausibility by the central laboratories of the Federal measurement networks. After that, the data are transferred to the Central Federal Agency for the Surveillance of the Environmental Radioactivity.

After having passed a first plausibility control, measurement data determined by the State measurement institutions are collected and transferred via the State data centers to the

Central Federal Agency. There they are selected according to environmental areas and forwarded to the guiding agencies carrying out synoptic plausibility checks. Then the data are sent back by the guiding agencies to the Central Federal Agency.

In the case of an event, the data - as far as they concern the air-ground-path - will arrive at the Central Federal Agency in the following chronological order, depending on the measuring method:

- Approximately two hours after measurement has been finished, the on-line-data of the Federal measurement networks will arrive, these include: gamma spectrometry, total-alpha-measurement, total beta-measurement, and gamma local dose rate
- The results of collective measurement (gaseous iodine, precipitation) are transferred daily after sampling and assessment have taken place.
- Within one day the results of the following measurements are also available: in-situ gamma spectrometry, alpha spectrometry, and H-3 measurements.
- It takes several days until the results from Sr-90 measurements are available.

The results of measurement carried out by the State measurement institutions will be available approximately one day later with exception of the Sr-90 measurements for which also several days will be necessary.

ASSESSMENT

On the basis of contamination measurements in different environmental areas prognoses are carried out for the contamination of those environmental areas where the surveillance cannot be effected at the time of the event (example: later ripening fruits).

For the estimation of current as well as future irradiation relevant exposure models are used. These models consider the specific environment of man (e.g. city, rural area, usual living habits (e.g. indoors, outdoors) breathing rates and consuming habits (food basket).

In the case of a radiological event appropriate precautionary measure ensure that the resulting exposure to man is kept below the established limits. These precautionary measures include:

- Prohibition or limitation of food and feedstuff etc.
- Recommendation of special rules of conduct for the population

In order to assess in advance the effectiveness of precautionary measure, models are being developed describing their effect on radioactive contamination or irradiation exposure, respectively

The model described above are integrated in the PARK model which is being developed by the Research Center for Environment

and Health (GSF). This model considers the chronologically registered report of data on the predicted diffusion and of measurement data. The PARK programm consists of the sub-programs AUTOPARK, DIAPARK, and DOSISPARK.

- AUTOPARK automatically calculates for a certain time scale the predicted irradiation exposure for all German administrative districts every two hours in intensive operation.
- DIAPARK is more flexible. all available parameters can be exchanged by the user, e.g. the composition of the food basket can be altered, which leads to correspondingly longer computing time.
- DOSISPARK calculates dose values from measured or predicted contaminations.

EVALUTATION

The results from measuring programs and accordingly developed assessment programs as well as possible additional information are the basis for the situational assessment. The assessment is done by considering the following aspects:

- classifying the situation
 - * observation of the time - and site related process of contamination
 - * comparison with courses of contamination of preceding events
- evaluating the situation
 - * comparison with environmental radiation exposure and its range of variation
 - * estimation of possible radiation damage and comparison with existing manmade exposure risks.

SUMMARY

The establishment of an Integrated Measurement and Information System for the Surveillance of the Environmental Radioactivity provides a system which guarantees the early detection of a radiological event with its consequences for Germany and which by its optimal use produces a rapid, early, and complete assessment of the situation.

LA MISSION ET LES MOYENS DU SCPRI, SERVICE OFFICIEL FRANÇAIS
DE RADIOPROTECTION, EN CAS D'ACCIDENT NUCLEAIRE

par Pierre PELLERIN, Jean CHANTEUR et Jean-Pierre MORONI

La réglementation française donne au Ministre chargé de la Santé et au Ministre chargé du Travail, *ministères de prévention*, la responsabilité déterminante de garantir, vis-à-vis des travailleurs et de la population, que le développement et l'exploitation de l'énergie nucléaire ne puissent menacer l'hygiène publique ou professionnelle. Cette mission essentielle est, notamment pour le Ministre de la Santé, concrétisée par l'*avis conforme* qu'il est seul à donner pour autoriser le fonctionnement de toute installation nucléaire, ce qui lui confère un véritable *droit de veto* en la matière. Le Service Central de Protection contre les Rayonnements Ionisants (SCPRI) est le "*bras séculier*" des ministères de prévention. Ce point fort du système français confirme que le dernier mot appartient à une autorité exclusivement chargée de la protection de l'homme, *qui n'est pas juge et partie dans la promotion du nucléaire*, ce qui distingue sans équivoque la responsabilité de la radioprotection d'une part, de celle de la *sûreté nucléaire* d'autre part :

LA SURETE NUCLEAIRE garantit la fiabilité technique de la *machine* (réacteurs, usines de retraitement, accélérateurs, etc.). C'est une *responsabilité d'ingénieurs* hautement spécialisés, sur laquelle s'appuie le Ministre de l'Industrie pour promouvoir l'énergie nucléaire.

LA RADIOPROTECTION garantit la *santé des individus* (travailleurs et population). Elle est de la *responsabilité de médecins* qualifiés en radiobiologie, radiotoxicologie et radiopathologie, totalement indépendants des impératifs de production nucléaire, qui conseillent les Ministres du Travail et de la Santé. *La santé passe avant la production d'énergie.*

1°) ROLE DU SCPRI EN CONDITIONS NORMALES : Outre ses missions d'hygiène publique et professionnelle (recherche en radioprotection, établissement des normes, centralisation des données, formation et information, agrément et surveillance de 50 000 installations radiologiques médicales et dentaires, surveillance de l'exposition de 120 000 travailleurs, etc.), le SCPRI assure en permanence le contrôle réglementaire des rejets des installations nucléaires et de leur environnement. Plus de 40 000 échantillons sont analysés annuellement dans ses laboratoires du Vésinet. Ces analyses systématiques, indépendamment des autres dispositions, assurent la détection d'incidents qui auraient pu échapper à l'exploitant.

2°) ROLE DU SCPRI EN CAS D'ACCIDENT NUCLEAIRE : La mission dévolue au SCPRI est primordiale en cas d'accident :

- il assure immédiatement avec ses moyens d'intervention avancés l'essentiel des mesures effectives de la radioactivité sur le terrain, et des analyses fines en laboratoire ;
- il coordonne les autres organismes effectuant des mesures complémentaires sur place ;
- il regroupe l'ensemble des résultats, en assure la synthèse et détermine pour le Préfet, qu'il est chargé de conseiller, les contre-mesures adéquates.

a) Son réseau de télésurveillance du territoire : En situation anormale, les puissants moyens mobiles du SCPRI doivent intervenir le plus tôt possible et au bon endroit. Il faut donc les éclairer par un système de veille permanente aussi performant qu'eux-mêmes. C'est l'objectif des *réseaux de télésurveillance en temps réel* du SCPRI. Ces réseaux du SCPRI totalisent plus de 100 stations, en particulier sur les principaux aéroports français, autour des installations nucléaires, aux frontières, au niveau des préfectures concernées par le nucléaire, etc..

b) Les moyens mobiles du SCPRI : Le SCPRI a développé de puissants moyens mobiles de mesure précise de la radioactivité, entièrement standardisés, pour le contrôle, en cas d'accident nucléaire, des populations, de l'environnement, et des produits agricoles.

Le moyen lourd : c'est une *voiture-rail spectrométrique*, apte à 200 km/h, capable de mesurer simultanément 32 individus ou échantillons (5 000 contrôles par jour).

Les moyens semi-lourds : ce sont deux *semi-remorques* de 20 tonnes dont l'une comporte à la fois 12 postes de mesure (1 500 contrôles par jour, le tiers de la voiture-rail), un laboratoire complet de radiochimie, et un laboratoire de dosimétrie.

Les moyens légers mobiles consistent en 16 "*Master Gemini*" (SCPRI et Services associés) avec chacun quatre postes de mesure (identiques aux précédents). Leur avantage, comme celui des semi-remorques, est d'aller là où le rail ne peut aller, avec une grande souplesse et la même autonomie. Chacun peut effectuer 500 contrôles par jour.

Au total, le SCPRI est capable de contrôler sur le terrain, en cas d'accident, jusqu'à 15 000 personnes ou échantillons par jour en spectrométrie gamma.

CARTOGRAPHIE PAR HELICOPTERE DES DEPOTS RADIOACTIFS AU SOL EN SITUATION ACCIDENTELLE

J. CORTELLA - C. BOURGEOIS - R. CHASTEL - A. ROSENBERG
CEA/SERVICE DE PROTECTION CONTRE LES RADIATIONS

Helicopter mapping of ground radioactive deposition in post-accidental situations.

In post accident situations where a release has resulted in the deposition of radioactive materials on the soil, it is essential to take contamination measurements immediately after the accident and throughout the recovery operations. A description is given of measurement equipment which has been developed in France for performing efficient measurements over large areas : it includes a gamma mapping device and an in situ gamma spectrometry system. These are compared and their use is described.

INTRODUCTION

Après un rejet accidentel ou une dispersion de matières radioactives, la mise en place de contre-mesures et la conduite des opérations supposent la connaissance préalable de la contamination déposée sur le sol et donc des mesures pour :

- faire le diagnostic initial
- suivre l'évolution de la situation

Un des moyens pour répondre à cet objectif est la détection gamma hélicoptérée.

Le système de cartographie gamma qui a été développé est constitué :

- d'un équipement embarqué à bord d'un hélicoptère léger pour l'acquisition des données,
- d'un équipement à terre qui, à partir des données acquises en vol, restitue la carte de la contamination.

Principe de l'acquisition des données en vol.

L'hélicoptère effectue au dessus de la zone à mesurer un balayage selon des trajectoires prédéterminées. Chaque seconde, on enregistre :

- le spectre gamma provenant du scintillateur NaI sur 256 canaux
- la position de l'hélicoptère : altitude par rapport au sol, coordonnées dans un système rectangulaire

Les données de positionnement peuvent être calculées par rapport à la position de balises préalablement disposées au sol. La bonne précision de localisation permet d'effectuer un balayage très serré et la surface cartographiée en une seule opération est de quelques km² à quelques dizaines de km².

On utilise aussi un autre système de localisation pour des grandes surfaces. Il utilise un ensemble de navigation par radar Doppler et permet l'examen de surfaces de plusieurs centaines de km², avec bien entendu une résolution spatiale inférieure.

TRAITEMENT DES DONNEES :

Le traitement des données enregistrées en vol s'effectue après le retour de l'hélicoptère au sol. Il utilise un matériel informatique transportable qui restitue une carte en couleurs de la contamination au sol. Selon le traitement choisi on peut obtenir la contamination caractéristique d'un radioélément donné ou encore la carte des débits de dose.

CARACTERISTIQUES OPERATIONNELLES.

La sensibilité du système est fonction de plusieurs paramètres :

- le rendement d'émission et l'énergie des rayonnements émis par le radioélément recherché (seuil en énergie : 50 keV)
- le bruit de fond dû à la radioactivité naturelle liée à la nature géologique des terrains

Pratiquement, pour un hélicoptère volant à 40 m et à 70 km.h⁻¹ on détecte des "taches" de ¹³⁷Cs ayant une activité égale ou supérieure à 2 kBq.m⁻² et une surface minimale de 2000 m² ou encore des sources ponctuelles de l'ordre 4 MBq.

Le matériel est mis en oeuvre par une équipe de 4 personnes. L'équipement de l'hélicoptère nécessite 1 à 3 h, 1,5 h de vol pour examiner une surface de quelques dizaines de kilomètres carrés, et 2 h environ pour obtenir les premières cartes de la contamination.

SPECTROMETRIE GAMMA IN-SITU :

Ce moyen est complémentaire de la détection gamma par hélicoptère.

Il est constitué d'une diode Germanium HP installée sur un mât télescopique (3 à 9m), lui-même monté sur un véhicule tout terrain.

Il est possible de mesurer des activités très faibles de l'ordre de 0.5 kBq.m⁻².

CONCLUSION :

Les matériels décrits cartographie gamma par hélicoptère et spectrométrie gamma in-situ, présentent, grâce à leur souplesse et leur efficacité un progrès très important pour les mesures à réaliser après un accident radiologique surtout quand on les compare aux méthodes utilisant des appareils portatifs.

D'autres utilisations de ces moyens sont envisageables : établissement de la situation radiologique sur les sites avant la mise en service des installations nucléaires, surveillance de l'environnement pendant le fonctionnement de ces installations, recherche de sources ponctuelles, etc...

CONCENTRATION OF STABLE CESIUM IN CALF SERUM

N. Ito

Department of Veterinary Radiology,
School of Veterinary Medicine and Animal Science,
Kitasato University, Towada, Japan

ABSTRACT

To analyse the relationship between cesium concentration of serum and age, stable potassium, cesium, and rubidium in cattle serum were measured. The calves and the adult cattle used in this work had been fed under almost the same condition. The cesium concentration of calf serum gradually decreased with the number of days after birth, then was maintained stationary level (0.4 - 0.6 ng/ml, one third of initial value) after 200 days. The rubidium concentration changed like cesium; however, the vivid change was not observed in potassium.

INTRODUCTION

Cesium-137 and Cesium-134 are the most important radionuclides after the short life nuclides have decayed, and livestock products are the largest contributor of the radiocesium to the diet, therefore many investigators made efforts to obtain the transfer coefficients (feed to milk F_m , feed to muscle F_f). Since it is difficult to feed the forage containing radionuclides to adult cattle, young cattle has been used widely for the experiments. Although the F_f of radiocesium of young cattle is higher than adult, the young-to-adult correlation factor has not been published. In this work, stable potassium, cesium, and rubidium in cattle serum were measured, and the relationship between cesium concentration of serum and age was considered.

EXPERIMENTAL

Twenty female calves aged from 100 days to 360 days (Japanese Shorthorn 10, Angus 10), and 45 female cattle aged from 1 year to 10 years (Japanese Shorthorn 25, Angus 20) were used. They were fed on the same forages, and their blood samples were drawn on the same date from jugular vein. The serum was separated from the whole blood by centrifugation, and was powdered by freeze-drier. Approximately 0.1g of the powder was weighed into a high-pure quartz ampoule and sealed. NBS Bovine Liver (SRM 1577) and Oyster tissue (SRM 1566) standards were prepared similarly.

Samples and Standards were irradiated in the JRF-4

reactor (Thermal neutron flux; $5.5 \times 10^{13} \text{ n} \cdot \text{cm}^{-2} \cdot \text{s}^{-1}$) of the Japan Atomic Energy Research Institute for 6 hours. The irradiated samples and standards were counted for 4 hours using a Canberra 30% HPGe detector coupled to a Canberra Series 35plus MCA after cooling for 4 weeks (rubidium), and after cooling for 2 months (cesium).

Potassium was measured by flame emission spectrometry without freeze-drying.

RESULTS and DISCUSSION

Averages of potassium concentrations of serum of adult cattle (>1year) were lower ($p < 0.05$, Japanese Shorthorn: $p < 0.01$, Angus; T-test) than calves. It is known that there is significant negative correlation between human age and potassium concentration of serum. However, there was no significant difference between adult cattle and calves on rubidium and cesium.

Figure 1 shows the change of the cesium concentrations in calf serum. It was the youngest calf (100 days) in this work that had the highest serum concentration of cesium (about 1.6 ng/ml). And the cesium concentration of serum gradually decreased with the number of days after birth, then was maintained stationary level (0.4 - 0.6 ng/ml, one third of initial value) after approximately 200 days. The average serum cesium concentrations of adult cattle were $0.62 \pm 0.20 \text{ ng/ml}$ (Japanese Shorthorn) and $0.59 \pm 0.19 \text{ ng/ml}$ (Angus) respectively, and there is no difference between both breeds.

Fig.1 The changes of cesium concentration of calf serum.

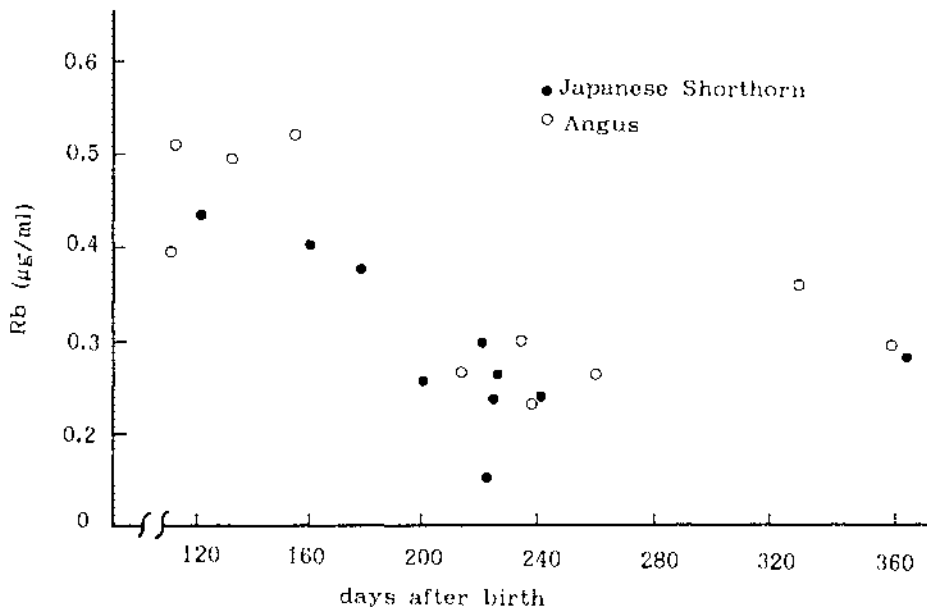

Fig.2 The changes of rubidium concentration of calf serum.

In Figure 2, the change of the rubidium concentrations of calf serum is shown. The rubidium concentrations of serum were three orders of magnitude larger than the cesium. However the rubidium concentration changed almost the same manner as cesium. The average rubidium concentrations of adult cattle serum were $0.31 \pm 0.08 \mu\text{g}/\text{ml}$ (Japanese Shorthorn) and $0.32 \pm 0.06 \mu\text{g}/\text{ml}$ (Angus), and the rubidium concentrations of adult cattle were approximately a half value of the 100-day-old calf.

In potassium concentration of calf serum, the vivid change like cesium and rubidium was not observed.

The calves and adult cattle used in this work had been bred under similar condition in the same stock farm, and were drawn blood simultaneously. So the cesium and rubidium concentrations of serum were kept stationary levels in adult cattle. In the calves, Both cesium and rubidium concentrations of serum gradually decreased with the number of days after the birth. It is known that the orally taken radiocesium is mostly absorbed in the alimentary tract. Therefore it is supposed that cesium and rubidium are absorbed easily at the intestine and/or are scarcely excreted before 200 days.

It is speculate that Ff of calf (<200 days) is two or three times higher than adult cattle on radiocesium.

MEASUREMENT IN THE FIELD OF THE CONCENTRATION
OF GAMMA EMITTERS NUCLIDES IN SOIL

Bortoluzzi S., Giacomelli R., Montalto M., Nocente M.,
Spezzano P.

ENEA - AREA AMBIENTE - DIPARTIMENTO ANALISI E MONITORAGGIO
MASAL - C.R.E. SALUGGIA - ITALY

SUMMARY

The measurement of the gamma emitter radionuclides is quicker if direct field gamma spectrometry is used. The operations of setting and determination of the parameters necessary for the calculation of the results are described below. Furthermore, the good agreement between the results obtained by the direct measurement and those obtained by the sampling and the subsequent measurement in the laboratory, is shown.

INTRODUCTION

The methodology for the determination of the radionuclides, present in the soil, by direct gamma spectrometry or in situ gamma-ray spectrometry was developed by the Health and Safety Laboratory (HASL) by Beck [1]. The advantages of this analysis technique awakened the interest of our laboratory. We decided to carry out a personal estimation of the method, so as to identify its real good qualities and disadvantages and the operating capabilities within the activities of our laboratory in the best way.

STRUMENTATIONS AND METHODS

In our case, we used a portable, type n, high-purity Ge detector. The detector was located on an adjustable tripod, so modified as to allow the adjustment of the height of the detector from the soil, and the correct positioning in respect of the horizontal plane. The instrumentation is completed by a portable multichannel analyzer and a portable computer for spectrum storage and processing.

The detector has to be located on an enough free and plane soil. The areas troubled by houses or other buildings and the tree-full or not really plane areas are to be avoided. Furthermore, if studies about the depositions of fall-out radionuclides should be carried out, the investigated soil must not be subjected to any human activity, which might have modified washing off of radionuclides or soil depletion by erosional processes.

During our tests, the detector-to-soil distance was set at approx. 1 meter; so, the useful area can be considered to be approx. 10 meters with a depth of 15 to 30 cm, depending upon the energy of the incident gamma rays [2].

DESCRIPTION OF THE METHOD

The area of a peak in an obtained spectrum represents a fraction of the integral of the incident gamma radiation flux, during the acquisition time, on the detector.

We can express the ratio between the gamma radiation, measured by the detector, and the specific activity of the radionuclide in the soil (N_f/A) by the equation by Beck [1]:

$$\frac{N_f}{A} = \frac{N_0}{\phi} \cdot \frac{N_f}{N_0} \cdot \frac{\phi}{A}$$

The determination of N_0/ϕ , intensity of gamma rays measured by the detector per incident flux unit parallelly to the symmetry axis of the detector, in respect of the energy of the incident gamma rays, is carried out experimentally. We used punctiform gamma rays sources having known activity, located 1 meter far from the detector, so that the radioactive flux, which acts on the detector is approximately parallel to its main axis. The trend of N_0/ϕ is obtained by the following function:

$$\frac{N_0}{\phi} = e^{-\alpha} \sum_{n=0}^3 a_n \ln(E)^n$$

The second quantity corrects the detector response to the energy-range of gamma rays for the flux, which do not acts orthogonally to the surface of the detector. Low-energy gamma (<150 keV) excluded, N_f/N_0 remains around the unit. In Helfer's work [2], those values are plotted in respect of the ratio between length and diameter of the german crystal of the detector and the energy of considered gamma rays.

To calculate the values of the incident gamma radiation flux on the detector (ϕ/A), we assumed the geometry of the 2π or semi-infinite source, by eliminating the absorption and local relief problems. The flux depends upon the peculiar distribution of the gamma emitter radionuclide in the soil. The concentration of the gamma emitter per surface unit is considered to be constant on the x-y plane, and having an exponential profile along the z-axis or depth.

The parameter α gives a values of the variation of the concentration by the depth, extreme situations are for $\alpha \rightarrow \infty$ a surface distribution, and for $\alpha=0$ a homogeneous distribution of the radionuclide in the soil.

For any value of α , the total gamma radiation flux, having energy E, at a distance h from the soil, we calculated by approximation by numerical calculation the solution of the integral mentioned by Beck [1].

DISCUSSION

In the method proposed, one has to estimate the dependance of the performed estimation upon parameter choice, and the degree of accuracy which is demanded for the value. The final result will be affected by the highest possible compliance of the characteristics of the measurement point with the conditions which support the model formulation, and by the errors, which are connected to the determination of every parameter.

In general, the careful planning and estimation of the characteristics of the measurement point in respect of the good quality of the results, which one would obtain, allows the optimization of the method.

However, it is necessary to take into account, that, if the assumption of a homogeneous distribution for the natural radionuclides, or surface distribution for a recent fall-out settling gives, in general, satisfactory results, for the estimation of settling due to past events (Chernobyl), the results are affected by the determination of the vertical distribution profile of the radionuclides in the soil. Unfortunately it is not possible to estimate a undependently upon one of

the parameters used. This is the true limit of the method; in fact, if a good accuracy is required, we are obliged to carry out an independent measurement campaign, by collecting core soil samples, which need to be analyzed in the laboratory for the determination of parameter α . To confirm if performed calibrations are good, we performed a set of comparisons. We chose unworked soils, complying with mentioned requirements, performed one or more direct measurements, and, then, the drawing of four or five soil surface samples (depth 30 cm) all around a 10 meters radius from the measurement point. Collected samples were analyzed by the traditional method, i.e.: drying and homogenizing of the soil, measurement by Ge detectors in unsealed Marinelli's container, to prevent balancing between radionuclides of the natural series, and determination of the radionuclides concentrations (figure 1). [3]

Activity τ

† Bq/kg for natural radionuclides
Bq/mq for fall-out radionuclides

figure 1 - Comparison between calculated activity of Viverone (VC-Italy) soil for the two method

CONCLUSIONS

To sum up, the field spectrometry technique allows a monitoring or research laboratory to have a valid and enough accurated methodology for the immediate estimation of the activity present in the soil. It is specially useful in those emergency situations, where a quick response about soil deposition is required. In that particular situation, the instrumentation supplies, during the same time, more complete and detailed information than usual procedures.

Abstract

A quality assurance programme for activity measurements in environmental samples was established by ENEA since 1982. The programme was based on intercomparison campaigns in which the participants were the laboratories of the radioactivity surveillance network in Italy. The results so far obtained show the effectiveness of these intercomparison campaigns in improving the measurement reliability of the participating laboratories.

1. Outline of the intercomparison campaigns

To assure uniformity and reproducibility of measurements carried out by the laboratories of the radioactivity surveillance network in Italy, the ENEA established since 1982 a standardization programme that is based on periodical intercomparisons on radioactivity measurement. Since the beginnings four intercomparisons have been so far carried out with a number of participant laboratories ranging from 12 to 40 about, according to the evolution of the network in the years. From 1983 to 1985 two intercomparisons were made with the objective to determine the activity concentration of ^{137}Cs and ^{90}Sr in spiked samples of milk by gamma spectrometry and beta counting, respectively. The aim of the first comparison (1983) was to obtain a preliminary information on the accuracy of radioactivity measurements currently made by the laboratories of the network. A second comparison (1985) was repeated in similar conditions to check the long term reproducibility of these measurements. Both the intercomparisons showed a not satisfactory degree of uniformity among the laboratories. The inadequacy of calibration procedures and of data handling was identified as one of the major error sources and this indicated the need to undertake further intercomparisons only after a calibration campaign for the laboratories involved. The validity of this indication was confirmed by the better uniformity obtained in the third comparison (1988), made after a calibration campaign. On the basis of these results a new standardization programme was defined. It is characterized by periodical calibrations and comparisons with a variety of radionuclides in different experimental conditions. According to the revised programme, a fourth

comparison was carried out in 1990 and the last one, started in 1991, is still in course.

Gamma spectrometry was performed by participants mainly by equipment based on HPGe and Ge(Li) detectors. However at the early stage of the intercomparison campaigns some of the laboratories were using traditional NaI-spectrometers. One of the positive effects of this standardization programme was to achieve a fairly homogeneous condition in the experimental equipment.

As for the beta counting, all the participants utilized low-background anticoincidence systems with different types of detectors.

2. Intercomparison procedures

The procedure of each intercomparison was agreed in preliminary meetings between the organizers and the participants. This was considered important to assure that the technical procedures proposed by the organizers could have been easily accepted and applied by each participant. The sources for the intercomparisons were prepared and distributed to the participants by the ENEA-LMRI, the national standards laboratory.

The radionuclides considered in the 1983-1985 comparisons were ^{137}Cs and ^{90}Sr for gamma spectrometry and beta counting, respectively, with an activity level of about 10 Bq/kg.

The experimental conditions regarding the 1988-1990 intercomparisons were rather different with respect to the previous intercomparisons. After the Chernobyl event, it was decided to increase the activity concentrations of the intercomparison sources by more than one order of magnitude with respect to the pre-Chernobyl conditions. The radionuclides considered for the gamma spectrometry intercomparisons were: ^{241}Am , ^{57}Co , ^{134}Cs , ^{137}Cs , ^{54}Mn , ^{88}Y , ^{65}Zn . For beta measurements, sources containing only ^{90}Sr and ^{90}Y at equilibrium were considered. In order to analyze the error sources due mainly to measurement procedures and data handling, it was decided to exclude sample treatment in the comparisons. Therefore the sources distributed to participants were aqueous radioactive solutions. In each intercomparison the participants were given a questionnaire, previously agreed, to be filled in with the measurement results and with a detailed description of the experimental means and of the method they used. The most relevant data to be reported in the questionnaire were: nuclear parameters used for data production, gross and net counting rates, counting time, detector efficiency, minimum detectable activity and the activity concentration of the intercomparison source with related uncertainties.

3. Calibration procedures

The objective of the periodical calibration was to assure traceability of radioactivity measurements to the national (and international) standards.

The not adequate instrument calibration was one of the major error sources in the 1983-85 intercomparisons. Therefore a periodical calibration campaign was agreed among the laboratories before starting any new intercomparison.

The radioactive sources used for calibration were prepared and standardized by the ENEA-LMRI. The standard sources were aqueous solutions prepared according to the same procedures as for the intercomparison sources. The following radionuclides were used to prepare the standard sources for calibration of gamma spectrometers: ^{241}Am , ^{109}Cd , ^{57}Co , ^{139}Ce , ^{113}Sn , ^{85}Sr , ^{137}Cs , ^{88}Y and ^{60}Co . These radionuclides are such to cover the photon energy range more frequently considered for gamma-ray spectrometry in environmental samples. The activity concentration of each radionuclide was about 400 Bq/kg.

The calibration sources used for beta measurements contained ^{90}Sr and ^{90}Y at equilibrium similarly to the intercomparison sources. The activity concentration of ^{90}Sr was about 15 Bq/g.

A peculiar aspect of the calibration procedures was the adoption of the same experimental condition (e.g. the same Marinelli beaker for a given laboratory, and the same source density for calibration and intercomparison measurements). This had a clear effect in error reduction.

Table 1 - Gamma spectrometry intercomparisons from 1983 to 1990. Deviations (%), from the reference value, of the activity concentrations determined by participants. The ^{137}Cs was not included in the 1990 comparison.

13	-	+4.9	-3.0	-	26	-	-	-0.5	+2.1

4. Results and Discussion

The results of the first intercomparison, carried out in 1983, confirmed that the degree of standardization in radioactivity measurements was on average rather poor for the laboratories of the network. The second comparison has shown a slight improvement, but a still not satisfactory situation with regard to the reproducibility of measurements performed by each laboratory.

In both comparisons the major source of error was a not adequate and uniform calibration practice of the experimental means. In addition, the procedures for the assessment of the uncertainties were found dissimilar among laboratories and not exhaustive. The calibration campaign performed in the 1988-1990 intercomparisons resulted fairly effective. After these campaigns the deviation of the results from the reference values were confined in the $\pm 10\%$ limits in more than 90% of cases, for both gamma spectrometry and beta counting intercomparisons.

Table 2 - Beta counting (^{90}Sr) intercomparisons from 1983 to 1990. Deviations (%), from the reference value, of the activity concentrations determined by participants.

lab code	1983 ^{90}Sr	1985 ^{90}Sr	1988 ^{90}Sr	1990 ^{90}Sr	lab code	1983 ^{90}Sr	1985 ^{90}Sr	1988 ^{90}Sr	1990 ^{90}Sr

6	-25	+7.8	-	-15	12	-	-	-1.2	+3.7

Table 3 - Improvement in the deviations from the reference value, in the course of the intercomparison campaigns from 1983 to 1990. The data in percent represent the percentage of results with deviation larger than 10% from the reference value.

period	1983	1985	1988	1990
type of measurement				
Gamma spectrometry	33%	33%	10%	8%
Beta counting	63%	55%	16%	4%

Some typical results are summarized in Tables 1,2 and 3. The details on source preparation and characteristics, on the questionnaire content and on the results concerning all other radionuclides not referred to in Tables 1 and 2, are reported elsewhere (1,2). The intercomparisons planned for the future will be based on radioactive sources in natural matrix other than water.

POST-CHERNOBYL FALLOUT IN ROMANIA

I. Osvath and C. Dovlete

Environmental Radioactivity Laboratory
Institute of Environmental Research and Engineering
Of. Postal 11, C.P. 11-2, Bucharest, Romania

As part of the Romanian environmental radioactivity monitoring programme, fallout samples have been systematically collected and analyzed for gamma emitters. Chernobyl fallout space-time patterns, radionuclide concentration ratios and deposition velocities have been determined. The resuspension process has been studied, environmental half-lives for ^{137}Cs and resuspension factors have been evaluated. Hot particles have been identified in some of the deposition samples.

INTRODUCTION - OUTLINE OF THE ROMANIAN ENVIRONMENTAL RADIOACTIVITY MONITORING PROGRAMME

In 1962, in response to the need for monitoring global fallout resulting from nuclear weapons tests, the National Environmental Radioactivity Surveillance Network (NERSN) was created in the frame of the existing Meteorological Network.

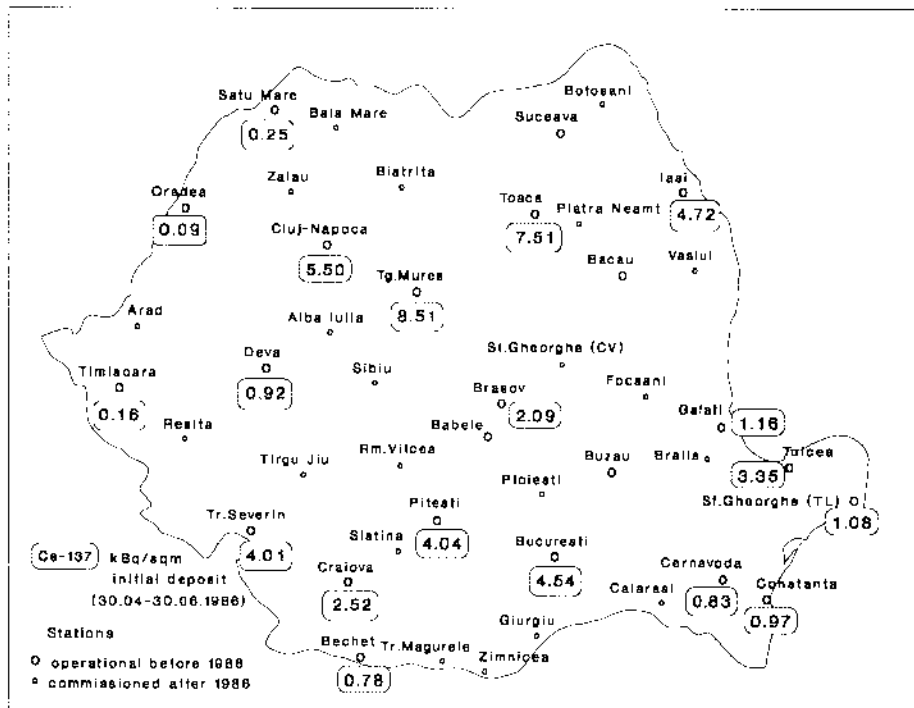

Fig.1. Stations of the Romanian National Radioactivity Surveillance Network. ^{137}Cs in fallout collected during 30.04-30.06.1986.

The NERSN has developed gradually, reaching a number of 23 stations in 1986. Following an increased interest of the public and of the counties' authorities for more detailed information regarding environmental radioactivity and radiological hazards associated with it, the number of stations has more than doubled in the years following the Chernobyl accident (Fig. 1) and activities at the Environmental Radioactivity Laboratory (ERL), which co-ordinates the Network, have been developed accordingly. Presently, the stations are affiliated to the counties' Agencies for Environmental Surveillance and Protection and report to ERL and the Ministry of Environment.

All stations follow a unitary methodology and programme in collecting and preparing samples, performing measurements and reporting data [1]. They sample atmospheric aerosol and deposition, soil, vegetation and surface, well and drinking water, perform gross beta measurements and forward the samples to the ERL for radionuclide analyses.

Among studies at ERL, those on fallout, hot particles and resuspension present a special interest due to the long-term radiological exposure pathways associated to them.

Fig.2. Annual ¹³⁷Cs deposition vs. ¹³⁷Cs in fallout collected during 30.04-30.06.1986, for several locations in Romania

METHODS OF SAMPLING AND MEASUREMENT

Fallout has been sampled employing 0.3 m² collectors. For most sites wet and dry deposition have been cumulated. For gamma spectrometrical analyses, monthly and annual samples have been prepared using samples collected daily. Exceptions were

made in 1986, when fallout has been cumulated over shorter periods in the first month after the Chernobyl accident, as well as with some individual daily samples showing relatively high activities, occurring in the following years. The latter have been successively divided and the resulting sub-samples analysed, some of them being thus demonstrated to contain hot particles.

Gamma spectrometrical analyses have been performed using high resolution, low background systems. All spectra have been analysed automatically. Complex spectra have also been evaluated using a semi-automated procedure which allows visual check and separate treatment for each peak or multiplet.

RESULTS AND DISCUSSION

The following radionuclides have been identified in fallout samples collected after the Chernobyl accident: ^{54}Mn , ^{95}Zr , ^{95}Nb , ^{99}Mo , ^{103}Ru , ^{106}Ru , $^{110\text{m}}\text{Ag}$, ^{125}Sb , $^{129\text{m}}\text{Te}$, ^{131}I , ^{132}Te , ^{132}I , ^{134}Cs , ^{136}Cs , ^{140}Ba , ^{140}La , ^{141}Ce , ^{144}Ce , ^{144}Ce , ^{147}Nd , ^{154}Eu , ^{155}Eu , ^{239}Np . Activity ratios and deposition velocities have been evaluated using specific activity data.

The levels of Chernobyl-derived fallout radioactivity, as resulting from samples collected at NERSN stations, were lowest in the North-Western part of the country, highest in the central, Eastern and Southern plains and at high altitudes (Fig. 1). Analyses of soil samples (in progress) show a more complicated pattern of contamination.

Fig. 3. Resuspension coefficient K vs. initial deposit of ^{137}Cs (30.04-30.06.1986) for several sites in Romania.

Measured monthly values of ^{137}Cs in atmospheric deposition show an exponential decrease with a site-dependent environmental half-life between 55-237 days during June 1986 - June 1987, and between 236-549 days during June 1986 - December 1991. Data on ^{137}Cs in yearly cumulated samples show that the magnitude of the initial deposit determines the magnitude of the subsequent deposition rate (i.e. sites with lower initial deposit associate lower deposition rates), but for values of the initial deposit above 2 kBq/sqm, the annual ^{137}Cs deposition does not vary with the initial deposit (Fig. 2). The resuspension coefficient K , defined in [2], decreases with increasing values of the initial deposit, as illustrated (Fig.3) by values computed for 1991, using yearly mean air concentration values [3]. K also decreases in time (Fig.4).

Fig. 4. Resuspension coefficient K , evaluated using ^{137}Cs data corresponding to several sites in Romania, vs. time.

During 1988-1990 several hot particles, with relatively high ^{144}Ce and ^{106}Ru activities, were identified in deposition samples, mostly originating from the Eastern part of Romania.

RADON IN THE HUMAN ENVIRONMENT: A GLOBAL APPROACH

F. Steinhäusler
International Atomic Energy Agency,
P.O. Box 100, A-1400 Vienna, Austria

ABSTRACT

The largest IAEA/CEC Co-ordinated Research Programme "Radon in the Human Environment" is described in terms of programme objectives, quality assurance, standardization of surveys and preliminary results.

1. GLOBAL RECOGNITION OF THE RADON PROBLEM

Already in 1956 the importance of the non-occupational radon (Rn) exposure was pointed out (1). However, the international scientific and regulatory community had only just started to acknowledge the significance of the occupational exposure to radon decay products (Rn-d) in the case of the uranium underground miners (2). In the following 20 years mainly European and US-scientists provided a growing number of data (e.g. in the Proc. of the US-DOE Symposium Series "The Natural Radiation Environment"), which indicated the widespread occurrence of elevated Rn-d exposure in a variety of natural and technologically-enhanced natural radiation environments. Nevertheless it took until 1977 when the International Commission on Radiological Protection addressed radiation protection issues in uranium mines (3) and until 1981 for it to recommend an occupational Rn-d limit of 4.8 Working Level Months (4). In the 1980's the Organization for Economic Co-operation and Development, Nuclear Energy Agency (OECD-NEA), Paris (France) and the Commission of the European Communities (CEC), Brussels (Belgium) reviewed the state-of-the-art of Rn- and Rn-d metrology and dosimetric methods (5). In the United States of America the US-Department of Energy and the US-Environmental Protection Agency undertook the so far largest national Rn-programme (6). Within the framework of the United Nations the International Atomic Energy Agency (IAEA) responded to the request from 56 Member States and initiated, jointly with the CEC, a co-ordinated research programme on "Radon in the Human Environment". This international programme will co-ordinate the research efforts to quantify the impact of Rn on man.

2. THE IAEA RESPONSE

For the IAEA - Co-ordinated Research Programme (CRP) "Radon in the Human Environment" altogether 108 research project proposals have been approved, making it the largest CRP within the Agency; 25 CEC-approved projects are part of the CRP. This CRP encompasses scientists of largely differing experience in Rn-research, using a wide variety of equipment and analytical methods. Therefore it is imperative to ensure comparability of results obtained from the various studies. The IAEA organized the International Intercalibration and Intercomparison Programme (IIIP) for Rn- and Rn-d measurement techniques as part of a comprehensive Quality Assurance Programme (QAP). Another major objective is the standardization of the Rn survey techniques for the different applications, ranging from establishing a Rn-potential map or conducting an epidemiological survey concerning Rn-d induced lung cancer. Furthermore the CRP emphasizes an institutionalized exchange of information on the available methodology concerning inhalation dosimetry, risk assessment and mitigation techniques. Finally it is planned to establish an international Rn-databank for both members of the international scientific community and national regulatory agencies. The CRP is implemented in two phases. Phase I started in 1990 and consisted of the award of 37 Research Agreements, 12 Research Contracts and 4 Consultant Contracts to the following countries: Algeria, Argentina, Australia, Austria, Belgium, Brazil, Bulgaria, China, Costa Rica, Ecuador, Egypt, Germany, Ghana, Hungary, Iran, Ireland, Israel, Italy, Japan, Korea, Luxembourg, Malaysia, Netherlands, Norway, Pakistan, Poland, Singapore, Spain, Sudan, Sweden, Switzerland, Syria, Thailand, Tunisia, Turkey, United Kingdom, USA, Vietnam, Yugoslavia. The overall technical guidance of the QAP is provided by the members of the IAEA-IIIP: Environmental Measurements Laboratory (New York, USA); Bureau of Mines (Denver, USA); National Radiological Protection Board (Didcot, UK); Australian Radiation Laboratory (Melbourne, AUS). At the secondary level Regional Coordinators act as technical/logistical interface between the CRP-participants and the primary laboratories; for the American region: Instituto de Engenharia Nuclear (Rio de Janeiro, Brazil); for the European region: Centre of Radiation Hygiene (Prague, CSFR); for the Eastern European and Middle East region: Laboratory of Dosimetry and Radiation Protection (Sofia, Bulgaria); for the Asian-Pacific region: Ministry of Public Health, Laboratory of Industrial Hygiene (Beijing, China). In addition, the US-Environmental Protection Agency (EPA) and the IAEA are conducting jointly international intercomparison exercises and Rn-detector test programmes under defined laboratory exposure conditions. Standardized protocols were developed to assist in the co-ordinated conduct of Rn-surveys. In the pilot-phase of such a survey the technical and logistical components are tested, survey personnel are trained and the necessary regional/national programme infrastructure is established. The subsequently conducted large scale Rn-survey is conducted mostly with the objective of determining yearly averaged indoor Rn-values, using a standardized questionnaire for randomly selected individuals.

In 1991 the following QAP-related activities have been organized within the CRP:

a) an international field-intercomparison exercise (Rn in air and water; Rn-d in air) for active and passive devices in the high background area of the Rn-spa Badgastein (Austria); b) an international laboratory-intercomparison exercise (Rn in air) for integrating passive devices used by CRP-participants at the US-EPA Rn-chamber in Montgomery (Alabama); c) a climatic Rn-detector performance test (Rn in air) for commercially available integrating Rn-devices, simulating dry/humid hot/cold environments in the US-EPA Rn-chamber in Las Vegas (Nevada).

Results from pilot-surveys have indicated new data for population groups with elevated indoor radiation exposure levels in different regions of the world, for instance:

In China several hundred thousand inhabitants reside in carbon-brick dwellings, which contain elevated levels of ^{238}U (≤ 20.8 kBq/kg) and ^{226}Ra (≤ 30 kBq/kg). This causes an increased gamma dose rate up to 940 nGy/h (7). Also millions of Chinese live in underground earth-dug cave-dwellings, in some cases exposed to Rn-levels in excess of 650 Bq/m³.

In Europe the environmental impact of Bulgarian uranium mining and milling activities has been studied. Areas were identified with ^{226}Ra -levels in soil up to 10 kBq/kg and elevated Rn-levels indoors (≤ 400 Bq/m³) due to ^{226}Ra -surface contamination on the walls (8).

In Africa elevated Rn-levels have been found in Ghana and Sudan. In the former case Rn-concentration in traditional Ghana-houses (clay bricks, small windows) was found to be significantly in excess of US-EPA action levels due to poor ventilation (9); in the latter case increased $^{238}\text{U}/^{226}\text{Ra}$ -levels in the high background area of Lake Miri can cause elevated exposure of the local residents up to 38.6 mSv/year effective dose (10).

3. THE NEED FOR INTERNATIONAL CO-ORDINATION

With regard to research increased co-ordinating efforts are warranted in the areas: source term characterization (contribution from thoron daughters, transport phenomena); aerosol sciences (interactions of Rn-d with other pollutants and aerosols); micro- and biological dosimetry (dose reconstruction for different species); molecular radiobiology (in vitro cellular approach). Details are discussed in ref. 11. Co-ordination is also required in the implementation of the large number of Rn-programmes planned worldwide, concerning: data collection and -storage methods; QAP; Rn-mitigation techniques. Harmonization of the international regulatory approach to risk limitation from Rn-d inhalation is of particular interest. Several exposure situations have to be addressed, such as non-occupational exposure

(residential use of owner occupied buildings vs. rented accommodation), occupational non-mining exposure (Rn-spas, public buildings vs. schools, offices and general workplaces) and occupational mining exposure (uranium-, non-uranium-mining and milling).

ABSTRACT

A non-linear lung cancer risk model has been developed, in which both the functional form of the dose-response relationship and its parameter values arise from radio-biological observations at the cellular and organ level. Depending on the effectiveness of ionizing radiation as either promoter and/or initiator, different dose-effect curves will be obtained in the low dose region, which are generally lower than the linear risk estimate.

INTRODUCTION

Because of the inevitable interaction of confounding factors, any estimate of lung cancer risk at low, environmental exposures to radon progeny must be based on some form of extrapolation from high radon levels. Current radiation protection regulations are based on the philosophy that the excess risk is linearly related to the cumulative exposure. Here, we contrast the linear hypothesis with theoretical predictions based on a non-linear cancer risk model. This model is based on radiobiological mechanisms at the cellular level. The intent is to provide a coherent understanding of in-vitro cellular transformation and in-vivo organ carcinogenesis. Such an approach requires a set of assumptions concerning cellular radiation effects of alpha particles relevant to radiation carcinogenesis. Predictions of the relative lung cancer risk are compared with epidemiological findings in U.S. uranium miners (1).

CELLULAR RADIATION EFFECTS

In line with radiobiological observations, our predictive model of lung cancer induction is based on three properties of radiation: (i) transformation of cells, (ii) inactivation of cells, and (iii) stimulated cellular division in a stem cell population. This model has been used to estimate the carcinogenic risk of beta-emitting hot particles in lung tissue (2). Here, an additional assumption has been incorporated, namely (iv) the need of a cell to be released from contact inhibition in order to express its full potential as a transformed cell (3).

In the present lung cancer induction model we assume five states in the development of a cell from the initial unirradiated

level (state 1) to a fully transformed one (state 5) (3). The intermediate steps are: production of a specific DNA damage (state 1 to 2), production of a less specific DNA damage (state 2 to 3), cellular division (state 3 to 4) and release from contact inhibition (state 4 to 5). Competing with these mechanisms at each transition is radiation-induced cell death. Lung cancer risk is then assumed to be proportional to the number of transformed cells.

According to the common terminology of "initiation" and "promotion" in carcinogenesis, movement from state 1 to 3 may be identified as the initiating event and the two subsequent transitions as promotion events. Radiation, like all carcinogens, has properties of both initiation and promotion.

LUNG CANCER RISK PREDICTIONS

Cumulative doses for a given exposure category are calculated assuming a median length of exposure of 4 years in all exposure categories (1) and a dose-exposure conversion factor of 3.9 mGy WLM^{-1} . Multiplication of the risk for a sensitive cell in bronchial epithelium, receiving a given cumulative dose, by the number of cells in a given generation (4) and summation over all bronchial generations (5) yields the carcinogenic risk for a defined exposure category.

First we assume that radiation acts both as initiator and promoter (IP-model). The in-vitro transformation frequency per viable cell for alpha particle irradiation (6,7) already represents the total probability of reaching the final stage of uninhibited growth, comprising all initiation and promotion steps. Two modifications have been made to obtain the transformation probability per exposed cell and to simulate in-vivo transformation under conditions of cellular replacement.

The relative lung cancer risk for the IP-model as a function of cumulative exposure is plotted in Fig. 1 together with the epidemiological data of Hornung and Meinhardt (1). Given the large statistical uncertainty of the epidemiological information, there is excellent agreement between predicted and observed lung cancer risks over the entire range of cumulative exposures. At low doses, our non-linear model predicts a slightly lower risk as has been observed in the epidemiological study. It should be noted, however, that such a sublinear shape with a rising slope is consistent with the lung cancer data reported by Samet et al. (8).

If we assume that cells have already been initiated by co-carcinogenic factors, such as cigarette smoke, then radiation can promote these initiated cells by stimulating cellular division and stopping contact inhibition (P-model). At the same time, however, it can also kill the cells. Lung cancer risk in the P-model is very similar to the predictions with the IP-model displayed in Fig. 1.

Based on the histopathological observations of smoke-induced hyperplasia of bronchial cells, we assume that the primary promotional role of cigarette smoke is through stimulation of cellular division (CSP-model). An increase in the efficiency of cigarette smoke promotion relative to that of radiological promotion produces a higher risk at low doses and a smaller risk at high doses when compared to pure radiological promotion. Thus the additional promotional effect of cigarette smoke yields an approximately linear dose-effect curve at low doses.

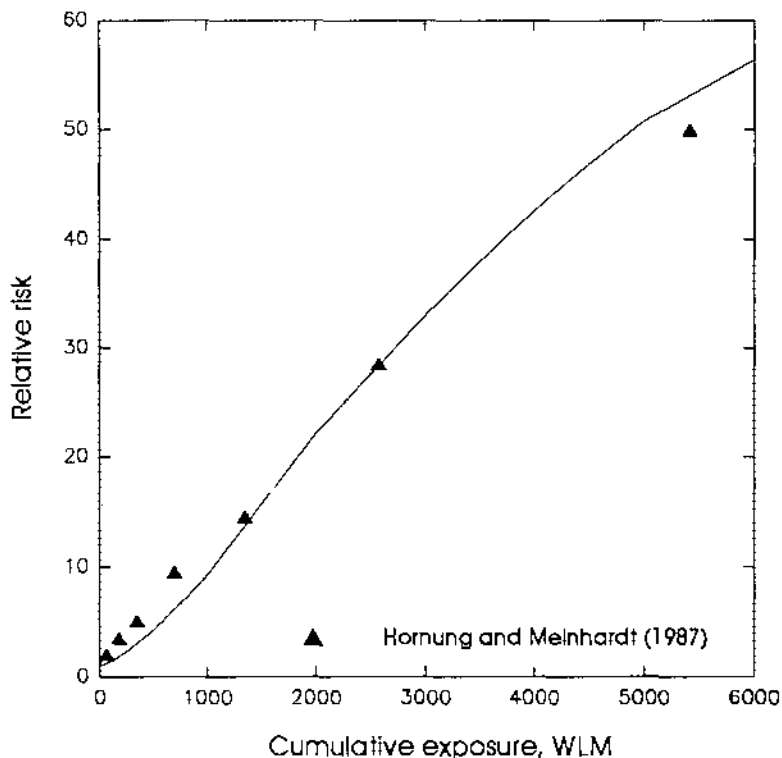

Fig. 1 Predictions of the relative lung cancer risk (radiation acts both as initiator and promoter) as a function of cumulative radon progeny exposure and comparison with epidemiological data.

CONCLUSIONS

If radiation is assumed to act as initiator and promoter (IP-model) or only as promoter (P-model), then the predicted lung cancer risk in the low dose regime is smaller than that based on the linear hypothesis. If radiation is effective primarily as an initiator (with cigarette smoke being the main promoter), then the

predicted incidence at low doses approaches the linear estimate.

While these models use mean doses, explicit incorporation of variability in cellular doses modifies the above risk predictions. Assuming lognormal cellular dose distributions, a larger variability increases the risk at high doses, but reduces the incidence at low doses (9). On the other hand, if enhanced deposition and reduced mucociliary clearance at bronchial bifurcations is factored into our risk analysis, then lung cancer risk is increased at low exposures relative to the current assumption of a uniform airway dose distribution used in the above models (10).

Considering the uncertainties of each modeling approach, a realistic combination of all factors discussed above suggests that the linear hypothesis represents a realistic upper boundary in the low doses region, thus being a viable compromise for radiation protection purposes.

**EXPOSURE TO COSMIC RADIATION:
A DEVELOPING MAJOR PROBLEM IN RADIATION PROTECTION**

**Wayne M. Lowder and Ferenc Hajnal,
USDOE Environmental Measurement Laboratory, New York, NY, USA
(possibly coauthors from NASA, FAA, and other agencies)**

Cosmic radiation at ground altitudes is usually a relatively minor contributor to human radiation exposure, producing a global collective dose equivalent that is about 10 percent of the total from all natural sources. However, more than a million people living at high altitudes receive annual dose equivalents in excess of 5 mSv. In recent years, there has been increasing concern about the exposure of aircraft flight crews and passengers, for whom annual dose equivalents of up to several mSv have been estimated. Recent EML results indicate the presence of an important high-energy neutron component at jet aircraft altitudes, perhaps producing dose equivalents of the order of 0.1 mSv/h at high latitudes. Finally, space agencies have been long concerned with the potential exposures of astronauts, especially from the rare massive solar flare events. As more people venture into space, this source of human radiation exposure will become increasingly important.

Available data on these aspects of cosmic radiation exposure will be reviewed, along with current and anticipated future research activities that may yield an improved assessment of the problem. The question of how such exposures might be controlled will be addressed, but not answered.

EXPOSURE TO RADON IN ABOVE GROUND WORKPLACES

THE EXPERIENCE IN GREAT BRITAIN (GB)

ABSTRACT

Regulations regarding exposure of employees and others to ionising radiation including exposure to radon were introduced in GB in 1985. Research by HSE over a number of years has identified the type and location of workplaces most affected by radon. Exposures in excess of the action levels in the regulations have been identified and appropriate action taken. Further research is underway to identify other affected areas and compare methods of measurement. Liaison has taken place between government departments to produce advisory material for employers and employees.

REGULATORY BACKGROUND

In Great Britain (GB) safety regulations for employees and others affected by their work are made under the Health and Safety at Work Act 1974. In 1986 the Ionising Radiations Regulations 1985 (IRR85)¹ were introduced. These regulations include requirements which are binding on GB by virtue of its Membership of the European Community. The requirements are contained in the Euratom Directives of 1980 and 1984 and are traceable to International Commission on Radiological Protection (ICRP) publications 26(1977) and 30(1979).

The requirements in IRR85 for radon are introduced under "work with ionising radiation". This is any work in which there is any exposure of a person to an atmosphere containing the short lived daughters of radon 222 at a concentration averaged over any 8 hour working period of greater than $6.24 \times 10^{-7} \text{ J m}^{-3}$ ie 0.03 Working Levels (WL). This corresponds to a dose of 5 mSv over a 2000 hour working year which is the supervised area level. Strictly exposure to 0.03 WL for 2000 hours corresponds to a dose of about 3.5 mSv, with a conversion factor of 10 mSv per WLM, and after allowance for exposure to natural sources other than radon 222. An important requirement of the regulations is the appointment of a radiation protection adviser at a concentration of 0.1 WL. Guidance on application of the regulations is given in an approved code of practice² which contains advice on for example restriction of exposure, personal dosimetry and area monitoring. Guidance has also been produced for HSE inspectors and environmental health officers. The latter inspect premises such as offices and shops. Inspectors have also been given training and are backed up by radiation specialists who have appropriate experience and radon monitoring equipment.

WORKPLACE STUDIES

In 1983 HSE commissioned a series of research programmes designed to obtain information on the type and location of premises where the IRR85 were likely to apply³. The first studies concentrated on Devon and Cornwall where it was known that high levels existed in some homes. NRPB undertook radon monitoring work for HSE using their track etch plastic detector, which is mounted in a housing which acts as a diffusion chamber and also acts as mechanical protection. Earliest measurements also included active sampling.

Monitors were sent by post individually to each employer with instructions for placement and return. Employers were asked to put the monitors in places that were routinely occupied. Account was also taken of the time of year in which the monitoring took place to allow for the annual variation that occurs in radon levels whereby levels are generally lower in summer than in winter. Since measurements of radon daughter concentrations can be laborious and time consuming, measurements with passive monitors over one month have been adopted in the UK as the routine method of screening to decide whether workplaces are likely to be affected by Regulations. Some care is needed in translating the results of radon gas measurements over one month to a radon daughter concentration during working hours, but for a typical diurnal variation, a screening value of 400 Bq m⁻³ measured with passive monitors over a month during winter provides an effective means of identifying workplaces where concentrations during the day might exceed 0.03 WL. Since these monitors are cheap, simple to use and can be sent through the post, they provide an effective means of screening large numbers of workplaces.

These initial studies showed that in premises such as workshops and production areas with good natural or forced ventilation it was unlikely that the action level of 0.03 WL would be exceeded. However places such as offices schools and hospitals may well exceed this level. Of the 50 workplaces studied 10 exceeded the supervised area level and 3 exceeded the controlled area level. The highest estimated annual dose was 24 mSv. The information was communicated to employers. Further research⁴ on the feasibility of simple methods of reducing radon daughter concentrations concluded that underfloor suction systems were likely to be very effective in many properties and that other methods were unlikely to achieve consistent and substantial reductions.

The latest studies undertaken by HSE surveyed a total of 670 premises in Cornwall, Devon, Derbyshire, Northamptonshire, Somerset and Scotland. The complete analysis is not available at the time of writing, but of the 145 results processed, 23 premises had levels in excess of the supervised area level. The highest radon gas concentration reported was 3000 Bq m⁻³ which gives an estimated 40 mSv dose for a 2000 hour exposure time. Although the premises with the highest concentrations were in Cornwall 20 premises in the other areas were identified as having concentrations likely to exceed the supervised area levels. Other studies have identified levels of several thousand Bq m⁻³ in a workplace in Derbyshire.

Further research has been commissioned with NRPB to obtain estimates of the distribution of radon gas concentration in workplaces throughout the country. This will be based primarily on correlation

with existing data for homes. Another area of current research is comparison of methods for monitoring exposure to radon. This work is designed to give further information on the accuracy and applicability of the methods for the purpose of complying with IRR85.

PROVISION OF INFORMATION

A recent development in GB in the approach to the radon problem is the consideration by government of exposures both at work and at home. This approach was advocated in the recent recommendations of the House of Commons Environment Committee⁵. It emphasised the need for a person to be given adequate information about the overall risk from exposure to radon. A leaflet is being prepared by the HSE which gives simple background facts about radon, gives guidance on action to be taken by employers and explains how to obtain assistance from the Department of the Environment for monitoring at home. In workplaces where it has been found necessary to take action to reduce radon levels employees are strongly recommended to have their homes tested as well. This is available free through the Department of Environment.

CONCLUSIONS

Research over the last 8 years has shown that workplaces with low natural ventilation in Cornwall and Devon are most likely to have the highest radon concentrations in GB. However other areas can have significant concentrations which require remedial action.

It is the experience in GB that a package of measures is necessary to achieve adequate protection from the risks posed by exposure to radon. This package should include research, regulations, production of guidance material, inspection and enforcement by the regulatory body.

It is likely that existing arrangements in GB will provide a good framework to cope with future developments in International Guidance and European Legislation for radon.

ABSTRACT

A natural radiation survey based on the choice of a statistically representative sample of 5000 dwellings began in Italy in 1989. The paper analyses the radon results obtained in 45% of the national sample. The arithmetic mean of the concentration is equal to 80 Bq/m³ and the number of dwellings exceeding 200 and 400 Bq/m³ is around 5% and 1% of the total, respectively. The concentration distribution could be described by a log-normal curve, but with a significant underestimation of the high concentration tail.

INTRODUCTION

The aim of the national survey was: i) to obtain the distribution of radon concentration and of absorbed dose rate in air; ii) to evaluate the average exposure of the population to natural radiation. These data might allow an assessment of the percentage of dwellings, which exceeds some reference levels of radon concentration, and the average risk - according to present knowledge - for the population due to radon indoors. The opportunity and the social and economical cost of regulatory choices could thus be evaluated.

The strategy chosen - a two stage stratified sampling according to administrative districts and population - is described in ref.1. The peculiarity of the survey is the involvement of several public laboratories in carrying out the measurements and local health authorities in approaching the families. The survey was designed to give representative data of radon concentration both at district and at national level, allowing also to proceed in different time steps.

The organization and the state of art of the survey, the experimental set up, the protocols and the questionnaires adopted, the acceptance of the public, have been presented elsewhere (ref. 2, 3). In this paper the quality control methodology and the experimental results in 45% of the sample are presented.

QUALITY ASSURANCE AND QUALITY CONTROL PROCEDURES

As the survey involves around twenty laboratories with different operational experience, a sound quality assurance/quality control programme has been set up. It foresees: the intercomparison among laboratories at the beginning of the measurement phase, the use of duplicate dosimeters (each containing two detectors), a strict protocol to assemble the detectors, to perform the measurements and to analyse the data. The QA/QC programme is

carried out by the two National Institutes in order to guarantee the comparability of the various data sets.

Regarding the quality assurance of the measurement apparatus, the dosimeters used in the survey were previously calibrated both at the NRPP radon chamber (twice) and at the USDOE-EML (once). The three calibration factors have a coefficient of variation of 5%. In the first two intercomparison runs organized in Italy at central level the coefficients of variation among the different laboratories were 8% and 11%.

The complete set of data from detector pairs (one detector for each dosimeter) were compared by means of parametric and non parametric tests (ref.4) to verify their consistency and to identify possible outliers. In these cases, the third detector is processed and, sometimes, even the fourth (used as back up detector by the National Institutes).

An evaluation of the errors affecting the measurements of the laboratories involved - connected with differences in batch, in etching procedure, in track counting, etc. - was performed. A first analysis allowed to assign a global uncertainty around 30% for radon concentrations up to 50 Bq/m³ and 20% for concentrations above the same value. A more detailed study is at present being carried out.

RESULTS

The survey is still in progress. Data from 45% of the national sample (northern and central districts) have been analysed. The distribution of annual radon concentration in dwellings (see fig.1) has approximately a log-normal shape. The Kolmogorov-Smirnov test was performed to assess the goodness-of-fit of the actual distribution with a log-normal curve. A negative result ($p < 10^{-6}$) was obtained.

The arithmetic mean of radon distribution in the different districts ranges from 43 to 117 Bq/m³ and the overall mean is 80 Bq/m³, with an estimated statistical uncertainty of 3 Bq/m³ (95% of confidence level). The median is equal to 61 Bq/m³, close to the geometric mean, which is equal to 62 Bq/m³, with a statistical uncertainty of 2 Bq/m³ (95% c.l.).

The fraction of dwellings with mean radon concentration exceeding 200 Bq/m³ and 400 Bq/m³ - the reference levels adopted by the European Community for new and existing dwellings - ranges in the different districts from 0.6% to 9.9% and from 0% to 4.9%, respectively. In the total measured sample this quantity is 5.1% and 1.3% respectively, with a statistical uncertainty of 1.0% and 0.6% (95% c.l.). The values obtained by the log-normal fit are 3.9% and 0.2%.

In conclusion, whereas the log-normal approximation gives a fairly good estimation of the distribution central value, it significantly underestimates the high radon concentration tail, as reported also by other authors (ref.5).

The mean ratio of the winter/summer concentrations ranges from 1.1 to 2.7 for different districts, with a mean value of 1.5. The correlation of radon concentration with floor level is shown in fig.2. The mean concentration decreases from basement to the ground and the first floor, becoming almost constant after the second floor.

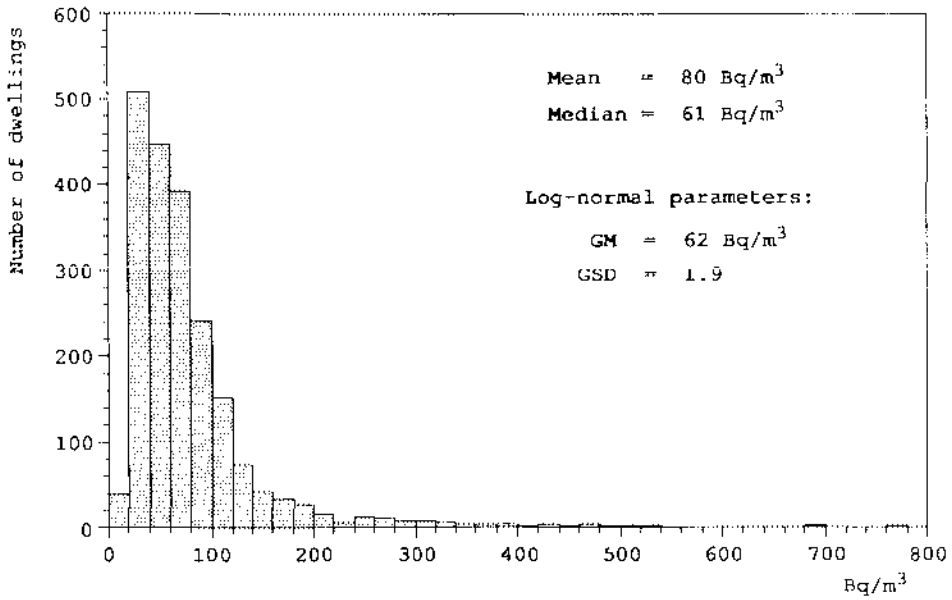

Fig.1 Distribution of annual radon concentration

Fig.2 Mean annual radon concentration vs floor.
 The error bars represent one standard error.

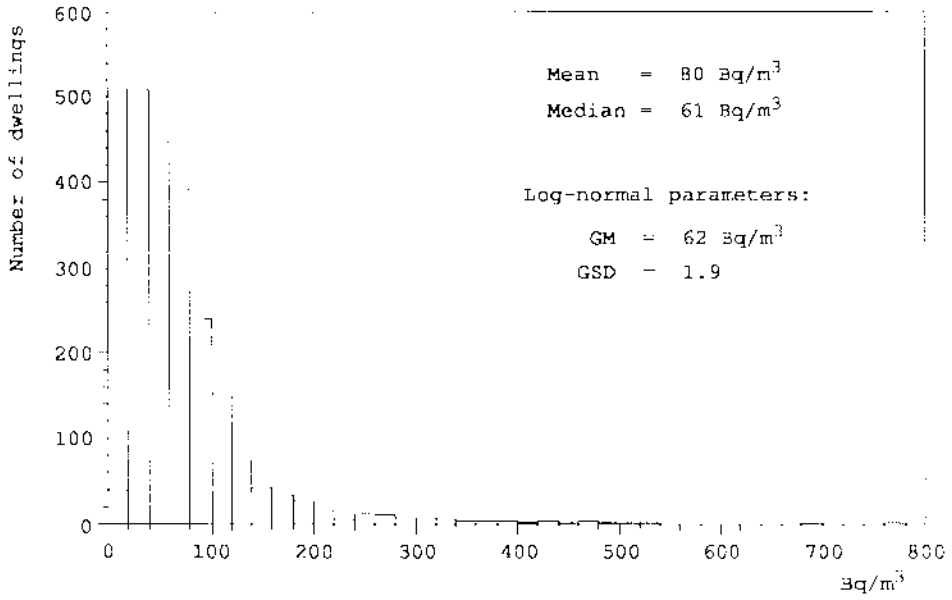

Fig.1 Distribution of annual radon concentration

Fig.2 Mean annual radon concentration vs floor.
The error bars represent one standard error.

CONCLUSIONS

Taking into account the occupation factors indoors at home and elsewhere, obtained in the survey through questionnaires, the mean effective dose has been calculated (ref.6). The value ranges from 2.2 to 6.1 mSv/y in the different districts, with a mean of 4.1 mSv/y.

This evaluation confirms even in Italy the relevance of radon as a source of exposure to ionizing radiation.

ACKNOWLEDGMENTS

The authors are very grateful to the personnel of the Laboratories for the environmental radioactivity control of: Friuli Venezia-Giulia, Emilia-Romagna, Lombardia, Umbria, Bolzano, Trento, Toscana and Piemonte for their collaboration.

Thanks are also expressed to M.Riccardi (ENEA/DISP) for his cooperation in the measurement programme, and to F.Felici and G.Moroni (Istituto Superiore di Sanità) for their assistance in the same programme.

The collaboration of Dr. R.Tommasi (ENEA/DISP) in the quality control tests has been much appreciated.

RADON IN THE OFFICE ENVIRONMENT

ABSTRACT

The results of weekly radon concentration measurements in an office environment using a novel envelope-type radon monitor for short term exposure periods are presented. The commercially available LR-115 damage track detectors are used and the chemically etched sheets are spark counted. The measurements were made over a period of one year. The indoor radon concentration varies from $\sim 20 \text{ Bq.m}^{-3}$ to $\sim 300 \text{ Bq.m}^{-3}$ with the average of 130, 81 and 73 Bq.m^{-3} for three different rooms resulting in the annual dose of 4.5, 2.8 and 2.5 mSv, respectively.

INTRODUCTION

Measurements of indoor radon concentrations have attracted much attention since early 1980. The correlation between lung cancer and exposure to radon has been well established [1], though the risk under normal indoor environmental conditions is somewhat uncertain [2]. There are a variety of radon detectors and dosimeters for indoor and outdoor radon measurements. The systems based on damage track detectors proved to be very attractive for their ability to integrate over long periods of time (months to years) [3]. Short-term exposure period as low as one week is needed when a screening survey is required [4]. This paper describes the results of weekly radon concentration measurements in an office environment using a gas radon sampling device for short-term exposure periods.

EXPERIMENTAL PROCEDURES

A novel envelope-type radon monitor has been designed and successfully used for short-term radon measurements [5, 6]. The commercially available LR-115 damage track detectors (9 cm x 12 cm) are used in this monitor. When the envelope is closed, the strippable LR-115 detector does not register alpha particles and the monitor is in the off state. When the envelope is opened, only half of the LR-115 sheet is exposed to the ambient. The second half of the foil, being protected by a plastic cover thick enough to stop all alpha particles, is used as "blank" detector. At the end of the exposure period, the LR-115 sheets are chemically etched in the 10% NaOH solution at 60 °C for 110 min and then spark counted [7, 8]. The radon concentrations were calculated using the calibration factor of $\epsilon = 2.03 \pm 0.07 \text{ cm}^{-2} \cdot \text{kBq}^{-1} \cdot \text{m}^3 \cdot \text{h}$ determined separately by the calibration exposure in the radon chamber.

RESULTS AND DISCUSSION

The weekly radon concentrations in an office situated in the lower ground level of a multi-storey building were measured using the envelope-type radon monitor. The office consists of three adjacent rooms with forced ventilation systems throughout the year. The measurements were made over a period of one year with no interruption.

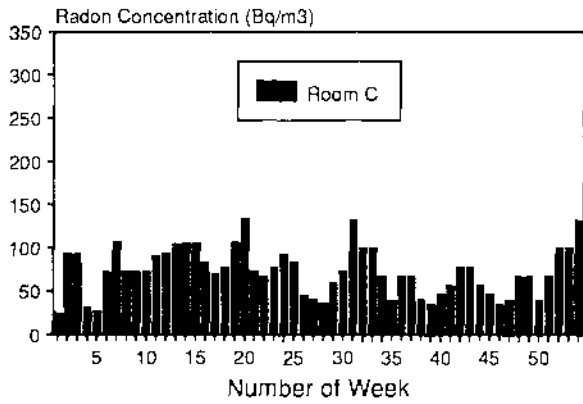

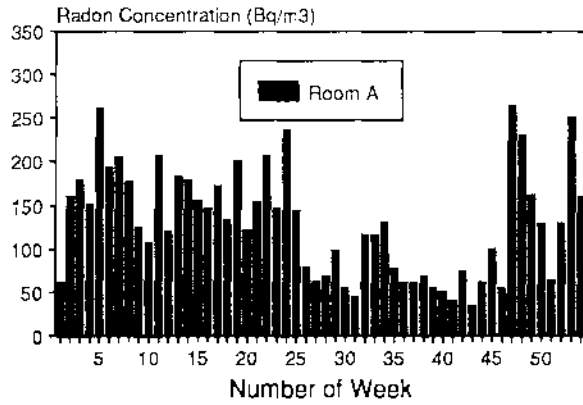

Fig. 1 Variation of weekly radon concentration in an office environment.

The variations of weekly radon concentrations for three different rooms are shown in Fig. 1. The results show that, in these rooms, the indoor radon concentration varies from $\sim 20 \text{ Bq.m}^{-3}$ to $\sim 300 \text{ Bq.m}^{-3}$. The average radon concentrations are 130, 81 and 73 Bq.m^{-3} for the Rooms A, B and C, respectively. The standard error of any single measurement did not exceed $\sim 10\%$ with the mean of $\sim \pm 4\%$. The annual dose resulting of radon concentration in the Rooms A, B and C are 4.5, 2.8 and 2.5 mSv, respectively, taking the concentration-to-dose conversion factor of $1 \text{ Bq.m}^{-3} = 0.035 \text{ mSv per year}$.

CONCLUSION

The envelope-type radon sampler in conjunction with spark counter proves to be the most convenient and simple method for short-term radon measurements as low as one week. These measurements are important for occupational health services. The weekly indoor radon measurements in an office over a period of one year showed that the concentration varies from $\sim 20 \text{ Bq.m}^{-3}$ to $\sim 300 \text{ Bq.m}^{-3}$ with the average of 130, 81 and 73 Bq.m^{-3} for three different rooms.

EXPERIMENTAL STUDY OF THE GENETIC EFFECTS OF THE
NATURAL RADIOACTIVITY

The dose rates of natural telluric radioactivity usually range between 0.3 and 3.0 mGy/year ; however, they sometimes reach considerably higher values (more than 1 Gy/year). Apart from rare exceptions, the living organisms present on or in such soils are apparently normal. Yet, laboratory studies on their progenies suggest that natural telluric radiations have genetic effects. This has been verified by means of plant and animal genetic markers. The former have also shown that other environmental factors may in the long run play some role in the evolutionary process.

INTRODUCTION

Peu de travaux ont été consacrés à l'étude des effets biologiques de la radioactivité naturelle. La synthèse présentée ici, concerne les principes de quelques expérimentations et les résultats les plus importants obtenus ces vingt cinq dernières années par un groupe de recherche pluridisciplinaire.

MATERIELS ET METHODES

Trois types de travaux ont été réalisés :

I - observation de végétaux inféodés à plusieurs sites uranifères présents dans le sud de la France et comparaison avec les mêmes espèces présentes sur des substrats voisins ne contenant pas d'uranium et ses descendants radioactifs.

II - récolte de graines sur des espèces végétales présentes à la fois sur des substrats uranifères et non uranifères, les deux types de semences étant semées, pour comparaison, dans les mêmes conditions de microclimat, de substrat et d'environnement faiblement radioactif (bruit de fond naturel).

III - utilisation de marqueurs génétiques cultivés ou élevés au-dessus de certains de ces sites uranifères et sur des sites témoins voisins afin de détecter et d'évaluer les éventuels effets génétiques soupçonnés grâce aux travaux précédemment réalisés *in situ*. Les principaux marqueurs utilisés sont :

- le système $a1+/a1$ $a2+/a2$ du Tabac : il est constitué par deux gènes indépendants $a1$ et $a2$ conditionnant la différenciation des chloroplastes dans la variété *xanthi* n.c. de *Nicotiana tabacum* L. A l'état hétérozygote ($a1+/a1$ $a2+/a2$), cette combinaison génétique qui donne une couleur vert jaune aux feuilles par suite d'une déficience chlorophyllienne partielle, permet de déceler facilement les variations somatiques liées à ses modifications. Les plus fréquentes correspondent à des réversions de $a1$ vers $a1+$ ou de $a2$ vers $a2+$ qui s'expriment sous la forme de taches vert foncé sur le fond vert jaune des limbes. Le taux de réversion moyen (ρ) par génération cellulaire, s'obtient par un calcul simple à partir de données faciles à mesurer : surface des

feuilles (S), surface totale des secteurs mutés sur les feuilles étudiées (Sg), densité cellulaire (d) :

$$p = 1 - \left[\frac{S-Sg}{S} \right]^{1/t} \quad \text{où } t = \frac{\log Sd}{\log 2} - 7 \quad \text{et } N = Sxd,$$

t étant le nombre de générations cellulaires nécessaires pour former le tissu foliaire étudié.

des petits mammifères : lapins venant d'un élevage régional et souris de la race BALB/c. Ils ont été élevés dans des dispositifs construits au-dessus du site radioactif de Riviéral dans le Bassin permien de Lodève (France), des animaux témoins étant maintenus au voisinage, dans des dispositifs similaires placés au-dessus de sites caractérisés par le seul bruit de fond naturel. Chez les lapins, l'étude a concerné les chromosomes des lymphocytes. Chez les souris, c'est la fertilité des individus mâles et femelles qui a été prise en compte.

Dans tous les cas, les marqueurs génétiques sont cultivés ou élevés de manière à n'être soumis qu'à l'action des rayonnements ionisants émis par les sites uranifères.

RESULTATS

I - Observation des végétaux inféodés aux sites uranifères :

- sauf exception, les formations végétales et les végétaux présents sur ces terrains ont des caractéristiques déterminées par le climat de la région, le sol, l'action humaine et la concurrence biologique entre espèces en mélange ou en compétition sur les sites radioactifs. Ces ensembles biologiques ne sont pas "marqués" par les irradiations chroniques subies.

- une seule fois au printemps 1977 et sur le seul site uranifère du Mas d'Alary dans le Bassin de Lodève un cas d'albinisme a été observé sur *Galactites tomentosa* L. composée produisant normalement des capitules à fleurs violettes. Parmi les individus porteurs de telles inflorescences, il en a été distingué qui ne portaient que des capitules à fleurs blanches et d'autres portant à la fois des capitules à fleurs violettes et des capitules à fleurs blanches.

Cette dernière catégorie montre que les potentialités en ce qui concerne la couleur des fleurs a changé au cours de développement des plants. Le fondement génétique de ce changement a été démontré en étudiant la descendance, hors site uranifère, des trois catégories d'individus.

- on peut affirmer que en dehors de cette exception, certes spectaculaire, la présence de radionucléides en quantités anormalement élevées dans les substrats des sites uranifères et l'augmentation concomitante de l'irradiation tellurique ne modifient pas en apparence, les caractéristiques des populations vivantes fixées sur ces sites.

II - Etude de la descendance des végétaux inféodés aux sites uranifères

Des graines appartenant à différentes espèces (*Aegilops ovata* L., *Leucanthemum vulgare* L., *Nigella damascena* L., etc.) récoltées sur différents sites uranifères et sur des sites voisins non uranifères ont parfois permis de détecter dans les descendance observées des différences significatives (taux de germination,

taille des plantules et des plants adultes, etc.), transmissibles à travers les générations.

Ce fait s'ajoutant au cas d'albinisme observé *in situ*, a suggéré l'idée de la possibilité de modifications génétiques dans les espèces vivantes présentes sur les sites uranifères. Peuvent-elles être attribuées à l'action des rayonnements ionisants émis par l'uranium et ses descendants radioactifs ? Seule une expérimentation impliquant des marqueurs génétiques bien connus, soumis aux seuls rayonnements émis par les sites uranifères a permis d'apporter une réponse.

III - Modifications de marqueurs génétiques importés :

- système $a1/a1$ $a2/a2$ du Tabac :

Plusieurs essais ont été réalisés sur des sites uranifères du Bassin de Lodève et du Lauragais : la fréquence des variations somatiques observées sur les feuilles formées au-dessus des terrains uranifères a, parfois très nettement, augmenté. Le calcul des taux de réversion par génération cellulaire a montré que :

- il existe un seuil de débit de dose entre 3 à 4 cGy/an au-dessous duquel la radioactivité naturelle ne modifie pas le système marqueur ;

- au-dessus de cette valeur, et jusqu'aux valeurs les plus élevées mesurées sur les sites uranifères choisis pour l'expérimentation (environ 0.5 Gy/an), la relation dose-effet génétique est linéaire.

- aberrations chromosomiques chez le lapin :

Alors que les lymphocytes témoins n'en n'ont jamais montré, ceux étudiés chez les lapins maintenus au-dessus du site radioactif de Riviéral dans le Bassin de Lodève étaient caractérisés, après un an de séjour (doses reçues suivant les animaux de 0.2 à 0.7 Gy), par la présence de chromosomes dicentriques. L'expérience s'est poursuivie pendant trois ans. Après deux ans d'irradiation chronique, la fréquence des chromosomes dicentriques a peu à peu diminué pour devenir nulle au cours de la troisième année.

- fertilité chez la souris :

En sept mois, les animaux témoins et irradiés ont reçu respectivement 1.275 mGy, 0.45 et 0.63 Gy. Alors qu'une dose de 0.45 Gy a accru la fécondité des mâles et diminué celle des femelles, comme ceci avait été déjà observé dans une expérience préliminaire d'une durée de quatre mois sur des animaux ayant reçu des doses de 0.13 et 0.15 Gy. La fertilité des animaux ayant reçu une dose de 0.63 Gy a diminué dans les deux sexes.

L'ensemble des résultats obtenus démontre la réalité des effets de l'irradiation tellurique et en même temps, la complexité des faits observés.

CONCLUSION

Ponctuellement, l'irradiation naturelle tellurique provoque des changements dans les marqueurs expérimentés dont l'utilisation permet de détecter et d'évaluer des effets discrets et même la plupart du temps cachés ou inexprimés dans les populations naturelles pour différentes raisons, notamment :

- masquage par ceux liés à d'autres facteurs écologiques agissant simultanément ;

- faibles valeurs dans la nature des taux de germination et de reproduction ;
- généalogies impossibles à reconstituer sur le terrain ;
- masquage dans les espèces spontanées d'éventuels effets génétiques par les structures au moins diploïdes des espèces supérieures constituant l'essentiel de la biomasse actuelle;
- disparition des individus porteurs d'éventuelles anomalies sévères, en particulier de ceux porteurs de mutations létales.

Des études complémentaires, ont montré que d'autres facteurs de l'environnement : pollution atmosphérique, composition chimique des substrats, etc., déterminent des changements comparables à ceux observés au-dessus des terrains fortement radioactifs. La radioactivité naturelle, là où elle est anormalement élevée, et d'autres composantes de l'environnement peuvent de ce fait être considérées comme des facteurs de novation génétique susceptibles de jouer un rôle dans les processus de la différenciation biologique et au delà de la spéciation.

TEMPORAL VARIATIONS OF INDOOR RADON CONCENTRATIONS

B. Majborn

Risø National Laboratory
DK-4000 Roskilde, Denmark

ABSTRACT

The results of a number of studies of temporal variations of indoor radon concentrations are presented and discussed. The studies include short-term temporal variations, seasonal variations and variations from year to year. The most noticeable results are that 1) for groups of Danish single-family houses the seasonal variation patterns were found to depend on the type of house substructure, and 2) the ratios of the seasonal to annual average radon concentrations were found to be less variable for the spring and autumn than for the summer and winter periods.

INTRODUCTION

Indoor radon concentrations may vary substantially with time on various temporal scales. The variations may depend on a number of factors, including meteorological and geological factors, house characteristics, and habits of the house occupants. Knowledge of temporal variations of indoor radon concentrations is important for a proper appraisal of the significance of monitoring results, and the identification of causes of such variations can contribute to improve our understanding of the mechanisms of radon entry into houses. During the period 1983-91 we have performed a number of investigations of radon in Danish dwellings, including studies of short-term temporal variations, seasonal variations, and variations from year to year. In this paper the main results of the various investigations are presented and discussed.

STUDIES OF TEMPORAL VARIATIONS

Temporal variations of indoor radon concentrations have been studied in different groups of houses:

- 1) In a pilot investigation of radon in Danish dwellings, integrating radon measurements were carried out in 70 single-family houses and 12 apartments for 3 months in winter and 3 months in summer (1983-84) (1).
- 2) Short-term and seasonal variations of indoor radon concentrations were studied in an investigation of influencing factors carried out in 1986-87 (2). The seasonal variation patterns were followed on a 2-month basis throughout the 2 years in 16 houses. Continuous radon measurements were carried out in an unoccupied house on an hourly basis for 2.5 months (spring 1986) and in five occupied houses on a 3-hourly basis for 2.5 months (spring 1987).
- 3) In 10 of the 16 houses mentioned above, the seasonal variation patterns were followed for an additional year, i.e.

integrating radon measurements were made in the 10 houses on a 2-month basis throughout 3 years (1986-88) (3). 4) Integrating radon measurements were made in 70 single-family houses on a quarterly basis throughout 1 year (1990-91) (4). The houses were selected according to type of sub-structure and type of soil underneath the house.

RESULTS AND DISCUSSION

The studies of short-term temporal variations of indoor radon concentrations reported in reference (2) were carried out in slab-on-grade houses. They predominantly showed a diurnal variation pattern with a maximum in the morning and a minimum in the late afternoon or early evening, indicating that pressure-difference driven flow of soil gas into the houses was the dominant mechanism of radon entry (5). This was in accordance with the seasonal variation patterns observed in the same houses which showed maxima in winter and minima in summer.

Figure 1 shows the seasonal variations of the geometric mean radon concentration for a group of 7 slab-on-grade houses during 3 years (3). In each house radon was measured in a

Figure 1. Seasonal variations during 1986, 1987 and 1988 of 1) the geometric mean value of the radon concentrations in 7 houses, and 2) the average outdoor temperature.

living-room and a bedroom on a 2-month basis. The figure also shows the average outdoor temperature (2-month averages) at a nearby meteorological station. As the variations of the average indoor temperature are small compared with those of the outdoor temperature, the results indicate a strong correlation on a 2-month basis between the average indoor-outdoor temperature difference and the geometric mean radon concentration for this group of houses. A major difference between the 3 years was an unusually cold January-February in 1986 and 1987 and an unusually mild January-February in 1988. This difference is clearly reflected in the observed radon concentrations. For the 7 living-rooms the geometric mean values of the annual average radon concentrations were 164, 160 and 125 Bq m⁻³ for 1986, 1987 and 1988, respectively. For the 7 bedrooms the corresponding geometric mean values were 132, 130 and 104 Bq m⁻³. Hence, the higher average outdoor temperature in 1988 is reflected in lower annual average radon concentrations, the geometric mean values for 1988 being 76-80 % of the corresponding values for 1986 and 1987. For the individual houses the largest year-to-year variation amounted to a factor of about 2, the annual average radon concentration in 1988 being 48 % of that in 1986.

In our studies of seasonal variations carried out during the period 1983-88, we found that mean winter/summer ratios of indoor radon concentrations in Danish single-family houses tend to show a dependence on the house substructure (3). Houses with slab-on-grade foundations had the highest mean winter/summer ratios, houses with a basement had intermediate ratios, and houses with a crawl space had the lowest ratios. A possible dependence of the seasonal variation pattern on the type of house substructure was further investigated in a new study carried out in 1990-91 (4). 70 houses were included. They were selected according to the type of substructure and the type of soil underneath the house. Five categories of substructure were included: Slab-on-grade, crawl space, basement, and combinations of basement with slab-on-grade or crawl space. In each house radon was measured in a living-room and a bedroom, in the basement if present, and in the crawl-space if present and accessible. The measurements were made with track detectors on a quarterly basis throughout a year. The study showed that the seasonal variation patterns of the geometric mean radon concentrations did depend on the type of house substructure. For living-rooms and bedrooms the seasonal variations ranged from being highly significant for the slab-on-grade houses to being insignificant for the crawl-space houses. For basements and crawl spaces the geometric mean radon concentrations did not show significant seasonal variations. A noticeable observation was that the ratios of the seasonal to annual average radon concentrations were less variable for the spring and autumn than for the summer and winter periods. This indicates that spring and autumn are the best seasons for carrying out screening measurements (say, of a few months duration) of radon in dwellings.

CONCLUSIONS

The main conclusions of our studies of temporal variations of indoor radon concentrations can be summarized as follows:

- 1) For a group of single-family houses with slab-on-grade foundations a strong correlation was indicated between the geometric mean radon concentration and the average indoor-outdoor temperature difference on a 2-month basis.
- 2) Year-to-year variations of indoor radon concentrations were observed, owing to a significant difference in average winter temperatures.
- 3) The seasonal variation patterns of the geometric mean radon concentrations for groups of Danish single-family houses were found to depend on the type of house substructure. For living-rooms and bedrooms the seasonal variations ranged from being highly significant for slab-on-grade houses to being insignificant for crawl-space houses. For basements and crawl spaces the geometric mean radon concentrations did not show significant seasonal variations.
- 4) The ratios of the seasonal to annual average radon concentrations were found to be less variable for the spring and autumn than for the summer and winter periods, implying that spring and autumn appear to be the best periods for carrying out screening measurements.

ABSTRACT

Natural radioactivity and radon exhalation rates on a large number of Italian building materials are presented and compared with identical measurements on coal ashes. The influence of fly ashes on concrete exhalation rates was investigated by performing accurate radon emanation measurements on slabs with different ash-to-cement ratios.

INTRODUCTION

High indoor radon concentrations are usually considered important sources of radiological hazard for the general public. For this reason an experimental program has been implemented to investigate the following parameters:

- a) the naturally occurring radionuclide content in different building materials selected according to the manufacturer's location and capacity, and in a large number of ash samples taken from Italian power plants;
- b) the radon emanation characteristics of above materials;
- c) the effect, on radon emanation, of ashes used as a partial substitute for cement in concrete.

MATERIALS AND METHODS

Naturally occurring radionuclide analysis

Germanium-detector gamma-ray spectrometry was used to determine ^{226}Ra , ^{228}Ra and ^{40}K concentrations (see Table 1).

Exhalation rate and emanating power

Exhalation rate and emanating power were measured in:

- a) powder samples (cements, hydrated limes, sands) analyzed without grinding;
- b) bricks and concretes analyzed both in their original form and ground (particle size between 4 and 10 mm);
- c) 20x20x10 cm concrete slabs made by mixing products individually characterized as described above.

Powder and ground samples were placed in containers which are small (11 cm dia. and 8 cm high) compared with radon diffusion length for this kind of material; it may therefore be assumed that radon will not decay significantly in the sample⁽¹⁾.

The radioactive gas emanation was assayed by evaluating the initial radon growth slope⁽²⁾ through the continuous monitoring of the gas concentration in a box sized to ensure easily measurable radon activity levels by keeping gas back-diffusion within acceptable limits. CISE-designed flask monitors⁽³⁾ ensuring an efficiency of 0.27 cpm/(Bq/m³) and a background of 1.2 cpm were used.

Analytical results (mean and standard deviation), are summarized in Table 2 for different kind of material.

Radon emanation from concrete and moisture content

The influence of free water content on radon emanation from 20x20x10 cm concrete samples was studied by measuring radon exhalation rates from concrete slabs saturated with water and then sequentially dried in oven.

Radon emanation from concrete with fly ashes

The effect of cement hydration on emanation properties was investigated measuring radon exhalation rates from 20x20x10 cm concrete slabs made with low-radium inert materials (white limestone) and different types of cement. In Table 3 are listed the radiological characteristics of the used materials.

The effect of fly ashes on concrete radon emanation was investigated on 20x20x10 cm slabs in which cement was replaced with South African and American fly ash in a proportion ranging from 5% to 40%. Results are reported in Table 4 (columns 2 and 3). In columns 8 and 9 are presented fly ash emanating power values computed on the assumption that a) cement has an average emanating power of 56.8%, calculated from the results of previous tests (see Table 3), and b) the inert material exhalation rate remains unchanged.

RESULTS AND DISCUSSION

Naturally occurring radionuclides and exhalation rates

Tables 1 and 2 show a marked variability in natural radionuclides concentrations and in exhalation rates for all groups of materials. Insofar as average values are concerned, coal ashes have ²²⁶Ra levels comparable with those found in volcanic materials, while exhalation rates are half-way between those of portland-pozzolanic cements and the other tested materials. Coal ashes have very low emanating power values, comparable with those of bricks.

Radon emanation from concrete and moisture content

Results show that the radon exhalation rate varies, with a good linear correlation, from 0.2 to 4 $\mu\text{Bq kg}^{-1} \text{ s}^{-1}$ when moisture content rises from 0% to 5%. This phenomenon may be due to the radon atoms adsorption on the pore surface within the concrete⁽⁴⁾⁽⁵⁾. The presence of water favours radon atoms migration outside the concrete. When there is no water inside the pores, radon atoms can adsorb on the pore surface; when water fills the pores, an increasing amount of radon can move out.

Radon emanation from concrete with fly ashes

Results summarized in Table 4 (columns 2 and 3) show that the addition of fly ashes causes a slight increase in radon emanation. Increase is smaller for American fly ashes than for South African ones.

Table 3 (column 4) and Table 4 (columns 6 and 7) show that concrete emanating power values are in the range 15-30%. These values are higher than those of cements, inert materials and fly ashes (see Table 3). Assuming that inert materials do not change their exhalation rate when imbedded in concrete, cement emanating powers after hydration can be calculated. Cements after combination show emanating power values in a narrow range from 55 to 59%

(average value 56.8%) for concrete slabs made with different kind of cement and inert materials. Now, assuming that a) inert materials do not change their emanation properties when they are in concrete and b) cements have an emanation power of 56.8%, fly ashes radon emanation power values inside the concrete (see Table 4 columns 8 and 9) range from 11.2 to 21.9% (average value 17%). Fly ashes show an increase from 1 to 17% which is similar to that showed by cements (from about 4 to 57%).

CONCLUSIONS

The investigation carried out on Italian building materials has shown a substantial homogeneity in natural radioactive levels, except for volcanic materials (tuff, pozzolana, etc.). As far as exhalation rate values are concerned coal ashes are at an intermediate level between portland cements and pozzolanic cements.

Tests on concrete with fly ashes show that there is a slight increase in radon emanation but the radiological hazard connected with the use of fly ashes in the building industry seems to be negligible taking into account that the incidence of radon exhaled by building materials on indoor radon levels can be estimated in the 10-20% range⁽⁶⁾⁽⁷⁾ of the total indoor concentration.

**RADON SURVEY IN
METROPOLITAN TORONTO SCHOOLS**

Ernest Becker* and Reza Moridi*

Canadian Institute for Radiation Safety (CAIRS)
*CAIRS National Laboratories, Saskatoon, Saskatchewan, Canada
+CAIRS National Office and Centre for Public Education, Toronto,
Ontario, Canada

ABSTRACT

The radon testing survey in Metropolitan Toronto public schools was the most intensive project of its kind ever undertaken in Canadian schools. It also included an extensive public education program on radiation and radon-in-schools.

The radon levels at 632 schools were measured using the CAIRS Radon Monitors. Ninety per cent of the locations measured were found to have a radon level equal to or less than 2 mWL. Two locations in two different schools were found to have a radon level at or above the Action Level (20 mWL). The remaining results were between the two extremes. Follow-up testing in those schools where more than 10 mWL of radon was found is in progress.

INTRODUCTION

Radon is produced by the radioactive disintegration of uranium which occurs naturally in soil and rocks. Radon gas moves through the earth and can seep into the air in buildings (1). It is well established (primarily through studies of uranium miners) that exposure to radon progeny may cause lung cancer (2).

CAIRS has screened all public schools in Metropolitan Toronto for radon. The project was carried out in two phases:

1. The initial phase was a pilot project conducted in 37 schools in early 1990. The purpose of this test was to check the screening procedures.
2. The purpose of the second phase, conducted in 1990-91, was to screen the remaining 595 schools and buildings.

In total, 2774 locations were tested for radon (3).

PROCEDURES

The intent of the initial screening was to determine if there were any high radon levels in a school. For this reason, rooms and areas that were likely to have elevated radon levels were selected. These included:

1. Basement classrooms

2. Occupied rooms which are isolated from the central ventilation system and in which only the room air is recirculated
3. Rooms on or near structural joints such as adjacent slabs
4. Rooms with a large floor/wall joint perimeter and appreciable gaps in this joint
5. Rooms that have floor slabs with significant cracks

After inspecting each school building and applying the above protocol, suitable locations for radon testing were identified and marked on the school floor plan.

CAIRS Radon Monitors, which are active alpha detectors, were delivered to each school in separate boxes. All monitors were numbered and labeled according to the Area Board of Education, school and monitoring location. The data tags were attached to the monitors.

About 700 school Chief Caretakers and other officials had education on radon-in- schools and were trained in procedures under the CAIRS public education program. The Chief Caretakers, following detailed instructions, placed the monitors at the designated locations on tables or shelves at a height of about 50-70 cm above floor level. As well, the monitors were placed away from radiators, hot air registers and draughty windows.

Testing was carried out during the winter when interior radon levels are generally higher. Because radon levels fluctuate, the monitors ran for seven days continuously to ensure a reliable average reading. At the end of the testing period, the monitors were returned to CAIRS for analysis.

QUALITY CONTROL

In order to maintain the quality of the testing program, various quality control measures were employed.

1. Inspection of Monitors

All monitors were inspected during the first or second day of the testing period in order to ensure that all the placement procedures were followed properly.

2. Duplicate Monitors

Duplicate monitors were placed side by side in one per cent of all locations monitored. These locations were selected randomly. The duplicate monitors were shipped, installed, stored, processed and analyzed under the same conditions as the primary monitors.

In 46% of these locations, both the primary and duplicate monitors produced exactly the same results. In the remaining cases the variation between the readings of the primary and duplicate monitors was very small.

3. Control Detectors

In order to determine the radon exposure that accumulated during the shipment and storage of monitors, twenty fresh detectors were selected as "field blanks". None of these detectors showed any reading above the lower limit of detection of the monitors.

4. Calibration

Monitors were calibrated regularly at the CAIRS Radon Calibration Facilities. Air flow measurements of the monitors were taken before and after the testing period. The air flow meter used in these measurements was also calibrated using a bubble tube and a stop watch.

THE CAIRS RADON MONITORS AND LABORATORY ANALYSIS

The CAIRS Radon Monitor is a Radon Progeny Integrating Sampling Unit.

The monitor head originally developed by the French Atomic Energy Commission (CEA) is, in essence, an alpha particle spectrometer capable of detecting separately the alpha particles from radon and thoron daughters (4). The alpha particles are detected by damage tracks they create on a film.

The films were etched chemically in 2.5 N NaOH solution at 60.0 C for 90 minutes inside a constant temperature bath. The tracks were counted using an image analysis system comprised of a Nikon camera, microscope and an Arteck counter. The data was fed into a computer and the radon levels were calculated.

The lower and upper limits of detection of the monitors are about 0.5 and 1,000 mWL respectively. The CAIRS Radon Monitor has passed Round 6 in the National Radon Proficiency Test of the U.S. Environmental Protection Agency.

RESULTS AND DISCUSSIONS

Table 1. Number of schools and locations monitored for radon

School Boards	Number of schools	Number of monitored locations
East York	28	102
Ethiocoche	87	405
French Language	4	22
MTSB	9	28
North York	158	663
Scarborough	167	786
Toronto	142	598
York	37	170
Total	632	2,774

Table 1 shows the number of schools and the number of monitored locations in each of the eight school boards within Metropolitan Toronto.

Figure 1 illustrates the distribution of the number of locations monitored. On average about five locations were monitored in each school.

Figure 2 illustrates the distribution of radon levels at all locations monitored. 90% of locations

monitored had a radon level equal to or less than 2 mWL.

Two schools were found with readings at or above the CAIRS recommended Action Level of 20 mWL. Three schools had readings

Figure 1. Distribution of the number of locations monitored.

Figure 2. Distribution of radon levels at specific locations

at the intermediate level (10-20 mWL). (Follow-up testing in these schools is underway.) Apart from these elevated levels, the remaining locations demonstrated a radon level below the action level.

ACKNOWLEDGEMENT

We wish to thank the Metropolitan Toronto School Boards (MTSB) for their permission to publish the results of the project. We are also grateful to Dr. Fergal Nolan, President and CEO of CAIRS, for his guidance and keen interest in this work. The collaboration of CAIRS and MTSB project teams on this program is greatly appreciated.

RECONSTRUCTION OF
THE RADON DAUGHTER EXPOSURE OF BEAVERLODGE URANIUM WORKERS

D.B.Chambers, R.H. Stager, F.D. Bernard, L.M. Lowe
SENES Consultants Limited
52 West Beaver Creek Road
Richmond Hill, Ontario
L4B 1L9

ABSTRACT

The lung cancer mortality of uranium mine employees at the Eldorado Beaverlodge mine in Northern Saskatchewan is an important source of data on the risks from exposure to radon daughters. This study presents a year by year re-evaluation of mine area and mine wide radiation levels. The analysis of a case control study group suggests that exposures have been underestimated in previous studies. Potential sources of bias and of uncertainty in the estimation of exposure are also discussed.

INTRODUCTION

This study was performed for the Atomic Energy Control Board of Canada (AECB) with the objective of investigating available data and developing independent estimates of workplace radiation levels and of worker exposures to radon daughters (1). Cameco (Eldorado's successor) provided records covering the period from early exploration to mine closing. Many types of data were provided, including operating statements, ventilation reports, radon and radon daughter measurement data, bonus contracts, previous exposure calculations and personnel records for employees in a previous case control study. As could be expected, the extent of information was more substantial in the later years than for the earlier periods.

Dr. G.R. Howe of the NCIC identified employees for a new case control study group of 195 men consisting of 65 lung cancer cases and 130 controls, with controls matched only by year of birth. The identification of employees with respect to cases or controls was not known to the study team during the exposure estimation.

APPROACH

Preliminary investigations suggested that regression models performed well for some data sets. However, explanatory variables for the regression models were not consistently available over the period of investigation. The

approach eventually adopted involved weighted averaging of the data. Since radon daughter concentrations vary widely between different time periods and locations within a mine, the analyses were performed at as detailed a level as possible, namely, the specific month and location of exposure.

The radiation measurements were merged with the production statistics by specific month and specific workplace. For each month, the radiation measurements in the workplace were averaged and the man shifts worked was estimated. Man shifts were determined by dividing the production (tons ore broken or lineal feet advance) in a workplace by the mine wide index of production per man shift. Annual radon daughter concentrations for each workplace were estimated as the weighted average radon daughter concentrations where the weights are the number of man shifts worked in the month. Workplace radon daughter concentrations were aggregated to mine area and mine wide concentrations by weighting the annual radon daughter concentrations by the total man shift durations in each workplace.

Radon daughter exposures were estimated for the 195 employees (selected by Dr. Howe) using 9 work type classifications (including 6 underground work categories). For a sample from the case control group, the bonus contracts were inspected to try to find their exact workplace location by month. Exposures developed on this basis differed substantially from the mine-wide estimate for the workplace type for some of the sample. The analysis suggests that the use of mine wide radon daughter concentrations may substantially over or under estimate individual exposures.

RESULTS

The mine wide radon daughter levels, averaged over all types of underground employees, calculated in this study are shown in relation to previous estimates in Figure 1. Overall, the new estimates are somewhat higher than the previous estimates (i.e. those presented by Frost, (2) and used as the basis of the studies reported by Howe et al. (3)) which were essentially medians of the data. Annual estimates based on simple averaging of the data, generally form an upperbound on the new estimates.

A large number of the employees within the case control study group had very low exposures. This partly arose from short employment durations, in the order of less than a year for many of the employees. Additionally, many of the employees did not work underground at any time. Overall, only 62 of the employees were found to have some underground exposure and worked more than 1 year.

The effect of the aggregation of work place radon daughter concentration estimates in the presence of variability between workplaces is illustrated in Figure 2 for 1963 stope data. Moving from the mine wide weighted average for stopes (left side of figure) to individual work areas (right side of figure), results in a dramatic increase in the differences between the minimum and maximum workplace values. As workers were known to work in individual mine areas for extended periods of time, the agglomeration of data results in the loss of important information, and introduces significant uncertainty to the exposure estimates.

Other sources of uncertainty (and potential bias) in worker exposure estimates include: uncertainty about the radon to radon daughter ratio in the early years of mining, uncertainty about time spent in individual workplaces, changes to ventilation and mining practices that occurred over time, and other mining experience. Several of the underground miners were found to have records of working at other uranium mines in the Beaverlodge area.

CONCLUSIONS

Based on the experience of case control group, previous estimates of exposures to radon daughters arising from Eldorado Beaverlodge work experience alone were too low by about 50%.

There is considerable residual uncertainty about workplace exposure conditions and the exposure of individual employees due to the substantial difference of radon daughter concentration between workplaces. The analysis suggests that the individual employees may have exposures that differ by a factor of 2 or 3 from the assigned exposures.

It is highly likely that many of the miners incurred significant radon daughter exposure from non-Eldorado Beaverlodge mining work.

MATHEMATICAL MODEL FOR CALCULATION OF THE LUNG DOSE FROM INHALED
RADON-222 AND ITS DAUGHTERS

Dragoslav Nikezić and Petar Marković

Faculty of Natural Sciences, 34000 Kragujevac, Yugoslavia

ABSTRACT. A mathematical model of a human lung is described in this paper. Result obtained using by this model were compared with data taken from references.

INTRODUCTION

Inhalation of radon and its short lived daughters leads to the population absorbed dose which is under "normal situations" larger than any other component due to the natural radiation. In order to estimate corresponding risk one needs to relate measurable quantities, such as are concentrations of radon and its daughters in air, etc., with the absorbed dose in the human respiratory tract. There are few parameters upon which the dose in respiratory tract depends. In this paper we describe a mathematical human lung model we have developed and used and which enabled us to examine lung dose dependence on different relevant parameters.

MODEL

The developed mathematical human lung model is used for calculations of absorbed dose in the layer of basal cells per unit exposure to radon daughters in the whole T-B tree. This quantity is named "alpha dose factor" ⁽¹⁾. A computer program, called LUNGDOS was made to carry out calculations by using this model. The basic characteristics of the used approach are as follows:

-Yeh-Schum's geometrical model of the human lung was used ⁽²⁾;
-In order to calculate distance from the mucus layer to the basal cells the Gastineau's distribution ⁽³⁾ of the bronchial epithel thickness was used.

-It was assumed that α -emitters were distributed homogeneously in the mucus layer.

-Expression for the α -particles stopping power calculation in the tissue and air was taken over from reference ⁽⁴⁾.

-Radioactive aerosol deposition was calculated by using Landahl formula ⁽⁵⁾ in the first six generations, and Gormley-Kenedy equation ⁽⁶⁾ for the rest of T-B tree.

-Clearance of the deposited radioactive aerosols is carried out by mucus movement upwards toward the nose and mouth. The data for the mucus speed was adopted from reference ⁽⁴⁾. Radioactive aerosol transport is the second important process which influences radioactivity decrease in the T-B tree. The transfer of the radioactive aerosols depends on their chemical form. According to reference ⁽⁷⁾ there is a "fast phase" which is transferred from T-B tree to the blood with transfer half time of 50 min (10%), and three slower phases with an average of transfer half times of 3^h (35%), 9^h (35%) and 45^h (10%), and about 10% is unknown.

In accordance with this it was estimated that the average half-transfer time into the blood was 3^h for the whole of the T-B tree, regardless of the bronchial generation.

According to the so far said four processes are responsible

for the radon progeny activity in the T-B tree. They are: deposition, decay, clearance by the mucus movement and transfer to the blood. All these processes together lead to establishment of activity equilibrium in each bronchi of the T-B tree.

One needs to calculate the equilibrium activity in each bronchi of T-B tree. In order to do this it is necessary to set up and solve a set of differential equations of the 1st order, such as

$$dN_{ij}/dt = B_{ij}/\lambda_i + A_{i-1,j} + \lambda_{c,j+1} N_{i,j+1} - (\lambda_i + \lambda_{c,j} + \lambda_k) N_{ij} \quad (1)$$

In equation (1) N_{ij} is the number of atoms of i^{th} radon daughter in the bronchi of the j -th generation; B_{ij} is deposition rate of the i -th progeny in j -th generation, given in Bq/s; λ_i is decay constant of the i -th radon progeny; A_{ij} is equilibrium activity of the i -th radon progeny in the j -th bronchi generation; $\lambda_{c,j}$ is the clearance constant by the mucus and λ_k is transfer constant to the blood. The solutions of the above differential equations are as follows:

$$A_{ij} = (\lambda_i A_{i-1,j} + \lambda_{c,j+1} A_{i,j+1} + B_{ij}) / (\lambda_i + \lambda_{c,j} + \lambda_k) \quad (2)$$

$i=1,2,3; j=1,1B$

System of equations (2) is solved by starting with the first progeny ($i=1$), from sixteenth (brochi) generation. The procedure is then repeated for $i=2$, and $i=3$. After that one repeats the whole procedure for 15th generation. In order to solve the set of equation (2) it is necessary to know the deposition rate of the i^{th} progeny in the j^{th} generation. The entire described procedure is programmed and is a part of the program LUNGDOSE.

Equilibrium activities calculated in the just described way were calculated with corresponding conversion factor ⁽⁸⁾, in order to obtain the absorbed dose in the layer of the basal cells, for given bronchi.

RESULTS

Among many obtained results by using the described model, we presented here two- dose dependence on the aerosol diameter and on breathing rate.

-aerosol diameter-

The value of the median diameter of aerosols was varied and α - dose factor was calculated for whole T-B tree. Deposition of aerosols in T-B tree decreases with its diameter increase, and that is the reason that the dose factor decreases with increase of the diameter. Results are shown graphically on Figure 1, parallelly with result from references ⁽⁹⁾ and ⁽¹⁰⁾. For aerosols diameter of 0.1 μm the value obtained in this work is among the referent values, while for larger diameters thi value is for about 10 % higher. That comes from the difference in assumed breathing rate. In this work that velocity was 0.3 m^3/ks , while referent values were 0.2 m^3/ks .

Breathing rate

Dependance of the average dose factor for T-B tree as a whole on breathing rate was examined in this work too. Obtained results are shown in Fig.2. One can see a linear increase of the dose factor with increase of the breathing rate. For a change of the breathing rate from 0.11 to 0.38 m³/ks (0.4 to 1.4 m³/h) the dose factor increases from 0.27 up to 0.4 mGy/(J·s·m⁻³). On the same figure are shown several data calculated based on (or simply taken from) different references^{(1),(9),(10),(11)}. All models are showing similar behaviour of the dose factor as a function of the breathing rate. However, there is a rather large difference in absolute values for different models. This difference comes from the difference in assumed value of the epithelial depth. Results of our work presented by the full line on Figure 2, agree rather well with results of reference⁽¹⁰⁾, beside that the line obtained in this work is with somewhat smaller slope.

CALCULATIONAL AND EXPERIMENTAL DETERMINATION OF THE CALIBRATION
COEFFICIENT FOR RADON MEASUREMENTS USING LR-115 DETECTOR IN A
DIFFUSION CHAMBER

ABSTRACT

Experimentally and calculationaly obtained data for calibration coefficient for radon measurements using LR 115 II detector in the diffusion chamber were given in this paper. Monte Carlo Method was used for calibration coefficient calculation.

INTRODUCTION

Radon measurements with bare (open) track detector are rough and with rather high uncertainties. This is due to the fact that calibration coefficient, k , which relates track density, ρ , per unit exposure time with average radon concentration, C , during exposure period, given by equation (1),

$$C = k\rho \quad (1)$$

depends on equilibrium factor among radon and its short living daughters. One usually needs to determine radon concentration independently on the equilibrium factor. Diffusion chambers are usually used for that. Diffusion chamber in this case is a vessel covered with a piece of filter paper, or some other permeable foil.

Usually, detector is fixed on the bottom of the diffusion chamber. Radon diffuses through the filter paper into the chamber. Its half life (3,825 d) is sufficiently large, so that filter paper is not some important obstacle for radon, while radon daughters can not enter into the diffusion chamber. Radon which enters the chamber, decays in it. Daughters formed inside the chamber can not leave it, so that an equilibrium between radon and its daughters establishes in the chamber. Their activities are equal; $A_{Rn}^{222} = A_{Po}^{218} = A_{Pb}^{214} = A_{Po}^{214} / \lambda_{Bi}^{214}$. However, this does not mean that their activities in the air in the chamber are equal. Process which disturb the equilibrium in the air is plate out effect, namely the deposition of the radon daughters onto the inner wall surfaces of the chamber. One can take that inside the chamber all ^{222}Rn atoms are in the air, while the atoms of the daughters elements are partially in the air, and partially are deposited onto the inner surfaces of chamber's walls.

Activities of the i^{th} radon daughter ($i=1,2,3$) in the chamber, which is the sum of the activities in the air and on the wall surface, is equal to the radon activity.

The radon daughters deposition changes the detector exposition geometry, so that the track density and calibration coefficient would be changed.

Calibration coefficient (and track density vs.) depends on

the yield of deposited radon daughters. That dependence is actually subject of this paper. Track densities were calculated under different assumption and compared with experimental data. Monte Carlo method has been used for these calculations.

CALCULATIONAL RESULTS

Detector track density was calculated using TRACKO and TRACKO1 programs ^{(1),(2),(3)}.

A conical diffusion chamber with base diameters of $R_1=2.6$ cm and $R_2=3.4$ cm and high $h=8.4$ cm was used.

Calculations were performed for rectangular detector LR-115-II, whose dimensions were 2×1 cm². Detector was placed on the bottom of the diffusion chamber and center of the detector was hatched with the center of the chamber bottom. Calculations were performed for the $4.7 \mu\text{m}$ of removed detector layer for two extreme cases;

a) no radon daughters depositing on the walls of the chamber, and

b) all radon daughters were deposited before decay.

Track densities for both cases were calculated and the following results were obtained:

Case a)

$$\begin{aligned} \rho_{Rn} &= 3.5810^{-3} \text{ track} \cdot \text{m}/(\text{Bq} \cdot \text{s}), \\ \rho_{a1} &= 3.2410^{-3} \text{ track} \cdot \text{m}/(\text{Bq} \cdot \text{s}) \\ \rho_{a3} &= 2.3110^{-3} \text{ track} \cdot \text{m}/(\text{Bq} \cdot \text{s}); \end{aligned} \quad (2)$$

in which index "a" denote that alpha particles due to the emitters placed in the air; ρ_{Rn} is the track density due to α particles emitted by radon and, ρ_{a1} and ρ_{a3} are track densities due to the α particles from ^{218}Po , and ^{214}Po respectively. The total track density ρ_{ta} is the sum of partial track densities

$$\rho_{ta} = \rho_{Rn} + \rho_{a1} + \rho_{a3} = 9.31 \cdot 10^{-3} \text{ track} \cdot \text{m}/(\text{Bq} \cdot \text{s}) \quad (3)$$

Corresponding calibration coefficient is just the reciprocal value of total track density:

$$k = 1/\rho_{ta} = 109.5 \text{ Bq} \cdot \text{s}/(\text{track} \cdot \text{m}). \quad (4)$$

In the case b), when all radon daughters decay after deposition, we obtained values for track densities as follows:

$$\begin{aligned} \rho_{w1} &= 1 \cdot 10^{-4} \text{ track} \cdot \text{m}/(\text{Bq} \cdot \text{s}), \\ \rho_{w3} &= 1.43 \cdot 10^{-3} \text{ track} \cdot \text{m}/(\text{Bq} \cdot \text{s}), \end{aligned} \quad (5)$$

where by the index "w" denotes that alpha emitters were situated on the walls surface. Total track density ρ_{tw} in this case is:

$$\rho_{tw} = \rho_{Rn} + \rho_{w1} + \rho_{w3} = 5.11 \cdot 10^{-3} \text{ track} \cdot \text{m}/(\text{Bq} \cdot \text{s}), \quad (6)$$

and the corresponding calibration coefficient:

$$k=1/\rho_{tw}=195.7 \text{ Bq}\cdot\text{s}/(\text{track}\cdot\text{m}) \quad (7)$$

Deposition of radon daughters, causes decreasing of the track density for a factor of 2 (see equation 3 and 6). Track density decreasing is especially conspicuous for the alpha particles energy of 6 MeV of ^{218}Po . The reason for so high decrease was the smaller ranges of this alpha particles, which were not able to expose the whole detector.

It could be taken that calibration coefficient for rectangular detector, dimensions $2 \times 1 \text{ cm}^2$, takes a value between 110 and 195 $\text{Bq}\cdot\text{s}/(\text{track}\cdot\text{m})$.

For more precise determination of the calibration coefficient it was necessary to determine that part of radon daughters which was deposited on the chamber walls. This was done by comparing experimentally and calculationaly obtained data for track density distribution on the track detector which covered the bottom of the chamber⁽³⁾. It was concluded that part of deposited ^{218}Po yielded 3/5; so the part of ^{218}Po which decay before depositing, amounts 2/5.

Radon daughters ^{214}Pb and $^{214}\text{Bi}/^{214}\text{Po}$ have a much longer half life, and we adopted that they deposited completely before decay. This means that f_3 could be close to zero, eg. $f_3 \approx 0$. Finally, the detector track density could be obtained from the following expression:

$$\rho_t = \rho_{Rn} + f_1 \rho_{a1} + f_3 \rho_{a3} + (1-f_1) \rho_{w1} + (1-f_3) \rho_{w3} \quad (8)$$

Where are:

f_1 - part of i-th radon daughter in the chamber air volume,

$1-f_1$ - part of i-th Rn daughter deposited on the wall surface,

For rectangular detector in the diffusion chamber, which was used in our environmental study, the following values were obtained:

$$\begin{aligned} \rho = \rho_{Rn} + \frac{2}{5} \rho_{a1} + \frac{3}{5} \rho_{w1} + \rho_{w3} &= 3.58 \cdot 10^{-3} + \frac{2}{5} \cdot 3.24 \cdot 10^{-3} + \\ + \frac{3}{5} \cdot 1 \cdot 10^{-4} + 1.43 \cdot 10^{-3} &= 6.37 \cdot 10^{-3} \text{ track}\cdot\text{m}/(\text{Bqs}) \end{aligned} \quad (9)$$

So, the calibration coefficient will be:

$$k=1/\rho=157 \text{ Bq}\cdot\text{s}/(\text{track}\cdot\text{m}) \quad (10)$$

EXPERIMENTAL RESULTS

A direct calibration experiments were performed in order to obtained the values of k and ρ . A set of five diffusion chambers, were prepared with rectangular (2×1) cm^2 detectors. Diffusion chambers were exposed to the high radon concentration, during one to seven weeks. Radon level concentration were measured using the scintillation cells. An average radon concentration during exposure period was $(6900 \pm 450) \text{ Bq}/\text{m}^3$. Detectors were etched under the following condition, (10% solution of NaOH on 60°C , during 2^h). Track density measurements were done with optical microscope. The results of this experiment are given in Table 1.

Table 1.

The results of calibration coefficient measurements, for ^{222}Rn determination with rectangular (2x1) cm² LR-115-II detector, placed on the bottom of the diffusion chamber

duration of the exposition [days]	track density track/m ² /s	calibration coefficient k Bq·s/(track·m)
7	46	150
14	47	146
14	43	159
28	44	155
49	39	172

The average value for the calibration coefficient obtained from this measurements, is 156.4 Bq·s/(track·m), with uncertainty about 20 Bq·s/(track·m).

In this way the final experimental results for the calibration coefficient using the LR-115-II track etch detector in diffusion chamber is:

$$k=(156\pm 20) \text{ Bq}\cdot\text{s}/(\text{track}\cdot\text{m}) \quad (11)$$

CONCLUSIONS

In conclusion it could be said that calculational results for the calibration coefficient taking into account the deposition on the chamber walls, agrees very well with value obtained experimentally. Further, this calculational model can be used to estimate the amount of deposition of radon daughters on the walls by knowing the detector track density distribution, what enable us to determine more realistic calibration coefficient.

**FACTORS AFFECTING RADON LEVELS
IN HOMES IN BRITISH COLUMBIA, CANADA**

by

ABSTRACT

British Columbia, Canada's most westerly province, has diverse geologic and climatic characteristics, making it a region where predicting radon gas levels is quite complex. Data recently obtained for eleven (11) communities confirm an association between background terrestrial gamma radiation measurements and indoor radon levels in homes. Direct links between radon levels and other factors such as home design/construction features and heating/ventilation systems were observed in data for some communities, but not necessarily from the overall data.

INTRODUCTION

In the mid 1970's, public health concerns about radon in homes began to emerge in Canada. At that time, radon/radon daughter surveys were carried out in homes in two areas of the province, using grab sample techniques (1, 2). The two studies identified widely differing levels, between those for the Vancouver area (which were low) and those in the Castlegar area, which were higher.

With the emergence of improved radon detection devices in the mid 1980's, the B.C. Ministry of Health commenced a program of long-term measurements in homes in a selection of eighteen communities with differing radon potential, to assess the extent of radon as an environmental health risk to the public. Results of radon measurements for eleven communities are presented in this paper, along with an assessment of the association with factors thought to impact the radon levels.

DATA COLLECTION

Communities were selected as a representative sample for the province, based principally upon a variety of geological,

climatic and geographical factors. Volunteers were solicited from each community to permit their homes to be tested for radon. Trained staff from the Ministry placed the radon detectors in appropriate locations in the home and they undertook the completion of survey questionnaire with the occupants, regarding the physical characteristics of the home and some lifestyle information. A minimum of seventy (70) single family dwellings were required for each community to provide a statistically representative sample.

Radon levels were assessed using commercially available alpha track detectors (available from the Barringer, REM and Terradex companies). Two detectors were normally placed in each home for a period of one year. One detector was placed in the lowest living area of the home (e.g. basement) and one in the main living area. Duplicate detectors were placed side by side in a selective number of homes to provide information on the reproducibility of the measurements.

Terrestrial gamma radiation levels were determined using a portable high pressure ionization chamber instrument (Reuter Stokes model RSS-111). At least five (and usually more) separate readings were made in representative locations in each community. Readings were corrected for local cosmic ray contribution, to provide the net terrestrial gamma component.

For each home selected, a questionnaire survey was completed, in which the following information was obtained:

- 1) Building factors - age of home, type of foundation, basement/lower level structure, heating system type and location, and air conditioning use.
- 2) Personal factors - number of persons in the home, occupancy factors, smoking habits, and incidence of cancer.

RESULTS

Table 1 presents a summary of the radon levels measured, for lowest/basement levels and for main floor areas of the home. The mean values for main floor areas ranged from a low of 18 Bq/m³ (0.5 pCi/l) for the Greater Vancouver area to a high of 240 Bq/m³ (6.5 pCi/l) for the City of Castlegar. In the Castlegar sample, approximately 41% of the main floor levels exceeded 150 Bq/m³ (4 pCi/l) while 6% exceeded 750 Bq/m³ (20 pCi/l).

Figure 1 illustrates the correlation between main floor radon levels and the local terrestrial gamma radiation level for each of the eleven communities given in Table 1. A positive correlation was observed, with a coefficient value of 0.66 (p=.04). From figure 1, it appears that more than one trend exists, suggesting that the radon levels may be significantly affected by more than one variable. For Castlegar and Prince George, which have clearly outlying radon values above the general trend (in figure 1), both communities are situated on permeable soil structures.

Figure 1

Results from the questionnaire surveys, relating to the building and personal factors, were analyzed for association with radon levels. The general findings are reviewed in the following discussion.

DISCUSSION

Good correlation exists between mean radon levels in a sample of homes and the general terrestrial gamma radiation levels for a community. This is to be expected since elevated terrestrial gamma levels are associated with increased concentrations of uranium and its decay products in surface soils. Radium-226 is the uranium decay product that produces radon.

Although terrestrial gamma measurement has been found to be useful technique for determining which communities may have elevated radon levels, other factors such as soil permeability, moisture content (3) etc. play an important role in radon transportation to affect the concentration in air. Work to date has indicated no correlation between the indoor radon levels in any individual home and the terrestrial gamma level measured at the site.

Building factors were evaluated in relation to radon levels, on a community-by-community basis as well as from the overall (pooled) data. The pooled data indicates that homes with air conditioning were more likely to have lower radon levels, both on the main floor (probability coefficient $p=0.078$) and in the basement/lower level ($p=0.025$). For homes with heating furnaces located in the basement, the main floor radon level was likely to be elevated ($p=0.065$). If uncovered soil areas exist in the lower level, then radon concentrations were likely to be higher ($p=0.059$).

Other building factors were statistically significant within an individual community's data, but were not consistent from community to community.

Such factors include (1) age of the home; (2) type of foundation; (3) type of heating system; (4) separation of lower level (basement) from main floor; and (5) the presence of opening windows in the lower level.

Personal factors did not appear to have any significant association with radon levels, either within individual community data or with the overall data.

NOTE

Data is expected for a further seven (7) communities which were still under test at the time of writing this paper. This additional information will provide valuable guidance on radon levels in British Columbia's more northerly and coastal communities, as well as adding to the overall data base for further analysis.

MEASUREMENT OF RADON ACTIVITY AT SOME RADIOACTIVE SITES IN INDIA

Jaspal Singh, Lakhwant Singh, Surinder Singh and H.S.Virk,
Department of Physics, Guru Nanak Dev University,
Amritsar-143005, India.

ABSTRACT-

The present study deals with the evaluation of radon levels in some houses at the radioactive sites of Himachal Pradesh, India. In one of the areas under study, the radon activity is found to be 983.60 Bq/m^3 in summer and 1115.04 Bq/m^3 in winter giving an annual exposure dose of 45.94 mSv to the inhabitants. In the second area these levels are found to be 611.92 Bq/m^3 and 685.14 Bq/m^3 , respectively, exposing the people to an annual dose of 28.39 mSv . The life time risk coefficients of lung cancer in these areas are 8.25×10^{-2} and 5.1×10^{-2} respectively.

INTRODUCTION

Almost one half of the natural radiation exposure received by human is from radon and its solid progeny in air⁽¹⁾, which can result in a significant risk to the general public. Until few years back it was considered to be a health hazardous only to the workers engaged in the mining and milling of uranium, but now surveys carried out all over the world⁽²⁻⁴⁾ shows high concentrations of radon in some dwellings that could entail significant health risks.

The daughter products of ^{222}Rn viz; ^{218}Po , ^{214}Pb , ^{214}Bi , ^{214}Po , which are solid under ordinary conditions, attach themselves to atmospheric dust. During inhalation these particles may deposit in the lung and damage the tissue. It is therefore, necessary to monitor levels of radon in places where people are exposed to radon, particularly at sites where the geological formations are enriched with uranium. So we have chosen two sites in radioactive areas-Rameda and Samurkalan in Himachal Pradesh, India.

EXPERIMENTAL TECHNIQUE

Track etch technique (LR-115 Type II) has been used for the measurement of radon activity in the dwellings. Small pieces (1 cm^2) of LR-115 were used to measure the radon activity in winter as well as in summer season. The detailed methodology of the experiment is given elsewhere⁽³⁾. The track density was converted⁽⁵⁾ into the units of Bq/m^3 using a calibration constant assuming an equilibrium factor of 0.5 between radon and its progeny.

RESULTS AND DISCUSSION

Radon measurements have been carried out in 18 houses of Rameda and 19 houses of Samurkalan villages. The choice of dwellings was random and one living room of each dwelling was selected for radon measurement. Tables 1 & 2 give the radon activity recorded in the houses of Rameda for the summer and the winter seasons, respectively. The right, front and left sides to the entrance are designated as wall A, wall B, wall C respectively and the entrance side as wall D. In both of these areas walls and floors have been constructed from local sand stones covered with a paste of mud. The roofs are made of wood. The surveyed houses are not properly ventilated.

WALL TO WALL VARIATION

From the Tables 1 and 2 it is clear that there is a large variation of radon activity from wall to wall in the same room. This variation shows that the members of a family while living in the same room may be exposed to different levels of radon activity depending upon their sitting side or bedside. This variation may be attributed to the fact that certain positions in a room may have more quantity of uranium enriched rock species than to the others and also on the ventilation system of the rooms.

HOUSE TO HOUSE VARIATION

The radon activity in the Rameda area varies from one house to the other as much as 489.14 - 2305.19 Bq/m³ (Table 1) and 542.05 - 1975.98 Bq/m³ (Table 2) during the summer and winter seasons, respectively. It is evident from this fact that the people while living in the adjacent houses at radioactive areas can have different exposures of radon activity.

SEASONAL VARIATIONS

The average radon activity recorded during the summer and winter seasons in the Rameda area is 983.60 Bq/m³ and 1115.04 Bq/m³, respectively. This variation is due to changed ventilation system for the summer and winter seasons. During winter season the houses are made air tight, as a result the ventilation is reduced and hence less mixing with the outdoor air which causes more accumulation of radon and its daughter product activity indoors.

Similar variations are noted in Samurkalan area. The average radon activity recorded in this area is 611.92 Bq/m³ and 685.14 Bq/m³ in the summer and winter seasons, respectively.

LUNG CANCER RISK

The average annual radon activity comes out to be 1049.32 Bq/m³ and 648.53 Bq/m³ in the Rameda and Samurkalan areas

repectively. This much radon activity gives an average annual exposure dose of 45.94 mSv and 28.39 mSv, respectively to the inhabitants of these areas. The life time lung-cancer risk-coefficients for the Rameda and Samurkalan areas⁽⁸⁾ are found to be 8.25×10^{-2} and 5.1×10^{-2} , respectively.

ACKNOWLEDGEMENTS

Jaspal Singh and Lakhwant Singh are thankful to the council of Scientific & Industrial Research (CSIR), New Delhi for providing the financial assistance in the form of senior research fellowship. Thanks are also due to Mr. Santokh Singh for his help in the field work as well as in laboratory analysis. The pepole of Rameda and Samurkalan area are gratefully acknowledged for their allowance to fix our samples in their houses and took care of them.

ABSTRACT

For measuring radon concentrations in air an electret ionization chamber of the diffusion type was developed. The change of the charge density on the electret surface is a measure of the radon concentration from which the concentration of radon daughters can be estimated assuming an equilibrium factor. This factor, however, varies strongly dependent on environmental and other conditions. In order to determine the equilibrium factor more precisely, a combination of three solid state nuclear track detectors was studied which allows the selective detection of alpha particles in defined energy intervals.

INTRODUCTION

The radiation exposure of the human respiratory tract is mainly determined by the concentration of short-lived radon decay products in the inhaled air. Using passive detectors inside diffusion chambers the radon concentration in air can be measured from which the concentration of radon daughters is calculated presuming an appropriate equilibrium factor^{1,2}. Because the equilibrium factor is not known with the required precision, the uncertainty of the estimated radiation exposure is relatively high³. The use of a multi-detector system is, therefore, proposed which allows to measure the radon concentration using an electret ionization chamber and separately the equilibrium factor using three solid state nuclear track detectors.

RADON DETECTION BY MEANS OF AN ELECTRET IONIZATION CHAMBER

The principle of an electret ionization chamber (EIC) of the diffusion type is shown in Figure 1. On the top of the diffusion chamber aerosols and radon daughters are retained on the diffusion filter whereas the radon gas diffuses into the chamber volume. Radon decay products generated within the EIC are almost completely plated-out on the inner surface of the chamber walls. The electret made of PTFE or FEP is characterized by a quasi-permanent electrical charge which generates a surface potential, the electret voltage U_E . Within the chamber alpha particles emitted by radon and its daughters result in an ionization of the air and thus in a degradation of the electrical charge of the electret surface.

Figure 1 Scheme of the electret ionization chamber for radon measurements⁴

The response of the EIC is given by

$$m_{Rn} = \frac{\Delta U_E}{c_{Rn} \Delta t} \quad (1)$$

where ΔU_E is the radiation induced change of the electret voltage, whereas c_{Rn} and Δt are the concentration of ^{222}Rn and the exposure period, respectively. The response m_{Rn} was calculated by means of a Monte Carlo program⁵ resulting in $m_{Rn,calc} = 0.065 \text{ V/Bq}\cdot\text{m}^{-3}\cdot\text{d}$. By exposing the EIC in different well-defined radon atmospheres, the experimental estimation resulted in a value of $(0.060 \pm 0.004) \text{ V/Bq}\cdot\text{m}^{-3}\cdot\text{d}$. The lower detection limit was found to be $40 \text{ Bq}\cdot\text{m}^{-3}$ (with $\Delta t = 7\text{d}$) and the upper limit $5 \text{ kBq}\cdot\text{m}^{-3}$ (with $\Delta t = 1\text{d}$).

DETECTION OF RADON AND RADON DAUGHTERS USING A SYSTEM OF NUCLEAR TRACK DETECTORS

It is the common technique to measure the radon concentration using, for instance, EIC or other types of diffusion chambers. For the estimation of the lung exposure by radon decay products, however, the equilibrium factor is needed. Because this factor varies strongly with a number of environmental and other conditions, a consistent system of three nuclear track detectors has been studied with the aim of a separate detection of radon and its daughters under free air conditions. Thus, the equilibrium factor can be determined as average value also for longer exposure periods.

The physical basis of such a detector system is formed by the creation of different energy response functions for the three detectors as the result of a suitable combination of the detector and absorber material and/or an optimization of the etching procedure. For this purpose the electrochemical etching technique of polycarbonate detectors (MAKROFOL DE, Bayer Leverkusen, FRG) and CR-39 detectors (PATRAS, Optische Werke Rathenow, FRG) have been studied.

Figure 2 Qualitative presentation of the track detection efficiency ϵ_{α} of the nuclear track detector system as a function of alpha energy E_{α}

- (1) MAKROFOL (electrochemically etched: 80 vol% 6N KOH + 20 vol% ethanol, 35°C, 5h 100Hz and 1h 2kHz, 26.7kV/cm)
- (2) CR-39/PATRAS (chemically pre-etched: 6N KOH, 60°C, 10h; electrochemically etched: 6N KOH, 60°C, 2h 2kHz, 15kV/cm)
- (3) CR-39/PATRAS (electrochemically etched: 6N KOH, 60°C, 5h 2kHz, 15kV/cm)

From Figure 2 follows that the MAKROFOL DE detector (1) has an upper energy threshold of about 4 MeV⁶. Using this etching condition, the detector registers only alpha particles from ²²²Rn and its decay products incident from an air layer in a certain distance of the detector. On the other hand, decay products plated-out on the detector surface do not contribute to the track density because the corresponding alpha particle energies of about 6 MeV exceed the upper energy threshold. The resulting track density of the detector (1) is thus given by

$$\rho_1 = m_1^{Rn} \cdot c_{Rn} + m_1^{DA} \cdot c_{DA} \quad (2)$$

where m_1^{Rn} and m_1^{DA} are the detector responses to ²²²Rn and radon daughters in air, respectively, and c_{Rn} and c_{DA} the corresponding activity concentrations in air.

The second detector of the system should have a lower energy threshold at about 5.5 MeV, in order to detect only decay products from a certain air layer in front of the detector as well as decay products plated-out on the detector surface, whereas alpha particles from ²²²Rn are not registered. The track density of the detector (2) follows from

$$\rho_2 = m_2^{DA} \cdot c_{DA} + m_2^{DD} \cdot c_{DD} \quad (3)$$

Here, m_2^{DD} is the detector response to daughters deposited on the detector surface and c_{DD} the corresponding activity concentration. The lower energy threshold of 5.5 MeV could be created by means of a suitable dimensioned absorber in front of the detector. Using CR-39/PATRAS, however, this threshold has been obtained by chemical pre-etching of the detectors for 10 hours (see Figure 2).

Finally, a third detector (3) without an energy threshold is needed. Then its track density follows from

$$\rho_3 = m_3^{Rn} \cdot c_{Rn} + m_3^{DA} \cdot c_{DA} + m_3^{DD} \cdot c_{DD} \quad (4)$$

Studies with CR-39/PATRAS detectors showed that without applying a chemical pre-etching this non-threshold behaviour exists (see Figure 2).

Thus, from equations (2), (3) and (4) the concentration of ^{222}Rn and its daughters in air can be determined separately whereas the plate-out effect on the detector surface is eliminated.

CONCLUSIONS

Using the track etched detector system described here, an energy-selective detection of alpha particles emitted by radon and its daughters is possible. From these results a mean equilibrium factor follows which can be used for the interpretation of the results of radon measurements using EIC or other types of passive radon diffusion chambers.

MEASUREMENTS OF RADON CONCENTRATIONS IN BUILDINGS - RESULTS OF INVESTIGATIONS IN MINING REGIONS OF SAXONY AND THURINGIA

R.Czarwinski, R.Lehmann, W.Röhnsch
Federal Office for Radiation Protection, F.R.G.

ABSTRACT

In the East German Federal States Saxony and Thuringia territories exist where rock formations with silver and cobalt ores and above-average uranium content are located and intensive mining has taken place. In these regions a series of measurements of radon concentrations in buildings is carried out to determine local mean values, local ranges and buildings with very high concentrations of radon.

INTRODUCTION

The radiological situation in certain regions of Saxony and Thuringia is characterized by above-average uranium concentrations in layers close to the surface and, in addition, by the mining influence. The local higher uranium concentrations determined by airborne gamma-ray spectrometry are shown in Figure 1.

By order of the Federal Minister for Environment, Nature Conservation and Nuclear Safety the "Project for the Registration, Investigation and Radiological Evaluation of the Mining Residues" has to be implemented by the Federal Office for Radiation Protection. The investigation of radon concentrations in buildings with the aim to estimate regional and local distribution patterns of radon concentrations as well as the identification of houses with very high concentrations and their reasons are essential parts of this project. Since November 1990, investigations have been carried out in houses located in mining regions with a high density of measuring points.

For the assessment of the results additional measurements are carried out in regions not influenced by mining, e.g. in the Fichtel Gebirge, in regions of Lusatian granite, in the Norddeutsche Tiefebene etc..

METHODOLOGY OF MEASUREMENTS

To get a rapid survey of the radiological situation, short-term measurements (screening measurements) with activated charcoal detectors analyzed by liquid scintillation counting are carried out. The exposure of the charcoal takes 24 hours under unfavourable ventilation conditions, i.e. closed doors and windows.

Dwellings, factories, schools, kindergarten and other buildings are investigated. Participation in measurements is optional and free of charge.

Results are compared with the recommendation of the German Radiation Protection Commission (Strahlenschutzkommission - SSK) who defined a "normal range" of the radon concentration in living rooms of Germany up to 250 Bq/m^3 .

If the radon concentration measured by the screening method in lounges and living rooms is evidently higher than 250 Bq/m^3 it is probable that the annual mean value exceeds this limit, too; the higher the level is exceeded the greater this probability. Therefore, in addition to the verification of short-term results long-term investigations are necessary to establish remedial measures. For these long-term measurements already started diffusion chambers with track etch detectors are used. Each citizen/institution involved in the measurements is informed about the results of the measurements and an assessment as demonstrated in Table 1 is given. The investigations will be extended to measurements in up to 100,000 buildings in about 200 communities.

RESULTS AND CONCLUSIONS

The results of the investigations hitherto achieved show that there is a strong correlation between radon concentration in houses and geological subsoil. A relatively great number of houses with above-average radon concentration has been found in granite and certain Zechstein subdivision regions whereas buildings above glacial sediments have much lower concentrations. Figure 2 presents the results of measurements in different regions without any mining influence.

Figure 3 shows the results of screening measurements in about 15,000 buildings in regions where uranium mining and milling as well as former ore mining has taken place. In general, there is no striking difference in the frequency distribution compared with regions of similar geology. Only in cases where geological and mining influences are overlapping extreme values of the radon concentration in houses have been observed. An outstanding example is the old mining town Schneeberg where radon concentrations up to more than $100,000 \text{ Bq/m}^3$ have been measured by the screening procedure (see Table 2).

An influence of mining and milling residues on the radon concentration in buildings can be attributed to

- building on waste rocks
- use of waste rocks for building purposes
- shallow drivings partly immediately under, or nearby, or connected with houses
- building over of outcroppings of geological disturbances and ore-bearing lodes.

Moreover, the investigations have indicated that the underground ventilation has a great influence on the radon concentration in houses constructed on shallow drivings.

At Schlemma, a centre of recent uranium mining, the mining facilities like ventilation installations are still in operation.

First experiments show that the radiological situation changes dramatically if the mining exhausters are switched off. An increase of the radon concentration two orders of magnitude higher can be observed in certain buildings after the ventilation has been stopped (see Figure 4). In this special case, it cannot be excluded that the results of screening measurements do not necessarily represent pessimistic information about the radiological situation.

ABSTRACT

The objective of this study was to evaluate the influence of three types of air cleaner on the concentration and size distribution of radon progeny in a normally occupied house. Using an automated, semi-continuous, graded-screen array system and a radon monitor, the activity size distribution and radon concentration was measured and the exposure of the occupants of the home to radon could be assessed. The dose model developed as part of the recently released U.S. National Academy of Sciences report was used to relate the exposure to deposited dose in the tissue of the bronchial epithelium. Thus, the effectiveness of the air cleaners in reducing both exposure and dose were evaluated.

INTRODUCTION

A critical factor for the effectiveness of radon decay products in providing dose to the human respiratory tract is the size of the particle to which the decay product is attached. Air cleaners can effectively remove most particles and radon decay products from indoor air. The removal of the particles results in the increase of the "unattached" fraction, that can deposit more effectively its dose of radiation to the lung tissue. In fact, the increased dose per unit exposure means that the dose reduction will be lower than the reduction of the radioactive concentration. Thus, the exact dose impacts of air cleaners are uncertain, and studies are needed to measure the concentration and size distributions of the radon progeny activities in real living conditions where air cleaners are being employed.

HOUSE CHARACTERISTICS AND INSTRUMENTATIONS

Experimental data used in this study were collected in a one-story, ranch home in Arnprior, Ontario. This house has a basement with an approximate area of 200m² while the first floor has an area of about 210m². The house was occupied by three people none of whom smoke. Measurements were made from May to July 1991. No heating or air conditioning was used during this period. The sampler and air cleaner were placed at the dining room end of the kitchen/dining area (23m²).

Three types of air cleaner were investigated, a ionization, filtration and air circulation system (NO-RAD), an Electronic Air Cleaner (EAC) with fan, and a multi-stage filter with fan (Pureflow).

Measurements of radon progeny size distributions were made using the Automatic Semi-Continuous Graded Screen Array (ASC-GSA) described in detail by Ramamurthi and Hopke (1991). The ASC-GSA system is a fully automatic device capable of measuring the activity-weighted size distribution of each individual short-lived radon decay product. It uses wire screens for particle segregation and alpha spectrometry for alpha particle detection. The measurements were made over a week long period with alternatively no air cleaner and air cleaner running (Table 1).

6	June 30-July 5	52	Pureflow on
7	July 5-6	11	Background

Table 1: Experiments conditions

Continuous measurements of radon gas were done using a passive radon detector.

RESULT AND DISCUSSION

Mean values plus standard deviation of radon concentration, PAEC and equilibrium factor are presented in Table 2. As expected, radon concentration was not affected by the air cleaners and the values were almost the same for every experiment with a mean of 1.1pCi/l (41 Bqm⁻³). However, we observed a reduction of PAEC and a significant decrease of the equilibrium factor when the air cleaners were running.

Exp.	Mean pCi/l	Radon std	Mean mWL	PAEC std	Equilibrium mean	factor std
1	1.2	0.5	5.8	2.0	0.50	0.13
2	0.8	0.5	2.2	1.1	0.31	0.14
3	0.7	0.4	2.6	2.0	0.41	0.22
4	1.1	0.6	2.1	1.6	0.18	0.12
5	1.7	1.2	7.5	6.2	0.43	0.19
6	1.1	0.7	1.6	1.1	0.15	0.08
7	1.1	0.4	5.0	2.1	0.45	0.13

Table 2: Measurements summary

From the equilibrium factor, one can observe that at fixed radon concentration, the NO-RAD reduced the mean PAEC by 38% while the EAC provided 56% and the Pureflow 65% of reduction.

Changes in size distributions (Fig.1) of the radon progeny as well as PAEC was also observed when the air cleaners were working. A peak in the size range of 1.5 to 5nm was induced when the NO-RAD was running. The EAC caused an increase in the activity fraction of the small particles with a distinct peak in the smallest particle size. Meanwhile, the activity fraction of particles greater than 15nm decreased. The Pureflow system did not seem to change the shape of the size distribution significantly. Those differences can be due

to the way air cleaners remove particles. With its HEPA filter, the Pureflow system eliminate particles of all sizes with almost the same efficiency. This is not the case for the other devices whose removal mechanism can have a greater effect on the largest particles.

Knowing the PAEC concentration and its activity fraction, the annual average exposure E_p and the dose to the bronchial epithelium can be calculated (Table 3). An occupancy factor of 0.68 (ICRP, 1987) was used to estimate E_p . The dose per unit exposure, for a male adult at a mean breathing rate of 0.74 m³h⁻¹, was calculated using the most recent dosimetric model (NRC, 1991 model modified by James et al., 1991). In the current model the dose to basal and secretory cells is evaluated taking account of the calculated deposition of activity as a function of particle size and breathing rate. As expected, the dose per unit exposure (D/E_p) was similar for the "backgrounds" (between 31 and 36 mGy/WLM). For the Pureflow the dose per unit exposure stayed at the same level;

however this value increased to 44mGy/WLM for the NO-RAD and up to 48mGy/WLM for the EAC. This implies that the reduction of exposure by both the NO-RAD and the EAC was much higher than the dose reduction. In fact, comparing the experiments

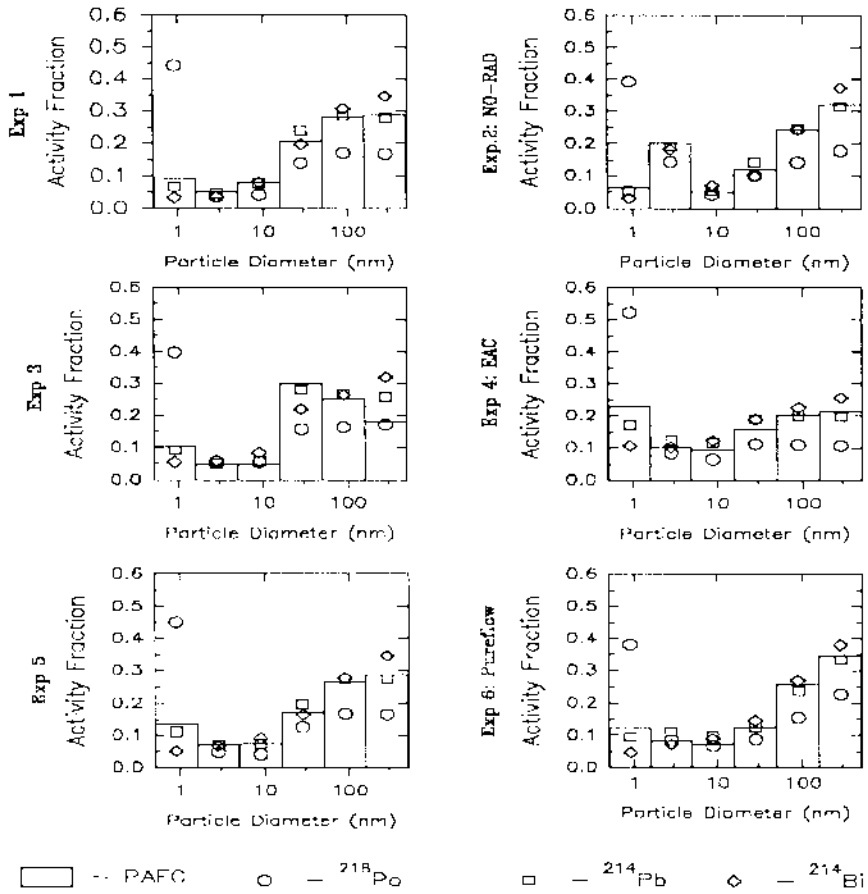

Figure 1: Size distributions

2, 3 and 4 when air cleaners were running with the experiments 1, 3 and 7 respectively, one finds that the exposure reduction per unit radon was 47% for the NO-RAD while the reduction of the doses per unit radon were 27%. The EAC diminished the exposure by 50% and the dose by 33%. A decrease of 67% was observed on both exposure and dose, for the Pureflow system.

Table 3: Dose exposure

SUMMARY

The effect of three types of air cleaner installed in a single family house in Arnprior, Ottawa, was investigated in

a series of measurements. Each device decreased the concentration of the decay products and reduced the equilibrium factor as well as the exposure. On the other hand, air cleaners producing a shift of the size distribution towards smaller particles, where the dose rate per unit exposure are substantially larger, induce a much lower reduction on the dose. Thus, dose impact of air cleaners depends strongly on the way particles are removed.

HIGH-ALTITUDE COSMIC RAY NEUTRONS:
PROBABLE SOURCE FOR THE HIGH-ENERGY PROTONS OF
THE EARTH'S RADIATION BELTS

Ferenc Hajnal* and John Wilson**

* US DOE, Environmental Measurements Laboratory, New York, NY, USA

** NASA Langley Research Center, Hampton, VA, USA

Several High-altitude cosmic-ray neutron measurements were performed by the NASA Ames Laboratory in the mid-to late-1970's using airplanes flying at about 13km altitude along constant geomagnetic latitudes of 20, 44 and 51 degrees north. Bonner spheres and manganese, gold and aluminium foils were used in the measurements. In addition, large moderated BF-3 counters served as normalizing instruments.

Data analyses performed at that time did not provide complete and unambiguous spectral information and field intensities. Recently, using our new unfolding methods and codes, and Bonner-sphere response function extensions for higher energies, "new" neutron spectral intensities were obtained, which show progressive hardening of neutron spectra as a function of increasing geomagnetic latitude, with substantial increases in the energy region from 10 MeV to 10 GeV.

For example, we found that the total neutron fluences at 20 and 51 degrees magnetic north are in the ratio of 1 to 5.2 and the 10 MeV to 10 GeV fluence ratio is 1 to 18.

The magnitude of these ratios is quite remarkable. From the new results, the derived absolute neutron energy distribution is of the correct strength and shape for the albedo neutrons to be the main source of the high-energy protons trapped in the Earth's inner radiation belt. In addition, the results, depending on the extrapolation scheme used, indicate that the neutron dose equivalent rate may be as high as 0.1 mSv/h near the geomagnetic north pole and thus a significant contributor to the radiation exposures of pilots, flight attendants and the general public.

RADON IN SHOW CAVES, VISITOR MINES, AND SPAS OF NORTHRHINE-WESTPHALIA

A. Rox and W. Herzog

Staatliches Materialprüfungsamt
Nordrhein-Westfalen
Marsbruchstraße 186
D-4600 Dortmund 41, FRG

ABSTRACT

Radon levels were measured in all show caves, visitor mines and thermal spas of Northrhine-Westphalia. Long-term measurements were performed by a passive time-integrating method using diffusion type dosimeter with nuclear track detector. Radon-222 concentrations up to 12000 Bq m⁻³ were found. Instantaneous measurements of Rn-222 were taken with Lucascells and a portable radon monitor. Decay products were determined via dust filter sampling followed by alpha spectrometry. Equilibrium factors ranged between 0.34 and 0.80.

INTRODUCTION

It is well recognized that the major contribution to the annual average dose received by man has its origin in natural radiation. About half of the effective dose equivalent is due to inhalation of radon and its decay products. Whereas radon concentrations have been measured continuously in almost all West-German coal mines for over 10 years now¹, there has been a lack of such data concerning the visitor mines, show caves and thermal spas where the annual effective dose equivalent may exceed the governmental limits for occupational radiation exposure.

METHODS AND INSTRUMENTS

For long-term Rn-222 determination diffusion cells of the so-called Karlsruhe-type have been used, equipped with cellulose nitrate nuclear track detectors (KODAK, type LR 115 II). The cells were protected against dust and humidity by silicone coated glass fiber filters. 5 to 10 dosimeters were installed along the visitors pathway in each cave or mine. Exposure time ranged from 60 to 90 days depending on radon concentrations. After etching the detectors were analyzed by automatic microscopic image analysis.

Instantaneous radon concentrations were measured using a radon monitor (Atmos-12 by ALNOR) with ionization chamber and/or with Lucas cells of 100 ml volume. Radon daughter products have been accumulated on membrane filters and determined by alpha spectrometry using a portable surface barrier detector spectrometer.

RESULTS

Table 1 contains the maxima, minima and mean values of all measurements, the equilibrium factors F, and the resulting annual effective equivalent doses. In cases where the radon progeny had not been measured an equilibrium factor of 50 % has been assumed. The effective equivalent doses have been calculated according to the following equation and assumptions:

$$D = A \cdot V \cdot t \cdot F \cdot C_D / \text{mSv a}^{-1}$$

A: activity concentration / Bq m^{-3}

V: breathing rate / $1,2 \text{ m}^3 \text{ h}^{-1}$

t: annual working time / 1600 h

F: equilibrium factor

C_D : dose conversion factor / $1,25 \cdot 10^{-9} \text{ mSv Bq}^{-1}$ *)

Some of the annual effective equivalent doses are close to or above the annual limit of 50 mSv for occupational radiation exposure. In these cases it was necessary to reduce the individual working time.

In Fig. 1 the frequency distribution of the radon concentrations in the show caves and visitor mines is shown. Five percent of all values are above 5000 Bq m^{-3} . Fig. 2 shows the radon concentration over time for one cave, exhibiting a distinct minimum during the winter season.

ABSTRACT

In the context of the National Survey on natural radiation indoors, based on a representative sample of 5000 dwellings, absorbed dose rates to air have been measured. Thermoluminescent dosimeters have been used and a well detailed measurement protocol has been elaborated. The paper analyzes the results obtained in 30% of the national sample. The arithmetic mean value obtained is 86 nGy/h. The distribution of absorbed dose rates in most of the Districts is well fitted by a Gaussian curve. The effective dose for the population has also been assessed, taking into account the occupation factors of dwellings.

INTRODUCTION

The influence of gamma and cosmic radiation on the effective dose received indoors by members of the public is generally far less important than that of radon concentration. However, measurements of the radioactive content of some natural and man-made building materials and surveys in certain areas, undertaken in Italy(1,2), indicated that a better evaluation of this irradiation source would be important. For this reason, in organizing the National representative survey on natural radiation indoors(3), it was decided to carry out measurements both of radon concentration and of absorbed dose rate to air. Moreover, the gamma measurements could also give information about the building materials as a source of indoor radon.

The survey is performed in each Italian District, in cooperation with local Health Services and Laboratories and involves a sample of 5000 dwellings selected through a two-stage stratified sampling technique.

METHODOLOGY

Due to the considerable number of District Laboratories involved, each one using different equipment and operators and having a wide spectra of thermoluminescent experience, it was decided to standardize - as far as possible - the whole measuring procedure by means of a detailed protocol. The use of the protocol should allow both to assure comparability of the data obtained in the different laboratories and to minimize dose uncertainties, so as to achieve an overall expected uncertainty in the range of (30÷40)% at 95% confidence level.

According to results in ref.4, LiF synthesized chips, either doped with Mg and Ti or with Mg, Cu and P, belonging to the same batch, have been used. The dosimeter is made of two pairs of TL chips, enclosed in light-tight plastic containers, 100 mg·cm⁻² thick. It is located, like the radon detectors, on a cupboard in one bedroom of each sampled dwelling.

The thermal cycles for re-use anneal, pre-heat and readout were defined, according with refs.4-7. In addition, two initialization cycles have been suggested for new detectors.

A check of sensitivity and zero signal of the reader at the beginning and the end of each daily reading cycle is required.

In order to further improve the homogeneity of the results obtained in the different laboratories, a number of preliminary tests are recommended in the protocol. Some of them regard just the detectors (individual sensitivity, batch homogeneity and fading), some others the whole TL system (reproducibility, and linearity) (8).

QUALITY ASSURANCE

A first intercalibration was carried out by exposing a sample of dosimeters prepared by each participating laboratories, to the beam of a Cs-137 source. Secondly, another set of dosimeters was exposed to the environmental radiation characterizing a selected high-background room, where dose rate had been previously evaluated. Both sets of detectors were read by the laboratories involved in the experiment, which ignored the actual value of the administered doses.

The results of the intercalibrations (see Fig.1) show good agreement among the different laboratories and confirm the reliability of the respective dosimeter systems.

Fig.1 Results of the intercalibration tests (ratio between evaluated and delivered doses)

At the end of the 6-month period of indoor exposure, an analysis of readout values was made. The aim was to identify the possible outliers, by statistical comparison of readout values of the four detectors placed in each dwelling.

RESULTS

The survey is still in progress. At present the absorbed dose measurements have been completed in 7 Districts, corresponding to about 30% of the whole representative sample.

Figure 2 shows the best fits of absorbed dose rates to air evaluated in different Italian Districts. The goodness of the Gaussian fit is generally acceptable.

Figure 3 illustrates the absorbed dose rate distribution in all the dwellings considered. The values higher than 250 nGy/h all belong to one District and are also connected with the use of high-radioactivity building materials (e.g.tuffs).

Fig.2 Best fits of absorbed dose rate to air evaluated in different Districts

Fig.3 Absorbed dose rate distribution in 30% of the national sample

CONCLUSIONS

The mean value of the absorbed dose rate to air, weighted over the dwellings under consideration, is equal to 86 nGy/h. Mean values in the different Districts range from 75 to 165 nGy/h. The occupation factors indoors at home and elsewhere, in each District, obtained through questionnaires(3) filled by the families in the sample, have been taken into account. For the same purpose a rough evaluation of cosmic radiation

contribution has been made and this value has been subtracted for all dwellings. The mean effective dose for the population associated to γ indoors was thus assessed as 0.33 mSv per year.

The values obtained confirm that - in the radiation exposure of the population - the γ absorbed dose contribution is far less relevant than radon concentration.

Lung Dose Modelling From Realistic Measurements Of Occupancy Exposure To Radon Progeny

Dr. A. Singmin
Thomson & Nielsen Electronics
Ottawa, Canada

Abstract

The risk of lung cancer resulting from exposure to radon, is directly related to the progeny concentration and the actual period of occupancy. Current exposure studies and dose models to date use the widely accepted protocol that the occupancy factor is 80%(1,2). Our experimental studies on real time simultaneous monitoring of both radon progeny and occupancy periods have shown that much greater accuracy in risk assessment can be achieved when occupancy periods are measured rather than assumed to be a constant 80%.

Introduction

The risk of lung cancer arising from exposure to radon progeny is directly related to the total cumulative exposure, expressed as the product of Working Level x Occupancy Factor. In order to improve the accuracy of estimation of the health risk associated with exposure to radon progeny, accurate measurements of personal occupancy are necessary. Customarily, an occupancy factor of 80% is assumed, in the absence of more appropriate data. A recent study undertaken by N.H Harley and B.R. Litt(3,4) utilized a passive radon gas monitor(CR39 alpha track) worn by the participants. Additionally, subjects were required to keep an activity log of where they had been and what they had done. An alternative approach undertaken by Thomson & Nielsen, is based on the simultaneous measurement of both the real time continuous radon progeny variations and the actual occupancy periods within that environment. All measurements were recorded automatically, without the need for any personal activity diaries. The data gathered from this study is later used for calculating WLM exposure levels based on direct measurements.

Experimental Measurements

The chosen study environment was the basement area of a typical family residence of four occupants. For this experiment, no attempt was made to distinguish individual family members. A continuous working level radon monitoring system(TN-WL-02) manufactured by Thomson & Nielsen, was configured to record hourly radon progeny concentration levels automatically. This system is based on the principle of active sampling of the ambient air onto a filter with subsequent determination of the gross alpha counts by a solid-state detector. Data from this system, collected over

a period of several months, was later analyzed on a standard PC computer to produce continuous hourly plots of the radon progeny. In addition, monitoring and recording of the occupancy periods were made using a customized surveillance system. Each time a family member entered the basement area, the system was activated to subsequently record the occupancy duration. The data from this system was also later analyzed on a PC and the two plots combined to form the composite exposure profiles, as seen in Figure 1.

Results

A summary of the results covering four consecutive days are shown below in Table 1. Random variations in both WL and occupancy patterns can result in a wide range of WLM values. Over a four day period, as seen in Figure 1, the working level concentration varies by a factor of 5:1. Occupancy patterns reflect typically the habits of two working adults and two school age children. Activity is greatest at times in the afternoon when the children return from school and also on Saturdays. During the hours of sleep there is obviously no activity in the basement and radon progeny levels then are less of an exposure risk.

	Table 1			
	<u>Thursday</u>	<u>Friday</u>	<u>Saturday</u>	<u>Sunday</u>
Rd Average	0.038WL	0.032WL	0.017WL	0.027WL
Rd std dev	0.012WL	0.010WL	0.005WL	0.005WL
Occupancy	13%	17%	30%	8%
WLM/yr	0.25	0.28	0.26	0.11

Based on these values a comparison can be made between calculations of exposure from actual and assumed occupancy factors. It is seen that under realistic conditions, the occupancy factor is not necessarily 80%. Previous studies in this basement area have determined the average annual value to be 0.04WL. Using the usual occupancy factor of 80%, the estimated exposure is given as:

$$\text{WLM/yr} = 0.04 \times 0.8 \times 730 \times 12 / 173 = 1.62$$

Using the measured values from table 1, the calculated exposure is given as:

$$\text{WLM/yr} = 0.028 \times 0.17 \times 730 \times 12 / 173 = 0.24$$

In terms of the effective dose equivalent, the conversion factor between dose absorbed in the bronchial region and exposure to radon progeny is: 10mSv/WLM, as adopted by the ICRP(8).

Conclusions

Commonly employed lung dose models i.e. Jacobi-Eisfeld(5), Harley-Pasternak(6) and James-Birchall(7), include a simple proportionality constant for the occupancy factor. We have seen however that the actual value can vary significantly and is not a constant. When estimating radon health risks therefore, it is preferable that both progeny and occupancy be measured continuously. This is entirely feasible using monitoring equipment from Thomson & Nielsen, additionally removing the encumbrance of having participants keep activity diaries. By going to a higher level of system sophistication, individuals within a monitored zone can also be analyzed separately.

WLM EXPOSURE CALCULATIONS

Using Measured Radon Daughter Values
and Measured Occupancy Values

Equipment: TN Proprietary Systems

Percentage Occupancy = 3/24 hr = 13%

$$WLM = \frac{0.038 \times .13 \times 730}{173} = 0.02$$

$$WLM/yr = 0.02 \times 12 = 0.25$$

Percentage Occupancy = 4/24 hr = 17%

$$WLM/yr = \frac{0.032 \times .17 \times 730 \times 12}{173} = 0.28$$

Percentage Occupancy = 7/24 hr = 30%

$$WLM/yr = \frac{0.017 \times .3 \times 730 \times 12}{173} = 0.26$$

Percentage Occupancy = 2/24 hr = 8%

$$WLM/yr = \frac{0.027 \times .08 \times 730 \times 12}{173} = 0.11$$

REVIEW OF MEASURES TAKEN TO IMPROVE THE SAFETY OF THE TRANSPORT OF RADIOACTIVE MATERIAL WITHIN THE MEMBER STATES OF THE EUROPEAN COMMUNITIES, AS A RESULT OF THE EXPERIENCE GAINED IN DEALING WITH ACCIDENTS AND INCIDENTS

Accidents and incidents involving the transport of radioactive materials have sometimes occurred in member states of the E.C. Most have not given rise to a significant radiological hazard but in some cases considerable remedial actions have had to be taken to deal with the radioactive material safely. In this paper the experience gained from dealing with these events has been examined. The lessons learnt from events that have occurred at various stages of transport operations are described, so as to be more widely available to those involved in the transport of radioactive materials. It is found that there are some general measures which can be taken that will reduce the frequency of these events, and facilitate the implementation of emergency procedures should such an accident occur.

Un certain nombre d'incidents ou d'accidents impliquant le transport des matières radioactives ont été recensés depuis 1975 dans les différents états membres des Communautés Européennes. La grande majorité d'entre eux n'a pas conduit à des conséquences radiologiques significatives, mais dans quelques cas d'importantes mesures d'intervention post-accidentelles ont dû être mises en oeuvre. L'examen de l'expérience tirée de ces incidents ou accidents a été fait. Les leçons tirées de ces événements, qui ont eu lieu à différentes étapes de l'opération de transport, sont décrites. Quelques mesures génériques pouvant être prises afin de réduire la probabilité d'occurrence de ces événements ou de faciliter les mesures d'intervention éventuelles ont été également identifiées.

INTRODUCTION

A la demande des Communautés Européennes, une banque de données regroupant la description des différents accidents ou incidents de transport de matières radioactives survenus au sein des Etats Membres de 1975 à 1986 a été réalisée par le CEA et le NRPB (1). Suite à cette première étude, l'analyse

des principales leçons tirées de ces événements a été faite (2).

Les principaux événements retenus ont été regroupés selon différentes rubriques, en fonction de leur cause principale, afin de pouvoir tirer des leçons génériques pour chacune des 10 rubriques suivantes :

1) PREPARATION ET FABRICATION DU COLIS :

La première étude (1) avait montré que les expositions les plus sévères avaient résulté d'accidents de transport de sources pour la radiographie industrielle. A titre d'exemple, on peut citer le cas d'un gammagraphe qui a été transporté pendant 18 heures avec sa source non protégée (hors de son tube guide). Il en est résulté une exposition de l'ordre de 200 mSv pour l'un des opérateurs. Cet accident n'aurait pas eu lieu si l'opérateur avait vérifié la position de la source avant le transport. Suite à de tels accidents, un code de bonne pratique a été rédigé au Royaume-Uni en 1975 insistant sur la nécessité d'une bonne préparation du colis. Depuis la diffusion de ce code, la fréquence de ce type d'événements a décru.

Après le naufrage du Mont Louis, quelques uns des colis d'UF6 avaient des protège-vannes détériorés. De nouveaux protège-vannes ont depuis été mis au point.

2) ETIQUETAGE ET DOCUMENTATION :

Certains colis radioactifs, trouvés sans étiquette, ont été ouverts sans précautions particulières. Ceci démontre l'intérêt du bien-fondé du suivi des procédures administratives en la matière.

Après un incident mettant en cause une grande source, le nom et le numéro de téléphone de l'expéditeur ont été clairement indiqués sur ces colis afin que l'on puisse le joindre immédiatement, sans alerter systématiquement les équipes d'intervention d'urgence.

3) OPERATION DE TRANSPORT PROPREMENT DITE :

La fixation des colis à l'intérieur du moyen de transport est un élément essentiel de sûreté. Différents accidents routiers, ferroviaires ou maritimes ont eu des conséquences significatives parce que le colis a été expulsé lors d'un accident ou a été endommagé lors du transport. Des codes de bonne pratique pour l'arrimage ont été développés depuis pour le transport routier et maritime.

Du minerai d'uranium concentré est transporté par mer dans des fûts. Lors de leur transport ou de leur manutention plusieurs fûts ont été percés, dispersant le minerai dans le navire ou sur le quai. Depuis, ces fûts ont été placés dans des conteneurs répondant aux normes ISO, ce qui a permis de diminuer la fréquence de ces accidents et de limiter la contamination à l'intérieur du conteneur.

4) MANUTENTION :

Bon nombre de petits colis ont été écrasés lors de leur chargement/déchargement dans un aéroport. Ces colis étaient posés sur un chariot de manutention qui devait franchir des ralentisseurs. Lorsque la vitesse du véhicule était trop importante, des colis tombaient et étaient écrasés. Depuis la pose d'une cage autour du chariot, la fréquence de ces événements a considérablement décru.

5) CONTROLE DE LA RADIOACTIVITE :

De nombreuses fausses alertes ont été déclenchées suite à une mauvaise mesure du niveau de radioactivité. L'utilisation d'appareils appropriés, par des gens qualifiés devrait pouvoir y remédier.

Par exemple, les colis en transit dans un aéroport étaient entreposés dans un local équipé d'un détecteur mural. Cet instrument, qui avait un seuil de détection trop bas, a été mis hors d'usage suite à de nombreux déclenchement intempestifs. Il a été finalement décidé de ne plus l'utiliser et de contrôler chaque colis par un appareil manuel après avoir pris soin de bien éloigner le colis de ceux déjà contenus dans le local de transit.

6) ASSURANCE DE LA QUALITE :

Le dispositif de fermeture d'un type d'emballage a été modifié sur tous à l'exception d'un seul qui n'était plus recensé, et lors de l'utilisation de cet exemplaire, l'exposition sévère du personnel a pu être évitée de justesse.

Les procédures d'assurance de la qualité du fabricant de ces emballages ont été mises en défaut.

7) FORMATION :

Lors de certains accidents ou vols, le chauffeur d'une importante société sous-traitante ne savait pas qui contacter. Dans ce but, des cours de formation et des plaquettes d'information ont été réalisés.

8) ORGANISATION ADMINISTRATIVE :

Lors du retour d'un colis, un réceptionniste, ignorant que le flacon était brisé, a été irradié. L'organisation du service "retour client" de cette société commercialisant des sources a été revue afin de considérer tout colis comme a priori suspect.

9) PROCEDURES D'INTERVENTION POST ACCIDENTELLES :

Suite au renversement d'un camion transportant des combustibles irradiés, il a fallu attendre une journée avant qu'une grue capable de soulever le colis n'arrive sur les lieux. Le recensement des grues de fort tonnage a été, depuis, réalisé.

10) RISQUES NON RADIOACTIFS :

Le risque principal de l'UF6 est le dégagement d'HF en cas d'incendie ou de contact avec l'humidité de l'air ou avec l'eau. La prise en compte de ce risque chimique, depuis l'accident du Mont Louis, a fait l'objet de réflexions à l'AIEA en vue de développer une réglementation pour le transport de cette matière. Un guide a été publié dans ce sens récemment par l'AIEA.

CONCLUSION

Plusieurs millions de colis radioactifs sont transportés chaque année dans les 12 pays membres de la Communauté Européenne, la plupart étant des colis de sources à usage industriel (gammagraphes) ou médical. On estime à environ quelques dizaines, voire à une centaine le nombre d'incidents ou d'accidents significatifs mettant en jeu chaque année des matières radioactives lors des transports réalisés au sein de ces pays.

Au vu de la diversité de ces transports, il est difficile de tirer des leçons génériques de ces événements. L'enquête réalisée a toutefois permis d'identifier des cas types selon leur origine et de recenser quelques mesures aisément généralisables à un type de transport. Il conviendrait maintenant de diffuser au mieux cette expérience et de continuer une telle analyse afin de pouvoir recenser d'éventuels autres cas types.

Abstract

A database of UK transport accidents and incidents involving radioactive materials assists those responsible for regulations and those who undertake transport operations. Data have been analysed from 1964 to 1990: accidents and incidents involving radioactive materials are infrequent and significant radiation exposures are rare. Inadequate preparation of packages has, however, resulted in unnecessary radiation exposures. The main areas for improvements are in quality assurance procedures, and in the training of staff.

Introduction

In the UK, a transport accident and incident database has been established through the cooperation of the Health and Safety Executive (HSE), Department of Transport (DTp) and the National Radiological Protection Board (NRPB). Information on events involving the transport of radioactive materials since 1964 has been obtained: data came from the files of HSE, DTp, NRPB and consignors and carriers of such materials. The main purpose of the databank was to assist in the assessment of the radiological impact of transport accidents and incidents on both workers and members of the public. Additionally, it would provide information pertinent to future transport legislation, codes of practice, and regulatory activities.

Database

For each event, information was obtained on the technical details of the source and package, the mode of transport, and any radiological consequences. Any other relevant information available on the event was also recorded. The data were transferred to a computer database to facilitate analysis: a coding system was developed in order to categorise each event. Up to the end of 1990 the database contained 406 events, the majority of which were reported under informal notification arrangements. The database is updated annually and reviews are published^(1,2).

The level of detail of significant information found in reports is variable: there are differences between modes of transport and information is sparse in some of the early reports. Steps have been taken to improve the uniformity of reporting.

Results

Classification and analysis of events by category of material are given in Table 1. Transport operations are divided into two parts, the movement or transport phase and the handling phase. There is a further distinction in each phase between accidents and incidents. A number of the transport incidents were non-events or false alarms but they did involve an emergency response. Of the 147 handling accidents involving radioisotopes, most occurred at airports during the 1970s and were caused by packages being damaged during handling and unloading operations using fork-lift trucks. Improved handling techniques have virtually eliminated this type of accident. All the incidents, involving the transport of irradiated nuclear fuel and residues by rail, were minor events such as derailments during shunting operations: none of these had any radiological consequences.

Table 1: Classification and analysis of events by category of material

Category of material	Transport		Handling		Totals
	Accidents	Incidents	Accidents	Incidents	
Uranium ore concentrate	2	8	12	1	23
Pre-fuel material	5	3	0	2	10
New fuel	1	3	0	0	4
Irradiated fuel	4	33	0	7	44
Residues	4	30	2	6	42
Radioactive wastes	3	5	0	2	10
Radioisotopes	20	25	147	33	225
Radiography sources	8	18	2	20	48
Totals	47	125	163	71	406

An important analysis is that of the effects on packages, this is detailed in Table 2. In 117 events there were no consequences but the potential existed. For 43 events there were administrative errors or false alarms. The remaining 246 events resulted in damaged packages or were due to faulty packages. Loss of containment occurred in 24 cases and many of these involved drums of uranium ore concentrate damaged in transport. These drums are now containerised and such events are now rare.

Table 2: Analysis of effects on packages

Type of event	Number of events for each package type				Total
	Excepted	Industrial	Type A	Type B	
Damage with loss of containment	2	15	7	0	24
Damage with an increase in dose rate, without loss of containment	0	0	5	1	6
Damage without increase in dose rate or loss of containment	6	5	161	4	176
No damage or increase in dose rate but with potential to cause damage to the package	11	8	37	61	117
Increase in dose rate or loss of containment owing to faulty packages	2	2	19	17	40
No damage to package. Minor events, e.g. labelling errors and false alarms	11	5	15	12	43
Total	32	35	244	95	406

The radiological consequences of accidents resulting in the release of unsealed radioactive material from packages have been very low: intakes have been insignificant. However, some events have involved the transport of inadequately shielded gamma ray sources and have led to appreciable exposure of workers. The exposure of members of the public from such events has been negligible. The highest occupational exposures were recorded by personal dosimeters and assessment. Only ten workers were reported as receiving doses above 100 mSv: the distribution of doses over 1 mSv is given in Table 3.

Table 3: Distribution of doses to workers

Dose range (mSv)	Number of workers	Number of workers with site radiography sources
1-10	22	16
11-100	15	15
101-1000	9	9
> 1000	1	1

The single largest dose involved a site radiography source which fell out of its container owing to the failure of a retaining bolt. A 190 GBq ^{192}Ir source was exposed outside the container for approximately 17 h before being discovered; three workers received whole-body doses of about 2400, 500 and 50 mSv. All of the remaining events with doses above 100 mSv were similar: all involved site radiography sources which fell from, or were not replaced in, their containers. On one occasion the exposure was found to be deliberate, and on another film badges were incorrectly used and led to a reported dose greater than the assessed dose. On several occasions it was noted that no monitoring had been carried out before transport of the sources. Most such events occurred in the 1970s: improvements have been made in the training, supervision and quality assurance, and no such events have occurred since 1985.

Discussion

The compilation and analysis of information on accidents and incidents involving radioactive materials during transport both assists those responsible for its regulation and those who consign and carry those materials. The lessons learnt from one event can often help to avoid similar occurrences.

The correct assembly of the package has been shown to be most important and adequate quality assurance measures are required. Regular reviews of operating procedures⁽⁷⁾ are necessary to ensure that all exposures are as low as reasonably achievable.

Adequate training of staff and the availability of information are important considerations. The level of training will depend upon the nature of the work⁽⁴⁾.

Conclusions

A database of accidents and incidents during the transport of radioactive materials in the UK has been compiled, covering the period 1964-1990: the data are reviewed annually. Some 400 events are recorded in the database, of which 70 involved either a release of radioactive material or inadequate shielding or loss of shielding. As a result, about 40 workers have received doses in excess of 1 mSv and 10 have exceeded 100 mSv. Accidents and incidents involving radioactive materials during transport are comparatively rare but their frequency can be further reduced by improvements in quality assurance procedures and in the training of staff.

ABSTRACT

The recent ICRP recommendations (ICRP Publications n°60 & 61, 1991) contain some new provisions, that can have an effect upon the AIEA radioactive materials transportation recommendations. The most important are :

- those provisions relating to the occupational & public dose limits and to the annual limits on intake based on the new dose limits,
- and the provisions for potential exposures and for occupational exposure in emergencies.

This paper assesses the effects of all those provisions upon the classification of workplaces, upon the dose rate levels close to the transportation packages, upon the activity limits for type A packages, and finally upon the spent fuel and radioactive waste packages design.

—ooo—

1/ LIMITES DE DOSE ANNUELLES POUR LES TRAVAILLEURS ET POUR LE PUBLIC

L'abaissement de la limite de dose annuelle moyenne de 50 mSv à 20 mSv recommandé par le CIPR (1) ne devrait pas poser de problème important pour la surveillance des travailleurs impliqués dans les transports. Bien que les valeurs publiées soient rares et incomplètes, les doses annuelles les plus élevées reçues en France et dans divers pays pour les travailleurs des transports sont de l'ordre de 15 mSv par an et ne concernent qu'un nombre très limité de personnes.

Les nouvelles recommandations de la CIPR fixent à 1 mSv en moyenne sur 5 ans la limite de dose annuelle pour les individus du groupe critique du public, cette limite pouvant être dépassée au cours d'une année isolée si la moyenne sur 5 ans ne dépasse pas 1 mSv. L'application de cette limite de dose pourra conduire à considérer comme travailleurs exposés professionnellement un certain nombre de travailleurs qui étaient jusqu'à présent considérés comme des individus du public et exercer une surveillance adéquate des expositions reçues. Le nombre de travailleurs concernés n'a pas encore été évalué mais ne serait sans doute pas très élevé. Cette mesure a le mérite de clarifier la situation d'un certain nombre de travailleurs et de marquer nettement la différence entre l'exposition professionnelle et l'exposition du public dans les transports.

2/ DETERMINATION DES DEBITS DE DOSE AU CONTACT ET A DISTANCE ET DES LIMITES DE CONTAMINATION DE SURFACE DES COLIS

Ces limites ont été définies pour atteindre les objectifs suivants :

- limiter l'exposition des professionnels amenés à manipuler ou à séjourner à proximité des colis de matières radioactives,
- limiter l'exposition des équipages des avions ou des autres moyens de transport ainsi que des personnes du public utilisant ces moyens de transport ou séjournant près des lieux d'entreposage en transit,
- limiter à 0,10 mSv par voyage la dose reçue par les films photographiques.

Il faut reconnaître que les données relatives aux objectifs de dose et aux scénarios et modalités d'exposition figurant dans les différents documents relatifs au transport (2.3) sont confuses et manquent de cohérence. Il sera nécessaire de réviser ces données en clarifiant les objectifs et en redéfinissant de façon précise ces scénarios et modalités d'exposition supportant ces différentes limites. Ceci ne devrait cependant pas conduire à des modifications importantes de ces dernières.

3/ CONTRAINTES DE DOSE

La réglementation des transports de l'AIEA (Agence Internationale de l'Energie Atomique) pour le calcul des distances de séparation et des débits de dose dans les locaux occupés de façon régulière, se fixe pour objectif en application du principe d'optimisation le respect d'une limite de dose annuelle de 5 mSv pour les travailleurs. Il est nécessaire de rappeler à ce propos que la fixation de ce type de "contrainte de dose" ne relève pas d'une décision internationale, sauf si un consensus suffisant existe sur ces valeurs. La fixation de contraintes de dose relève en effet des autorités nationales ou même de décisions prises par les directions des compagnies ou des installations. Ce point devra être discuté lors des réunions internationales pour la révision de la réglementation des transports.

4/ CONDITIONS ACCIDENTELLES - CALCUL DES VALEURS A1 et A2

Dans la réglementation actuelle pour le calcul des valeurs A1 et A2 admissibles dans un emballage de type A on définit des niveaux de dose considérés comme admissibles en cas d'accident par référence aux valeurs des LAI ou des limites de dose à l'organisme entier ou à la peau pour les travailleurs. La CIPR a publié récemment (4) de nouvelles valeurs des LAI mais il ne paraît pas judicieux de recalculer les valeurs A1 et A2 en tenant compte de ces valeurs qui ne prennent pas en compte le nouveau modèle respiratoire de la CIPR.

En conditions accidentelles, il n'y a pas de limites de dose mais la CIPR recommande d'utiliser des "niveaux d'action ou d'intervention" tels que ceux proposés dans la publication CIPR 40 (5) au dessus desquels il peut être nécessaire d'effectuer certaines actions ou interventions définies par l'autorité compétente.

Dans ces conditions les valeurs de A1 et A2 pourraient être recalculées en tenant compte du "niveau d'intervention" dont les valeurs pourraient être identiques aux niveaux de dose considérés actuellement comme acceptables en cas d'accident ce qui éviterait de modifier profondément les valeurs actuelles et de désorienter les utilisateurs.

5/ CONCEPTION DES EMBALLAGES - PRISE EN COMPTE DES NOUVELLES VALEURS DE WR

Dans le cas des transports de combustibles neufs et de combustibles irradiés, les débits de dose à distance et au contact des colis étaient parfois mesurés sans tenir compte des neutrons, et lorsqu'ils étaient mesurés, on attribuait à ceux-ci un facteur de qualité de 10. Il va falloir à présent tenir compte des neutrons en leur affectant un facteur de pondération WR fonction de l'énergie (qui remplace le facteur de qualité Q) de 20.

Or, il se trouve que la composante neutronique peut représenter une fraction importante du débit d'équivalent de dose total. Dans tous les cas où, en tenant compte du rayonnement γ seul, les limites de débit de dose au contact et à distance étaient approchées, la prise en compte du rayonnement neutronique va majorer ces débits de dose dans une proportion qui n'est pas encore exactement connue mais qui pourrait dépasser ces limites. Dans ces conditions, certains transports ne seront plus conformes et une solution devra être trouvée : transitoire d'abord (dérogations) puis définitive (coques de protection, réduction des activités transportées, modification des emballages existants ou création de nouveaux emballages).

L'impact économique de cette modification peut donc être important.

6/ VERIFICATION

En vue de s'assurer du respect des limites de dose pour les travailleurs et le public la CIPR recommande que les doses reçues par les travailleurs soient relevées et vérifiées périodiquement, et l'AIEA recommande d'effectuer ce relevé tous les cinq ans. Cette recommandation revêt une importance certaine dans les transports où la surveillance des travailleurs exposés est rendue difficile par leur dispersion et leur mobilité et où la surveillance du public est également difficile. Elle est réalisée en France et dans divers autres pays et peut être effectuée directement ou au moyen de modèles développés par l'AIEA (6).

Cet inventaire des problèmes n'est pas exhaustif et nous l'avons limité qu'à ses aspects les plus importants.

7/ CONCLUSION

La qualité d'une réglementation s'évalue dans la durée et une réglementation, pour être respectée, doit évoluer dans la continuité. On peut également juger de la qualité d'une réglementation en fonction des résultats obtenus. Ceux-ci sont évalués régulièrement dans quelques pays et en France depuis 1978. En France, entre 1978 et 1990, alors que le nombre de transports de matières radioactives augmentait dans des proportions considérables (de 40 000 à 173 000 colis pour les produits radio-pharmaceutiques), les doses moyennes pour les personnels les plus exposés sont demeurées stables et relativement faibles ainsi que la dose collective (de l'ordre de 1 homme.Sievert), situation qui peut apparaître relativement satisfaisante.

Néanmoins, l'évolution de la doctrine de la CIPR, reprise dans les normes de base de l'AIEA, et la nécessité de corriger certaines imperfections devront être prises en compte lors de la prochaine révision de 1995. Il faut souhaiter que, compte tenu de certains correctifs et de certaines mises à jour rendus nécessaires par l'évolution de la réglementation internationale, l'originalité de la réglementation des transports soit conservée et qu'une certaine continuité des règles de sûreté et de radioprotection soit préservée.

**RADIATION DOSES FROM THE TRANSPORT OF RADIOACTIVE MATERIAL
IN THE UNITED KINGDOM**

C K Wilson
UK Department of Transport
and
K B Shaw
UK National Radiological Protection Board

ABSTRACT

The assessment of the doses arising from the incident-free transport of radioactive material in the United Kingdom is performed periodically by means of a programme of work looking at the land, sea and air modes in turn, separately. A database containing details of UK accidents and incidents involving radioactive material over a period of more than twenty five years has been established.

The doses from routine operations are generally low, apart from those of a small number of drivers regularly delivering technetium generators for medical use. The highest accidental exposures have been from the transport of inadequately shielded industrial radiography sources.

INTRODUCTION

The transport of radioactive material in the United Kingdom is controlled by regulations based upon the International Atomic Energy Agency's model regulations¹. These regulations require that the exposures from the handling, storage and transport of radioactive material shall be kept as low as reasonably achievable, economic and social factors being taken into account. However, the dose rates around packages containing radioactive material can be as high as 10mSv/h. The justification for the continued use of these levels is that radiation exposures arising from transport are in fact low and that the regulations provide for their periodic assessment by the Competent Authority. In the United Kingdom the Department of Transport, as Competent Authority, has instigated a programme of assessment of the exposures arising from the transport of radioactive materials. This is done on a cyclical basis looking at each transport mode in turn under incident free conditions^{2,3}. A database of reported transport accidents and incidents in the UK and their radiological consequences is also maintained⁴. This work is performed under contract to the Department by the National Radiological Protection Board a statutory body one of whose functions is to provide advice on radiological protection matters to government departments.

SEGREGATION

It is a basic requirement of the IAEA Regulations that radioactive material is properly segregated both from people and photographic film. For the former, the Regulations prescribe limiting values of annual dose of 5mSv for workers

and 1mSv for members of the public and from these values segregation distances can be calculated using hypothetical but realistic models. If these criteria are met in practice neither special work patterns nor detailed monitoring of radiation doses are required.

NORMAL TRANSPORT

(i) Transport Characteristics

It is convenient to consider the transport of radioactive material under three broad headings: unirradiated nuclear fuel cycle materials; irradiated nuclear fuel cycle materials including wastes; and radionuclides for medical and industrial use.

The greatest weight of radioactive material transported is in unirradiated nuclear fuel cycle materials such as uranium ore concentrate, or uranium hexafluoride. These are bulky materials of low specific activity. Uranium ore concentrate travels by road or sea in 17 tonne loads of industrial grade steel drums overpacked into 6 or 12 metre long freight containers; uranium hexafluoride whether natural, depleted or enriched travels in purpose-built cylinders holding between 2 and 12 tonnes, usually by road or sea.

Irradiated nuclear fuel cycle materials such as imported spent nuclear fuel from European and Japanese power and research reactors travel by sea with associated secondary rail journeys; domestic irradiated nuclear fuel travels mainly by rail. The highest activity of radioactive material transported is found in this category; a typical flask of seven PWR elements contains of the order of several hundred petabecquerels.

Low level waste arises from both the nuclear fuel cycle and from isotope production and is transported by road and rail to an authorised repository. Its transport is, as yet, not radiologically significant.

The transport of radionuclides for medical use, both within the UK and abroad is extensive by road, sea and air: this category of material accounts for the greatest number of movements and the largest number of packages moved with around half a million packages transported each year⁵. Roughly 90% of these contain insignificant quantities of radionuclides which are exempt from many of the design and use requirements of the transport regulations. The remainder are radiologically significant and are the major source of worker exposure in routine transport.

ii) Exposures

Individual and collective doses for workers and members of the public have been estimated and are summarised in Tables 1 and 2.

Table 1: Worker Exposure

Mode	Max. Individ. (mSv)	Collective (manSv)
Road/Rail	16.0	0.4
Air	0.4	0.1
Sea	0.4	-

Table 2: Exposure of Members of the public

Mode	Max. Individ. (mSv)	Collective. (manSv)
Road/Rail	0.006	0.04
Air	0.1	0.5
Sea	0.05	-

The highest occupational doses arise in road transport from the movement of technetium generators for hospital use. Doses to members of the public are low: the highest doses are from the air transport of medical radionuclides⁶.

ACCIDENTS/INCIDENTS

Accidents and incidents occur in all modes of transport to all types of goods, radioactive materials are no exception. Although the lower types of packaging for radioactive materials are not required to retain their contents in the event of a severe accident, experience over 25 years in the UK has shown that such packages do retain their contents and shielding in most accident conditions. The higher grade of packaging, Type B, is required to meet severe accident conditions without significant loss of contents or shielding and no such package has lost its contents in the UK.

The UK has a transport event database on accidents and incidents involving radioactive material; since 1964 some 400 events most of which have had trivial radiological consequences have been recorded.

Analyses of the UK events shows that in 43% of the cases the package was damaged but that there was no increase in radiation level or loss of containment; in 39% of the cases no damage occurred to the package. Radiological consequences were possible in the remaining 18% of the cases but significant exposures occurred in only a few, all involving site radiography sources. The highest radiation doses resulted from faulty packages where the radiography sources were not properly shielded.

LOOKING AHEAD

The new ICRP recommendations will have an impact on transport. There will be greater pressures to constrain doses and this could involve substantial increases in some transport costs. The application of ALARA will need to be carefully examined. The permitted surface dose rates on packages will need to be reviewed and certain handling procedures may need to be revised.

CONCLUSIONS

Although the exposures from incident free transport are currently generally low they are dependent upon particular work and traffic patterns and the need for continuous review is, therefore, justified. The analysis of accidents and incidents confirms the adequacy of the IAEA packaging standards but emphasises the need for the application of quality assurance in transport.

The highest individual occupational doses arise from the transport of technetium generators. For a few workers these can be as high as 16mSv. Other transport occupational exposures are almost an order of magnitude lower.

The collective dose to members of the public due to the transport of radioactive materials by road and rail has been estimated at 0.04 manSv. For the transport of radioactive materials from the UK by air, the collective dose has been estimated as 0.5 manSv. No estimate of collective dose has been made for sea transport.

The new ICRP recommendations will have an effect on transport: in particular the application of dose constraints needs to be carefully considered. Transport is an international matter and requires international consensus.

STATUS OF SHIELDING ANALYSIS METHODS FOR TRANSPORT PACKAGES

C. V. Parks, B. L. Broadhead, and M. C. Brady

Oak Ridge National Laboratory*
Oak Ridge, Tennessee 37831

ABSTRACT

Shielding analysis methods for transport packages are becoming more important to the cask designer because optimized cask designs with higher payloads can yield doses near the limits set by regulatory authorities. Uncertainty arising from generation of radiation sources, selection of cross-section data, and the radiation transport methodology must be considered. Recent comparison studies using popular U.S. codes illustrate calculational discrepancies arising from each of these areas.

INTRODUCTION

Accurate results from shielding analyses of spent fuel transport packages (or casks) have become more important as the desire for optimized designs increases. In order to obtain accurate, defensible results, it is necessary to identify and evaluate uncertainties arising from three major analysis areas: radiation source generation, utilization of cross-section data, and radiation transport and dose evaluation. This paper reviews recent efforts carried out at Oak Ridge National Laboratory (ORNL) to evaluate the impact of various codes, data, and analysis assumptions on the calculation of radiation doses from spent fuel casks.

RADIATION SOURCES

In the United States, radiation sources for spent fuel and high-level waste are typically obtained with the ORIGEN2 or ORIGEN-S codes. ORIGEN-S and ORIGEN2 employ the same point depletion/decay methods and use virtually identical decay data and photon data. The different methods used to develop and supply burnup-dependent cross-section libraries to ORIGEN2 and ORIGEN-S represent the major difference between the codes.

Radiation source strengths calculated by ORIGEN2 and SCALE/ORIGEN-S have been compared for burnup values of typical light-water-reactor (LWR) fuel.¹ The photon source strengths and spectra showed good agreement. The primary discrepancy in the spectra was observed above 2 MeV where there can be a reversal in the magnitude of adjacent energy groups caused by the

*Managed by Martin Marietta Energy Systems, Inc, under contract DE-AC05-84OR21400 with the U.S. Department of Energy.

different strategy used to bin photons to assure energy conservation (important for accurate shielding analysis). Photon dose rates on the surface of a cast-iron cask were also calculated using the ORIGEN2 and SCALE/ORIGEN-S sources. For the pressurized-water-reactor (PWR) sources, the doses agree to within 1.8% at a 5-year cooling time and 5% at 50-year cooling. Results for the boiling-water-reactor (BWR) cases showed agreement within 2.9% and 6%, respectively, for the 5-year and 50-year cooling times. One current limitation of ORIGEN2 is that the photon spectrum is provided in a fixed group structure whereas ORIGEN-S can provide a spectrum in any user-specified format. Conversion of the ORIGEN2 spectrum to fit a cross-section group structure is an approximation and should be performed with care.

The neutron production rates obtained for the comparison study¹ indicate discrepancies between ORIGEN2 and SCALE/ORIGEN-S as large as 30% for spent BWR fuel. For PWR fuel, the sources agree to within 2%. ORIGEN2 does not provide a neutron energy spectrum, whereas ORIGEN-S uses measured isotopic spectral data to provide a spectrum in any user-specified group structure.

The comparison study demonstrated that radiation sources from ORIGEN2 and SCALE/ORIGEN-S agreed very well for decay-only cases (codes started with same isotopics). The largest discrepancies occur in situations where the actinide concentrations offer an important contribution to the radiation source. This fact implies that the discrepant results discussed above arise from differences in the burnup-dependent cross-section data and the methods used to generate the data. Validation against measured data is needed to determine the accuracy of the calculated radiation sources. Unfortunately, the availability of measured isotopic data is severely limited for many of the fission products and actinides (e.g., curium) that are important contributors to the radiation source.

The radiation source emitted by activated light elements in the hardware of LWR fuel must often be considered in a cask shielding analysis. Activation of ⁵⁹Co to ⁶⁰Co is of particular concern. Typically, analysts use activation ratios based on neutronic calculations or measurements to adjust the ORIGEN (2 or -S) input to enable reasonable source terms to be obtained for fuel hardware zones. Conservative assumptions to cover the large uncertainties associated with the initial concentration values and activation analyses are typically not a problem for transport cask design unless the designer significantly reduces the radial shield thickness (due to weight constraints) in the hardware regions.

CROSS-SECTION DATA

The thick shielding and, hence, deep-penetration characteristics found in spent fuel casks make calculated dose

rates particularly sensitive to the cross-section data. Several standard multigroup libraries were selected and/or altered by ORNL to analyze dose sensitivity due to resonance self-shielding, energy-collapsing spectrum, and parent fine-group data. A 1-D cylindrical cask model with a homogenized spent fuel source region and 38-cm-thick cast-iron body was used in the evaluation study.² Comparison of dose results using the different libraries showed (a) absence of resonance self-shielding for iron decreased the neutron dose 33%, (b) the neutron dose decreases 8 to 10% in going from ENDF/B-IV to ENDF/B-V data, (c) an inappropriate weighting spectrum for the neutron data can easily alter the neutron dose by a factor of 2, and (d) a fine-group (45 to 60) photon library needs to be utilized and/or careful attention paid to the collapsing spectrum for more accurate results. Improper weighting (e.g., concrete flux rather than iron flux) and use of broad groups in the important energies (1 to 3 MeV) yielded 30 to 50% changes in the photon dose. Although limited to spent fuel shielded by cast iron, this study does point out the common error of using "off-the-shelf" cross-section libraries without regard to particular aspects of the radiation source, geometry, and material compositions. Work has begun at ORNL to generate multigroup cross-section libraries specifically applicable to spent fuel cask analysis.

Cross-section interpolation techniques used in point kernel and point Monte Carlo codes can also lead to small cross-section changes that have a larger impact on the dose. For the iron cask above, varying the interpolation method from linear (QAD-CG) to log-log (QAD-CGGP) yielded a 2% change in the cross section, which was sufficient to cause an 8 to 10% variation in the dose results.

RADIATION TRANSPORT CODES

Time and available funds often dictate the selection of radiation transport techniques. Point kernel and 1-D discrete ordinates codes are often used by cask designers because they are fast, inexpensive, and relatively easy to use. In the past, Monte Carlo and two-dimensional (2-D) discrete ordinates codes were typically reserved for specific problems and/or to validate the simpler methods. However, cask vendors for the new cask designs being developed for the U.S. Department of Energy repository program are utilizing Monte Carlo (MCNP) and 2-D discrete ordinates codes (DORT) in their shielding analysis.

An evaluation of several codes used in the United States for cask shielding analysis has been performed using the cast-iron cask model (with homogenized fuel and basket region) described above.² All of the codes utilized ENDF/B-V data libraries. The results obtained from the SAS1/XSDRNPM sequence of SCALE indicate that 1-D discrete ordinates codes can be used to obtain acceptable sidewall doses for casks with height-to-

diameter (H/D) ratios greater than two. For dose locations at the cask axial midplane but away from the surface, slightly conservative (with respect to multidimensional calculations) results were observed. The 1-D results showed a 20% overprediction at 10 m from the cask surface. The QAD point kernel (gamma only) results similarly agreed quite well with multidimensional calculations on the cask sidewall surface, but were up to a factor of 2 conservative at dose locations 10 m from the cask surface. The point kernel methods also perform quite well for doses at the cask top and bottom.

Multidimensional calculations were performed using a 2-D discrete ordinates method (DORT) and two three-dimensional (3-D) Monte Carlo codes (SAS4/MORSE and MCNP). In general, the SAS4 and DORT agreement is quite good, generally within the SAS4 standard deviations. Comparing SAS4 and DORT versus MCNP also indicates very good agreement for the gamma doses, but the groupwise neutron doses from SAS4 and DORT are about 20% lower than those based on point cross-section values (MCNP).

The results of the comparison study discussed above are for a model with a homogenized (fuel assemblies and basket) source region. Modeling the assemblies (five) as an array of homogenized source zones within a 1-cm-thick steel basket increases the neutron dose by 6% and decreases the photon dose by 26%. The small increase in neutron dose (6%) is of only slight concern; however, the significant decrease (26%) in the photon dose indicates the improved accuracy that can be obtained with more detailed modeling of the source region. Work with explicit pin-by-pin models of the assemblies showed no significant difference from results obtained with a model using homogenized individual assemblies placed heterogeneously within the source region.

SUMMARY

The user must ensure that the codes and data interact effectively to produce an accurate shielding analysis of a cask. The available radiation transport codes are reliable tools when handled by the knowledgeable user. However, more work is needed to reduce and/or quantify the uncertainty in the dose arising from specific source characterization methods and cross-section libraries.

ABSTRACT

In the first step for the AI application to radiation safety control, we have developed a prototype of the expert system for the transport of radioactive materials. The system is composed of three subsystems, which are "Judgment on the packages", "Diagnosis of conformity of the packages and the packagings", and "Judgment on transportable activities". With the system, it becomes easy to judge the type of the packages and the packagings, the labellings and the number of labels and transportable activities, etc. according to the regulation.

INTRODUCTION

Recently, an expert system(ES) which has functions to aid our interpretations and judgments is increasingly being used in a variety of business managements and manufacturing fields with the progress of the artificial intelligence(AI)-techniques.

In the field of radiation safety control, the technical system has been rapidly sophisticated with the specialization of radiation safety control techniques, and the work load has also been increasing with the increase in the number and the complexity of nuclear facilities. It is necessary for the experts on radiation safety control to promote the rationalization of their interpretations and judgments, the improvement of reliability on their judgments, the standardization of radiation protection procedure and the transmission of the accumulated knowledge. An application of AI to radiation safety control will facilitate to introduce the knowledges and the experiences of the experts, and also to utilize new knowledges and experiences with respect to radiation protection.

In the first step for the AI application to accomplish our aim, we have developed a prototype of the expert system for the transport of radioactive materials, which can be often used on our jobs and which would enable to be built as a standalone system. This paper presents the prototype of the expert system for the transport of radioactive materials.

DEVELOPMENT BACKGROUND

Under the Japanese regulations, the concept of "transport" includes not only the movement of radioactive materials but also the design, fabrication and maintenance of packagings, and the preparation, consigning, handling, carriage, storage in transit and

receipt at final destination of packages. In the case of the transport of radioactive materials, the staff of radiation safety control should interpret and judge either radioisotope(RI) or nuclear fuel material, the type of the packagings, the labellings and the number of labels on the activity limits from input information of radionuclide, activity, physical state of radioactive material to be transported. Hence, even the well-experienced staff might not interpret and judge the type of the packages and the packagings quickly because the activity limits are given for the special form and other form of radioactive material. Moreover, in the case of two or more nuclides, it will be much more difficult to interpret and judge on the possible combination of radioactivities to be allowed for the transportation with the limited packaging. Accordingly, the objectives of the development of the expert system are to achieve the improvement of rationalization, uniformity and reliability in the interpretations and judgments for the transport of radioactive materials, and to build one of the data bases so that it will be able to be used in the advanced radiation monitoring system.

SYSTEM ARCHITECTURE

The system consists of the following computer hardware and software.

- Hardware : Sun 3/260
- Operating system : UNIX
- Programming language : Lucid Common Lisp
- Knowledge engineering tool : KEE 3.1
- Size of the system : around 1,000 units

KNOWLEDGE BASE (KB)

The system consists of the RADIONUCLIDE-KB which holds common information of radioactive materials for the system and the TRANSPORT-KB which holds information of procedures for the transport of radioactive materials. These KBs are managed by the KEE knowledge base management system.

1. RADIONUCLIDE-KB

The RADIONUCLIDE-KB has the physical knowledge which includes the activity limits of A₁ for special form and A₂ for other form of radioactive materials permitted in a type A package, half lives, types of emitters, and atomic numbers of RI and nuclear fuel material described in the regulations. These knowledges are represented in a frame called an unit in the KEE system. The frame is made from about 400 units. The RADIONUCLIDE-KB is built so that it is possible to add various standard values referred in the regulations such as the derived air concentrations (DAC), the surface density limits, etc..

2. TRANSPORT-KB

The TRANSPORT-KB consists of the rules for the transport of radioactive materials, the interface frames and the record of

transported radioactive materials. The frame is made from about 300 units. These rules provide the following functions for interpretation and judgment.

- (a) Judgment on either RI or Nuclear Fuel Material.
- (b) Judgment on either Low Specific Activity Material(LSA), Surface Contaminated Object(SCO) or Others.
- (c) Calculation of Activity.
- (d) Judgment on the Packages and the Packagings.
- (e) Diagnosis of Conformity of the Packagings.
- (f) Judgment on Transportable Activities.

USER INTERFACE

User interface is composed of the powerful graphics display, on which each slot is attached directly to the graphic image, and various mouse menus so that we can easily operate the system.

SUBSYSTEM IN USE

In the system the "production rules" (rules in an "IF-THEN" format in KEE's inference functions) and the user-defined Lisp functions which are called "method" are adopted. The subsystems to judge mainly the type of the packages by using the reasoning methods are detailed below and shown in Fig.1.

1. Judgment on the Packages and the Packagings

All information required for the reasoning such as radionuclides, activities, states and conveyances of the radioactive material to be transported are given through the dialogue type of interface by a mouse or a keyboard. After the input of these information, the system will judge the type of the packages and the packagings, the labellings and the number of labels by activating KEE's inference engine, i.e., the forward chaining method.

2. Diagnosis of Conformity of the Packagings

The system will judge whether or not the radioactive material is transportable with the packagings by given information such as the above transport factors. The backward chaining methods (see Fig.1) is applied to this reasoning method in the KEE's inference engine.

3. Judgment on Transportable Activities

When there are several radionuclides at the transport planning and when we want to know the transportable activity of each radionuclide with own packagings, there will be following two problems to be solved in connection with these situations; 1) a lot of solutions will exist, 2) it will be difficult for a computer to solve some scheduling problems in reasonable time without an appropriate methods because of the restriction by the memory capacity. The system has the functions to explore the hypothetical situations and to pick up the suitable combination. The rules in Lisp language in the subsystem include an intelligent back-track mechanism to generate solutions quickly. The system has the

inference function made from about 60 functions defined by users, and derives the appropriate combinations of transportable radionuclides. The restriction of exploration is placed on the transportable activity of each radionuclide and the activity ratio which means the ratio of the quantity of the transported radioactive material to the activity limit(A₁,A₂). The solution can be to get the combination so that the sum of the activity ratios is less than 1/1000 or 1 according to the type L or A, respectively.

CONCLUSION

Subsystems, "Judgment on the Packages and the Packagings" and "Diagnosis of Conformity of the Packagings", have brought the improvements on the rationalization, the uniformity, and the reliability for our interpretations and judgments on the preparation of the transport of radioactive materials. Too much time had been spent to interpret and judge transportable activities for each radionuclide before the system was developed. The new system, however, has contributed to reduce the time spent for our judgment. Based on the experiences of the development of the system, we will build the advanced radiation monitoring system to provide for support of our interpretations and judgments on radiation safety control from the design stage to the normal and abnormal operation stage of nuclear facilities.

SECURITY AND MANAGEMENT.

Summary : All the studies performed about accident causes have emphasized the influence of Human Factors in the field of Safety and Radiological Protection.

Human actions cannot be understood but also improved without exploring the enormous field of mental representations and emotions, therefore, all the sources of comportments.

Among a working group, safety can be the field of all the comportments relative to this group : relationship with work and between persons.

This leads to management questions. There is no a specific management for the safety. It must be include in the general management policy.

Pedagogy must consider this fact for the training of workers.

INTRODUCTION

Les accidents industriels majeurs ont souligné l'importance du "facteur humain" dans le domaine de la Sûreté et de la Sécurité.

L'analyse des causes d'erreurs a conduit à la réflexion sur les interfaces matériels homme-machine, aux études d'ergonomie des salles de commande et de présentation des informations.

L'attention est portée également aux questions de fatigue, de surcharge de travail, de surmenage... aux éléments physiologiques.

La dimension humaine n'en est pas pour autant réglée. En effet, les actions humaines, les comportements, ne peuvent se comprendre et, éventuellement évoluer, sans que soit exploré le vaste domaine des représentations mentales et des émotions.

Le monde de l'émotion est abordé dans l'analyse des phénomènes opposés et complémentaires de l'accoutumance aux risques d'une part, et de rumeur et de panique d'autre part.

L'émotion conduit, en fait, tous les actes qui apparaissent incompréhensibles sur le plan de la logique objective, sur le plan de la raison, qui apparaissent "irrationnels".

Il reste à trouver les origines de l'attitude ainsi qualifiée si on veut lui apporter un remède efficace.

Nous en venons alors, puisque nous nous trouvons dans un collectif de travail, à rejoindre les questions de **management** et, pour cela, à porter attention aux mécanismes humains fondamentaux.

LE PHENOMENE DE L'EMOTION

L'émotion fondamentale est l'émotion peur **qui est particulièrement présente dans le domaine du risque radiologique.**

Il y a d'autres émotions que l'émotion peur. Toutes sont liées à la satisfaction ou à la non satisfaction des **aspiration fondamentales** que l'on classe en trois grandes catégories :

- * se sentir en sécurité. C'est l'aspiration première : exister, dans notre intégrité.
- * avoir une activité qui ait un sens, dont nous connaissons et acceptons la finalité.
- * être intégré et libre au sein d'une collectivité. Y avoir notre part de pouvoir.

On les appelle aspirations fondamentales parce qu'il ne peut pas ne pas y avoir malaise si l'une d'entre elles n'est pas, pour l'intéressé, et selon son point de vue satisfaite.

Un malaise lié à une insatisfaction ne peut pas ne pas s'exprimer.

Le domaine de la sécurité, qui est le domaine de base se rapportant à la relation au corps et à nous-même est le domaine privilégié d'expression sous la forme de la maladresse, de l'erreur, du comportement inadapté, et, à la limite, de l'accident.

On peut y voir, selon les cas :

- un appel, une demande d'attention,
- un mécanisme d'auto-punition lié au sentiment de ne pas avoir répondu à ses exigences de responsabilité (ou sentiment de culpabilité),
- un besoin de recherche des limites personnelles par la confrontation avec le danger afin de compenser le sentiment d'ennui ou d'enfermement.

Tchernobyl a été décrit, sur le plan des erreurs humaines, comme une conséquence de l'"incurie", de l'"irresponsabilité" et de l'"indiscipline". C'est une illustration à l'extrême des relations entre les comportements humains et les dysfonctionnements sur les plans de la relation au travail et des relations dans la collectivité de travail, autrement dit, du Management.

LA FORMATION EST LIEU D'EXPRESSION.

Une formation à la sécurité ne s'adresse pas uniquement au savoir comme peut le faire une formation technique ou scientifique en physique ou en chimie. C'est-à-dire qu'elle ne concerne pas uniquement la mémorisation de concepts puisqu'elle se donne pour objectif fondamental d'influer sur les comportements.

La formation doit utiliser la méthode dite active, celle qui adopte une démarche centrée sur les stagiaires, partant de leur situation, de leur point de vue, en développant l'aspect concret de leur existence, permettant leur expression.

C'est cette expression verbale qui doit limiter la nécessité du recours inconscient à l'expression comportementale.

D'autre part, c'est lorsque l'expression, l'échange, sont conduits au sein du groupe de travail que peuvent apparaître des changements dans les systèmes de valeur et comportements désignés par la notion de "culture de groupe" directement liée au domaine du Management.

LE MANAGEMENT ET LA SECURITE VONT DE PAIRE

Expression, mise en relation des personnes entre elles, élaboration collective, dynamique d'évolution, sont des notions qui se rapportent à la fois au domaine de la sécurité et au domaine du management des ressources humaines, du management participatif et de la communication dans l'entreprise.

De même que la sécurité peut être le domaine d'expression comportementale de tous les thèmes relatifs au milieu de travail, elle peut être le domaine d'expression verbale dans lequel les personnes se sentent autorisées à décharger leurs tensions ou, à contrario, dans lequel les personnes peuvent recommencer à entrer en communication.

Bref, la sécurité **est** outil de management. Il n'y a pas de management de la sécurité sans management tout court. Réciproquement, tout management à démarche participative qui veut privilégier l'établissement de communications, c'est-à-dire d'échanges entre les personnes, en se centrant sur la satisfaction de celles-ci, ne peut pas ne pas s'appuyer sur la sécurité en tant que base, assise de la démarche.

Tout est lié : la sécurité n'est pas seulement un "indicateur" de la qualité des autres éléments de la situation

de travail : motivation au travail et climat social. La sécurité est un **outil de management** et un **outil de communication**.

Réciproquement, l'écoute, la formation active, la communication, le management sont fondamentalement des outils de sécurité, des outils de sécurité radiologique en particulier, domaine si privilégié des expressions émotionnelles comme l'ont montré les événements de cette dernière période.

**STANDARDIZED RADIOLOGICAL HAZARD ANALYSIS
FOR A BROAD BASED OPERATIONAL SAFETY PROGRAM**

W. Wadman III¹ and L. Andrews²
Health and Safety Division
Los Alamos National Laboratory (LANL)
Los Alamos, New Mexico

ABSTRACT

The Radiological Hazard Analysis (RHA) Manual provides a methodology and detailed guidance for systematic analysis of radiological hazards over a broad spectrum of program functions, housed in a wide variety of facilities. Radiological programs at LANL include: research and experimentation; routine materials operations; production; non-destructive examination or testing; isotope and machine produced radiations; chemistry; and metallurgy. The RHA permits uniform evaluation of hazard types over a range of several orders of magnitude of hazard severity. The results are used to estimate risk, evaluate types and level of resource allocations, identify deficiencies, and plan corrective actions for safe working environments.

INTRODUCTION

Laboratories within the U.S. Department of Energy are undergoing significant changes in the manner by which they conduct operations. Operational Health Physics groups are not an exception. With budgetary constraints becoming more severe, staffing and resources strained or severely limited, methods had to be devised to provide equal or better service in spite of the hardships. Standardization of the methodology and consistency of evaluating the types and levels of radiological hazards involving several hundred projects in over 150 facilities, spread over 43 square miles, was essential for the operational Health Physics personnel. The Standardized Radiological Hazard Analysis Manual was determined to be one of several practical working tools for Health Physicists in the field. The 300 page manual starts with a detailed index from which an analysis plan is constructed. Once in the field, the use of the manual index provides ready access to guidance, assessment details, and forms for other hazards or issues that were either unexpected or not obvious during the initial assessment. The guidance contained in the manual is detailed, but allows for independent input by each Health physicist that uses it. The training on the use of the RHA Manual emphasizes that the guidance should be used as a tool to direct and focus analysis thought processes, but should not limit the RHA performance to merely a check list task.

Data from the detailed Radiological Hazard Analysis report sheets is subsequently input to a commercially available relational database which is both an analysis tool and the database for each and every facility for which a Radiological Hazard Analysis has been performed.

Blank pages of forms and reports are obtained from stock to replace those used from the binder to be ready for the next facility analysis.

DEVELOPMENT OF THE RHA MANUAL

There are existing methodologies for risk assessments of specific processes, and a few for multi-function facilities. The Nevada Operations Office of the DOE produced the 150 page "Radiological Safety Functional Appraisal and Program Review Guide," in 1990. (Do90) This has direct application to DOE/NVO facilities. It is based upon a radiological environmental program. A method for determining hazard classifications of DOE facilities was developed at Battelle PNL (Lu91). The hazard classification required a walkthrough by an inspection team of persons with considerable expertise in the various disciplines. More than one DOE Operations Office required the technique to be used by operating contractors of DOE facilities, to determine gross hazard classification values for their facilities. These determinations were not sufficiently in-depth to provide the level of detail LANL felt to be necessary for our operational hazard evaluations. The technique also did not provide useful data regarding operational hazards routinely faced by facility operations personnel, or health and safety support personnel.

The concept of the Standardized Radiological Hazard Analysis Manual was originated by one of the authors (LA). With access to a consultant with a broad spectrum of "hands-on" experience in the field of Health Physics, Industrial Hygiene, and Radiological Environmental Monitoring Programs, the project was undertaken.

The manual was conceived as a light-weight, notepad-sized document with outline formatted "reminders" for review while doing field facility walk-throughs. The document is now about 300 single side printed pages, maintained in a three inch thick binder, and requires training in its use to provide familiarity and a reasonable level of surety that it will be used uniformly by the trained staff.

Each type of radiological facility or operation was considered as an independent unit during the drafting of the RHA Manual. Details from observations, physical measurements, radiological measurements, locations of components, and similar pertinent data, are called out in the text of each hazard analysis section. In the initial draft, in both the manual and the software, each hazardous item was separate, as was each mitigation process, and was considered only for that room, building, or process. Subsequently, common items, such as glove boxes, filtrations, detection and alarm systems, were coded in the relational database software. This served to provide more rapid input, reduction in errors, and conservation of RAM and storage required by the computer program.

Hazard levels, risk assessments and hazard mitigating equipment or engineered features are analyzed in the software. All values obtained from the analytical results, relate to hazards present during normal operational circumstances. No attempt has been made to extend the analysis into accident scenarios. With the availability of information regarding radionuclides, inventory on hand, physical and/or chemical form, and details of the

monitoring systems, and ventilation systems, assessing limited accident scenarios remains a possibility.

Each developmental iteration has only expanded the size of the overall program, both software and Manual. Some future consideration may be to purchase the relational database "engine", and write the specific RHA database applications program. Several advantages would be, easier commercial or public domain releases of the software component which could save 50% of the RAM occupied by features that are not used from the standard database product. Time savings could be realized by having direct page access to pertinent input requirements, rather than have to page through irrelevant subject matter to arrive at the appropriate page for the next input.

TYPES OF FACILITIES INCLUDED

The RHA Manual is designed to be used to evaluate radiological hazards associated with the following programmatic elements:

Research and Experimentation: explosion dynamics; armor, anti-armor; criticality; weapons enhancement; controlled thermonuclear reactions; free electron lasers,
Routine Operations: reactor operations; radioactive waste management; weapons production related operations; weapons testing operations; retirement storage operations,
Production: quality control; materials purity; lathe and milling shop operations; purification; enrichment; weapons related activities; medical aspects of LAMPF operations; X-ray crystallography confirmations,
Non-Destructive Examination or Testing: fixed X-Ray radiographic facilities; fixed facility Van de Graaf radiography; high speed x-ray of explosive events; portable radiographic unit safety; eddy current testing of radioactive materials; magnaflux testing of radioactive materials; betatron narrow beam, thick target radiography,
Isotope Produced Radiations: calibrations; sealed source radiography; activated accelerator component radiological protection; heat source radiological protection; incidental weapons component exposure control; weapons debris analysis; reactor fuel processing hot cell operations,
Machine Produced Radiations: Los Alamos Meson Physics Facility; IBF tandem Van de Graaf; single stage Van de Graaf; free electron laser; plasma focus devices; pulsed power conversion; health center x-rays; neutron generator facility; electron guns; ion implantation,
Chemistry: analytical; alloy; quality control; quality assurance; medical isotope purification hot cell operations,
Metallurgy: analytical; developmental; design improvement; stability improvement; yield improvement; induction heating; laser isotope separation,
Transportation: On-site, inter-area, intra-area, for safety and compliance with State and Federal shipping requirements on public roads,
Compliance Assessment: Confirm compliance with Health and Safety

requirements imposed by all applicable State, Federal Agency requirements, laws, DOE Orders.

In the above 10 major areas, each of the 56 categories of operation, project, or facility has its own set of RHA forms. Each analysis must be independent in-so-far that it is not a component of a larger complex. If the latter is the case, the RHA forms are grouped into a facility package. The results of the full analysis of the units as a system will result in a different hazard rating because of the concurrent and dependent mode of operation.

CONCLUSIONS

Present operating facility inspections are performed with a perspective focused on the problem of immediate concern. The use of the RHA Manual will provide consistency for such evaluations. Performing full facility radiological hazards analyses will accomplish several objectives: Advance knowledge of the facility's or operation's hazards; provide a global perspective of concurrent but unrelated hazards of adjacent operations; consistent or uniform approach to evaluations and solutions; applications of "lessons learned"; greater confidence to younger professionals in the Health Physics Groups; a cross-training tool for professionals and technicians not familiar with areas outside of their duty areas; a computerized database with rapid access for rapid retrieval for the line organization, security, fire, and emergency response teams. Two peripheral uses of the RHA Manual may be:

1. The RHA may have use as a formal tool during the drafting of facility Safety Analysis Reports (SAR) and Updated Safety Analysis Reports (USAR).
2. There may be some value in training the facility supervision to use the system, to provide them with the capability to perform more frequent reviews of their facilities than can the limited staff of operational Health Physicists. This is beneficial for the Laboratory through the heightened awareness for radiological hazards in the workplace.

L'OPTIMISATION DE LA RADIOPROTECTION
SUR LE SITE DE MARCOULE

A. CLECH, A. DEVITA, Service de Protection
contre les Rayonnements - Etablissement COGEMA MARCOULE

OPTIMIZATION OF RADIATION PROTECTION
ON THE MARCOULE SITE

This paper presents the mean and methods used to optimise the exposure of workers mainly during maintenance and breakdown operations. The evolution during the ten last past years of the collective and the average annual dose per worker show the efficiency of the method.

I - INTRODUCTION

Le Site de Marcoule regroupe des installations nucléaires à vocations multiples :

- un réacteur à neutrons rapides Phénix,
- un atelier pilote de traitement de combustibles irradiés avec ses laboratoires de recherche,
- une usine de retraitement de combustibles irradiés graphite gaz.

Ces installations sont exploitées soit par le CEA soit par la COGEMA. Pour assumer leur responsabilité en matière de radioprotection, les deux directeurs de ces entités sont assistés par un Service de Protection contre les Rayonnements (SPR) dont les missions sont principalement l'assistance conseil en matière de prévention, le contrôle et la surveillance des nuisances radiologiques dans les installations et l'environnement du Site.

L'expérience montre que la plus grande partie des doses reçues par le personnel est liée aux opérations d'intervention (maintenance préventive ou corrective, intervention d'urgence) qui sont communément appelées "chantiers".

Dans cet exposé nous présentons plus particulièrement les actions que nous avons développées pour optimiser et limiter l'exposition des intervenants.

II - OBJECTIFS VISES

Dans notre démarche d'optimisation et de limitation des expositions nous visons les objectifs suivants :

- Mettre tout en oeuvre pour que l'exposition interne reste toujours la plus faible possible (si possible nulle) et soit donc négligeable devant l'exposition externe.
- En matière d'exposition externe notre objectif est de réduire au maximum l'exposition collective, de limiter l'exposition des personnels les plus exposés (notre valeur guide est de limiter l'exposition individuelle à 15 mSv/an), de limiter le nombre de personnes ayant des doses supérieures à 10 mSv/an et par conséquent d'avoir une dose moyenne individuelle faible.

III - ACTIONS DANS LE DOMAINE DES INTERVENTIONS

Pour atteindre notre objectif, sur les chantiers notre action s'exerce principalement sur:

- la préparation de l'intervention à l'aide de la fiche de travail en milieu radioactif (FTMR),
- le suivi permanent en temps réel des expositions à l'aide d'un dosimètre opérationnel à lecture automatisée associé à une gestion informatisée des doses,

III.1 LA FICHE DE TRAVAIL EN MILIEU RADIOACTIF (FTMR)

Il y a établissement d'une FTMR (Fiche de Travail en Milieu Radioactif) chaque fois que le niveau prévisible d'exposition des agents participant à un chantier est supérieur à un seuil, elle décrit :

- le chantier (avec éventuellement son mode opératoire détaillé d'intervention),
- l'état radiologique de la zone,
- les protections individuelles nécessaires,
- l'exposition provisionnelle (collective et individuelle),
- la liste nominative des intervenants.

III.2 LA DOSIMETRIE OPERATIONNELLE

Cette dosimétrie ne se substitue pas à la dosimétrie légale. Elle est effectuée par des stylos dosimètres utilisables :

- par les opérateurs, leur indiquant continuellement leur dose.
- Par la radioprotection pour piloter les doses individuelles et les coûts radiologiques.

Au niveau local (dans chaque installation) des lecteurs de stylos dosimètres permettent d'associer à un agent la dose intégrée. Au niveau central, un système informatisé calcule et gère les doses des différents lecteurs (Il y a en moyenne 25 000 mesures par mois).

III.3. LE SUIVI OPERATIONNEL DU CHANTIER

Pendant toute la durée du chantier le suivi de l'exposition est effectuée de la manière suivante:

- Sur le lieu même de l'intervention, une feuille permet de recenser les agents et ils doivent y inscrire leur dose journalière.
- Chaque étape de l'intervention est décrite (personnel intervenant, protections individuelles, doses intégrées, renseignements d'ordre radiologique) sur un cahier de zone.
- Chaque jour les agents de radioprotection s'assurent que la dose indiquée sur la feuille du chantier correspond à celle enregistré informatiquement.

- Périodiquement (suivant l'importance du chantier) un bilan est effectué afin de s'assurer que l'objectif (bilan dosimétrique) sera respecté, ce bilan est réalisé à partir des terminaux disposés dans chaque installation et reliés au système central informatisé. On peut consulter les doses d'un individu isolé ou d'un groupe d'individus définis par l'opérateur.

IV - LA GESTION PREVISIONNELLE DES DOSES INDIVIDUELLES LES PLUS ELEVÉES

Dès le dépassement d'un seuil d'intégration (12 mSv/12 mois glissants), un suivi particulier des doses est mis en place. Le responsable de la radioprotection et l'encadrement de l'intervenant établissent une prévision d'intégration stylo mois par mois afin de ne pas dépasser les 15 mSv/an.

Cette prévision se traduit par un examen détaillé des opérations auxquelles peut participer l'intervenant, et, son affectation préférentielle à celles qui présentent le minimum d'exposition potentielle.

V - CONCLUSION

La mise en application de cette méthode de travail a permis de maîtriser et réduire au fil des années l'exposition des personnels malgré le vieillissement des installations qui a nécessité d'effectuer des chantiers importants de rénovation qui sont sources d'exposition.

Sur les figures 1, 2 et 3 sont représentées les évolutions sur 10 ans de l'exposition globale, qui a baissée d'un facteur 2,5, de la dose moyenne annuelle par agent qui a été réduite d'un facteur 3 et le nombre d'agents ayant subi une exposition annuelle supérieure à 10 mSv/an qui est passé de 200 à 10.

Il faut aussi signaler que tous les dossiers d'intervention sont archivés et sont utilisés en retour d'expérience pour la préparation des interventions futures.

Figure 1 : Evolution de la dose totale de l'établissement de Marcoule (HmSv)

Figure 2 : Evolution de la dose moyenne annuelle par agent (mSv)

Figure 3 : Evolution du nombre d'agents ayant une dose annuelle supérieure à 10 mSv

REMOTE OPERATIONS AND ROBOTS IN NUCLEAR POWER PLANTS-OUT LOOK AND REALITIES

JEZEQUEL Patrick - ELECTRICITE DE FRANCE

Résumé : Ce document, tout en rappelant les différents domaines actuels et potentiels d'utilisation des robots, propose une démarche de développement dans ce domaine.

ABSTRACT

This document propose to discover why the robotic discipline has not become an integral part of current maintenance procedure, and shows some areas to be improved and tested. It provides the different topics, where safety on workers and population could be improved by using robots and the means to reach this goal.

INTRODUCTION

Remote operation and robotics techniques were introduced into French nuclear power plants at the most seven years ago, particularly with the pilot repair of internal core structures in the CHINON A3 G.G.C.R. system, christened the I.S.I.S. Since then, E.D.F.'s operational and research sectors have been organized to officially encompass the notion of "robotics" development. However, these sectors remain somewhat on the fringe with respect to the overall development of equipment. The concept proposed i.e. that of robots or remote tools, often provides an alternative to the set, but much more dedicated notion of the "*special machine*". In the case of robots or remote tools, their versatility, both with regards to the tools used and to programming of a given task, offers the definite functional advantage of a large range of potential applications, but poses an organizational problem if they are to become directly operational.

The complexity of the system created also increases the level of training required, with regards to both control and maintenance.

This brings us to the crux of the problem : is the alternative a necessity in the unavoidable terms of technical means, safety and (or) cost ?

I DIFFERENT ASPECTS OF SAFETY

A) Aspects concerning the active population of nuclear power plants

These aspects stem from two basic problems :

- *the reduced accessibility of components :*

this first restriction, imposed by the question of accessibility, induces man to explore ways of remote intervention, which does not necessarily mean remote operation or robotics, since the tools used can be specific to a task and a given component (example : micro- mechanics).

- *dose rates* :

this aspect means that the designer must find a compromise between the development of remote working methods and duplication of the same tasks by an increasing number of personnel. The factors to be considered here are collective dosimetry and individual dosimetry. The solution will be optimized from this point of view by use of the ALARA method. In certain cases, analysis is rapid and remote controlled intervention is necessary (fuel).

The following fields come into play during the lifetime of a power plant :

1) Normal maintenance

This depends on the three complementary notions of productivity, safety and speciality. A typical example is that of steam generators, where control and maintenance (of tubes) are often dissociated, but where there is an increasing harmonization of the means being developed to solve the problems involved. The current aspects of dosimetry inside steam generators has led both operators and manufacturers to study the solution of robots and truly multi-task remote manipulators which have direct access from outside the water bowl. At the same time, safety will necessarily be reinforced by the need to use computer-based tools to memorize the work carried out (where, when, how).

2) Incidents

Incident-related phases are based on the assumption that a stable state of the system will be rapidly achieved. The robotics aspect must always be compared with the human aspects of intervention (rapidity, competence, physical potential). When it comes to the question of "*mobility*", robotics is currently slow to be implemented ; on the other hand, the "*remote operation*" aspect can offer a long term solution. Structures which facilitate logistics and communications (standby and backup facilities, tracks, maintenance networks, etc...) in order to solve the problems of rapidity, accessibility and communication (reduction of wiring times, etc...) could be discussed.

3) Dismantling

Remote operation methods are definitely a potential aid for the implementation of special machines which could work for long hours in a given place (transport aspect) or for direct work on components when the latter require particular skill and a degree of adaptability which cannot be either programmed or modelized beforehand.

B) Workers and the surrounding population - Accidents

The accident related situation covers two aspects :

- the immediate intervention solution which supposes both rapid organization and special means of intervention (aimed at protecting people and providing maximum confinement),
- maintaining and then going back to a specific configuration, which supposes appropriate logistics and on-going work carried out on a long-term basis.

Potential solutions have unfortunately been tested with varying degrees of success at CHERNOBYL and T.M.I.

With regards to intervention which is both internal and external to the reactor building, mobile land and air vehicles of the remote operated type and manipulator arms must be developed on a transborder level and with an exchange potential in mind.

This means, in particular, that it is possible to envisage the creation or reinforcement of structures :

- on a technological transborder level (eg. standardization, telecommunications),
- on a trans "orderer" level (eg. civil safety, armament, nuclear, space),
- on a financial level (industrial consortiums, insurance pools) in order to facilitate the development of appropriate means to separate budget-related aspects concerning normal maintenance from those concerning "risk-related" developments.

II POTENTIAL ACTION

A) Techniques

1) Means of analysis

It is essential that the following computer type analysis tools be developed or adapted to nuclear power plants :

- value analysis,
- simulation C.A.D.,
- definition of specifications and organization (eg. S.A.D.T.),
- analysis/dosimetric reports (eg. DOSIANA - DOSIECO, C.E.P.N. software).

Or of the physical type :

- benchmark and performance tests,
- on-line telediagnosics for maintenance and troubleshooting,
- reliability studies.

2) Improvement of logistics

3) Feedback on the design of new power plants

The integration of robotics can be envisaged :

- with regards to the actual design and construction of power plants, in so far as productivity is concerned (modularity, manufacturing control). This would facilitate the design of machinery to be used during the maintenance and development phases,
- with regards to the integration of standby facilities in proximity to components, thus facilitating maintenance work.

B) Structures and organizations

1) Standardization/training

2) Information networks

3) Consortium for reflection on future development

CONCLUSION

We saw above that many points remain to be studied and defined to quantify the real potential benefit of the robot or remote operation in the nuclear field.

There are two levels to be considered :

- 1) The Designer : Should be solve the problem in termes of a specially dedicated machine, a programmed robot with a certain modularity and versality or from a remote operated approach ?
- 2) The User : What is the best quality service and what motivation is there, given that robots turn operators into simple supervisors whereas remote operation necessitates a specific know-how of normally manual tasks ?

One could also ask, as concerns recent mixed (robot and remote-operated) instrumentation and control modes, if it is fruit of a purely technical nature or express desire to keep man's initiative computerized aid rather than a tailor-made pushbutton approach.

VENTILEX
An Expert System on Nuclear Ventilation

VENTILEX provides a computer help for safety analysis of nuclear plants ventilation systems. It uses knowledge on nuclear ventilation regulation and on the state of the art. Data relative to rooms, process and draft of the ventilation system are taken into account. Conformity of the user's solution with safety and protection principles is checked. Particular points are recognized and memorized when justifications are needed. All conclusions of the system are updated when inputs are modified. Using VENTILEX would facilitate the dialogue between safety analysts and nuclear plants conceptors.

1. Introduction.

La ventilation d'une installation nucléaire a des fonctions de confinement, d'épuration, de surveillance, d'assainissement, de conditionnement et de confort. Les cinq premières sont des fonctions de sûreté qu'un système de ventilation nucléaire doit assurer aussi bien que possible. Le concepteur de l'installation est tenu de présenter successivement aux autorités de sûreté les rapports préliminaire, provisoire puis définitif de sûreté.

1.1. Le rapport préliminaire de sûreté.

Le rapport préliminaire de sûreté rappelle les données relatives au génie civil de l'installation, au procédé industriel ainsi que les objectifs de sûreté. L'installation est considérée comme un ensemble de locaux avec leurs liaisons réciproques. Le terme source de chaque nuisance et les contraintes d'accès en personnel pour l'exploitation, la maintenance et l'intervention sont pris en compte pour chaque local. Les moyens qui seront mis en oeuvre pour atteindre ces objectifs de sûreté sont exposés. Il ne s'agit pas encore d'un schéma précis du système de ventilation, toutefois, l'ordonnement des flux de ventilation et le dimensionnement des circuits sont déjà déterminés. Les points qui devront faire l'objet d'une démonstration par un calcul complémentaire d'aérodynamique sont identifiés.

1.2. Le rapport provisoire de sûreté.

Après acceptation du rapport préliminaire, le concepteur détermine le routage précis des conduits et le choix des composants. Cette tâche peut en partie bénéficier du recours à des programmes de conception assistée par ordinateur.

1.3 Le rapport définitif de sûreté.

Le rapport définitif de sûreté doit démontrer que le système de ventilation réalisé permet bien d'atteindre les objectifs fixés dans les précédents rapports.

1.4. Utilisation de VENTILEX.

VENTILEX est doté de connaissances permanentes sur la réglementation et l'état de l'art en ventilation nucléaire. Ces connaissances sont issues du manuel de référence [Réf. 1] et du jugement d'experts.

L'utilisateur fournit des données disponibles sur l'installation, issues du génie civil et du livre de procédé, devant figurer dans le rapport préliminaire de sûreté. Les solutions, entrées sous la forme d'un schéma de principe, sont évaluées. L'utilisation de VENTILEX va ainsi de la conception du rapport préliminaire de sûreté jusqu'au seuil de l'utilisation des programmes d'aérodynamique et de conception assistée par ordinateur.

2. Description.

VENTILEX utilise deux écrans de travail. Le premier permet la saisie et la vérification des données relatives au génie civil et au procédé. Le second permet la saisie des composants et de la structure du réseau de ventilation ainsi que l'accès aux modes d'évaluation du réseau dans ses diverses configurations.

2.1. Ecran Installation.

Trois écrans présentent côte-à-côte la fiche complète relative au local choisi par l'utilisateur, une fiche de liaison entre ce local et un autre, au choix parmi ceux qui sont en liaison avec lui, ainsi que le résumé de la fiche de ce second local.

La cohérence et la conformité des données relatives à chaque local sont vérifiées dès leur saisie. Cette vérification utilise un système expert d'environ 300 règles. Pour chaque donnée, le système peut accepter sans réserve, accepter avec un simple avertissement (exemple d'un local à accès permanent avec une température maximale en été légèrement supérieure à 25°C), accepter sous réserve de la fourniture de justifications ultérieures (exemple de dépressions relatives a priori trop proches dans deux locaux mitoyens mais qui pourront être justifiées par un calcul) ou refuser la saisie (il est impossible de déclarer une piscine de stockage contenue dans une boîte à gants ou un réacteur dans une infirmerie).

Les liaisons entre locaux sont des trois types suivants : mitoyens, dessus/dessous et intérieur/extérieur. Elles sont déclarées avec la nature de la paroi, ses ouvertures et leur éventuel mode d'obturation.

2.2. Ecran Ventilation.

Cet écran présente le fichier des locaux restreint au résumé des fiches de local ainsi que le fichier des matériels composant le système de ventilation. Il laisse la plus grande surface de l'écran pour la présentation de schémas partiels du circuit, calculés en fonction de

la nature de la vérification demandée par l'utilisateur.

Chaque matériel peut prendre plusieurs états (marche, arrêt ou panne pour un ventilateur; normal, déchiré ou colmaté pour un filtre; etc...). Il est possible de déclarer des asservissements entre matériels (exemple : si le ventilateur V1 est à l'arrêt alors le registre motorisé R1, s'il n'est pas lui-même en panne, sera fermé). L'utilisateur peut choisir entre trois types de configurations : standard (confinement dynamique assuré), panne de tous les ventilateurs (confinement statique) et configurable par l'utilisateur.

Pour chaque configuration, tous les circuits entrant - ou sortant - du local affiché depuis - ou vers - l'extérieur ou un autre local sont recherchés et tracés. Les niveaux d'épuration pour chaque nuisance (aérosols, iode et tritium), le sens des transferts, les risques de rétrodiffusion et les caractéristiques des matériels en fonction de la nature des flux qui les traversent sont vérifiés. Cette vérification porte, une fois les calculs effectués, sur une quarantaine de règles. La reconnaissance de rétrodiffusions possibles demande que les états résultant de pannes des ventilateurs d'extraction soient étudiés.

3. Conclusion.

La maquette de VENTILEX a d'abord été testée sur des exemples d'école, destinés à mettre son jugement en défaut dans des cas de complexité irréaliste (présence d'aérosols, d'iode et de tritium dans des circuits imbriqués). Elle a également été appliquée sur un exemple issu d'un cas réel d'une taille significative.

Le domaine d'application de ce système peut être étendu par la prise en compte des risques voisins : incendie, gaz explosifs et toxiques chimiques.

Il est possible d'effectuer un couplage avec des codes de calcul existants en aéraulique. Dans ce cas, VENTILEX générerait les jeux de données relatifs aux vérifications numériques qu'il demande. De même, un couplage avec les programmes de conception assistée par ordinateur est possible par la génération d'un fichier de contraintes lisible par ces programmes.

La version opérationnelle de VENTILEX devrait être disponible au cours de l'année 1993.

PANTHERE RP : A TOOL FOR PREVISION OF DOSE RATES

BRISSAUD ALAIN RIDOUX PHILIPPE
EDF SEPTEN 12-14 avenue Dutrievoz Villeurbanne 69200

ABSTRACT:

Different tools can be used for the preparation of maintenance. One of them is **PANTHERE RP**: it allows the prediction of dose rates.

RESUME

Différents outils peuvent être utilisés pour la préparation de la maintenance. **PANTHERE RP** est l'un d'eux: il permet de prévoir les débits d'équivalent de dose.

I INTRODUCTION

With the aim to maintain the fair dosimetric results of french nuclear power plants, tools allowing a better preparation of normal and exceptional maintenance are currently developed by EDF. Among these tools, one is "PANTHERE RP" that allows the detailed prediction of dose rates for complex geometries with distributed radioactive sources. These abilities are required to simulate the most frequently encountered situations in NPP.

II COLLECTIVE DOSE (CD)

CD is defined, for a given task, as follow: $CD = DR * WORK VOLUME$
man.Sv SV/unit time MAN.unit time

The simplicity of the formula should not hide the practical difficulties:

- a whole maintenance task is a sum of elementary subtasks,
- a unique DR for a given subtask is indeed a crude approximation,
- feeding sound values of DR and WV is not at all straightforward.

It may be useful to remind that DRs values, job organisation, actions to minimize/optimize DRs should not be considered as independant parameters. To optimize CD, it is of course necessary to minimize both factors DR et WV. Because of the scope of EDF SEPTEN Radiation Protection Group, we have focused on the DR factor.

III PANTHERE RP

The name is an acronym for: " **P**rediction and **T**heoretical **A**nalysis of **E**xposition at **R**eactors for **R**adiation **P**rotection "

The prediction of DRs when a given job will be performed can be obtained by various means: from existing experience (prope or foreign) and from direct measurement. In both cases, one is confronted to the same problem: Dose Rate is a global parameter: you still do not know where it comes from! Anyway, DR measurements cannot be performed in same situations. For example, you cannot measure the dose rate in the axis of a primary pipe before you have cut it

It appears that the best solution is to simulate the dose rate via calculations: this is precisely the aim of PANTHERE RP.

3-1 where does PANTHERE RP come from ?

Softwares to calculate the DR have been developed and used by EDF during the design

stage of nuclear units .

The shifting to the utilization for maintenance (preparation of jobs) has actually begun with the steam replacement at DAMPIERRE 1 .The importance of DR prevision in the overall process of doses prediction has led to further developpments of existing softwares .The resulting product is a linkage between numerous softwares , and has been named PANTHERE RP V0

PANTHERE RP V0 allows :

- to perform DR mapping for complex lay out ,(figures 1)
- to give , for any point where DR is calculated , the contribution of the various parts of the installation ,
- to precise the influence of source composition (isotopes/evolution with time).

3-2 PANTHERE RP AT WORK

PANTHERE RP allows the calculation of DR , starting from a 3 dimensional re-presentation of the geometry and the knowledge of radioactive sources .This repre-sentation is more or less easily obtained wether you can extract it of a computerized mockup or not . In this last case , appropriate softwares of PANTHERE RP help the user to build up the geometry from charts : this construction is interactive .

The computering process can then be performed This step does not need an important participation of the user .The underlying idea has been that the user was not interested in the details of the calculation process ,but rather by the results !

These can be represented in different ways :tables (figure2),graphs ,graphic display .

The description of figure 2 shows the interest of DR calculation :

The geometry is organized in "lines" , each line is composed of elementary "sections": The lines are here hot leg (BC) , cross over leg (BU) and so on ..the total dose rate is split in participation from the lines (absolute and relative in per cent of total DR) .For each line we can see the relative participation of the most important sections (>0%) and the participation of the main isotopes (here the CO58 et the sum of CO58 and CO60 ("Co")).

With the diversity of the results representations ,one has ready at hand the right indications to propose protection actions such as :partial or total decontamination,suppression of this or that portion of pipe at the beginning of the job rather that at a later date ,additional shielding .

The effect of any of these proposed dispositions can be verified by calculation :this is achieved in the simplest manner ,i.e going back to the geometry input and modifying it consequently .

3-3 validation-qualification

A comparison of measured and calculated DR has been performed by the mean of special surveys, for example at DAMPIERRE 1 and FESSENHEIM 1.It has been shown that a good agreement was obtained .

In both cases , the sources were monitored directly by gamma spectrometry with the EMECC system: a good knowledge of sources is very important to perform a good prediction .

But in addition of gamma spectrometry ,PANTHERE RP allows the use of DR measurements : different hypothesis can be easily tested to simulate the repartition and strength of sources .

IV PERSPECTIVE NEXT FUTURE

PANTHERE RP is a powerful tool that allows to cope with a large span of problems . This software is implemented on the EDF computer network so that the multiple shuffling informations (data base results ..) is not a problem .

We work to create a **PANTHERE RP version V1** for which the specifications are :

- equal or enhance PANTHERE RP V0 capacities ,
- be more user friendly
- available on work stations (and if possible a micro-computer)
- use near worksites .

V OTHERS TOOLS CONNECTED WITH PANTHERE RP

We can distinguish the tools above et below PANTHERE RP .

TOOLS UPSTREAM PANTHERE RP

It are used for the knowledge of sources .

We can cite :

- **FACTOLE** computer code (CEA/SCOS) for the prediction of corrosion products contamination (water and deposit) for the PWR's reactors ,
- **PROFIP** computer code (CEA/SCOS) for the transport of fission products from nuclear fuel ,
- **TRIPOLI** computer code (CEA/SERMA) for the prediction of the transport of gamma or neutrons ,
- **EMECC** (CEA/SCOS) a portable spectrogammameter for the measurements of the volumic or surface contamination for corrosion and fission products : it will be connected with diagnosis softwares for analysis of hot spots or on line survey of fuel cladding .
- **DATA BASE** on the EDF network ,as TIGRE RP from EDF, to manage and analyze the observations on reactors .

TOOLS DOWNSTREAM PANTHERE RP

They are performed to the prediction of individual or collective doses . We can cite the **DOSIANA** code from CEPN/EDF/FRAMATOME , which uses measurements or calculated (with PANTHERE or other code) dose rates .

VI CONCLUSION

PANTHERE RP allows the calculation of the dose rates We hope that it will be used ,in the future, near the worksites of maintenance to be included entirely in the largest process of the prediction of collective doses .

ON THE SURVEY AND EVALUATION OF RESEARCH SUPPORTED BY THE
SWEDISH RADIATION PROTECTION INSTITUTE

Lars Persson and Leif Moberg

Swedish Radiation Protection Institute
Box 60204, S-10401 Stockholm, Sweden

ABSTRACT

The Swedish Radiation Protection Institute supports research and development (R&D) in the field of radiation protection. A review of the research programme is now being performed. An evaluation of the programme based on this review is then planned to take place. Different methods exist for the evaluation of research and development. The method presently discussed to be used for the evaluation of the Swedish research programme can be described as primarily a judgement of its relevance for the users.

INTRODUCTION

The Swedish Government has supported research and development (R&D) in the field of radiation protection as a part of its atomic research programme since 1945, channelled through the Atomic Research Council. Since July 1st, 1976 the scope of this research has been broadened and the Swedish Radiation Protection Institute (SSI) has become responsible for coordinating the radiation protection research in Sweden. An important objective of the research programme is to produce information that can assist the Institute in making decisions regulating the radiation protection in the country. At the same time support is also given to research of a more fundamental nature. The programme is also complementary and supports the research performed at the Institute. An Advisory Research Board appointed by the Government assists the Institute in establishing the yearly revised research programme and in allocation of grants to the individual research projects.

The research projects are carried out under contracts with SSI. The research is performed mainly at Swedish universities and in disciplines like physics, chemistry, radiophysics, radiobiology and medicine. It is to some extent also performed at different national laboratories and by consultants. Some of the research projects are carried out in cooperation with the equivalent authorities in the other Nordic countries. The international contacts are increasing.

The R&D budget has increased year by year and amounts to 16.6 MSEK (2.7 MUS\$) during the fiscal year 1991/92 of which 9.5 MSEK (1.6 MUS\$) was for radiation protection research connected with nuclear energy and 7.1 MSEK (1.1 MUS\$) was for other research (non-nuclear), including a cooperation with the Radiation Protection Research Programme of the European Communities.

THE RESEARCH AND DEVELOPMENT PROGRAMME

The research programme is divided into two main areas, nuclear energy and other radiation protection research. The first one is divided into projects dealing with radioecology and environmental transfer, radioactive waste and accidents in nuclear power stations. The second main area concerns sources of ionizing radiation in medicine, industry, homes, and research, and sources of non-ionizing radiation.

Nuclear Energy

Radioecology, which is presently the most important research field, involves the behaviour of radionuclides in the biosphere, especially the environmental transfer and bioaccumulation in aquatic and terrestrial ecosystems. The research is based on experimental work in the laboratory and in situ, and on theoretical studies, mainly modelling. A vital question is - how well do the models describe the real world? This has been studied in an international exercise called the Biomovs (BIOSpheric MODEL Validation Study). Phase 2 of Biomovs was initiated in October 1991. As a consequence of the wide spread of radioactive elements in Sweden from the Chernobyl accident a large number of radioecological studies have been performed (ref 1).

In Sweden, as well as internationally, large resources are allocated to research on the management of radioactive waste. Problems of special interest from a radiation protection point of view are questions concerning waste characterization, waste properties and treatment, decontamination, declassification of scrap material, transport, decommissioning and waste storage. Repositories for high level waste and spent nuclear fuel constitute specific problems due to the large time periods involved, which raises questions also of ethical and social nature. Current interests are, for example, understanding various aspects of the decommissioning of commercial nuclear power plants and developing criteria for high level waste repositories.

The research on accidents in nuclear reactors are concentrated on consequence analysis, countermeasures, dose calculations and health effects. There exists a constant development takes place of computer codes and data bases for the evaluation of possible nuclear emergencies.

Non-nuclear research

The research in this field is divided into two main areas: ionizing radiation and non-ionizing radiation.

About 15% of the average dose of ionizing radiation to a person living in Sweden is due to the medical use of radiation, while the radiation from radon and radon daughters in homes contributes 65%.

The present research includes, for example, studies of radiation doses and the quality of diagnostic radiography,

optimisation of the diagnostic procedure, studies of the doses to the patients and cost-benefit analysis, studies of the consequences of new techniques on the radiation protection, studies of optimisation in therapy, a large scale epidemiological study on the lung cancer risk due to radon in houses.

The research on non-ionizing radiation includes mainly studies of radiation in the radiofrequency region and ultraviolet radiation. The research area is relatively new and the possible health effects on living organisms are only partly known.

Besides the research fields which have been briefly described above, research is also performed on risks (analysis, perception, assessment), epidemiology and dosimetry.

A review of the research programme since 1976 is now being performed by one of the authors (L P). All the project reports are looked through and for each project a brief summary is written. The summaries are included in a report to be published in the report series of the Institute.

METHODS FOR EVALUATION OF RESEARCH PROGRAMMES

Scientific evaluation has long been a standard practice. Proposed articles in scientific publications have been reviewed by scientific editors. A so-called peer review has taken place as a normal step before publication. The importance of research for the national productivity and economic growth has led the governments and authorities to implement research programmes and then also to rationalize the spending for research programmes in an optimal way for the country. As a result of this trend towards increased accountability of public spending, evaluation of research programmes has become an issue of importance. It is not only seen as a tool for efficient management of research but also as a help to decision-makers for the future.

There exists several methods today to evaluate research programmes. The following methods have been used for evaluations:

1. Peer reviews,
2. Judgement of the relevance for the users,
3. A cost-benefit analysis,
4. Bibliometric indicators of the scientific value, and
5. Patents as indicators of the utility.

The Commission's of the European Communities evaluation of its Radiation Protection Research Programme may be mentioned (ref 2) as an example of recent work in the field. The impact of the Research Programme on world-wide radiation protection and on human society, as well as the impact on the Commission's own regulatory and economic activities, were also reviewed. The scientific evaluation was carried out by a panel of independent scientists. The efficiency of the management and the socio-economic impact of the programme were evaluated on the basis of

discussions with managers of contracting institutions, with the present and past managers of the programme and the Commission staff. This evaluation was supplemented by the results of a questionnaire sent to all contractors. The method used may be described as a combination of methods one and two.

PREVIOUS EVALUATIONS OF RADIATION PROTECTION RESEARCH PROGRAMMES

The Swedish Natural Science Research Council decided in 1978 to evaluate the fields of radiobiology and radioecology. A peer review was carried out using a mixed Swedish-international scientific panel. Material from the research contract holders was collected and then the members of the evaluation committee performed project site visits. A final meeting was held to discuss all the projects.

The main conclusion by the evaluation panel indicated that some projects might have a considerable importance for applied studies of the environment although the importance for basic research was limited. The development of new technology for survey of environmental hazards should primarily be the responsibility of the authorities, which are concerned with surveillance and monitoring of the environment. The panel proposed negotiations be undertaken to transfer some of the projects to these authorities. The conclusions of the scientific panel have in its main lines been implemented by the Natural Research Council and the Institute.

SURVEY AND EVALUATION OF THE RESEARCH AND DEVELOPMENT PROGRAMME

The decision was recently taken to investigate the possibilities for an evaluation of the Swedish Radiation Protection Institute's radiation protection research and development programme with a judgement of its value primarily for the users. The evaluation procedure planned may, for example, involve the use of the expertise of the decision-makers of the Institute, the users of the R&D inside the Institute, and the Advisory Research Board of the Institute. The credibility of the process will in this way be guaranteed and the utilization of the results and decision-making in the future will benefit from this procedure. The evaluation paper work is carried out by the staff of Research Secretariat of the Institute as a part of its normal duties and it thus also means a building-up of competence in the field. The work to carry through the survey and evaluation of the research programme is still in progress.

DOSIANA has been developed by CEPN for Electricité De France and FRAMATOME, as an ALARA tool, in order to handle operational doses and to integrate radiation protection and management objectives. It allows to calculate potential collective exposure and to assess the impact of various radiation protection actions. DOSIANA is a standardised tool for any nuclear installation or operation. DOSIANA, is nowadays in use at EDF, FRAMATOME and other european nuclear firms. In particular it has been very helpful for the preparation, follow-up and past experience analysis of the steam generator replacement that took place at Dampierre 1 in 1990.

DOSIANA : LOGICIEL POUR LA PREVISION ET L'ANALYSE DE LA DOSIMETRIE OPERATIONNELLE DANS LES INSTALLATIONS NUCLEAIRES

DOSIANA a été développé par le CEPN pour le compte d'EDF et de FRAMATOME, en tant qu'outil d'une politique ALARA, pour mieux maîtriser la dosimétrie opérationnelle. Il permet d'évaluer "a priori" les doses collectives et l'impact de multiples actions de radioprotection. DOSIANA est un outil standard qui peut s'appliquer à n'importe quel type d'installation nucléaire ou de chantier. DOSIANA est actuellement en cours de diffusion à EDF, à FRAMATOME et dans diverses installations nucléaires européennes. Il a, en particulier, servi de support pour la préparation, le suivi et l'analyse de retour d'expérience du chantier de remplacement de générateurs de vapeur de Dampierre 1 en 1990.

INTRODUCTION

L'analyse de l'historique d'opérations de maintenance répétitives sur le parc REP français, a mis en évidence que la dosimétrie des premières opérations aurait pu être réduite significativement si la radioprotection avait joué un rôle plus important dans les différentes phases de ces opérations [1]. Au vu de ces constatations EDF et FRAMATOME ont demandé, en 1987, au Centre d'Etudes sur l'Evaluation de la Protection dans le domaine Nucléaire (CEPN) de développer un logiciel pour assister, dans le domaine de la radioprotection, les responsables d'intervention au niveau de la préparation, et de la réalisation des chantiers en centrales nucléaires.

1 Principes de Base

Le développement de cet outil informatique a été réalisé afin de satisfaire aux objectifs suivants :

- intégrer la radioprotection dans la préparation, le suivi, et l'analyse de retour d'expérience des opérations.
- réaliser une gestion analytique fine de la dosimétrie opérationnelle;
- évaluer les actions de radioprotection au niveau de l'exploitation,

de la maintenance et du démantèlement des installations;
- faciliter la mise en commun des expertises et les interactions entre exploitants, intervenants et .. la radioprotection

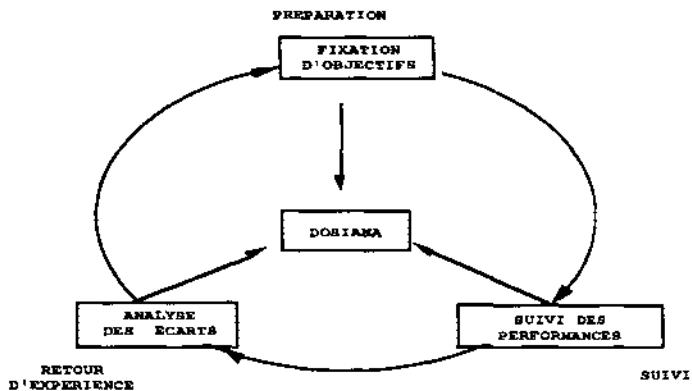

De tels objectifs sont cohérents avec l'application du principe ALARA, qui implique une gestion " a priori " de la dosimétrie collective, en complément du contrôle traditionnel " a posteriori " des doses individuelles. Concrètement il s'agissait de combiner ce qu'il est convenu d'appeler " le cycle du contrôle de gestion " avec les phases d'une opération en vue de proposer un outil de dosimétrie analytique.

1.1 Le cycle du contrôle de gestion.

Quel que soit son domaine d'application, un système de contrôle de gestion doit permettre:

- d'établir des objectifs
- de mesurer des performances
- de comparer performances et objectifs
- d'analyser les causes d'écart
- de proposer et de suivre des actions correctrices

Un tel système est récurrent par définition puisque la dernière phase conduit à fixer de nouveaux objectifs pour l'étape (chantier, année...) suivante. Le logiciel DOSIANA n'est autre qu'un outil pour appliquer un tel système au domaine de la radioprotection.

Pendant la phase de **Préparation** (d'un chantier, d'une année...), la quantification prévisionnelle de divers scénarios de réalisation du travail doit aboutir à la fixation d'objectifs dosimétriques. Pendant la phase de **Réalisation**, les performances réelles doivent être systématiquement mesurées et comparées aux prévisions. En cas d'écarts significatifs des actions correctrices peuvent être définies, quantifiées et mise en œuvre. Pendant la Phase de **Retour d'expérience**, l'analyse fine de l'information recueillie permet de proposer des améliorations pour les opérations à venir.

1.2 La Dosimétrie Analytique

Sans une bonne connaissance des débits de dose ambiants, de la durée des tâches, et des conditions de travail, il est très difficile d'interpréter

l'évolution des doses, d'une opération à la suivante ou d'une année sur l'autre; et il est même pratiquement impossible d'identifier les paramètres sur lesquels il est possible d'agir en vue d'améliorer la situation. Dans ces conditions le logiciel DOSIANA a été défini en tenant compte de ces données fondamentales (débits, durées d'exposition...). Pour différencier un tel système de ceux qui se focalisent sur le contrôle des doses individuelles, l'appellation de **DOSImétrie ANALYtique** a été retenue par analogie avec le système de comptabilité où l'on distingue comptabilité générale et comptabilité analytique; la première aboutissant à des bilans et résultats globaux et la seconde permettant d'expliquer la genèse de ces résultats.

2 Le Logiciel DOSIANA

DOSIANA est un logiciel qui fonctionne sur micro ordinateur, éventuellement portable, et utilise un Système de Gestion et d'Analyse de Bases de Données Relationnelles (EXADATA). Il s'agit d'un logiciel interactif et convivial, dont l'utilisation ne requiert pas de connaissances informatiques préalables.

2.1 Structure et Résultats

DOSIANA permet de **créer des bases** de données intégrant tous les paramètres nécessaires à la description et à l'analyse d'une opération du point de vue dosimétrique. Chaque opération y est divisée en phases, sous phases opératoires,..... le niveau le plus fin correspond à des tâches élémentaires dont le découpage apparaît pertinent au regard de l'exposition des opérateurs. Chaque tâche élémentaire est caractérisée par un débit de dose ambiant moyen, et un nombre d'opérateurs. Chaque opérateur participant à une tâche est décrit par l'entreprise à laquelle il appartient, sa spécialité, sa tenue, et son temps d'exposition.

Le logiciel **calcule la dose collective et le volume de travail exposé ainsi que le nombre minimum d'opérateurs satisfaisant les "contraintes" dosimétriques retenues pour l'opération**. Ces résultats sont disponibles pour le chantier dans son ensemble ou éclatés en fonction de critères divers tels que les phases opératoires, les spécialités des opérateurs, les entreprises intervenantes.....

Les fonctionnalités du Système de Gestion et d'Analyse de Bases de Données permettent de générer des scénarios différents de la référence initiale. L'utilisateur de DOSIANA peut alors aisément **évaluer l'impact de multiples actions de radioprotection sur les doses et les temps d'exposition**. Les résultats issus de DOSIANA, en termes d'efficacité des actions envisagées pour réduire l'exposition, sont directement utilisables pour les études ALARA.

2.2 Fonctionnalités

Le logiciel est conçu pour permettre :

- à **plusieurs équipes** de fusionner leur travail dans une base commune;
- de communiquer l'intégralité d'une base à un autre utilisateur, qui peut ensuite l'adapter à l'environnement propre à son installation; ce qui est particulièrement intéressant pour les exploitants disposant de plusieurs installations similaires ;

- de traiter les données et les résultats avec d'autres traitements de texte, tableurs ou logiciels graphiques.

L'utilisateur peut choisir et créer sa propre structure d'édition de données et de résultats:

- tableaux croisés (ex: dose collective pour une opération par phase et spécialité d'opérateurs)
- tableaux d'écart (ex: gains en volume de travail exposé par spécialité et condition de travail après mise en œuvre d'une option de radioprotection)
- tableaux intégrant données, résultats, et opérations algébriques sur ces données et résultats (ex: calcul des débits moyens par phase, ou des doses individuelles moyennes par tâche élémentaire.....)

DOSIANA permet d'effectuer des sorties graphiques, des analyses statistiques simples sur données ou résultats (moyennes, écarts types, régressions simples), de sélectionner tout ou partie d'une base de données et de fusionner plusieurs modalités d'une variable lors d'une édition.

2.3 Applications

DOSIANA est tout à fait adapté à la gestion de bases de données importantes correspondant à des opérations majeures ; le logiciel a été utilisé pour :

- la préparation, le suivi et l'analyse du retour d'expérience du remplacement de générateurs de vapeur de Dampierre 1 (France) en 1990 par EDF et FRAMATOME ; DOSIANA a été particulièrement utile pour éclairer les décisions en matière de décontamination, mouvements d'eau dans les circuits...; pour mettre en place des entraînements spécifiques et ajuster le nombre d'opérateurs aux doses collectives prévues [2].
- la préparation, le suivi et l'analyse du retour d'expérience du démantèlement du réacteur BR3 à MOL en Belgique ; 1990/1991.

DOSIANA est tout aussi utile pour la préparation d'opération spécifiques de moindre importance: - comparaison de différents procédés de soudures des tuyauteries primaires; 1990 (FRAMATOME); - travaux sur l'échangeur-régénérateur du contrôle chimique et volumétrique ; 1991 (FRAMATOME)

DOSIANA commence aussi à être utilisé par EDF pour évaluer l'impact de la robotisation de diverses opérations de maintenance.

Ces premières applications ont démontré que DOSIANA pouvait être utilisé après une formation très courte et qu'il est suffisamment flexible pour être appliqué à des opérations de taille et de complexité très différentes.

DOSIANA sera prochainement doté d'un module spécifique de suivi des opérations et complété par un module d'analyse économique.

BEHAVIOUR OF RADIOCESIUM IN FOREST ECOSYSTEM CONTAMINATED DURING A NUCLEAR ACCIDENT.

Vegetation and soils sampling were realized in 2 forest zones near the accidented power plant of Chernobyl. The ^{137}Cs distribution in a red pine stand is established; many specific measures of wood complete the study. Results discussion point out the difficulties to manage the contaminated forest area without a good knowledge of the radioelement biochemical cycle.

INTRODUCTION

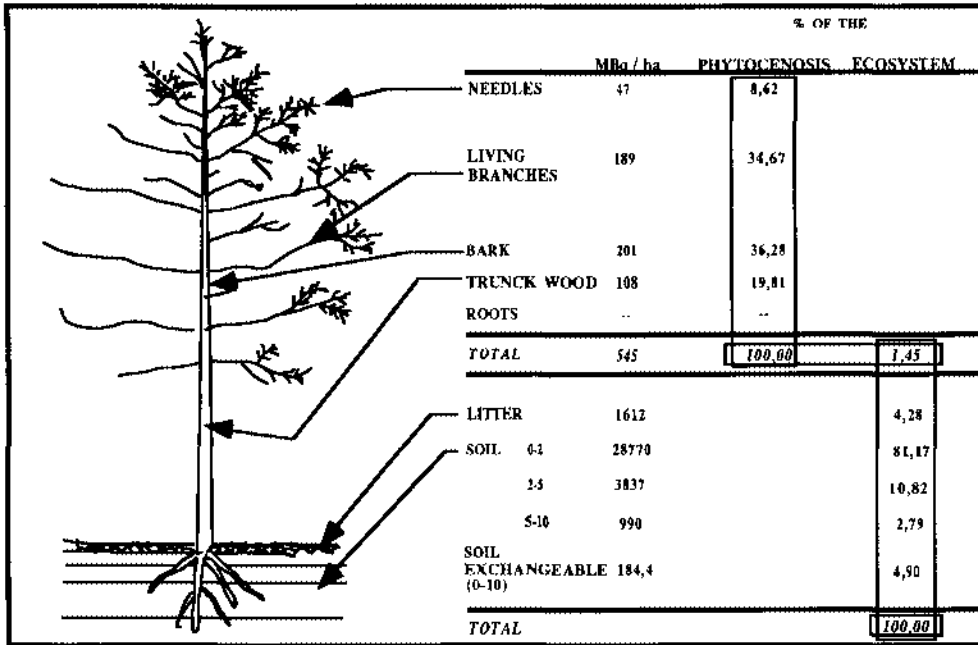

En Europe de l'ouest, comme en URSS, l'efficacité du couvert forestier à piéger la radioactivité a mis en évidence le rôle important et complexe que peuvent jouer les forêts en cas de retombées radioactives. Dès après l'accident de Tchernobyl, les arbres (détruits par irradiations directe et indirecte) de la forêt rouge ont été enterrés sans tenir compte de l'avis des radioécologistes soviétiques. Les effets négatifs qui sont actuellement observés illustrent le manque de concertation entre responsables des contre-mesures (Tikhomirov et al., 1991(1)). Particulièrement en zones naturelles, les décisions prises par les agents de la radioprotection responsables des opérations d'assainissement dans les régions contaminées, doivent se baser sur l'étude radioécologique (multidisciplinaire) du comportement de la radioactivité interceptée. L'aménagement de surfaces forestières contaminées requiert donc une très bonne compréhension du cycle des radioéléments entre les divers compartiments qui constituent l'écosystème "forêt".

L'objectif de cet exposé est de présenter la distribution du radiocésium entre les compartiments primordiaux d'un peuplement de pin sylvestre près de Tchernobyl, celle-ci résultant de l'évolution du cycle du radiocésium depuis l'accident (4 ans). Différents enseignements peuvent être tirés du point de vue de la restauration sanitaire des sites forestiers.

RESULTATS ET DISCUSSION

Après interception par la canopée (80-90 % du dépôt), certains radioéléments dont le radiocésium sont susceptibles d'être incorporés rapidement au cycle biologique naturel suite à son absorption au niveau du feuillage. En même temps, le ruissellement des précipitations sur le houppier contribue à l'accumulation d'une grande partie de l'activité à la surface du sol. Tikhomirov et al. (1991)(1) ont évalué respectivement à 1 et 6-8 mois les demi-vies du phénomène de lessivage de la radioactivité interceptée par les arbres dans les zones contaminées de Tchernobyl et de Kyshtym. L'"autoépuration" naturelle du couvert forestier est maintenant achevée dans le cadre de la contamination accidentelle de Tchernobyl. La figure 1 présente l'état de contamination actuelle d'un peuplement de pin sylvestre (30 ans) à Bourakovka (zone forestière à 15 km à l'ouest de Tchernobyl). Si on fait abstraction du poste "écorce" sur laquelle les dépôts radioactifs résiduels peuvent expliquer la contamination élevée, il apparaît que les organes pérennes: branches et bois du tronc, peuvent stocker à court terme une part non négligeable du radiocésium incorporé dans la phytocénose (Thiry et al., 1996).

Figure 1

Le sol contient de loin la majorité du radiocésium déposé; la migration est peu efficace puisque plus de 80% de l'activité est toujours localisée dans les couches organiques de surface (0-2 cm). En plus d'un blocage physique de la migration des particules radioactives, des processus physico-chimiques de fixation interagissent à ce niveau. En effet, des phénomènes spéciaux de rétention du Cs ont été mis en évidence spécialement dans les couches du sol où matières organiques et minérales sont intimement confondues. L'affinité pour le Cs des complexes argilo-humiques semble plus élevée que celle déjà connue des particules minérales du sol (Thiry et al., 1991).

Fig.2: Distribution des teneurs en ^{137}Cs dans les organes de pin sylvestre.

Malgré l'efficacité de la rétention du Cs, 5% ($1844 \cdot 10^6$ Bq/ha) du Cs contenu dans l'écosystème sont échangeables dans le substrat. Cette observation montre qu'il persiste un risque de contamination croissante de

la végétation. La Fig. 2 met en évidence l'augmentation des teneurs en ^{137}Cs dans les aiguilles et rameaux (pin sylvestre) formés après 1986 (prélèvements effectués à Novo-Shepolichi, zone forestière à 5 km de la centrale accidentée). De simples mécanismes de retranslocation acropétale n'expliquent pas à eux seuls la contamination croissante. En effet, à la fig. 3 sont présentées les teneurs en ^{137}Cs dans les rameaux d'un jeune plant de pin sylvestre (prélevé à Bourakovka) qui s'est développé après l'accident. La stabilité, voire l'augmentation du niveau des concentrations en Cs montre qu'il existe un phénomène efficient d'absorption racinaire (micorhizes?). Celui-ci correspond à un facteur de transfert maximum vers les rameaux de $8 \cdot 10^{-3}$ (Bq/g.M.S./ Bq/g.sol sec) à partir du substrat 0 (0-2cm). En outre, l'écorce semble concentrer le Cs; malgré sa faible biomasse, plus de 50% de l'activité des rameaux y est localisée.

Fig.3: Teneurs en ^{137}Cs dans les rameaux de pin sylvestre.

En ce qui concerne la distribution du radiocésium dans les cernes annuels du tronc (pin sylvestre(35 ans) échantillonné à Bourakovka), la Fig. 4 montre que le bois est contaminé globalement de façon homogène, l'aubier étant légèrement plus contaminé que le duramen (2 fois plus). Les cernes formés après 1986 présentent cependant des teneurs supérieures en ^{137}Cs . La teneur élevée du cerne à peine élaboré de printemps 90 témoigne de l'intensité des mouvements du radiocésium au niveau des tissus jeunes (cambium). Si l'activité du bois formé se maintient à un niveau moyen de $8,98 \text{ Bq/cm}^3$, on peut raisonnablement évaluer que dans les conditions étudiées ($0,39 \text{ Ci/ha}$), la contamination de ce type de peuplement augmentera au minimum de $45 \cdot 10^6 \text{ Bq/ha.an}$ de Cs incorporé dans la masse nouvellement formée du tronc (production de $5 \text{ m}^3/\text{ha.an}$). Si on se réfère aux niveaux permis en ^{137}Cs estimés par Thikomirov et al. (1991(2)) pour l'utilisation de bois contaminé, le bois qui serait produit par ce peuplement ne pourrait même pas être utilisé à des fins industrielles (même décortiqué), ni servir à la construction et encore moins comme source de combustible (respectivement 1.1, 1.1 et 5.5 fois trop contaminé).

Fig.4: Evolution de l'activité en ^{137}Cs dans le tronc de pin sylvestre.

CONCLUSIONS

Le comportement du radicésium en forêt est complexe. La mobilité qui caractérise la redistribution du Cs au niveau de la végétation contraste avec les mécanismes de rétention qui agissent à la surface du sol. Le substrat représente indubitablement le pool primordial de Cs dans l'écosystème forestier. L'incidence d'une modification de la stabilité physico-chimique des couches organiques (par coupe à blanc, éclaircie, enlèvement de litière..) est prioritaire dans l'étude du risque à long terme d'une contamination des compartiments annexes (végétation, nappe phréatique,...).

La variabilité des facteurs écologiques (type de sol, d'humus, d'essence) et économiques (forêt de production, de protection, de récréation,...) conditionne le choix des contre-mesures à adopter.

Dans ce contexte, les opérations d'assainissement nécessitent pour chaque site la connaissance de la distribution des radionucléides et des mécanismes qui influencent leurs mouvements. A ce propos, des opérations d'abattage massif ou de travail de sol doivent être envisagées avec prudence. De plus, ce type d'opération est justifiée dans certaines conditions écologiques très locales mais est économiquement peu applicable sur de grandes surfaces (Mishenkov et al., 1991). L'exploitation du bois en territoire contaminé doit également tenir compte des possibilités d'accumulation de la radioactivité avec le temps et du rôle que joue l'écorce dans ce phénomène.

ABSTRACT

The importance of the limnological character of lakes on the transport processes of longlived radionuclides from the Chernobyl fallout (Cs-134, Cs-137, Ru-106, Sb-125) is exemplified at Lake Constance, a large hardwater lake, and Schreckensee and Vorsee from the same prealpine region, which are small lakes with high organic loads. For Cs radionuclides in Lake Constance adsorption at clay particles is the dominating process, whereas in the other lakes the interaction with organic substances plays an important role with respect to their ecological behaviour.

INTRODUCTION

As a consequence of the Chernobyl accident radionuclides become introduced into freshwater lakes in Europe at a well-defined date, which then participated in the ecological transport processes according to their respective speciation /1/. Of particular interest are long-lived radionuclides like Cs-137 or Sr-90, which are speciated in cationic form, and Ru-106 and Sb-125, which are anionically speciated in freshwater /2/, since they participate in seasonal cycles in lakes. This contribution is mainly focussed on Cs radionuclides and emphasizes the importance of the ecological structure of lakes for self-cleaning processes in the waterbody and the transfer into aquatic food chains. Examples are presented for different types of lakes represented by Lake Constance (Bodensee) as a deep hardwater lake, which is an important drinking water reservoir, and Schreckensee and Vorsee from the same prealpine region as small lakes with high organic load. Implications with respect to Kiev reservoir are discussed.

RESULTS AND DISCUSSION

In Lake Constance radionuclides from the Chernobyl fallout were introduced in the time interval between the establishment of summer stratification (mid-April) and the calcite precipitation event induced by the spring algae bloom (mid-May, see fig. 1). The input occurred mainly across the water surface during rainfalls and the contribution from tributaries was only minor /3/. Therefore the dissolved radionuclides were initially restricted to the epilimnion. There Cs radionuclides became adsorbed at suspended clay mineral particles, which subsequently, during the calcite precipitation event, acted as nucleation sites for the growth of calcite crystals resulting in a considerable increase in their sinking velocity /4/. This caused an effective cleaning of the epilimnion and a rapid

Fig. 1: Transport processes of dissolved radionuclides from the Chernobyl fallout in Lake Constance.

transport to the sediment and explains (i) the peak in the vertical radiocesium flux in settling particles during calcite precipitation /5/, (ii) the minimum of dissolved radionuclides in the epilimnion observed at the end of the stratification periods in 1986 and 1987 /1,6/ and (iii) the formation of a sharp horizon of Cs radionuclides from the Chernobyl fallout in the bottom sediment, which is well separated from the Cs-137 input originating from the nuclear weapons testing fallout (fig. 2). This removal process could be reconstructed quantitatively within an epilimnetic scavenging model /4/. Since Cs radionuclides became incorporated into clay mineral particles at internal binding sites, their resolvability from sediment is very small: Not more than 10% of the Chernobyl-related Cs-137 inventory of a representative sediment sample could be brought back into solution in a five-step selective extraction procedure leaving only clay, quartz and feldspars as solid residues (fig. 3).

Fig. 2: Depth distribution of Cs-134 and Cs-137 in bottom sediments from Lake Constance sampled in 1991.

Ru-106 and Sb-125 were also transported to the sediment mainly during calcite precipitation in May 1986 and the removal efficiency for these radionuclides was even higher than for Cs /5/. From model calculations, however, particulate organic matter turned out to be the reactive phase in the adsorption process prior to precipitation /4/, which corresponds to the anionic speciation of these radionuclides. Accordingly, by treating sediment samples with respect to the extraction of organically bound anions, about 30% of these radionuclides could be brought back into solution.

Fig. 3: Residual fractions of Cs-137 radionuclides in sediments from Lake Constance (Bodensee) and Schreckensee after Cs ion exchange (1), dissolution of carbonates (2), organic matter (3), Fe- and Mn-hydroxides (4) and amorphous silicates (5).

These processes have important implications with respect to food chain transfer of Cs radionuclides from the Chernobyl fallout: (i)

The rapid and efficient removal of dissolved Cs radionuclides restricted drinking water contaminations to very low levels (below 1 Bq/m³ Cs-137 in 1991 /7/); (ii) the danger of redissolution of Cs radionuclides from sediments is very low; (iii) the initial accumulation of dissolved Cs radionuclides in the euphotic zone and their early removal explains the time dependence of the observed specific Cs-137 activity of planctivorous fish (whitefish). A rather steep increase in spring 1986 was followed by a rapid and continuous decrease with an effective half-time of about 4 months (fig. 5). As a consequence the transfer of Cs-137 radionuclides in the trophic chain remained limited and the contamination of carnivore fish (pike and eel) never exceeded the initial contamination of planctivorous fish.

Schreckensee and Vorsee, whose watershed includes swampy regions, suffered the same input event at the same time. In Vorsee, the specific activity of dissolved Cs-137 in the water even in 1991 persisted at a level of about 200 Bq/m³ (as measured after precipitation of dissolved Cs ions with ammoniummolybdenumphosphate ion exchanger at pH = 4) and exhibited a significant maximum in winter 1990/91 (fig. 4). This was attributed to the redissolution from sediments due to a decomposition of organic substances, to which organically speciated Cs radionuclides were bound. Correspondingly, in deeper Schreckensee a considerable increase of specific Cs-137 activity towards the sediment was observed during the stratification period (7). The binding strength of Cs radionuclides to sediments in this lake is much weaker than in Lake Constance; about 50% of the Cs inventory could be brought back into solution applying the same extraction procedure (fig. 3). This is attributed to a predominantly organic binding of Cs radionuclides in these sediments. The implications on fish contaminations became evident from fig. 5:

The general contamination levels of fish are higher than in Lake Constance and the specific Cs-137 activity of carnivorous fish is higher than that of herbivorous fish due to food chain accumulation. Additionally, the decrease of contamination is much slower than in Lake Constance. The importance of organic processes in these lakes is emphasized by a considerable increase of the Ru 106 and Sb-125 to Cs-137 isotopic ratio in sediments from these lakes.

Fig. 4: Concentration of dissolved Cs-137 and water temperature in Vorsee 1990/91.

Fig. 5: Specific Cs-137 activity in carnivorous (top) and herbivorous (bottom) fish species from Lake Constance (Bodensee) and Schreckensee.

Results of the radiocesium contamination of fish from Kiev reservoir suggests a closer similarity to the second type of lakes: Both the contamination distribution among different fish species as well as the time constants of the decrease of contamination of fish from the central part of Kiev reservoir are similar to findings from Vorsea (fig. 6). This may be considered as an indication for continuous input of Cs radionuclides or due to redissolution from sediments as well as for the absence of effective self-cleaning processes in this reservoir. It is emphasized, however, that Sr-90 radionuclides in this aquatic ecosystem are of much higher importance than in any other European lake outside Sowjetunion, mainly due to the release of this radionuclide from nuclear fuel particles /8/.

Fig. 6: Specific activity of Cs-137 in perch, tench and rudd from Kiev reservoir (left) and Vorsea (right) in 1990.

RADIOCESIUM BODY BURDENS IN NORTHERN CANADIANS

B. L. Tracy and G. H. Kramer

Bureau of Radiation and Medical Devices
Department of National Health and Welfare
Ottawa, Canada

ABSTRACT

Whole body measurements were carried out on 1117 Canadians living in five Arctic communities during 1989 and 1990 in order to assess the uptake of radiocesium from the lichen-caribou-human food chain. The Cs-137 body burdens increased with age, and were twice as high for men as for women. There was a discrepancy between the reported meat consumption and the measured body burdens. Average radiation doses from ingested radiocesium varied from 0.01 to 0.10 mSv/a.

INTRODUCTION

It has been known since the early 1960's, when intensive testing of nuclear weapons was carried out in the atmosphere, that the lichen-caribou-human food chain is an important pathway for the uptake of radiocesium. This is particularly true in far northern regions where fallout radionuclides accumulate on slowly growing lichens. These in turn serve as the major food source of reindeer and caribou during the long winter months. Many northern Canadians depend on caribou hunting for their main supply of meat.

After the Chernobyl accident in 1986, renewed concern was raised about possible contamination of Canadian caribou herds by fallout radiocesium. Measurements carried out on caribou meat by this laboratory between 1986 and 1988 showed that only about 25% of the radiocesium in Canada resulted from the Chernobyl accident; the remainder was residual fallout from early weapons testing. However, exposure to radiocesium depends on the diet and lifestyle of the people, as well as on the levels in caribou meat. The only way to obtain a direct measure of exposure to humans is to carry out whole-body monitoring. This paper describes such a set of measurements.

EXPERIMENTAL MEASUREMENTS

Measurements were carried out in the following communities:

Baker Lake, NWT	Feb., 1989	416 subjects
Rae-Edzo, NWT	March, 1989	378 subjects
Old Crow, Yukon	March, 1990	92 subjects
Aklavik, NWT	March, 1990	115 subjects
Ft. McPherson, NWT	April, 1990	116 subjects

Efforts were made to obtain a good representation from both sexes and all age groups.

The counting equipment was usually set up at the nursing station in each community. The subject was seated comfortably in a chair. A 5" x 4" Harshaw NaI(Tl) scintillation detector was placed close to the abdomen and thighs and a 3" x 3" detector was placed close to the chest. In the case of a small child the chest detector was omitted. Each measurement required only 5 minutes. The signals were processed by a Canberra S100 data acquisition system and the resulting gamma ray spectrum was displayed on a video screen which was visible to the subject. Cesium-137 was identified by its photopeak at 661.6 keV. At the end of the measurement the subject was given a printout of the result and an explanation of its significance. The counting system had been previously calibrated at the laboratory by using phantoms resembling an adult male, a 10-year old, and a 4-year old and filled with water containing a solution of Cs-137. The detection limit varied between 0.1 and 0.3 kBq of Cs-137, depending on the background at the nursing station. Each subject was asked to complete a dietary survey, with the assistance of a native interpreter. The subject estimated the amount of caribou eaten at each meal by pointing to models of various sized pieces of meat. Radiocesium analyses were carried out on samples of caribou meat obtained from recent kills in each community.

RESULTS AND DISCUSSION

Figure 1 shows how the radiocesium body burdens varied with age group and sex in one particular community -- Baker Lake. Results for the other communities were similar. Note that the levels were very low in children, then rose during the adolescent and early adult years to reach a peak in middle age (50 - 60). After age 60 the levels declined. Results for males were consistently about a factor of two higher than those for females.

Table 1 summarizes the results for the five communities for all adults (age >20). The predicted body burdens were calculated as follows:

$$BB(kBq) = \text{Conc. in meat}(kBq/kg) \times \text{consumption}(kg/wk) / 7 \times \text{GI uptake} \\ \times \text{biological half-time}(days) / \ln(2)$$

The average weekly consumptions of caribou meat were based on results provided in the dietary survey. GI uptake was assumed to be 100 % (1). The biological half-times for radiocesium in the body were taken to be 96 days for men and 65 days for women (2). In all cases, the observed body burdens in men were about twice as high as those in women. This is only partially explained by the differences in reported consumption. The remainder of the factor of two can be explained by the shorter biological half time for radiocesium in women (65 as opposed to 96 days). The observed body burdens are well correlated with the measured concentrations in

meat for each community ($r = 0.973$ for men and 0.985 for women).

The most notable feature of Table 1 is that the predicted body burdens are consistently 2 to 4 times as high as the measured values. Aklavik would appear to be an exception, but the measured values for this community are too close to the detection limit (0.2 kBq) to draw any conclusions. The discrepancy between predicted and observed values is difficult to explain. One possibility is that the GI uptake factor is considerably less than 100% for radiocesium in meat. To test this possibility, several volunteers from this laboratory consumed known amounts of caribou meat containing Cs-137(3). Whole body, urine and fecal measurements were all consistent with a GI uptake factor $>98\%$. The experiment also showed that the biological half times assumed here are quite reasonable. The only remaining possibility is that the people were consistently overestimating their consumption of caribou meat. It is curious that the degree of overestimation should be consistent between sexes and from one community to another. Furthermore, the degree of overestimation was found to be consistent even between different age groups in the same community. If people were, in fact, overestimating their meat consumption, then the radiocesium body burden measurements provide an independent means of estimating consumption. This could be useful for an accurate assessment of the intake of other toxic substances. The annual dose to each sex group in each community from the observed Cs-137 body burden has been calculated from:

$$\text{Dose (mSv/a)} = 0.043 \times \text{body burden (kBq)}$$

This assumes a) body burden is maintained for one year
b) energy deposited per disintegration is 0.59 MeV
c) an adult weighs 70 kg.

The values are given at the bottom of table 1. These values represent an insignificant increase over natural background exposure of 2 to 3 mSv/a. The highest body burden observed for any individual was 9.5 kBq, which gave a dose of 0.41 mSv/a.

1. Introduction

Fallout nuclides derived from the Chernobyl reactor accident (from now on CRA) in April 26 of 1986, were detected at Matsue in Shimane Prefecture (SW Japan located about 7,800 km East from Chernobyl reactor site) in rain water and airborne particles collected in May 4 (local time). The Shimane Prefectural Institute for Public Health and Environmental Science (SPI) started monitoring of the effect of CRA mainly by non-destructive gamma-ray spectrometry of various environmental samples collected from entire area in Shimane. Details of this observation will be given in the Science Report of SPI¹⁾. Besides the laboratory measurement of the samples collected, in-situ gamma spectrometry using high purity Ge detector was performed from May 9 to early July. This paper describes the results of in-situ measurement of the effects of CRA.

2. Measurement and Data Analysis

Two portable Ge detectors were used for in-situ measurement of gamma-ray spectrum. One is a Ge detector with efficiency of 40.5% relative to a 3"x3" NaI(Tl) detector and 1.77 keV of energy resolution (FWHM) at 1.33 MeV, and the other is a Ge detector with relative efficiency of 7.2 %. Techniques of data analysis of in-situ measurement for obtaining dose rate and/or accumulation of fallout nuclides is almost the same as the method developed by Beck et al²⁾. The Ge detector was set facing down 1 m above the ground surface, and gamma-ray spectrum was measured for 1 to 2 hours. To compare the result obtained by in-situ measurement with those by soil sampling method, surface soils of 0 - 21 cm were collected at 3 cm intervals just below the Ge detector.

About 200 measurements were made from May 9 to early July. Gamma-ray spectra were analyzed by an automatic peak search program. The dose rates for the fallout nuclides derived from CRA together with those for natural radionuclides belonging to the U- and Th-series and K-40 were calculated by multiplying the count rate of gamma-ray peaks with conversion factors obtained for each Ge detector. Depth profile of Cs-137 accumulated in surface soil before CRA was simulated by an exponential function given by $A_x = A_0 \exp(-\alpha x)$, where A_0 and A_x are the Cs-137 activity at soil surface and depth x , respectively. The α is a fitting parameter of depth profile. The α value obtained by the analysis of the soil samples ranged from 0.4 to 0.9 cm^{-1} . Detail of the calibration method of the Ge detectors will be described elsewhere¹⁾. The density of surface soil was measured to be 1.5 - 1.6 g/cm^3 , therefore, 1.6 g/cm^3 was adopted in the calculation of conversion factors.

Fig. 1. In-situ gamma-ray spectrum of 200 - 700 keV region measured at 12:00 to 14:00 of May 9, 1986. Measuring time and gain setting were 120 min and 0.667 keV/ch, respectively.

3. Results and Discussion

In-situ gamma-ray spectrum obtained in May 9, 1986, is shown in Fig. 1. Fallout nuclides identified are Te-132 (228, 668 keV), I-131 (284, 364, 637 keV), Ru-103 (497 keV), I-132 (523, 727 keV), Cs-134 (605, 795 keV) and Cs-137 (662 keV). Results of analyses of In-situ measurements are summarized in Tables 1, and 2, and the time variations of dose (exposure) rates of Cs-137, I-131 and Ru-103 are shown in Figs. 2 to 4.

[Cs-137] Dose rate and/or accumulation of Cs-137 was calculated by assuming the depth profile of Cs-137 being exponential and/or exponential + surface distribution before and after CRA, respectively. Contribution of nuclear weapons tests is shown by a dotted line in Fig. 2. Accumulation of Cs-137 at the measuring point is order of magnitude lower than the value measured at typical uncultivated area in Shimane, because the construction of the SPI building begun in 1975. Accumulation of Cs-137 in surface soil begun since that year. As known from Fig. 2, dose rate has increased from 0.15 to 0.32 uGy/h by CRA. Appreciable increase of dose rate was not found after the initial increase during early May, because most of Cs-137 had fallen in a short time during this period. If in-situ measurements were made at uncultivated area with high amount of Cs-137, such a small increase of dose rate could not precisely be evaluated by in-situ measurement. Accumulation of Cs-137 estimated by in-situ measurement agreed well with soil sampling method within 15%. Increase of Cs-137 accumulation by CRA was estimated to be about 70 MBq/km² at Matsue.

Table 1. Dose and accumulation of Cs-137 before and after CRA.

Measured Date	Dose (nGy/h)		Accumulation (MBq/sq.km)		Depth profile used in the calculation
	Average	Range	Average	Range	
Before CRA	0.156	[0.119 - 0.186]	110	[87 - 123]	Exponential
After CRA	0.324	[0.257 - 0.366]	180	[153 - 196]	Exponential + Surface

Fig. 2. Variation of dose rate due to fallout Cs-137 measured at Matsue.

[I-131] Dose rate and accumulation of I-131 at May 9 were calculated to be 0.918 nGy/h and 536 MBq/km², respectively, by assuming surface distribution ($\alpha = \text{infinity}$) on the ground. As shown in Fig. 3, apparent half-life of I-131 in an early stage (May 9 to 20) was evaluated to be 12.8 days, however, after this period, it became 7.9 days, which corresponds to the physical half-life of 8.06 d. Concentration of I-131 in the surface air measured by high volume air-sampler showed two peaks in May 8 (before the beginning of in-situ measurement) and May 13 (1/4 of that observed in May 8). Longer apparent half-life of I-131 in early stage might be explained by the delay of the deposition of I-131 (compared with other fallout nuclides), because significant fraction of I-131 was found to be in gaseous state as evidenced by the sampling with charcoal filter, and partly by the contribution of second plume observed in May 13. Integral dose due to I-131 during May 8 (when maximum air concentration was observed) through the beginning of July was estimated to be 338 nGy.

[Ru-103] As shown in Fig. 4, apparent half-life of Ru-103 was calculated to be 36.8 days, which is a little shorter than the physical half-life of 39.6 days. This may be explained by the downward migration of Ru-103 due to the rain fall during this period. Dose rate and accumulation of Ru-103 estimated for May 9 are 0.305 nGy/h and 140 MBq/km², respectively. Integral dose due to Ru-103 was calculated to be 436 nGy, which is little higher than that of I-131.

Dose rate due to Cs-137 measured after 8 months of CRA was 0.28 nGy/h, which is 4/5 of that measured at Ibaraki Prefecture (0.35 nGy/h), located 700 km East of Shimane.

Table 2. Dose, accumulation, integral dose and apparent half-life of fallout nuclides.

Nuclide	May 9, 1986		Integral Dose (nGy)	Apparent Half-life
	(nGy/h)	(MBq/sq.km)		
Cs-137	0.318	177	0.32 x hour	>1000d
I-131	0.918	536	338	12.8 d (until May 20) 7.9 d (after May 20)
Ru-103	0.305	140	436	36.7 d

COMPARISON OF MEASURED RADIOECOLOGICAL PARAMETERS IN
AACHEN AFTER THE CHERNOBYL ACCIDENT WITH VALUES USED IN THE
FEDERAL REPUBLIC OF GERMANY

H. Bonka

Lehrgebiet Strahlenschutz in der Kerntechnik,
RWTH Aachen.

ABSTRACT

After the nuclear reactor accident at Chernobyl it was possible just like after the nuclear weapon tests to measure important radioecological parameters. It could be explained why the transport of I 131 from air into milk was overestimated by a factor of approx. 5 due to the used compartment model. The most important measured parameters in Aachen are stated.

INTRODUCTION

The calculation method as well as the applied data for the calculation of the radiation exposure of the population in the vicinity of nuclear plants are fixed in licensing procedures of the government in the Federal Republic of Germany¹. At the time, when the nuclear reactor accident happened in Chernobyl, the regulation had to be modified because of the amendment of the radiation protection regulation. As an example, Fig. 1 shows the compartment model to calculate the transport of the radionuclides without H 3 and C 14 from air into the edible part of plants and of pasture grass into milk and meat. For licensing procedures the food groups leafy vegetables, non-leafy vegetables, cow's milk and beef are taken into consideration.

DEPOSITION VELOCITY

From May 1st 1986 until the evening of May 3rd 1986 radionuclides were deposited in Aachen only due to dry deposition. The deposited aerosolbound activity on grass increased continuously whereas the I 131 activity showed two peaks before the first rainfall². The first peak most probably results from the change of air activity. The second peak can be caused by the sorption and desorption due to dewfall during the night. Taking into account the activity concentration in air a deposition velocity of 0.025 to 0.11 cm/s with a mean value of 0.07 cm/s results for the aerosolbound Cs 137 on 10 to 15 cm high grass. Without taking into account the two peaks, the deposition velocity for the total I 131 lies between 0.13 and 0.17 cm/s. For the peaks the deposition velocity amounts to 0.28 cm/s. Referring to elemental iodine only, a mean value of approx. 0.7 cm/s results. For the new licensing procedures in the Federal Republic of Germany¹ the deposition velocity for aerosolbound radionuclides was enhanced from 0.1 to 0.15 cm/s. For elemental iodine a value of 1 cm/s is still used. For aerosolbound radionuclides however, the size distribution of the particles must be considered. Since about two years Cs 134 can be used to measure the higher deposition velocity in forests compared to the deposition velocity on grass. Values result which are 3 to 8 times higher.

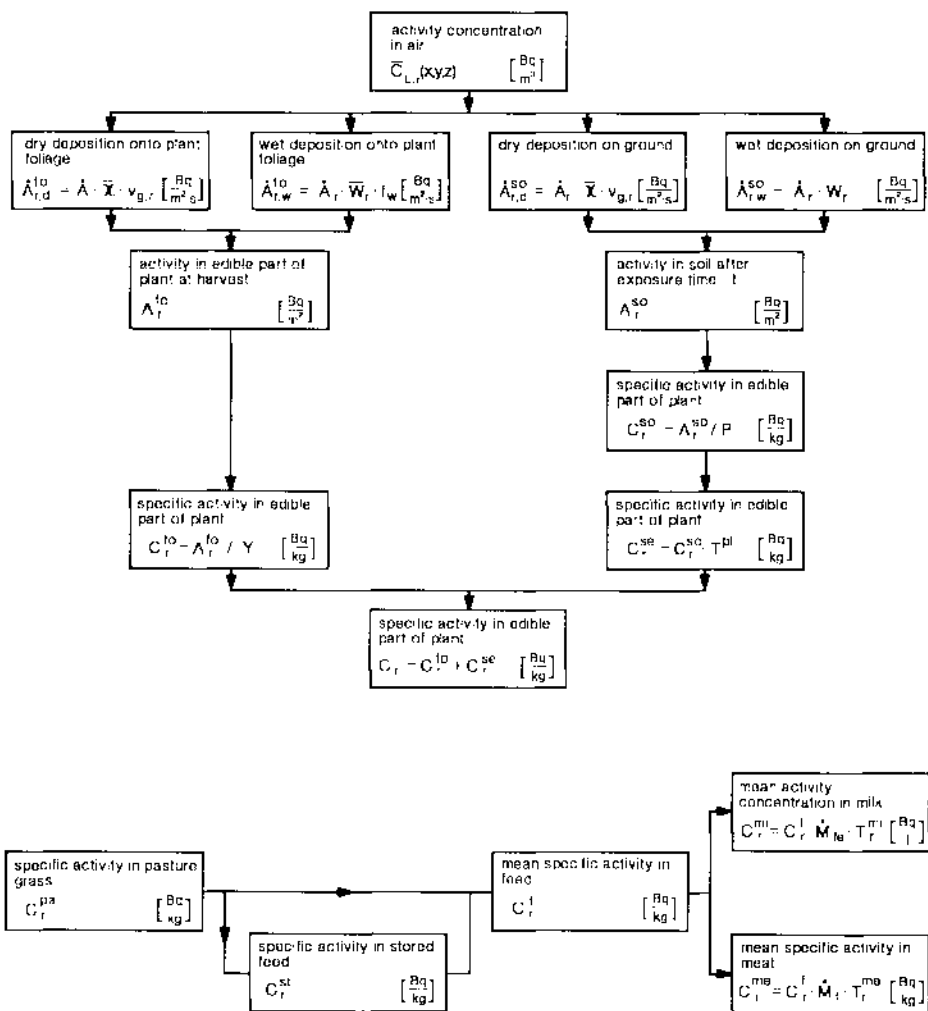

Fig. 1: Compartment model to calculate the transport of radionuclides in nourishment at air pathway

WASHOUT COEFFICIENT AND RETENTION FACTOR ON GRASS

During two rain events on May 3rd 1986 of 0.25 mm and 0.95 mm on May 5th 1986, the washout ratio in dependence of the rain intensity I could be measured. Assuming the activity concentration to be constant over the height, a value can be derived which is comparable to the washout coefficient². This value increased during the first rain event with $(I/I_0)^{0.74}$ and at the second with $(I/I_0)^{0.56}$. According to the licensing procedures¹ the washout coefficient A can be calculated for aerosolbound radionuclides and elemental iodine to $7 \cdot 10^{-5} \text{ s}^{-1} \cdot (I/I_0)^{0.8}$. The measured retention factor lies between 0.2 and 0.6 with a mean value of approx. 0.4. In reference¹ the f_w value was enhanced from 0.2 to 0.3.

HALF LIFE FOR THE REMOVAL OF ACTIVITY ON PLANTS

When the activity concentration in the air became neglectable, the half life for the removal of the activity on grass due to weathering could be determined by measuring the deposited activity per unit ground area. A half-life of approx. 10 days results for I 131, one of approx. 14 days for Cs 134 and Cs 137. A value of 8 days results for Ru 103. In reference¹ a value of 14 days was defined for all radionuclides.

TRANSFER FACTOR FOOD-MILK

The determination of the transfer factor food milk for I 131 showed the most important result. In the frame of licensing procedures a value of 0.01 d/l was used. It was obvious for all scientists working in the field of radiocology that using this value and the above mentioned deposition velocity the transfer of I 131 from air into milk was overestimated by a factor of 5. Measurements in cow's milk of one smaller and four larger farms showed in May and June 1986 a I 131 transfer factor of approx. 0.002 d/l and an effective removal rate constant of approx. 0.6 d⁻¹. For Cs 137 a value of approx. 0.003 d/l results for the transfer factor as well a value of approx. 0.4 d⁻¹ for the removal rate constant³. The transfer factor increased during the grazing period to approx. 0.007 d/l, if only taking into account the specific activity in grass that was cut approx. 1 cm above soil. Tests showed that this was caused by the additional activity of cows which partly tore grass roots and took in soil as well⁴. For licensing procedures¹ the transfer factor food milk for I 131 was lowered to 0.003 d/l and for Cs 137 from 0.012 d/l to 0.005 d/l.

TRANSFER FACTOR FOOD-BEEF

In order to determine the transfer factor food beef the specific activity in beef was measured in detail from 1986 until 1990. When comparing the specific Cs 137 activity in beef with the activity concentration in cow's milk of 3 farms it can be seen that the value in beef is approx. 6 times higher. According to this the transfer factor lies between 0.015 and 0.04 d/kg. In licensing procedures¹ the transfer factor was already increased from 0.004 to 0.03 d/kg in 1982. This step was right according to the measured values.

TRANSFER FACTOR SOIL GRASS

Soil and grass samples were taken over the whole Federal Republic of Germany in order to analyze the local and temporary variability of the transfer factor soil-grass after a single contamination. Table 1 shows the measured values. In licensing procedures¹ a value of 0.05 is used.

Table 1: Measured transfer factor soil-grass

	1987		1988		1989		1990	
	Cs 134	Cs 137	Cs 134	Cs 137	Cs 134	Cs 137	Cs 134	Cs 137
mean value	0.21	0.19	0.077	0.055	0.043	0.038	0.044	0.037
Maximum value	2.8	2.6	0.75	0.57	1.13	0.85	0.21	0.18
number of samples	79	82	39	41	94	96	50	57

SPECIFIC CS 134- AND CS 137-ACTIVITY IN HUMAN BODIES

Parallel to the very detailed determination of the specific activity in food in Aachen the specific Cs- activity in bodies of adults was measured gammaspectrometrically. Assuming realistic alimnetation habits a very good agreement can be stated between calculation and measurement⁵ for an effective half life of 110 days as shown in Fig. 2.

Fig. 2: Measured mean specific activity of Cs 134, Cs 137 and K 40 in arms of male adults in Aachen compared with calculated values

ABSTRACT

At a roedeer population from a prealpine forest area (1600 km²) periodic contamination maxima in autumn, a slow overall decrease with an effective ecological half-time of 2,6 +/- 0,4 years and a regional pattern with characteristic small-scale variations representing the transfer of Cs radionuclides from the soil to the animals are observed. The depth distribution of Cs radionuclides in the layered forest soil is peaked in the uppermost humic layer and it is inferred that binding to organic substances plays an important role in the fixation of these radionuclides. This is corroborated by observations in a highmoor, where the shape of the depth distribution and the transfer to plants turned out to be rather similar to those of forest soils and at fertilized forest areas, where the transfer factor was significantly reduced.

INTRODUCTION

In the glacially formed prealpine region of Oberschwaben in the south west of Germany the contamination with Chernobyl fallout is among the highest in central Europe. The specific activity of Cs radionuclides in roedeer from this area, grazing mainly in forests, is higher than for other animal species and decays only slowly in time /1/. Additionally it exhibits a characteristic seasonal structure /1,2/, which was similarly observed for roedeer from Sweden /3/ and from Bavaria /4/, and a small-scale regional structure, which was well reproduced over several years. We propose that these structures are related to the particular type of speciation of Cs radionuclides in layered forest soils, in particular to their association with organic substances in the uppermost humic layer /5-9/.

RESULTS AND DISCUSSION

In collaboration with local forest authorities the specific activities of Cs-137 and Cs-134 in most of the roedeer shot in this area - about 800 samples per year - have been measured gamma-spectrometrically since 1987. The time dependence of the roedeer contamination - in fig. 1 the arithmetic mean over two weeks is shown - exhibits periodic contamination maxima in autumn, which are correlated with the well-defined season of mushrooms. Several mushroom species - among them the abundant edible species chestnut boletus (*xerocomus badius*) - have extraordinarily high cesium transfer factors /1/ and mushrooms are part of the diet of roedeer in autumn /3/. Therefore grazing of mushrooms is considered to be mainly responsible for the steep increase of roedeer contamination in autumn and its subsequent decrease is due to the abrupt end of the mushroom season. An additional reason for the in-

fig. 1: Specific activity of Cs-137 in roedeer meat versus time. Amount and season of mushrooms is indicated on the time scale.

creased contamination levels may be the general increase of roe deer intake in autumn /4/. The overall effective ecological half-time of the specific Cs-137 activity in the roe deer population, obtained from an exponential least-squares fit to all existing data for 4 years of monitoring, is 2.6 ± 0.4 years.

Within this rather small and geologically uniform region (glacially formed moraines) the radiocesium (Cs-134 and Cs-137) contamination levels of individual animals varied widely between less than 10 and more than 3000 Bq/kg. The regional distribution of the contamination (individual animals were attributed to the sites of shooting), on the other hand, appeared to be stable over several years exhibiting small areas with groups of animals showing substantial contamination (fig. 2). Taking into account the restricted grazing areas of individual animals it is proposed that this contamination pattern reflects the pattern of local transfer factors from soil to roe deer via grazing plants. This was studied in detail in the largest forest of this area with a spatial resolution of $0,5 \times 0,5 \text{ km}^2$, where differences of about a factor 50 in local transfer factors soil-roe deer were obtained between the northern and southern part of this forest (fig. 3).

These observations can be explained by (i) local variations of the availability of Cs radionuclides in the forest soils for the uptake by grazing plants or (ii) local changes of the abundances of grazing plants with different plant-specific transfer efficiencies. Since a similar pattern was obtained for the transfer factors soil-blackberry (fig. 4), we conclude that the type of binding of Cs radionuclides in the forest soils, i. e. the bioavailability in soil, is of major importance for the

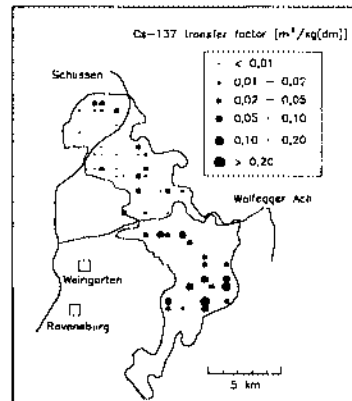

fig. 4: Cs-137 transfer factor soil-blackberry measured 1991.

contamination pattern.

The investigation of the depth distribution of Cs radionuclides in the soil of this forest revealed a high fraction of Cs radionuclides from the Chernobyl fallout still present in the uppermost humic layer of the soil, i.e. not deeper than 4 cm, in accordance with results for several other European forests /6-9/. A depth profile obtained from a sampling side in Altdorfer Wald is shown in fig. 5 together with the layering of the soil. Since the uppermost soil layer mainly consists of organic substances we presume a rather strong binding of Cs to organic substances, which prevents Cs radionuclides from transport to larger depths. This is in accordance with the results of laboratory experiments showing a high retention of Cs in O horizons /5/. The transfer factors soil-plant in this forest vary with the thickness of both O and A₁ horizons showing highest values for total thicknesses as low as 2 cm (fig. 6), which emphasizes the importance of a well-developed O horizon for Cs immobilization. Another corroboration comes from depth profiles and transfer factors to plants measured in sphagnum bogs of this region. Despite of the lack of mineral components and layering of these soils, the shape of the depth profile in these soils is quite similar to that in forest soils (apart from an extension towards greater depths, fig. 7) and transfer factors soil - plants do not differ as much for plant species growing both in forest and sphagnum bogs /2/.

As a consequence organically bound Cs radionuclides will be remobilized by the decomposition of their organic carriers as proposed by Dörr and Münnich /10/ and thus become available for the uptake by plants. Thus this system is very sensitive to changes of the chemical milieu, which can e.g. be induced by fertilizer treatment of the forest soil. Correspondingly, on a forest area treated with a fertilizer consisting mainly of CaCO₃ prior to the Chernobyl contamination, the transfer factor for several plants is significantly reduced as compared to a neighbouring untreated forest area (fig. 8). This effect might be explained by (i) the known faster decomposition of organic matter after liming inducing higher concentrations of ions in the soil solution; (ii) the definition of the transfer factor itself: the above-ground biomass of the bottom layer plants regarded on the limed field exceeds the biomass on the control area considerably; or (iii) an enhancement of Cs association with organic matter.

fig. 5: Layering of soil horizons and Cs-137 depth profile in a forest soil from Altdorfer Wald (20.12.90).

fig. 6: Cs-137 transfer factor soil-blackberry versus thickness of humus layer (O- and A₁-horizons).

fig. 7: Depth profile of Cs-137 in sphagnum bog of Brunnenholzried.

CONCLUSION

The observed seasonal and regional structures in the radiocesium contamination of the roedeer population of a prealpine forest (picea abies) area emphasize the importance of the organic speciation of Cs radionuclides from the Chernobyl fallout in forest soils with respect to transfer processes.

The support of the Ministry of Environment of the State Baden-Württemberg is gratefully acknowledged.

A STUDY OF CONTAMINATION IN CESIUM 137 IN MUSHROOMS
IN FRENCH REGION AFTER CHERNOBYL ACCIDENT

After the accident at Chernobyl on 26 April 1986, we have
study the radiocontamination of 36 species of fungus gathered in
1988 and 1989 on 17 sites in eastern France (Franche-Comté). The
species selected based on their biological characteristics, were
analyzed by gamma spectrometry. 25% of species contained amounts
of Cesium 137; for 8% exceeded the level of 600 Bq.Kg⁻¹ of fresh
matter. 75% of the species mycorrhizal, 25 were saprophytes.
Edible species showed little or no contamination.

INTRODUCTION

Après l'accident de Tchernobyl, des mesures ont été
effectuées sur différents champignons dans quelques pays touchés
par le nuage radioactif en mai 1986 (1, 3, 4).

En France, des mesures ponctuelles, effectuées çà et là
(2), ont montré que dans certains cas les accumulations de
cesium 137 dans les carpophores étaient loin d'être négligeables.
La région de Franche-Comté (Est de la France) fut touchée par le
nuage radioactif durant le mois de mai 1986.

Il était important de connaître comment les champignons
avaient fixé les éléments radioactifs ambiants et surtout s'ils
présentaient un danger à la consommation.

MATERIEL ET METHODES

- Choix des espèces et des sites de récolte

Nous avons choisi les espèces en fonction de leur position
taxonomique et de leurs caractéristiques biologiques.

Les échantillons ont été récoltés sur 16 sites en Franche-
Comté, déterminés en fonction de leurs caractères écologiques
(altitude, exposition, sol, microtopographie, végétation).

- Méthodes de mesures

Chaque échantillon broyé et séché est placé dans une cellule standard pour le dosage précis de la quantité de césium 137 contenue.

La mesure de ce radionucléide est réalisée sur une chaîne de mesure étalonnée de spectrométrie gamma (Ge(Li)).

L'ensemble des résultats (tableau 1) est présenté en Becquerel par kilo de matière fraîche ou sèche (Bq/kg). L'erreur relative dans la plupart des cas est égale à 10 %.

TABLEAU 1 : Ensemble des résultats d'analyse

RESULTATS ET DISCUSSION

En tout, 60 mesures concernant 36 espèces réparties sur 16 sites ont été réalisées. Ces résultats révèlent que 30% des

espèces analysées sont plus ou moins contaminées par le césium 137.

Parmi celles-ci 8% dépassent le taux de 600 Bq/kg de matière fraîche, limite recommandée par la CEE pour la concentration en césium 137 dans les aliments non laitage; ce sont par ordre de valeurs décroissantes: *Collybia peronata*, *Cortinarius cyanopus*, *Cystoderma amianthinum*.

Les champignons mycorrhiziques sembleraient plus exposés à la contamination puisque 75% d'entre eux montrent des taux d'imprégnation significatifs, alors que seuls 25% des saprophytes sont touchés. Parmi ces derniers les espèces, dont le mycelium se développe au dépend des litières superficielles, absorbent une grande quantité d'éléments radioactifs. Par contre les champignons, dont le mycelium est au contact des couches humifères plus profondes, sont dénués de radioactivité (*Laccaria amethystina*).

La seule espèce parasite enviaagée est négative vis à vis de nos tests.

Les champignons lignicoles, qu'ils soient parasites ou saprophytes, semblent exempts de cesium 137 (*Piptoporus betulinus*, *Hypholoma sublateritium*, *Xylaria polymorpha*, *Crepidotus mollis*).

Un autre aspect à considérer est celui de l'ouverture des milieux. Les taxa des milieux ouverts (praticoles) semblent exempts de radioactivité.

En ce qui concerne l'évolution du taux de radioactivité dans le temps, nous avons constaté pour *Cantharellus tubaeformis*, une valeur plus importante en 1989 qu'en 1988 pour des exemplaires récoltés dans la même station.

Le problème de la radiocontamination des espèces comestibles est évidemment important pour le public. Dans cette étude, on constate que les espèces les plus contaminées ne sont pas comestibles ou sont dénuées de tout intérêt culinaire.

Cependant, *Cantharellus tubaeformis*, *Hydnum repandum*, *Russula cyanoxantha*, espèces comestibles, ne sont pas totalement dépourvues de surcharge radioactive, bien que leurs teneurs ne dépassent pas le seuil de 600 Bq/kg de matière fraîche. Il est à signaler que l'impact radiologique de ces espèces reste faible au regard des consommations nécessaires pour atteindre la limite annuelle d'incorporation (L.A.I.), qui pour le césium, est de 4.10^5 Bq/an.

Enfin, les meilleurs comestibles de la région (*Morchella conica*, *Agaricus campestris*, *Boletus edulis*, *Calocybe gambosa*) n'étaient pas contaminées par des éléments radioactifs en 1988 et 1989. Il en est de même pour le champignon de Paris (*Agaricus hortensis*), espèce cultivée.

CONCLUSION

Cette analyse donne un aperçu de la radiocontamination des champignons dans l'est de la France en 1988 et 1989, suite à l'accident de Tchernobyl. Les teneurs en radioisotopes varient en fonction des espèces, des sites de récolte et du temps. Nous envisageons de poursuivre cette étude dans le but d'examiner un plus grand nombre d'espèces et de suivre l'évolution dans le temps des teneurs en radionucléides.

THE SHORT LIFE RADIONUCLIDES IN MEAT AFTER THE NUCLEAR ACCIDENT IN CHERNOBYL

Smelcerovic M., Popovic D.* and Djuric G.*

Institute for Nuclear Sciences, Vinca and * Department of Physics and Department of Radiology, Faculty of Veterinary Medicine, Beograd, Yugoslavia

ABSTRACT

The paper presents the results of identification and short life radionuclides (I-131, Te(I)-132, Cs-136, Ce-141, 144, Ru-103, 106, Ba(La)-140, Zr-95, Nb-95, Mo-99, Sb-125) mass activities evaluation in meat (lamb, rabbit, game) after the nuclear accident in Chernobyl in 1986.

INTRODUCTION

Immediately after the nuclear accident in Chernobyl in 1986, at the end of April and during May 1986, the magnitude of contamination of the biosphere was mainly determined by short life radionuclides, I-131 above all. Later on, as I-131 decayed, the comparatively short life radionuclides (Sr-89, Zr-95, Nb-95, Ce-141, Ru-103, Ba-140) made an appreciable contribution to the radioactivity on the whole and finally, the main role in the contamination process overtook the long life radionuclides: Sr-90, Cs-134, 137 and partially, Ru-106 (5). But the accident differed from those usually considered in radiological assessments of hypothetical accident releases from nuclear power plants, as the release was prolonged and varied in rate and the composition of the radionuclides mixture was complex (3).

During the accident and afterwards, only I-131, Cs-134 and Cs-137 have been systematically considered, as these are the most important contributors to the total dose. Other radionuclides were only reported in air or deposition although several of them are important short term contributors to external irradiation from deposited material. As for ingestion, some of the short life radionuclides are unjustly neglected considering their amounts found in some foodstuff (2)

In Yugoslavia, the degree of radiocontamination was rather ununiform, mainly due to the uniformity of the rainfalls. However, the overall conclusion was that the sheeps and game were the most endangered again due to the season the accident occurred in (4).

Therefore, the aim of this paper was to identify some of the short life radionuclides in meat immediately after the accident and afterwards. We have also tried to evaluate the contribution of the identified short life radionuclides in the total dose due to ingestion compared to I-131 and the long life Cs-134 and Cs-137.

MATERIALS AND METHOD

Samples of meat (lamb, rabbit, game) were collected by random sampling on highly contaminated area in Serbia and Macedonia, in May and June 1986.

The contents of the radionuclides in the fresh samples of meat was determined on a Ge(Li) detector (ORTEC, relative efficiency 23%) and a 4096 channel analyzer (ND-100). The geometric efficiency for a 200 g PVC cylinder was determined by a secondary standard for solid state matrices (1). The counting time interval was 4.000 - 40.000 s depending of the total activity of the sample. The total error of the method was less than 20%.

RESULTS AND DISCUSSION

Mass activities of the identified short life radionuclides in meat, together with those referring to isotopes of cesium, are presented in Tables 1, 2, 3 and 4. The presented values are given within the estimated ranges of activity. Mark < indicates that the radionuclide was identified only in some of the investigated samples, whereas the activities smaller than 0.100 Bq/kg were indicated as "traces".

Table 4. Short life radionuclides in beef giblets, June 1986

Radionuclides	beef liver	beef heart	intestines
I-131	< 21	< 34	3 - 8
Cs-134	< 40	< 12	3 - 10
Cs-137	< 90	< 100	7 - 16
Ru-103	-	-	< 0.9
Ru-106	< 14	< 22	-
Cs-136	< 4	-	< 0.8
Sb-125	< 7	< 3	traces
Ba(La)-140	traces	-	traces
Rh-102	-	traces	traces
Zr-95	-	-	< 0.5
Ce-141	-	-	< 0.5
Ce-144	-	-	traces

All of the short life radionuclides were identified on more than one energy line. Note that some of them (Ru-106, Sb-125, Ce-141,144, Rh-102) could be detected only after the decay of the interfering gamma lines, that is in the samples collected later on. As for radionuclide Ag-110m it is supposed to originate from the material used to bury the reactor.

The results presented in Tab. 1-4 give a preliminary estimation of the contribution of the short life radionuclides in the the total activity of meat immediately after the accident. For more accurate estimation many other parameters should be considered. Nevertheless, the results indicate that the short life radionuclides should not be neglected in the estimation of the total dose due to ingestion immediately after nuclear accidents similar to one in Chernobyl.

CONCLUSIONS

Immediately after the nuclear accident in Chernobyl, in 1986, some of the short life radionuclides, besides I-131 (Te(I)-132, Cs-136, Ba(La)-140, Ce-141,144, Zr-95 ecc) deposited in air and on the ground, reached the meat and game in unneglectable amounts. This was especially significant for lamb and lamb giblets, as the production of lamb happened to be more that 40% of the total meat production in Serbia and Macedonia. Therefore, in the estimation of the total dose due to ingestion in the first month after the accident and immediately afterwards, one should also consider the contribution of the short life radionuclides.

I. Introduction

On 26 April 1986 an accident occurred in the No.4 unit of the Chernobyl nuclear station in Ukraina, USSR, which led to a global dispersion of radioactivity. Since then numerous reports on the radioactive fallout due to this accident have been reported in different countries¹⁻⁷⁾.

We prepared the environmental samples collected from Biwa-lake which is the largest lake in Japan and is located in the center of Japan. Radioactivities of the samples were measured over a three-year period in order to estimate the radioactive contamination in Japan.

II. Method

Collection of the Biwa-lake biosphere samples was done every half year for 3 years after 28 May 1986, one month after the Chernobyl accident.

2.1 One cubic meter of lake water was collected at a point one meter deep. The water was evaporated to dryness at 70°C under reduced pressure using a rotary evaporator. The residue was submitted for radio-assay.

2.2 Mud was collected up to 50 ~ 80 cm in-depth from the bottom surface at a point 2 meters deep. The collected mud was fractionized to 2 ~ 5 cm along the depth and sieved with a 16-mesh sieve after dryness.

2.3 Several kilograms of black basses, bluegills, roaches, carps, shell-fishes and water-weeds were collected. The fishes were separated into flesh, internal organs and bones. The shell-fishes were divided into shells and flesh. These parts and the stalks and leaves of the water-weeds were burnt to ashes at 500°C.

2.4 The radio-analyses of all the samples were done using a low-background Ge-γ-ray spectrum analyzer made by NAIG.

III. Results and Discussion

The variation in the radioactivity concentrations of the samples is shown in the figure 1.

3.1 The radio-nuclides in the water residue collected one month after the accident were I-131, Ru-103, Ru-106, Cs-134 and Cs-137. However, after half a year only Cs-137 was detected. The concentration had been reduced to less than one-tenth of the initial value. Three years after the accident the level was 0.12 mBq/l, which was the pre-accident value.

3.2 Radio-nuclides detected in the bottom mud were Cs-137 and natural radioactive nuclides, i.e. K-40, thorium decay products (Th-232, Ac-228) and uranium decay products (Pb-214, Bi-214). Cs-137 depth distribution in the bottom mud showed a maximum at 10 ~ 20 cm under the bottom surface, especially high in the clay-rich mud. This nuclide, however, is estimated to be mainly due to the fallout before the Chernobyl accident, because Cs-134 was hardly detected in the mud, since the cesium isotopic ratio, Cs-134/Cs-137, originating from the Chernobyl accident was 1/2.

3.3 In the organisms living in the lake Cs-134, Cs-137, Zr-95 and a trace of Ag-110m were detected. Among all the samples Cs-137 in the flesh of black basses showed the highest value, 2.0 Bq/kg. Existence of Cs-134 shows that a part of the cesium originated from the Chernobyl accident.

3.4 The concentrations of Cs-137 in the flesh of black basses and carps were 2.0 Bq/kg a half year after the accident. It decreased to 1.45 Bq/kg after one year, 1.1 Bq/kg after 2 years (June 1988), and 0.53 Bq/kg 2.5 years after the accident.

3.5 Variation of cesium in the biosphere organisms is shown in figure 2. The concentration of black basses, bluegills and water-weed was high, on the other hand that of the flesh of shell-fishes was considerably lower. The latter was detected until one year after the accident, however, thereafter under detection limit. Cs-134 concentration of the flesh of the above organisms except water-weed was detected up to 2 years after the accident. That of water-weed was scarcely detected in the whole period. The apparent effective life of Cs-137 in the flesh of black basses was estimated to be about one year, although the radioactivity of Cs-137 was not measured for the identical fish.

IV. Conclusion

Defining the cesium concentration factor as the ratio of the concentration of the organism to the one of the water, the concentration factor of black basses, roaches and bluegills were 1000 ~ 4300. Those of carps and shell fishes were 200 ~ 1000 and 100 ~ 170, respectively. Black basses, etc. are the most appropriate fishes as index organisms for monitoring the dispersion of fission products released from nuclear plants, since the cesium concentration factor of black basses is one order higher than that of other aquatic organisms.

AIR TO MILK TRANSFER OF CESIUM-137

C.Papastefanou

Nuclear Physics Department
Aristotle University of Thessaloniki
Thessaloniki 54006 Greece

ABSTRACT

Cesium-137 data in air, grass and cow's milk are presented over a 4-y period (July 1987 - September 1991). The Cs-137 transfer rates in cow's milk and grass, C_m/C_a ranged between 0.032 and 1.82 kg/l, while the transfer rates in cow's milk and air, C_m/C_a ranged between 4470 and 163350 m³/l. Both the Cs-137 transfer rates were decreased with time passing depending on the Cs-137 concentration of cow's milk, C_m which was decreased with time passing.

INTRODUCTION

Milk is one of the sources for ingestion of Cs-137 in the air-grass-cow-milk-man pathway¹⁻³ and is considered to be a major pathway of exposure to fallout radioactivity⁴. The Cs-137 content of cow's milk was examined over a 4-y period after the reactor accident at Chernobyl (26 April 1986) starting from July 1987. This paper reports data obtained on the basis of continuous monitoring, in order to study transfer phenomena of Cs-137 from air to cow's milk, via the air-grass-cow-milk pathway and explore the possible relation between the Cs-137 concentrations of milk, grass and air. The Chernobyl accident provided a unique opportunity for a such study because of large releases of reactor-generated radionuclides, transport over long distances and dry and particularly wet deposition on pasture or root uptake.

EXPERIMENTAL METHODS

Cow's milk samples (1 kg each) from local dairies were collected at the beginning of each month from two different regional milk plants AGNO Milk Industry and MEVGAL Macedonian Milk Industry, in the Thessaloniki area, in Northern Greece (40° 38'N, 22° 58'E). In parallel, air sampling was carried out using Staplex high-volume air samplers, model TFIA-2 with Staplex type TFAGF 810 Glass Fiber filters 20.3x25.4 cm² (8"x 10") with an average flow rate of 1.84 m³/min (65 ft³/min), in order to determine the Cs-137 concentration of air. Grass samples were cut from an area of ~3 m² (0.125 kg grass per m²) for each sample.

The Cs-137 content of milk, grass and air samples was counted using a high-efficiency (42%), high-resolution (1.9 keV at 1.33 MeV), low-background Ge spectrometer in a standard geometry (6 cm diameter plastic can for air samples and 1-L Marinelli beaker for milk and grass samples. The gamma spectroscopic system was calibrated using NPL (National Physical Laboratory, UK) standard reference sources in both cases, the overall efficiency being known to accuracies of better than 5% for the filter (plastic can) geometry and about 12% for the Marinelli beaker.

RESULTS AND DISCUSSION

Cesium-137 data were obtained for air, grass and cow's milk for the AGNO and MEVGAL regional milk plants over a 4-y period after the Chernobyl accident (26 April 1986) starting from July 1987. A summary of annual data of Cs-137 for the period 1987-1991 is presented in Table 1. Unusual high Cs-137 level₃ in air was measured in July 1987 (0.166 mBq/m³), August 1990 (0.250 mBq/m³) and June 1991 (0.154 mBq/m³), in grass (June 1990: 77.73 Bq/kg) and in cow's milk (July 1987: 33.49 and 39.96 Bq/l for the AGNO and MEVGAL milk plants, respectively). The ratio of Cs-137 to Cs-134 in air, grass and milk samples was as expected because of decay reasons. Although the Cs-137 concentration in air and grass had not significantly been changed on annual basis, whereas the Cs-137 concentration in cow's milk was decreased with time passing, indicating that the Cs-137 concentration in cow's milk depends not only on the grass but other contaminated food for which Cs-137 concentration was decreased with time.

Table 1. Summary of Cs-137 concentrations in air, grass and cow's milk

Year	Air $\times 10^{-5}$ Bq/m ³		Grass Bq/kg		AGNO milk Bq/l		MEVGAL milk Bq/l	
	min	av.	min	av.	min	av.	min	av.
1987	6.29-16.61	9.13	2.67-19.28	6.83	4.2-33.49	10.76	6.5-39.96	14.19
1988	3.03-7.50	5.09	1.96-20.60	7.17	1.96-10.20	4.90	1.84-16.40	6.09
1989	1.50-5.35	2.98	2.48-23.30	7.91	0.27-4.91	1.96	0.44-4.72	2.29
1990	1.23-25.00	4.59	1.12-77.73	10.71	0.15-0.73	0.41	0.27-2.19	0.79
1991	1.07-15.00	3.53	1.14-25.20	6.45	0.13-0.32	0.23	0.14-0.93	0.44

Cesium-137 transfer rates, C_m/C_g (kg/l) and C_m/C_a (m³/l), where C_m is the average concentration of Cs-137 in cow's milk (Bq/l), C_g is the average concentration of Cs-137 in grass (Bq/kg) and C_a is the average concentration of Cs-137 in air (Bq/m³) were determined based on the data corresponding to the period of April-September each year as the cows were mainly fed on grass that period. A summary of the data is presented in Table 2.

Table 2. Cesium-137 transfer rates in cow's milk

Period	C_g $\times 10^{-5}$		C_m		C_m/C_g		C_m/C_a	
	AGNO	MEVGAL	AGNO	MEVGAL	AGNO	MEVGAL	AGNO	MEVGAL
Jul-Sep 87	11.52	10.36	14.57	18.82	1.41	1.82	126504	163339
Apr-Sep 88	5.57	4.85	5.25	6.21	1.08	1.28	94196	111521
Apr-Sep 89	2.45	4.77	2.01	2.57	0.42	0.54	82053	104906
Apr-Sep 90	6.69	15.20	0.49	0.98	0.032	0.064	7283	14646
Apr-Sep 91	4.85	4.19	0.22	0.44	0.052	0.106	4466	9163
Average					0.60	0.76	62900	80715

The ratio C_m/C_a ranged between 0.032 and 1.41 kg/l for the milk of AGNO milk Industry and between 0.064 and 1.82 kg/l for the milk of MEVGAL milk Industry. The lowest values are pretty close to those referred in the literature⁴, e.g. 0.022 or 0.023 kg/l for grass.

The ratio C_m/C_a ranged between 4470 and 126500 m³/l for the milk of AGNO and between 9180 and 163350 m³/l for the milk of MEVGAL. The data of Table 2 shows that the Cs-137 transfer rates, C_m/C_a for both milk plants were decreased with time passing depending on the Cs-137 concentration of milk, C_a which was decreased with time. Very low values of C_m/C_a as low as 71 and 200 m³/l have been reported in the literature⁴.

Papastefanou et al. (1991)⁵ reported that there is a dependency of Cs-137 in milk with air concentration of Cs-137 (high correlation coefficients $r=0.74$ for the AGNO milk and $r=0.84$ for the MEVGAL milk).

The Spanish Environmental Surveillance Radiological Network
(REVIRA)

J.L. Butragueño; J.P. García; E. Gil and M.J. Granada

Nuclear Safety Council
Justo Dorado 11
28040 Madrid
SPAIN

ABSTRACT

The Spanish Environmental Surveillance Radiological Network (REVIRA) has about 25 automatic stations and several associated laboratories (normally university labs) distributed over the state. The automatic network has been designed to measure dose rate and alpha, beta, radon and iodine air concentration. The measurement equipments consist of a ZnS(Ag) plastic scintillator, a NaI(Tl) crystal detector and a GM detector.

The automatic stations are connected with a Control Center sited in the Nuclear Safety Council headquarter in Madrid. The connection uses the National Telephonic Network and the central software is able to call from the Control Center to each local station, call from the stations if a setpoint is reached and call from the Control Center to set up the microprocesor governing the local stations.

INTRODUCTION

At first, the REVIRA project was an I+D General Program of the Nuclear Safety Council (CSN), but after Chernobyl's accident became a priority objective of CSN. The national surveillance radiological network has been designed to meet the following objectives:

- To know the radionuclide distribution and evolution in environment and the environmental radiation levels.
- To have experimental data for estimating the potential radiological risk to population due to a radioactive contamination, and to help the decision making process.
- To make periodic reports with these data.

REVIRA STRUCTURE

The REVIRA has two different stations:

- Automatic stations to measure air activity concentration and the dose rate.
- Stations in which a sample is taken and an analysis program is followed.

SAMPLE AND ANALYSIS STATIONS NETWORK

This network is constituted by a set of both, national research and university laboratories in all the national territory. These stations sample periodically: air, rain water and soils. The radioactivity contents is then analyzed in a lab. (total alpha and beta activity concentration and dose rate). A special interest is taken in iodine and strontium activity concentrations and the dose rate levels are measured with TLDs.

There are also taken samples of superficial water (continental and marine) foods (milk, vegetables, meat and fish) and its analysis are made.

AUTOMATIC STATIONS

The automatic stations measure the following variables in continuous form:

- Air activity concentration of total alpha aerosols.
- Air activity concentration of total beta aerosols.
- Air activity concentration of radioiodines.
- Air activity concentration of Radon.
- Dose rate.

The equipments have a particle aspiration and retention systems. The aspiration system has a constant flow pump of 0.0017 m³/s. The retention system has filters for aerosols and for radioiodines. This system is constituted by the following devices:

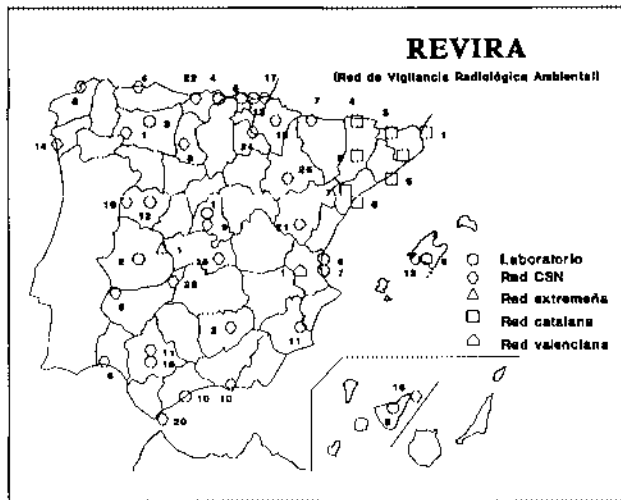

- PLASTIC SCINTILLATOR DETECTOR
 - . Efficiencies

Cl-36	28% - 35%
Am-241	17% - 22%
 - . Alpha Background 0.01 cps
 - . Beta Background 0.40 cps
 - . L.I.D. =< 0.5 Bq/m³
- CRISTAL DETECTOR
 - . Efficiencies

Ba-133	>= 5%
--------	-------
 - . Minimal concentration detectable for I-131 (sample time 3600 sec) =< 0.5 Bq/m³
- GEIGER-MÜLLER DETECTOR

	LOW DOSIS	HIGH DOSIS
Background (cps)	0.183	0.033
Energy response (Mev)	(0.05 - 1.5)	(0.05 - 1.5)
Accuracy Cs-137	± 20%	± 20%
Measure range (Gy/s)	8.3 10 ⁻¹³ -5.5 10 ⁻⁷	5.5 10 ⁻¹¹ -8.3 10 ⁻⁴

A graphic representation of the automatic network is presented in the following figure.

These stations are located in the same places that some National Weather Institute automatic stations. So, the meteorological parameters (air temperature, relative humidity, wind direction and speed, rain intensity and air pressure) are also received.

TRANSMISSION DATA

The radiological and meteorological data, collected in the automatic stations, are transferred by the national telephonic network. A hardware device called DSIC (Selective and Intelligent Discriminator of Calls) is located in each station and stores each 10 min the radiological and meteorological parameters (having a maximum storage capability of 48 hours). The DSIC has an internal Modem connected to a telephone number and is called automatically from Control Center.

THE CONTROL CENTER

The Control Center sited in the Nuclear Safety Council headquarter in Madrid, has three personal computer (Mod. 80386). These PCs are linked by a Local Area Network. Two of these three PCs takes charge of the communication with the DSIC, and the other one makes the management of the data collected from the others PCs.

The PCs main functions are :

- To set alarms detections if a set point is reached for a parameters.

- To call manual and automatic to all the remote automatic stations (radiological and/or meteorological parameters).
- To request the parameters state from the radiological equipment (configuration of parameters, calibration factors, backgrounds, set points, etc)
- To display graphics and prints of time and spatial evolutions for all the parameters of automatics stations (daily and monthly evolutions, low and high value for each day and station, spatial values in all the National Territory, etc.).

Progress on the IAEA/GEC Programme on Validation of
Environmental Model Predictions (VAMP)

International Atomic Energy Agency, Vienna, Austria
and

G.N. Kelly

Commission of the European Communities, Brussels, Belgium

This programme seeks to take advantage of the unique opportunity created by the Chernobyl Accident for testing and improving models used for radiological assessment and involves laboratories in more than 20 countries.

Data acquired from the extensive post-Chernobyl measurement programmes in Europe and the former Soviet Union have been used as a basis for reviewing our understanding of important transfer processes and for developing model test scenarios. This paper describes the progress of VAMP since its inception in 1988 and the work and achievements of its four working groups: Terrestrial, Urban, Aquatic and Multiple Pathways.

USE OF MICRONUCLEI IN BIOLOGICAL DOSIMETRY WITH GAMMA
RAYS: A METHOD FOR RAPID SCREENING IN THE CASE OF
LARGE-SCALE RADIATION ACCIDENTS

DI GIORGIO, M.; FERRARO, M.; THOMASZ, E.

Comisión Nacional de Energía Atómica
Gerencia Seguridad Radiológica y Nuclear
(1429) Av. del Libertador 8250
Buenos Aires - Argentina

The dose-effect relationship of micronuclei frequencies in cytokinesis-blocked human lymphocytes after in vitro gamma irradiation of whole blood in the range from 0,5 to 4 Gy was studied. A linear-quadratic response was obtained. Due to the high background micronuclei frequency and their large interindividual variability observed ($0,013 \pm 0,008$) the micronucleus assay may be potentially useful to estimate gamma radiation doses above 0,5 Gy.

INTRODUCTION

For nearly 30 years the frequency of chromosomal aberrations (particularly dicentric) observed in cultured peripheral blood lymphocytes has been used as a biological dosimeter for assessing accidental overexposures to ionizing radiation.

In recent years there have been some serious accidents, such as Chernobyl and Goiânia, that have involved large numbers of people. The time needed for scoring a sufficient number of metaphasic cells for dose estimation, specially in the case of large-scale accidents as well as the need for properly trained and experienced personnel, justified the search for other methods. The micronuclei assay provides an easier and faster method for quantifying chromosomal damage.

Several laboratories studied the dose-effect relationship for micronuclei frequencies X-ray-induced but there is scarce information for γ -ray-induced micronuclei.

Taking into account all the above mentioned facts, we have performed a dose-response relationship using γ -rays from a Co-60 source.

MATERIALS AND METHODS

Radiation exposure protocol: Heparinized venous whole blood samples were collected from two healthy adults aged below 35 years old to perform the dose-response relationship. Samples were exposed at 37 °C to 0,5- 1- 2 and 4 Gy of Co-60 gamma radiation, delivered at a mean rate of 0,70 Gy/min (Picker C4M60 machine) in our Secondary Standard Dosimetry Laboratory. An extra blood sample of a single donor was irradiated with 3 Gy in the same conditions. The micronuclei base-line was estimated from blood samples of ten healthy donors.

Culture methodology : Whole blood samples were incubated in medium RPMI 1640 complemented with 15 % fetal calf serum at 37 °C for 72 hs. Stimulation of lymphocytes was reached by addition of phytohemagglutinin P at a final concentration of 1 µg/ml. At 44 th hour of incubation, cytochalasin B at a final concentration of 4,5 µg/ml was added to the cultures. Cells were spread onto slides after a mild hipotonic treatment (1) and fixed in acetic acid-methanol 1:3 mixture. Cells were stained by Giemsa 10 % .

We established the micronuclei frequencies scoring 500-2000 binucleate cells per dose and per blood sample. The criteria of Countryman and Heddle (2) were applied to identify micronuclei in binucleated cells.

Curve fitting and data handling : A weighted least squares method was used for curve fitting, using as a weight the value of the observed frequency of micronuclei for each observation. The distribution of micronuclei in binucleate cells for each value of studied dose were compared with Poisson distribution using the u test (3), χ^2 test and the variance to mean ratio.

RESULTS

Table 1 shows the spontaneous frequency of micronuclei and the distribution in unirradiated cytokinesis-blocked lymphocytes from 10 donors. The mean base-line frequency was $0,013 \pm 0,008$. The great variability between donors have already been described by various laboratories (4, 5, 6)

The dose response data obtained by scoring cytokinesis-blocked cells from 2 donors as well as the distribution of micronuclei in binucleate cells are given in table II.

The parameters of the yield equation were obtained by fitting data of individual donors separately. The best fit in the range of 0-4 Gy was linear-quadratic and the relationship is :

$$Y = c + \alpha D + \beta D^2 \quad D = \gamma\text{-ray dose in Gy}$$

$c = 7,44 \text{ E-}03 \pm 2,25 \text{ E-}03$	$\alpha_1 = 2,15 \text{ E-}02 \pm 3,7 \text{ E-}03$
$\beta = 3,17 \text{ E-}02 \pm 1,12 \text{ E-}03$	$\chi^2 = 5,36 \text{ E-}02$

Records were kept of the proportions of binucleate cells having 0, 1, 2 or 3 or more micronuclei in preparations from donors 1 and 2. Table III

The distribution of micronuclei were overdispersed relative to that expected based on Poisson assumptions, except for 1 Gy. So we can not find a clear dose-distribution relationship.

The yield of micronuclei in a 3 Gy irradiated blood sample of a single donor was $0,31 \pm 0,025$. This value is quite similar to that obtained using our curve coefficients ($0,35 \pm 0,03$).

DISCUSSION

The high background micronuclei frequencies and their large interindividual variability could impose some uncertainties on using micronucleus assay for estimating individual low dose whole body exposures in vivo. Thus micronucleus analysis may be potentially useful to estimate X-ray doses above 0,1 Gy (5, 7) and γ -ray doses above 0,5 Gy, according to our data. We have not observed saturation of the dosimeter after exposure to 4 Gy

Our data show a very good fit to the linear-quadratic model with a χ^2 of 5,36 E-02 with 15 df. In order to check our curve fitting we have compared a 3 Gy irradiated blood sample of a single donor (0,31 \pm 0,025) with the curve value at the same dose (0,35 \pm 0,03) being quite similar. These values are in good agreement with the value reported by Huber et al (8) at the same dose with Cs-137 (0,345 \pm 0,027).

Distribution of micronuclei among cells were found to be overdispersed for 0,5- 2 and 4 Gy relative to that expected by Poisson statistics. Thus we have not found a clear dose-distribution relationship in contrast with the data reported by Prosser et al (7) where the distribution of micronuclei was overdispersed and moreover the variance to mean ratio, increased as the dose increased.

According to our results, the micronucleus assay is a suitable dosimeter for estimating in vivo whole body exposures to γ rays for doses above 0,5 Gy, and it is particularly useful for large scale screening programs due to its simplicity and to the short time required for its analysis.

MEDICAL ASPECTS OF RADIATION PROTECTION IN NORMAL AND ACCIDENTAL SITUATION

D.Stojanović

"Boris Kidrič" Institute of Nuclear Sciences, Vinča, Belgrade, Yugoslavia

ABSTRACT

The most important radiation medicine aspects of the diagnostics of the radiation damage, problems of differential diagnosis, having in view the persons in the field of medicine and industry. The effect of decontamination in the prevention of irradiation was evaluated at persons employed on the Reactor RA in Vinča, in laboratories which produce and use radionuclides in period of time over 30 years.

A special interest was given in work to contemplation of some methods of biological indications, as well as to the haematological, biochemical, cytogenetical parameters with estimation of their relevancy for evaluation of the possible postirradiation effects in normal and accidental situation and expert opinion at occupational exposition too.

INTRODUCTION

Investigations are included experimental materials in the frame of decontamination of normal skin contaminated with radioiodine or radiocaesium in experimental conditions from aspects of the influence of some decontamination means on the skin permeability and the degree of internal contamination in dependence of the state of the skin, type and chemical form of radiocontaminant. In experimental conditions the efficiency of decontamination based on evaluation of the total body burden of radionuclides and residual radioactivity in the decontaminated region. In human praxis the decontamination treatment presents the most effective medico-prophylactic procedure in the prevention of local and total irradiation, although base on phenomenal evaluation.

The investigations in experimental conditions concerns also the reactivity of some radiosensitive systems at condition whole body gamma irradiation as well as effects of application of the antiradiation means on the haematopoietic tissue. At small laboratory animals were observed: lethality and surviving, clinical changes, quantitative changes of total leucocytes, erythrocytes

and platelets count, differential blood picture, change in percentual ratio between small and large lymphocytes in peripheral blood, occurrence of cytomorphological changes in white cells of peripheral blood, haemoglobin, haematocrite and other changes.

The effect of the applied drugs on the postirradiational haematologic reaction and reparatories, have been observed in dependence on ordinary time in some phases of acute radiation illness.

In epidemiological study the results of medical supervision of persons occupationally exposed to ionizing radiation, controlled in period of ten years have been presented. Observations were selected according to occupation (workers employed in metal, chemical, paper and tobacco industries and avia companies), to the sex, age, character of exposition (external and internal exposures), and dosimetric data of the received doses.

In the paper the problems of the differential diagnosis of some states and diseases according to the systems (skin, eyes, cardio-vascular system, endocrine and nervous system, haematopoietic tissue), have been discussed with special attention to focuses in the organism, which can change numerical values in the peripheral blood or as far as their look is concerned that could be very similar to changes affected by action on of ionizing radiation.

On the basis of the existed criteria for evaluation of haematological parameters, pathological states of the skin, lenticular injury, changes in cardio-vascular system and changes in other systems too, indications and contra-indications for work with ionizing radiation have been observed. The incidence and persistence of morphological changes of lymphocytes and granulocytes in peripheral blood and anaemic states in correlation with changes, caused other harmful factors arised from working environment.

METHODS

Methodology includes the experimental study and the analysis of epidemiological data taken from the human praxis.

Experimental: The experiments were performed on the white male rats, narcotized with urethane. The skin made "Fat-free" using soap before contamination. The radioactivity of the applied amount of solution $^{131}\text{I}\text{NaI}$ and $^{137}\text{CsCl}$ was 1,85 MBq. Decontamination of the skin: five treatments were performed in duration of the minute each. Means for decontamination, saline, 1% Cetavlon, 2,5% Sterigal, 0,5% iodine tincture, 5% HMF, 0,25% DBS-7R, PAM-03.

Radiation source and exposure conditions: Irradiation was carried out using cobalt-60 gamma-rays at a dose rate of 23,5 Gy/min and at a distance of 70 cm. During irradiation each animal was placed in a separate compartment of the wooden box. The integral dose to the whole body was 6 Gy what represents a sublethal dose under the given experimental conditions. The animals were isolated in a separate cage and kept under the usual conditions of feeding and care until the end of the experiment.

Treatment with Plibex and pyridoxine: Plibex is given every second day in quantity of 0.1 ml per animal beginning first day or tenth day after irradiation. Given content of Plibex^(R) is following: thiamine-chloride 0.2 mg, riboflavin 0.02 mg, nicotinamide 0.5 mg, calcium-pantotenate 0.05 mg, pyridoxine chloride 0.04 mg and cyanocobalamine 0.02 µg. Pyridoxine was applied i. m. every day at a dose of 0.3 mg/animal.

RESULTS AND DISCUSSION

1. Decontamination of persons at an operating nuclear plant and in laboratories of Institute "Boris Kidrič" - Vinča

- Period of observation: over 30 years
 - Number of cases: 76
 - Anatomical locality: fingers of handful, handfuls, forehead, hair forehead, nose, neck, face, lips, temple, ears, foot, fingers of foot, frontal bump, eye, cheek.
 - Radiocontaminants: ^{131}I , ^{198}Au , ^{239}Pu , ^{137}Cs , ^{60}Co , ^{111}Ag , ^3H , ^{24}Na , ^{109}Ag , Unknown composition.
 - State aggregation: dust, gas, liquid.
 - Decontamination: contained 4-5 procedures by use of cotton, wool and rinsing or by cleaning with solution of means for decontamination: 5% detergent, toilet soap, 3% citric acid, saline, 2% boric acid, combination 5% detergent with 2% versen, permanganate.
2. The observed changes, deviations and diseases of the supervised persons in dependance of working exposition is given in Table 1.

Table 1. Number of supervised person

Working exposure (years)	N	Skin	Haematologic changes		Eyes
			Numerical	Morphologic	
1 - 5	50	14	5	5	1
6 - 10	31	5	8	8	1
11 - 15	34	26	19	5	2
16 - 20	16	5	6	3	1

CYTOGENETIC MONITORING OF NUCLEAR POWER PLANT WORKERS IN FINLAND

S. Salomaa and A. Koivistoinen

Finnish Centre for Radiation and Nuclear Safety
P.O.Box 268, 00101 Helsinki, Finland.

ABSTRACT

Twenty nuclear power plant (NPP) workers from the two plants in Finland are scored annually for chromosomal aberrations. Results from the first two years of surveillance show that the NPP workers had significantly higher frequencies of radiation-related chromosome-type aberrations in their lymphocytes than the controls. The frequencies of dicentric and ring chromosomes were, however, well within the range that could be expected on the basis of their cumulative radiation exposures. Lymphocyte micronucleus analysis did not reveal any differences between the exposed and the controls.

INTRODUCTION

The frequency of chromosomal aberrations in peripheral blood lymphocytes is a sensitive, dose-dependent indicator of exposure to ionizing radiation. In the present study, we have applied the analyses of chromosomal aberrations and micronuclei in the surveillance of occupational exposure of NPP workers to low-level radiation (mean annual doses of about 5 mSv). As also other factors than the occupational radiation exposure affect the extent of chromosomal damage, the results of the cytogenetic analyses were compared to an unexposed control group of the same size, matched by the known confounding factors (age, sex, smoking habits and medical X-ray examinations).

MATERIAL AND METHODS

Altogether 20 workers from two different plants, a boiling water reactor (BWR) plant and a pressurized water reactor (PWR) plant, were scored annually for chromosomal aberrations. The workers attending the cytogenetic analyses represented the most exposed personnel at their plants, with the highest life-time and/or annual radiation doses. The mean life-time doses were 34 mSv in 1988 and 36 mSv in 1989 for the group working at the BWR plant, and 71 mSv in 1988 and 77 mSv in 1989 for the group working at the PWR plant. The mean employment times were about 10 years in both groups. The results of the cytogenetic analyses were compared to an unexposed control population of the same size, matched by age, sex, smoking habits and X-ray examinations. Domestic radon exposure was also taken into account in part of the material. Indoor radon measurements were carried out during winter with α -film boxes (type SSNTD with Makrofol polycarbonate film).

For the chromosomal aberration analysis, peripheral blood was cultured for 48 hours with Eagle's MEM medium, human AB serum and leukoagglutinin. The control cultures were run parallelly with the exposed group. Five hundred cells from each subject were analysed from Giemsa-stained, coded slides. The

chromosomal aberrations scored included both chromatid aberrations (breaks, gaps) and chromosome-type aberrations (breaks, gaps, dicentrics, rings, translocations and inversions).

Cultures for the micronucleus analysis were established from the same blood samples as the chromosome cultures. Lymphocytes were isolated with Ficoll-Paque, and cultured with RPMI-1640 medium, foetal calf serum and phytohemagglutinin. Cytokinesis of the daughter cells was blocked by cytochalasin-B, which was added at 44 hours, and after 72 hours in culture, the cells were harvested by cytocentrifugation, fixed with methanol and stained by May-Grünwald-Giemsa. From each subject, 3000 binucleated cells were analysed for micronuclei.

The Mann-Whitney U-test and the Fisher's exact probability test were used in the statistical analysis of the cytogenetic data.

RESULTS

The annual data of chromosomal analyses are shown in Table 1. In 1988, the workers of the BWR plant did not differ from the controls, but most of the workers in the PWR plant group had higher frequencies of chromosome-type aberrations than the controls ($P < 0.05$, Mann-Whitney U-test).

Table 1 Frequencies of chromosomal aberrations (per 1000 cells, gaps excluded) among the NPP workers of the BWR and PWR plants and the parallel controls.

Group/year	Number of			Cells with	
	dic, r	cs	ct	cs	ct
BWR/1988	0.8	5.2	4.4	4.2	3.6
Control	1.2	4.6	4.6	4.0	4.0
PWR/1988	1.4	9.0*	9.0	6.2	7.0
Control	0.8	7.0	9.0	4.4	7.0
BWR/1989	1.8*	7.4*	7.4	5.6	6.2
Control	0.4	4.6	8.2	3.8	5.6
PWR/1989	2.3*	6.6*	6.8	5.4	6.0
Control	0.8	4.7	7.3	4.1	6.3
Radon control	0.8	3.8	6.0	3.8	5.2

dic, dicentric chromosomes; r, rings; cs, chromosome-type aberrations; ct, chromatid aberrations; * $P < 0.05$

After the first year, it turned out that the workers of the PWR plant live in houses with high indoor radon concentrations (mean winter concentration, 600 Bq/m³), whereas the radon concentrations in the dwellings of the controls were estimated to be close to the country's average, about 100 Bq/m³. This was also later verified by measurements. Thus, next year, an additional control group was gathered of persons living in the area; the mean radon concentration in their dwellings was 490 Bq/m³. However, the aberration frequencies of the radon controls were

similar to those of the other controls, but the PWR plant workers differed significantly from both of these control groups. Thus, the domestic radon exposure did not explain the increased frequencies of radiation-related aberrations. In the second year, also the workers at the BWR plant had significantly higher frequencies of chromosome-type aberrations. At the individual level, there were no exceptionally high frequencies of dicentric and ring chromosomes, and the biological dose estimates were in the range that could be expected by the cumulative radiation doses.

The combined chromosomal aberration data from the first two years of surveillance are in Table 2, showing significant elevations in radiation-related chromosome-type aberrations among the NPP workers. Moreover, those aberrations are also more frequent among the subjects with higher radiation doses.

Table 2 Frequencies of chromosomal aberrations (per 1000 cells, gaps excluded) among the NPP workers, divided into two subgroups by their life-time doses, and the controls. The statistical analyses have been performed only between all the NPP workers and their matched controls.

	Control	NPP; all	NPP; < 50 mSv	NPP; 50-100 mSv
No. of cultures	40	40	19	21
No. of individuals	23	23	13	11
Total no. of cells	19,932	19,845	9,500	10,345
Mean age (yr)	43.0	42.7	40.9	44.3
Mean dose (mSv)	0	54.7	30.1	76.9
% smokers	58	58		
% with X-ray exam.	43	48		
No. of chromosome ab.	5.3	7.2**	6.4	7.8
No. of dic. and rings	0.8	1.5*	1.4	1.6
No. of fragments	3.5	3.8	3.1	4.5
No. of stable aberr.	0.7	1.3*		
No. of chromatid aberr.	7.3	6.9	5.8	7.9
Cells with chromosome aberr.	4.1	5.3*	4.7	5.9
Cells with chromatid aberr.	5.7	5.7	4.7	6.6

* $P < 0.05$; ** $0.05 < P < 0.001$

Some effect of ionizing radiation could be seen also after medical exposures. Among the controls, those with medical X-ray examinations had significantly more cells carrying translocations and inversions than those with no (major) examinations (1.1×10^{-3} v. 0.3×10^{-3}).

Chemical agents, like compounds in cigarette smoke, mostly cause chromatid aberrations in peripheral lymphocytes. In the present study, the frequencies of chromatid aberrations were higher among the smokers in both the NPP workers (8.5×10^{-3} v. 4.5×10^{-3}) and the controls (8.5×10^{-3} v. 5.5×10^{-3}); the differences were highly significant ($P < 0.01$).

Micronucleus analyses in cytokinesis-blocked lymphocytes did not show any differences between the NPP workers and the controls (Table 3). Neither was there any difference between the smokers and the non-smokers (data not shown).

Table 3 The frequency of micronucleated lymphocytes among the NPP workers and their controls. There were ten subjects in each group.

Group	No. of cells	Cells with MN (per 1000)	Total No. of MN (per 1000)
BWR plant	30,000	8.0	9.7
Control	28,793	9.9	11.6
PWR plant	30,000	10.8	13.2
Control	30,000	10.2	12.3

CONCLUSIONS

Low-level exposure to ionizing radiation was shown to cause a significant increase in the frequency of chromosome-type aberrations in the lymphocytes of nuclear power plant workers. Domestic radon exposure did not explain the elevated frequencies observed at the PWR plant, that is located in a radon-rich area. The effect of medical X-ray examinations was seen as a significant increase in the frequency of stable chromosome aberrations. Smoking caused a highly significant increase in the frequency of chromatid aberrations.

The micronucleus analyses failed to reveal any differences either with respect to radiation exposure or smoking. Thus, at present, it seems to be a less sensitive method than the conventional chromosome aberration analysis in the detection of cytogenetic effects of genotoxic exposures.

CHROMOSOMAL ABERRATIONS IN PERSONS PROFESSIONALLY EXPOSED TO IONIZING RADIATION

G. Joksić and B. Marković

Institute of Occupational and Radiological Health
University Clinical Center of Belgrade, Deligradska 29
11000 Belgrade, Yugoslavia

ABSTRACT

Dicentric aberrations indicate significantly greater incidence (25-28% of cases analysed) in the group dealing with radionuclides when compared to those exposed to sealed sources of radiation (8-12% of cases analysed), with the similar duration of professional exposure. Dicentric frequency in professionals depends on the source of radiation, working conditions and applying of radiological protection measures.

INTRODUCTION

Professional exposure of a great number of working population to various mutagenic agents represents an exceptionally significant field of research. The results of this research have an important practical application in prevention of occupational diseases. For over 20 years the frequency of chromosomal, particularly dicentric, aberrations observed in cultured peripheral blood lymphocytes have been used as a biological dosimeter for assessing accidental overexposure to ionizing radiation (1). In professional exposure, chromosome aberration analysis is most commonly qualitative in character (determines the type and incidence of aberrations), and it is performed in cases when medical parameters or dosimetric data indicate possible irradiation (4).

MATERIAL AND METHODS

The results of several years long study on chromosomal aberrations in persons occupationally exposed to ionizing

radiation are presented in this paper. The professionals are classified in groups according to the type of work and duration of the exposure in the zone of ionizing radiation. For each patient detailed anamnestic professional questionnaire is completed and data on possible therapy with physical and chemical agents as well as on diagnostic procedures with ionizing radiation for the past 12 months are registered. The results of chromosome aberration analysis for the 634 professionals are presented in the following results.

RESULTS AND DISCUSSION

The results, presented in the Table 1., from investigations lasting several years, indicate that the largest percent of subjects with chromosomal aberrations are found in professional groups working with radionuclides, and those are health workers in nuclear medicine, personnel in research laboratories using radionuclides as markers and workers in industries applying tritium. In the group working in nuclear medicine and research laboratories the percent of subjects with dicentrics was 25, while 5.4% was with symmetrical chromatid interchanges or triradials. In the group of workers in tritium applying industries (tritium was in the form of gas), dicentric chromosomes were found in 28.9% of cases, while in the group of workers exposed to tritium in the form of radioactive luminous paint, percent of cases with dicentrics was 8.3%. In the group of radiologists and technicians, 12.2% of cases was found with dicentric aberrations. In the group of professionals working on application of invasive hemodynamic methods in cardiology 8% of cases was found with dicentric aberrations, and in 12% of cases chromatid interchanges and triradials were found. The results indicate significantly greater incidence of chromosomal aberrations in the group dealing with radionuclides when

 **** professionals in tritium applying industry

Table No.1.

compared to those exposed to sealed sources of irradiation with the same duration of the exposure. Additionally, the presence of symmetrical chromatid interchanges and triradials may be frequently observed in persons dealing with radionuclides. This type of aberration is otherwise extremely rare in professional exposure to unsealed sources of radiation. A high incidence of such changes was encountered in a group of routinely controlled workers, with urine tritium contamination evidenced several years ago (2), chromatide interchanges were found only in patients with dicentric and rings. All of them received a certain dose of ionising radiation. Since a large number of investigators state that chromatide aberrations are probably a consequence of "non-radiation" events (1), we would like to indicate to the fact that they may be the

consequence of ionizing radiation effects. In both groups dealing with radionuclides several subjects with higher number of chromosomal aberrations are noticed. One of the important factors influencing this result was the cumulative effect of ionizing radiation. The second important factor was the radiation type and activity, as well as the type of diagnostic method, therapeutical approach or technological procedure (3).

A whole range of radioisotopes are being used in nuclear medicine and research laboratories. With the application of higher activity isotopes the risk increases. This especially concerns the risk of internal contamination with radionuclides. Special attention must be given to personnel education and planning of appropriate working premises for work with radionuclides, which will provide maximal protection.

CONCLUSION

Dicentric aberrations indicate significantly greater incidence (25-28% of cases analysed) in the group dealing with radionuclides when compared to those exposed to sealed sources of radiation (8-12% of cases analysed), with the similar duration of professional exposure. Dicentric frequency in professionals depends on the source of radiation, working conditions and applying of radiological protection measures.

PRELIMINARY REPORT OF A FETAL-THYROID OVEREXPOSURE CASE DUE TO THE
ADMINISTRATION OF I-131 DURING THE SECOND TRIMESTER OF PREGNANCY

INTRODUCTION

Sixty to eighty per cent of patients with Graves' disease have antibodies directed against thyroglobulin or against thyroid microsomes. A contemporary interpretation is that thyroid stimulatory immunoglobuline TSI mimics the action of TSH and stimulate the synthesis and release of thyroid hormone. In patient whose thyroids are capable of responding to such a trophic stimulus, TSI may be the mediator of hyperthyroxinemia. TSI cross the placenta and cause transient hyperthyroidism in some neonates (0,5-1 %) born to mothers who have high circulating levels of the antibodies.

As regards adults aged 25 and up, administering I-131 radioactive iodine seems to be a satisfactory treatment for Graves' disease. Such a treatment, however, is to be avoided when treating either pregnant or breast-feeding women due to the effects that irradiation is likely to cause to the fetus or the suckling child. Even though such effects depend on the intrauterine developmental stage, the principal effects are as follows: (a) The embryo may be lethally affected; (b) Malformations and structure changes, or changes in the child's development are likely to occur; (3) The child may be mentally retarded; (4) An induction to cancer and leukemia is possible, and (e) Hereditary effects may be expected.

Moreover, it is a well-known fact that the fetal thyroid is able to capture and integrate iodine as of the 10th/12th gestation week. Thus, administering I-131 according to prescribed doses may define or suppress the thyroid function. Therefore, the highest precautions must be taken in order not to carelessly administer I-131 therapeutic doses to pregnant women. Any woman within the reproductive capacity range should be strongly advised that a pregnancy test is to be performed to avoid her fetus being irradiated. Precisely, the present paper deals with the inadvertent administering a I-131 therapeutic dose to pregnant woman with Graves' disease whose child -unexpectedly enough- turned out to be suffering from hyperthyroidism.

A CASE STUDY

Patient with thyroid background on the maternal side.

After a stressful situation during year 1988, patient evidences the characteristic signs and symptoms of hyperthyroidism, namely: ophthalmopathy, and diffuse goitre, confirmed by an I-131 catchment and hormonal measurements. Results obtained in 1988 were

as follows: TSH < 0.5 uu/ml ; T3 = 800 ug/dl; t4 = 19.8 mcg/dl;
Catchment % = 11 - 51 - 68

Patient is treated with 30-45 mg methilmercaptioimidazol q.d.. However her compliance is quite poor. In 1989, patient comes back to consultation after having suspended the treatment: She is clinically toxic. Again, she is prescribed 45 mg methilmercaptioimidazol q.d.- she nonetheless relapses in poor compliance. In 1990, a new examination is performed, appearing a toxic symptomatology. Patient, however, denies being pregnant: She claims she has been having her menses up to August 1990. Thyroid catchment was 58-100-96 %. Patient is administered a I-131 therapeutic dose, i.e. 5 mCi (185 MBq).

COURSE OF PREGNANCY

Later, during a clinical control, an abdominal palpation reveals a 5-month pregnancy. An abdominal echography certifies a 23-week gestation, which allows us to guess that the I-131 dose was administered during patient's 17th-pregnancy-week. During her 34th week, patient is referred to SAMARI (The Spanish acronym stands for Medical Care System for the Exposed to Ionizing Radiations). Clinically as well as biochemically speaking, patient evidences normal thyroid values: TSH = 0.17 uU/ml; T4L = 1.3 mcg/dl. Fetal heart rate is 180/min with a positive vagus response coinciding with the 110/min maternal pulse rate. A rear-located placenta is seen on echography. A puncture of amniotic liquid is performed with a measuring of TSH 0.16 uU/ml which was a normal value at that time. Fetal heart rate was between 150/170 pulse/min. A new puncture of amniotic liquid evidenced that the liquid was macroscopically mature, with a slightly higher TSH value = 0.4 uU/ml, with vernix caseosa. Echography allowed to see the distal ossification nuclei of a femur as well as the proximal ossification nuclei of a tibia: Those results allowed us to disregard a possible fetal hypothyroidism diagnosis.

CLINICAL CHARACTERISTICS OF THE NEWBORN INFANT

With a normal delivery, a 50-cm long, 2.600-kg, and 9-10 Apgar boy is born alive. As per a clinical examination the gestational age is deemed to be 42 weeks.

The newborn infant evidences ophtalmigthisis, goitre, a point-like fore fontanelle, and a closed rear fontanelle. Infant is irritable, with tachycardia (FC = 170/min); tachypnea (FR=60/80/min) and high blood pressure (120-60) mmHg. The infant progress is shown on table I. As of age 3-month up to now, infant evidences clinically and biochemically normal thyroid values.

RADIOLOGICAL EVALUATION

Doses estimates in fetus for different iodine radioisotopes have been developed for individuals with normal thyroid values. Such models, however (2,3) failed to consider the metabolic differences of female patients suffering from Graves's disease. Taking incorporation and retention in patients suffering from Graves's disease, M.G. Stabin et al (4) have developed a model allowing a dose estimation in hyperthyroid patients who were

administered I-131. The model affords a dose estimate in the whole body of the fetus involved as well as the fetal thyroid. A dose in the whole fetal body from maternal organs was estimated, considering that the bladder contributes with 70 % of the total dose, for a maximum incorporation of thyroid. The dose in the whole body of a 17-week fetus, and 100 % of maternal catchment was estimated in 4.25 mGy. Even with the worst conditions being assumed, such a dose implies a risk lesser than $1.7 \cdot 10^{-5}$ of mental retard as well as another much lesser risk ($1.19 \cdot 10^{-4}$) of cancer in childhood. Estimating the dose in the fetal thyroid as of 3-month old up to 9-month old infants was taken from two different sources, namely: An estimate adapted by Watson (5) assuming a biological $T_{1/2}$ constant in the fetal thyroid at any age range, and an estimate by Elsasser (6) accepting a biological $T_{1/2}$ varying all over gestation.

According to the proposed dose factors, an estimated dose in the fetal thyroid at the 17th week could be included between 40.7 and 101 Gy. If the inorganic iodine distribution space is shared between mother and fetus, the offer of I-131 should be similar for both involved. Assuming that the fetal thyroid is more radiosensitive (7) than the maternal thyroid, hypothyroidism is likely to be expected. Surprisingly, however, the newborn infant we are referring to was with hyperthyroidism. We are lacking a dose-effect relation for the induction of hyperthyroidism in the fetal thyroid. C. Schümichen (8) estimates 463 MBq to be the minimum activity inducing a permanent hypothyroidism. Applying Watson's, and Elsasser's dose measuring factors, such activity would correspond to a dose included between 101 and 254 Gy in the fetal thyroid.

There exist very few cases of an I-131 treatment carelessly administrated during the late semester of a gestation in literature. Only 3 similar cases have been found by our research team: They deal with female patients suffering from Grave's disease that were administered 536.5, 296, and 225.7 MBq, respectively, with 53, 63, and 83 % catchments in the maternal thyroid, respectively (9, 10, 11). The newborn infants corresponding to the first and second case study were hypothyroidic. The third case -i.e. the closest to our case -was a newborn infant who was thyroidically normal. Such case received a lesser activity, with a higher catchment of the maternal thyroid. It is necessary to keep in mind that, whenever adults are involved, a threshold dose likely to induce hypothyroidism within a 5-year lapse of time after I-131 has been incorporated, is 10 Gy. It is compulsory that the child involved be followed up during his or her growth process for an early detection of hypothyroidism thus avoiding its repercuting on the intellectual development by means of an adequate treatment. It is quite possible that the higher TSI levels in the mother induced a maximum catchment of I-131 with a lower "offer" to the fetal thyroid than the one producing hypothyroidism.

It is also compulsory to have all countries strictly ruling that a pregnancy test be applied to hyperthyroidic women within the reproductive capacity age range before they are administered therapeutic doses.

In such cases where a careless administering of I-131 in pregnant women during the first semester or early last three months of pregnancy has occurred, the results of the evaluations should be published.

GUIDELINE VALUES FOR SKIN DECONTAMINATION MEASURES BASED ON
NUCLIDSPECIFIC DOSE EQUIVALENT RATE FACTORS

Drs. H. Pfob*, G. Heinemann **

2160 Stade, Germany

ABSTRACT

Corresponding dose equivalent rate factors for various radionuclides are now available for determining the skin dose caused by skin contamination. These dose equivalent rate factors take into account all contributions from the types of radiation emitted. Any limits for skin decontamination measures are nowhere contained or determined yet. However, radiological protection does in practice require at least guideline values in order to prevent unsuitable or detrimental measures that can be noticed quite often. New calculations of dose equivalent rate factors for the skin now make the recommendation of guideline values possible.

INTRODUCTION

While German and international ordinances call for limiting values for protective measures where surface contamination of workplaces and objects has occurred, they do not contain any limits for skin decontamination measures. The resulting danger is that decontamination measures that are unsuitable or too expansive could harm the skin or encourage incorporation. That is why radiological protection in practice does at least require guideline values to limit decontamination. Prerequisite for this is the possibility of determining the skin dose. On the basis of new calculations, we have now a list of dose equivalent rate factors for the skin of 611 and all nuclids relevant for radiological protection. Following this, guideline values can be recommended. Moreover, findings on the intake of radioactive substances into the skin and their transport through the skin have to be taken into account. Between these two limits - the unreasonable skin dose on the one hand and the incorporation through measures of decontamination - are the reasonable measures of the decontamination of individuals.

THE COMPILATION OF A RECOMMENDATION BY THE GERMAN COMMISSION
ON RADIOLOGICAL PROTECTION

By order of the German Commission on Radiological Protection a team of specialists developed a recommendation "Measures to Be Taken in Cases of Radioactive Contamination of the Skin" in the years 1988 and 1989, which was published by the Secretary of the Environment, Ecological Protection and Reactor Safety on March 3rd, 1990. The team could refer to the results of discussions in the Professional Association for Radiological

Protection Inc. and the Association of Specialists for Radiological Protection Medicine about the limiting of measures of decontamination based on practical experience in nuclear power plants and on dermatological findings.

Major points of the recommendation are:

- Derivation of a Guideline Value for Measures where Skin Contamination Has Occurred
- Transport of Radioactive Substances into and through the Skin
- Preventive Measures for the Avoidance or Limitation of a Contamination
- Organization and Execution of Skin Decontamination in the Practical Work of a Company
- Possible Radiation Exposure of Medical Staff when Treating Contaminated Patients

DETERMINATION OF THE SKIN DOSE

The dose equivalent rate factors take into account all contributions from the types of radiation emitted (alpha-, beta-, gamma-, and AUGER-radiation). When calculating the dose equivalent rate factors, it is assumed that the layer of the skin regarded as sensitive to radiation is usually 50 - 100 μm below the surface. With the help of the dose equivalent rate factors, the local skin dose can be calculated by multiplying these with the surface-related activity on the skin (in Bq/cm^2) and with the duration of contamination (in seconds), taking into account the respective half life.

The German Commission on Radiological Protection takes into account the following presumptions for the calculation of a guideline value:

- The major part of the activity concentrates on the skin surface. Its amount is crucial for the dose.
- The activity that has penetrated the horny layer decreases very quickly (exponentially with a half-value thickness of around $2\mu\text{m}$).
- The remaining activity stays on the skin in its full strength for a week. This is a very conservative assumption. In fact, the complete horny layer undergoes full exfoliation within two weeks. Hence there is a rapid decrease of the activity situated in the higher layers of the cornea.

DERIVATION OF A GUIDELINE VALUE

The primary limit for skin contamination of 300 mSv in any one calendar year is used as a basis when deriving a guideline value. This guideline value should provide a sufficient safety distance even if

- the contamination appears several times a year
- there are uncertainties regarding the dose determination on a daily basis
- there are contributions from radioactive daughter nuclides which are not included in the contamination measurement.

These aims are guaranteed by a simple, practicable and easily remembered guideline value for surface-related activity of 10 Bq/cm² (averaged over 100 cm², where the contamination is largely distributed over the entire area). Further decontamination measures are not required below this value. This means that for more than 90% of the nuclides listed, including those of relevance to radiological protection, less than 1% of the aforementioned annual dose limit is reached with a retention time of one week. Moreover, with one exception (Cf 254), all doses are less than 5% of this limit. The doses even are significantly lower if contamination is quickly and fully eliminated.

The uniform guideline value of 10 Bq/cm² should also be applied to those radionuclides which, due to the short range of their radiation, do not make any contribution to the dose of the layer of skin regarded as radio-sensitive. This constitutes sufficient provision against risks caused by the spreading of radioactive substances outside the controlled area. In this context, it is assumed that cases of persistent residual contamination are very rare and that any remaining activity adheres firmly to the skin. Special reflection is necessary where contamination spreads beyond the surface of a person's head or hands.

TRANSPORT OF RADIOACTIVE SUBSTANCES INTO AND THROUGH THE SKIN

The skin represents an effective, but not completely impenetrable barrier against radioactive substances. As long as a liquid wets the surface of the skin, substances are transported from the surface into and through the skin. The activity absorbed by the horny layer and its transport through the skin (permeation) are proportional to the activity concentration of the liquid and to the size of the area of skin affected, as well as the amount of time the contaminating liquid is on the skin. The horny layer absorbs about one microliter of liquid per cm², and thus the activity contained therein.

CONSEQUENCES FOR THE PRACTICAL WORK OF DECONTAMINATION

As the amount of time that a radioactive solution is on the surface of the skin is important, the removal of the contaminating liquids should be commenced as quickly as possible and must halt any further deposition in the skin and reduce permeation through the skin. The incorporation, however, can only play a role where a very large area of the body is affected and where there is a long period of contamination with high activity concentrations.

In principle, preventive measures to avoid or limit contamination represent the most effective form of protection. Preventive measures include regular checks on the condition of the skin and constant personal skin care, for a healthy skin offers the best protection against percutaneous incorporation of radioactive substances. German nuclear power plants, for example, check the condition of the skin in several steps: the

yearly radioactive protection checks by the company physician, monitoring by the radiological protection officer at the entrance to the control zone and - most importantly - self-monitoring by the individual plant-member. Additional protective measures specific to the workplace are recommended, for example the wearing of protective clothing or specific measures of skin care. The measures of decontamination recommended by the Commission on Radiological Protection can be summed up by the following formula: begin with the simplest measures, but aim them directly to the part of the body affected.

Low levels of contamination can usually be eliminated in one step by washing with water. Wherever possible, only the contaminated areas of the skin should be washed with lukewarm water. Usually the palms of the hands have to be washed first. The exact diagnosis of contamination that can also be done by the automatic exit monitor and the directed measure of decontamination are among the most important basics of the catalogue of measures recommended by the German Commission on Radiological Protection.

If single cases make contamination measures that are above simple washing with warm water necessary, the radiological protection officer and authorized physicians should be consulted. These measures should be classified as medical treatment.

CYTOCHEMICAL INVESTIGATION METHODS AS A CONTRIBUTION
DIAGNOSTING LEUKOCYTE TRITIUM DAMAGE

S. Milačić, S. Dodić and V. Nikolić

University clinical center
Institute of Occupational and Radiological Health-
Belgrade

ABSTRACT

The study analyses cytochemical characteristics of neutrophilic granulocytes. Alkaline phosphatase and myeloperoxidase activity was semiquantitatively determined from capillary blood smears stained acc. to Kaplow. Lipids content was examined with Sudan black B staining. The results of these cytochemical reactions are significantly different ($p < 0,05$; Mann-Whitni U-Test). Score values negatively correlate with absorbed doses but not linearly so that these methods contribute to diagnosing irradiation damage of granulocytes; but they do not have biological-dosimetric importance.

INTRODUCTION

Tritium, a radioactive isotope of hydrogen is widely used in numerous different scientific and economic fields. The specific role of tritium application is seen in so called "scintillating colours" which are mixtures of different, especially prepared, tritium compounds, so that they have a property of producing greenish scintillations. Having in mind the energy of tritium beta particles, the high activities are needed to accomplish this effect. Tritium is easily evaporable and contaminates the working environment. After the exposure, regardless to the way of penetration (respiratory or digestive tract, skin), it is easily found in blood circulation and is evenly distributed in all tissues and organs, as a component included in water metabolism. Biological half-life of elimination is 4-18 days. Leukocytes cytochemical properties were studied in workers exposed to scintillating colours, contributing in diagnostics of tritium induced damages.

MATERIALS AND METHODS

We analysed the number of neutrophilic granulocytes and values of cytochemical parameters in 21 tritium exposed workers and 11 controls. Capillary smears were stained for alkaline phosphatase activity by Kaplow's method, for peroxidase activity by benzidine reaction and for lipides by Sudan black. The intensity of staining is directly proportional to the extent of chemical reaction which is determined by microscopy on 100 cells and expressed as a score. On the basis of chromosome aberration the assessed absorbed irradiation dose is 0.12-0.59 Gy.

RESULTS AND DISCUSSION

The number of neutrophilic granulocytes is not significantly changed in tritium exposed workers (T-test for the small statistical group, $p > 0.05$) while the alkaline phosphatase (APL) and peroxidase (MFO) scores are significantly lower ($p < 0.05$, Mann Whitney's U-test). There is no significant changes in Sudan reaction (Table 1).

Table 1.

The number of neutrophils, APL, MFO and SUD scores in tritium exposed workers and controls

Examined group	n	N	NPL	MFO	SUD
E	21	3,2	36	148	214
K	11	3,8	58	196	224
p		0,7NS	0,05S	0,05S	0,3NS

APL score correlation with the absorbed dose is significant and correlation coefficient is 0.46. (Short 1). MFO score correlation with absorbed dose is negative, but statistically insignificant while Sudan reaction was not in correlation with the dose.

Figure 1.

The correlation of APL scor
with the absorbed dose
($r = - 0.46$)

Cytochemical reaction to alkaline phosphatase and peroxidase suggested significant tritium-influences changes in leukocytes when their number was unchanged. Both scor-values correlation with the dosis showed that the reaction intensity is decreased together with the dosis, although not linearly, therefore, they can't be used for biodosimetry. No changes were shown in Sudan reaction, thus it was insignificant in diagnostics of leukocytes damages induced by tritium, i.e. beta irradiation.

CONCLUSIONS

Applied cytochemical reactions to ABL and NPO are semiquantitative and easily followed tritium effects on exposed workers leukocytes which could help in early diagnosing of its function impairment related to body defence reactions.

CLINICAL CRITERIONS FOR BIOSIMETRY AT WORKERS EXPOSED TO LOW DOSES OF
IONIZING RADIATIONS

Nikolic,V.Joksic,G.Milicic,S.

University Clinical Center of Belgrade

Institute of Occupational Medicine and Radiological Health

Deligradska,29

11000 Belgrade

Yugoslavia

In the course of routine general examination of workers who work under the circumstances of exposition to the low doses of ionizing radiations,15 of them with clinical indications were underwent to chromosome aberrations analyze,such as 64 workers without any clinical indications.In the first group there were 40.6% of subjects with increased frequency of chromosome aberrations,against the only 7.5% in the second group.Considering the kind of the ionizing source,it could be noticed the higher frequency of chromosome aberrations at nuclear medicine workers (27.7%),against the workers exposed to the sealed sources (9.8%).According to our results we consider the justification of clinical indications for chromosome aberrations analyze,as the very specific biosimetric procedure.

INTRODUCTION

Chromosome aberrations analyze is of particular importance for estimation of ionizing radiations absorbed doses during the accidents (1).For the professional exposition,chromosome aberrations analyze has qualitative nature (confirming the effects of some radiation dose),and it is the case of possible irradiation indicated by medical criterions and biosimetric data (2).Clinical criterions are decisive for further biosimetric investigations during the general health examination of workers exposed to ionizing radiation.In the most cases it is appearance of presenile incipient bilateral cataract or some malignoma.More often there are present nonspecific discomfords,such as exhaustion,fatigue,headache,bad appetite for food all followed by some hematological disorders.Almost,it is always leucopenia with inverse leucocyte ratio,persisting hypochromic anemia,isolated thrombocytopenia and sometimes the immunodeficiency,all mentioned above without any other etiology.

Among the others indicators of chromosome aberrations,it is also personal dosimetry data showing the exceeding of annual (monthly) limit dose of radiation for professionals.Clinical criterions are completed with data about the kind of ionizing source and the time of professional exposition.

RESULTS

Based at the clinical criterions,15 subjects were underwent to chromosome aberrations analyze.All of them showed the most of the nonspecific discomfords,10 subjects had leucopenia (4 of them less than $4 \times 10^9/L$),and

5 of them (50%) had relative leucopenia followed by lymphocytosis. Only 1 person had presenile incipient cataract. There were no cases of malignant disease. The time of professional exposition was between 5 and 15 years.

Among these 15 subjects, there were 5 of them who showed dicentric chromosome (200 cells in the first in vitro partition by one subjects were analyzed), and 2 persons showing chromatide interchanges and triradials. The next 2 persons showed acentric fragments (within allowed limits for professionals considering the annual and monthly maximal dose). In this group, there were 40.6% of subjects with increased frequency for chromosome aberrations.

The chromosome aberrations analyze was performed at second group of 64 workers during the general health examination with no clinical indications. There were found dicentric chromosomes at 4 subjects (6.0%), only one person (1.5%) showed chromatide interchanges, and 10 persons (15.6%) had acentric fragments. In this group, there were 7.5% of subjects with increased frequency for chromosome aberrations.

If the both analyzed groups would be considered according to the ionizing radiation source (see table 1), the significantly higher frequency of chromosome aberrations (27.7%) could be noticed at the group of nuclear medicine workers, against to the workers exposed to sealed source of ionizing radiation (with similar time of exposition and working operations), showing the 9.8% of persons with increased frequency for chromosome aberrations.

CHROMOSOMAL ABERRATIONS AT THE GROUP OF PROFESSIONALS EXPOSED TO SMALL DOSES OF IONIZING RADIATION				
	number of cases analyzed	with dicentric	with chromatide interchanges	with other aberrations
professionals selected by medical indications	18	5 (33%)	2 (10.6%)	2 (10.6%)
professionals in the course of routine examination	64	4 (6.%)	1 (1.5%)	10 (15.6%)
professionals exposed to radionuclides	18	2 (11.1%)	3 (16.6%)	3 (16.6%)
professionals exposed to sealed sources	61	6 (9.8%)	/	11 (18%)

TABLE 1

CONCLUSION

According to our results, it could be emphasized the role of well selected clinical indications by experienced clinician, as the very important indicator for performing complex biological tests (in this case it is chromosome aberrations analyze). This attitude needs to be supported by more strictly and continuous biodosimetric supervision at subjects exposed to small doses from opened source of ionizing radiations.

A CASE STUDY OF AN ACCIDENTAL INHALATION OF Am-241
FROM A RUPTURED SOURCE

J Kruger, P J Kruger, D J J C Bouwer and J Albasini
Atomic Energy Corporation of SA
Pretoria, Republic of South Africa

ABSTRACT

Four workers who were involved in the accidental inhalation of americium-241 were monitored over a period of 660 days post-accident. DTPA treatment commenced on day 1 and was sustained up to 100 days. From measurements on the initial respiratory deposition, the chest and lower abdominal regions, faecal and urinal excretions, initial intakes from 7,8 to 54,4 kBq were estimated. Lung clearance with half-lives of approximately 1,50 and 500 days were identified. No significant bone deposition was measured. Committed effective dose equivalents were estimated from 2 mSv to 74 mSv for the four individuals concerned.

INTRODUCTION

During a routine transfer operation in August 1987 the encapsulation of a commercial 37 GBq (1 Ci) americium gamma source was accidentally ruptured, resulting in an air-borne release of americium oxide aluminized powder. Significant external contamination was identified on the three operators involved in the operation (cases 1, 2 and 4) and on a Health Physics technician called in after the accident (case 3). Referral to a Phoswich chest counter on the same day confirmed significant intakes. A monitoring programme was effected from day 1 post-accident. As the initial measurements on day 0 indicated possible intakes of up to 50 times Annual Limit on Intake (ALI), the individuals were also placed under medical supervision from day 1 and a DTPA treatment programme was initiated in consultation with the medical officer.

MONITORING PROGRAMME

A monitoring programme to identify the intake and initial respiratory deposition, the deposition and excretion patterns over the first few days, and the deposition and excretion patterns over an extended period of time was initiated from day 0 and maintained up to 660 days post-accident or until minimum detection levels were reached.

The initial respiratory deposition on day 0 was measured with a 7,6 cm (3") diameter NaI crystal over the upper nasal passage N-P region (as defined in ICRP-30 lung model¹), and a 25,4 cm (10") diameter CsI-NaI Phoswich detector posterior over the chest region (i.e. partly the trachea-bronchial (T-B) region and the pulmonary (P) region). 24-hour faecal and urine samples were collected and gamma-counted directly with a Ge-Li detector over the first 3 days. Posterior lower abdominal counts with the Phoswich detector were also initiated from day 1 onwards.

Deposition in the chest area was measured, initially daily, then weekly and eventually monthly using the Phoswich chest counter. Measurements on the lower abdominal region were similarly performed to determine partly chest deposition and removal and G-I tract clearance, and most important, liver deposition. A minimum detection level of 20 Bq for the Phoswich arrangement was estimated. 24-hour faecal and urine samples were collected at regular intervals, ashed and gamma-counted with a Ge-Li detector. A minimum detection level of 1 Bq/day was estimated. A procedure for alpha-counting to improve detection limits was unsuccessful.

MEDICAL TREATMENT

Treatment with DTPA chelating agent intravenously injected started on day 1 with 0,25 g Ca-DTPA, followed from days 2 to 5 with 0,5 g daily²⁾. From day 6 onwards Zn-DTPA became available and replaced Ca-DTPA. Treatment continued from days 6 to 9 with 0,5 g daily, days 12 to 35 twice weekly and thereafter twice weekly for cases 1 and 2 and once per week for cases 3 and 4 up to 61 days, and then once per week for cases 1 and 2 up to 103 days. Treatment was stopped at stages where no further chelating advantage was considered applicable. Strict medical supervision was maintained throughout the treatment period.

MONITORING RESULTS

Days 0 to 4: Results over the first few days are summarized in Table 1. It shows the initial deposition pattern and a fast 0,5 to 1 day rapid excretion through the faeces. This excretion through the G-I tract was confirmed by the abdominal measurements.

Table 1

	Case 1	Case 2	Case 3	Case 4
Initial upper N-P deposition in kBq (day 0)	13,7	3,2	3,4	0,5
Initial chest activity in kBq (day 0)	7,2	5,3	1,1	5,9
Total faecal excretion 0-4 days in kBq	36,7	38,8	4,0	1,5
Total urinary excretion 0-4 days in Bq	189	214	30	12

Day 4 onwards: The monitoring points for chest activity are given in Figures 1 and 2, and the daily urinary excretion measurements in Figures 3 and 4. In Figures 1 and 2, C designates the cases, i.e. C1 is case 1, and R designates a least squares fit with slopes 2 (intermediate) and 3 (long term). In Figures 3 and 4, C again designates the cases but D_p is the calcu-

figure 1. CHEST COUNTS

figure 2. CHEST COUNTS

figure 3. URINARY EXCRETION

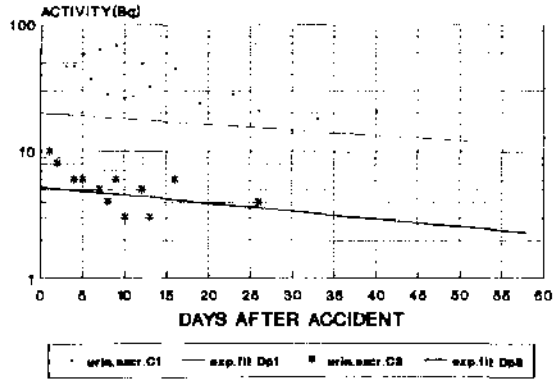

figure 4. URINARY EXCRETION

lated daily decrease in lung pulmonary deposition for each case.

Three lung clearance half-lives were identified, a short one at 0,5 to 1 day, an intermediate one at approximately 50 days (i.e. 70 days, 40 days and 30 days respectively for cases 1, 2 and 3) and a long one at approximately 500 days (i.e. 700 days, 450 days and 350 days). Abdominal measurements supported the excretion patterns found, and showed no liver deposition. Efforts to identify bone deposition were, within the limitation of detection levels, all negative.

DISCUSSION

Experimental measurements sufficiently confirmed the ICRP-30 lung model to warrant using the model to assess intake, removal and dose commitments. Deviations in case 4 could be ascribed to an emphysema condition. Using results in Figures 1 and 2 to define the initial pulmonary depositions and using initial chest measurements, total faecal excretion and the lung model total intakes were determined for cases 1 to 4 as 54,2 kBq, 48,3 kBq, 7,8 kBq and 6,4 kBq. A particle size of approximately 5 μ m was estimated.

From Figures 3 and 4 it can be seen that the urinary excretion closely followed removal from the lung for the intermediate clearance rate (50 days). This was confirmed by no deposition in liver or bone being detected. It was concluded that during this period no significant bone or liver deposition occurred. Deposition in bone on the long term after cessation of DTPA treatment was estimated by assuming that all chest activity from then on deposited in bone and liver. A committed bone dose equivalent of 4,2 Sv and a committed effective dose equivalent of 233 mSv were estimated for the worst case (case 1). It must be noted that such deposition was not in fact experimentally confirmed.

CONCLUSION

After the inhalation of Am-241 from a commercial gamma-source, followed by a DTPA-chelation treatment up to 100 days, lung clearances with half-lives of approximately 0,5 day, 50 days and 500 days were identified. No liver or bone deposition was detected within measurement limitations. Committed effective dose equivalents as a result of lung exposures were calculated for cases 1 to 4 as 74, 45, 12, and 2 mSv respectively.

MONITORING OF URINE BY EXTRACTION CHROMATOGRAPHY WITH
TRI-N-OCTYLPHOSPHINE OXIDE SUPPORTED ON A POLYPROPYLENE COLUMN

N. Bonino, J. Diodati, M. R. Cena

Gerencia de Seguridad Radiológica y Nuclear
Comisión Nacional de Energía Atómica
Buenos Aires- Argentina

ABSTRACT

Monitoring of personnel working with 20% enriched uranium implies development of techniques for excreta analysis, mainly for urine, with very low detection limits.

The method described allows the determination of 20% enriched uranium after extraction in tri-n-octylphosphine oxide (TOPO), 0.5 M in toluene, supported on polypropylene capillary columns [1]. Alpha activity is later measured in a low background liquid scintillation equipment [2] and the fluorescence in a fluorimeter [3], with detection limits, for 500 mL of urine, of 15.0 ± 4.0 mBq L⁻¹ and $5 \times 10^{-2} \pm 10^{-2}$ µg L⁻¹.

INTRODUCTION

The control of 20% enriched uranium in the urine of workers requires periodic analysis of a large number of samples from different areas. Since the radiological risk is very important, it is necessary to rely on a technique able to detect levels well below the values established in the monitoring of natural uranium and adapted to the performance of a large number of determinations. Kel-F columns in reversed phase partition chromatography were used to purify urine [4], as well as extraction with organic compounds such as tributylphosphate (TBP) or bis-2-ethylhexylphosphoric acid (HDEHP) [5], with adjustment of the media prior to measurement.

The microcapillary chromatographic technique using TOPO as the supported phase is very adequate to concentrate uranium since this selective reagent, in permanent contact with the solution, enhances the extraction of uranium through a stable complex formed. As elution with toluene is performed instead of stripping, losses are minimized so that the efficiency in the application of the sample, regulates the efficiency of the column. The eluate is a purified solution, 160 times more concentrated than the original sample. Fluorimetry and gross alpha activity by low background liquid scintillation are performed on different aliquots.

REAGENTS AND EQUIPMENT

Nitric acid, Cicarelli pa.
Hydrogen peroxide, Douglas pa.

Tri-n-octylphosphine oxide, Mallinckrodt A.R.
Ethyl alcohol pa.
Toluene scintillation grade
Naphthalene scintillation grade
PPO scintillation grade
Sodium fluoride, Merck pa.
Calcium orthophosphate dibasic solution (100 mg mL⁻¹)
Ammonium hydroxide, Merck pa.
Polypropylene PR-125
Jarrell Ash 26000 Fluorimeter
Platinum dishes
Fusion furnace, 1300 °C
Beckman LS-3150 T Liquid Scintillation, equipped with a low background system.

EXPERIMENTAL

Mineralization of organic matter

10 mL of concentrated nitric acid and 3 mL of calcium orthophosphate dibasic solution are added to 800 mL of urine in a beaker. The solution is left at 60 °C for one hour. Ammonium hydroxide is slowly added while stirring up to pH = 10. The precipitate is digested overnight, centrifuged and the supernatant discarded. The solid is mineralized to white ashes on a hot plate with 1:1 nitric acid and hydrogen peroxide. The ashes are dissolved in 80 mL of 1M nitric acid and hydrolyzed for one hour at near boiling temperature.

Setting the chromatographic column

The chromatographic column, 5 m long, is coiled downwards on a cylindrical plastic support 50 mm diameter. The microcapillar of 1.2 mm of internal diameter is imbibed with 300 µL of a 0.5 M solution of TOPO in toluene. The column is previously washed with ethyl alcohol and vacuum dried.

Loading and elution

The cooled hydrolyzed liquid is poured through the column, previously treated with 1 mL of 1 M nitric acid, at a rate of 20 drops per minute and the contents are eluted into a liquid scintillation vial with 5 mL of toluene. Three 200 µL aliquots are used for fluorimetry and 5 mL of a scintillation cocktail containing 10 g of PPO and 160 g of naphthalene in 1000 mL of toluene are added to the remaining solution into the vial and it is measured by low background liquid scintillation. A blank of urine and a recovery test are run together with the urines and measured in the same conditions.

RESULTS

The following considerations were taken during the standardization of the technique:

Pyrophosphates formation

The pyrophosphates formed during mineralization tend to compete with TOPO for the uranium, resulting in very widespread recovery values. To avoid this interference an acid hydrolysis

is performed during one hour.

Urine volumes

Volumes of urine ranging from 200 to 2000 mL were processed, with no influence in recovery values. Volumes of 1 M nitric acid used to solubilize the ashes varied accordingly, since 10 mL of 1 M nitric acid are needed for every 100 mL of urine. 800 mL of urine are adequate regarding both detection limits and amount of sample to be requested.

Capillary length

Capillary tubes 1, 3 and 5 m long were used. Recoveries were poor in the first case, improved in the second case but were not reproducible. Columns 5 m long proved to be optimum regarding high recoveries and reproducibility.

TOPO concentration

Recoveries did not change in the 0.5 to 1.0 M concentration range and a 0.5 M value was adopted. Since the minimum amount of extractant needed to imbed the whole column was 300 μ L, this was the volume chosen.

Percolation rate

There were no significative changes in recovery values for flow rates ranging from 20 to 40 drops per minute, but recoveries were very low for rates over 50 drops per minute.

CONCLUSIONS

Since the concentration factor is high enough to detect very low uranium levels, this technique is suitable for controlling personnel working with different uranium compounds. Besides, it is very convenient when dealing with many samples in different matrixes, because measurements are done immediately after elution, requiring only the addition of the scintillation mixture.

DIAGNOSIS OF THYROID NODULES AND MEDICAL FITNESS FOR RADIATION WORK:
CASE CONTRIBUTIONS

E.STRAMBI* M.VIRGILI**

* RADIOPROTEZIONE MEDICA, UNIVERSITA' CATTOLICA POLICLINICO GEMELLI,
ROME, ITALY

** RADIOPROTEZIONE MEDICA, USL FR/4, FROSINONE, ITALY

ABSTRACT

The nodular thyroid disease frequently involves delicate diagnostic problems, in particular concerning the diagnosis of thyroid cancer. Therefore, in case of a palpable thyroid nodule the physician must first of all perform the proper procedures (ultrasonography, scintigraphy, fine-needle aspiration biopsy, etc.) for a selective approach to diagnosis, as a necessary step before an eventual surgical treatment.

MANAGEMENT OF THYROID NODULES

In this study are discussed the first results obtained by the application of the decision matrix for the management of a thyroid nodule, which has been suggested in previous work (see fig.1).

According to that protocol, workers professionally exposed and known as carriers, at the moment of preventive or periodical visit, of alterations of the glandular morphology have been tested with scintigraphy, ¹³¹I thyroid uptake and eventually T₃ suppression test in case of doubtful differential diagnosis between hot and cold nodules. Ultrasonography has been performed to distinguish between cystic and solid cold nodules. In case of solid nodule serum calcitonin level could erase the doubt to be in presence of a medullary thyroid carcinoma.

In presence of cold and solid nodules a fine-needle aspiration biopsy has been performed to diagnose malignant nodules, benign nodules or follicular neoplasms.

Malignant nodules and follicular neoplasms have been referred directly to the surgeon.

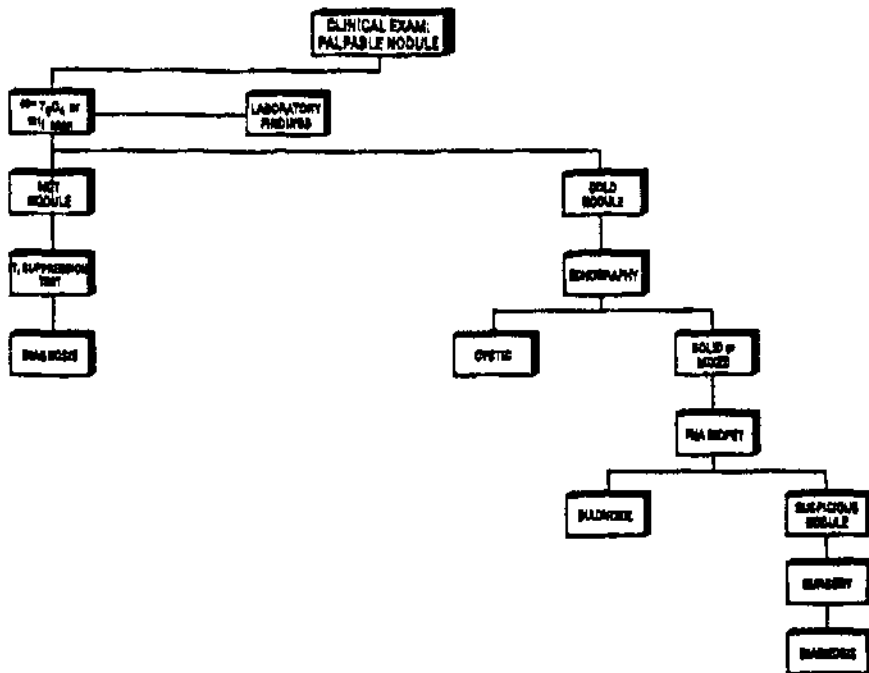

Fig. 1. DECISION MATRIX FOR WORKUP OF A THYROID NODULE

CASE DESCRIPTION

In this study are presented 34 cases of palpable thyroid alterations regarding patients observed in the last 3 years. The following diagnoses have been made:

- a) isolated nodules - 18 cases of which: 4 colloidal nodules, 4 pure cysts, 2 hyperfunctioning adenomas (one autonomous, the other not autonomous), 1 follicular adenoma, 1 papillary carcinoma; in the remaining 6 cases the diagnostic procedure at the moment has not been completed
- b) simple goiter - 7 cases
- c) multinodular goiter - 8 cases

DIAGNOSTIC DISCUSSION

Ultrasonography has allowed to exclude the presence of nodular formations in 2 cases of goiter with palpable irregularities and to recognize as multinodular 2 situations that, based exclusively on the clinical findings, should have been defined as uninodular. For this purpose, it must be noted that the multinodular goiters, even if they sometimes contain suspicious nodules that deserve the same caution of a solitary nodule, have a much smaller probability of cancer compared to the solitary nodules. Hot nodules, that as a rule are not malignant, have not been suspected of malignancy. However, it has to be emphasized that such nodules, although rarely, can hide follicular, papillary and even medullary carcinomas.

For this reason serum calcitonin level and eventually also fine-needle aspiration biopsy should be performed in such cases. Also cystic nodules, that as a rule are not cancer, have not been considered suspicious of malignancy, but since cancer is occasionally found in the wall of the cyst, it has been thought necessary the ecographic surveillance of cystic lesions at the moment of each periodical visit.

Considering the limits of fine-needle aspiration biopsy in the pre-surgical differential diagnosis between follicular adenoma and follicular carcinoma, we have referred to the surgeon the case of follicular adenoma and the case of papillary carcinoma.

The diagnostic scheduled procedure suggested by us then is based on the clinical finding of a palpable nodule. However, it has to be emphasized that the possibility to clinically diagnose the presence of thyroid nodules depends on their size that must be less than 1 cm., while the resolution of ^{99m}Tc pertechnetate scan with the pinhole collimated gamma camera is about 0,5 cm. and the resolution of small parts echography is about 1 mm.

Ultrasonography is of immense value in the early diagnosis of tumors, since it can easily identify small tumoral lesions already in a pre-clinic phase. Consequently, a systematic application of this technique in the medical surveillance of radiation protection on each exposed worker could be proposed.

However it must be considered that a patient with a thyroid carcinoma not clinically detectable (occult) has no risk of metastatic spread

of the tumor, that as a rule remains confined in situ. Therefore, as far as thyroid gland is concerned a systematic application (not aimed) of ultrasound against stochastic effects would not find adequate justification in a correct evaluation of cost/benefits balance.

In conclusion, we think that the physical exam, moreover undoubtedly facilitated by the superficial position of the organ should usually represent the main diagnostic procedure, reserving the instrumental tests to who presents palpatory anomalies.

The 2 cases of follicular adenoma and papillary carcinoma in particular show how the diagnostic protocol suggested above could become useful also from the point of view of the secondary cancer prevention, which is one of the main goals of the radiation protection.

MEDICAL JUDGEMENT OF FITNESS FOR RADIATION WORK

In case of a patient known as a carrier of a thyroid nodule clinically detectable, the physician first of all must approach a precise diagnosis. Before the examinations have been completely performed, the judgement should generally be "in observation" and the subject will be consequently maintained as a rule at his normal work in controlled area without any limitation, considering the possible doses to thyroid outcome from radiation work. At the end of the instrumental diagnostic procedures, as has been said above, anytime surgical treatment is needed for a diagnostic and therapeutic reason, the eventuality that the subject will or will not accept the surgical treatment must be faced. In this last case should not automatically outcome a judgement of unfitness, but the potential risk and actual real damage resulting from such a judgement should be evaluated case by case.

As far as risks are concerned, it should not be considered the possibility of a nodular cancerous degeneration caused by work exposure to ionizing radiation (hypothesis with no probability), but the possibility that in reality we are dealing with a carcinoma not detectable at the moment with the used techniques.

The last hypothesis can involve in some psycho-social contexts the possibility of future legal controversies and therefore can justify a more restrictive judgement.

In any case, as far as the medical judgement of fitness for radiation work is concerned, one has to keep in mind some main criteria, i.e. the clinical findings; the specific risk evaluation; the social, economical and psychological parameters.

Thus, in his evaluation, the physician should always consider the risk/benefits balance.

THE DEVELOPMENT OF NRPB ADVICE FOR THE DISPOSAL OF SOLID RADIOACTIVE WASTE

J R Cooper, I M Barraclough and S F Mobbs

National Radiological Protection Board, Chilton,
Didcot, Oxon, UK, OX11 0RQ

In the past, problems have been encountered in the practical application of radiological protection principles to solid waste disposal. In order to aid in the interpretation of existing advice and to encourage improvements in the presentation of safety cases for solid waste disposal facilities, NRPB has updated and clarified certain aspects of previous advice. Among other things, it is recommended that, for the purposes of risk assessment, the future should be divided up into time frames, with the emphasis of the assessment changing as the period of prediction increases.

1. INTRODUCTION

As a result of past recommendations by ICRP and others, the basic radiological protection principles for determining the acceptability of disposal facilities for solid radioactive wastes are now well established: namely the optimisation of protection and the limitation of individual risk. Furthermore, it is widely accepted that individuals who might be alive at any time in the future should be accorded a level of protection at least equivalent to that which is accorded to individuals and populations alive now. Nevertheless, there are particular problems in applying such basic principles to solid waste disposals. These problems arise in part because of the long time periods, often hundreds of thousands of years, over which radionuclides could be released into the biosphere from a solid waste disposal site. As a consequence, the rate of release may depend upon events and processes which have probabilities associated with them (eg, faulting in a rock formation) and, furthermore, the exposure of individuals alive in the future will depend upon their habits which are difficult, if not impossible, to predict.

In order to aid in the practical interpretation of existing advice, particularly in the light of ICRP's 1990 recommendations^[1], the UK National Radiological Protection Board, a UK Statutory Advisory Body, is updating its advice for the disposal of solid radioactive wastes. The proposed advice applies to land-based disposal in engineered facilities as described in detail in a consultative document^[2]. The purpose of this paper is to describe some aspects of this advice.

2. LIMITATION OF INDIVIDUAL RISK

In the case of solid waste disposal it is difficult to apply any standards, which are based solely on dose limitation because it will generally be possible to envisage circumstances, even if they have a low probability of occurrence, which if they were to occur would lead to doses above any selected limit. Therefore, the quantity to be limited is individual risk where risk is defined as

the probability that a dose will be received x the probability that the dose will give rise to a deleterious health effect

A risk limit could be derived directly from the dose limit, however, this would not be strictly appropriate to solid waste disposal. Such a risk limit would pertain to the sum of the risks from all sources to an individual; instead risk limitation is achieved by setting risk constraints for each source. The constraint is an upper bound on the optimisation of protection for that source to prevent unacceptable risks to individuals who are exposed to more than one source.

3. ASSESSMENT OF INDIVIDUAL RISK IN THE FUTURE

In order to ensure the protection of future generations it is usually necessary to assess the risks to individuals over long timescales. However, the sophistication of the assessment methods should reflect the confidence which may be attached to the assumptions made in the assessment. This confidence will tend to decrease as the timescale of the assessment increases and therefore it may be appropriate to change the emphasis of the calculations relating to the far future. One way to achieve this is to divide the time period of the assessment into the following series of time frames with the level of calculational detail being changed in each successive time frame:

i) *Site operation and up to c 100 years after closure*

This period is the 'institutional control period' and it is assumed that the relevant dose limits will apply.

ii) *c 100 years to c 10,000 years*

This period represents the time between the end of institutional control and the next major environmental 'event' such as glaciation. For this period 'predictive' models can be used to simulate the transfer of radionuclides through the geosphere and biosphere to a hypothetical critical group. This group should be reasonably homogeneous and representative of those individuals likely to be exposed to the greatest risk. The assumptions about human behaviour should be representative of the type of area being studied but not site-specific.

iii) *c 10,000 years to c 1,000,000 years*

In this time period the uncertainty associated with any detailed calculations related to the biosphere is likely to be so great that an appropriate approach is to define and model an arbitrary 'biosphere' populated by a 'reference community' with reasonably conservative habits such as subsistence farmers. Thus, by requiring a hypothetical reference community to be 'protected', a reasonable degree of assurance will be provided that any real communities which actually exist will not be subject to unacceptable risks. In this time period, the criterion could be expressed as probability weighted releases of radionuclides from the geosphere.

iv) *After c 1,000,000 years*

This is the approximate lifetime of the human race to date. The scientific basis for risk calculations in this time frame is therefore questionable and NRPB recommends that assessments covering longer time periods should concentrate on qualitative discussions.

4. HIGH CONSEQUENCE EVENTS

The treatment of risk described above only applies to situations where exposures are somewhat less than those which would give rise to deterministic effects (eg, <0.5 Sv). However, in the case of disposal of high level waste and, perhaps, intermediate level waste, situations could be envisaged, albeit improbable ones, where deterministic effects could be experienced. These situations could arise if the waste was brought to the surface by direct human intervention. Requirements to limit the consequences of such improbable events are not desirable; to modify a repository design solely for compliance with such a limit would not be sensible, particularly as such modifications might otherwise detract from the performance of the repository. Therefore, it is suggested that waste disposal sites should be chosen and facilities designed so that the total probability of all events having the potential to lead to doses which would cause deterministic effects should be as low as reasonably achievable.

5. TREATMENT OF UNCERTAINTY

Uncertainty can originate from several sources including, for example, inadequate knowledge of the future behaviour of the disposal site or lack of knowledge of the value for a particular parameter in a model. It is important to present and discuss separately the uncertainties arising from different sources. As an aid to this, it is suggested that uncertainty as to the future evolution of the site could be addressed by selecting a range of scenarios to represent qualitatively different futures. Each of the scenarios should then be assigned a probability, to represent the relative likelihood of that scenario actually occurring. Parameter uncertainty analysis should be undertaken to determine the confidence in the results for each scenario.

6. OPTIMISATION

The main radiological input to optimisation has generally been integrated collective dose. Even with relatively short integration times, collective dose estimates are so dependent on human behaviour that predictions must be treated with caution: with integration times of thousands of years the values are meaningless. Some alternatives have been suggested by ICRP^[3] including truncation and discounting, however there are disadvantages to each of them.

To assist in clarifying these issues, NRPB have suggested that a design target, set at a level of individual risk sufficiently low to be of very little concern, may be used as a guide to the extent of optimisation study required. If the estimated risks from a facility are likely to exceed this target,

then a full demonstration that the proposed facility is the optimum solution for that particular waste would be required. However, if the estimated risks are below the target, then the optimisation requirement may be confined to the detail of facility design. In the latter situation the release of radionuclides to the biosphere could be used as a surrogate for collective dose in the optimisation.

7. CONCLUSIONS

The ideas described in this paper will form the basis of NRPB's formal advice on the radiological protection aspects of the disposal of solid radioactive wastes in land-based facilities in the UK. It is hoped that the adoption of these ideas will lead to a clearer understanding of the issues and to a more transparent presentation of safety cases.

**LONG-TERM UNCERTAINTY IN RADIOLOGICAL PERFORMANCE ASSESSMENTS
OF LOW-LEVEL WASTE FACILITIES AT THE SAVANNAH RIVER SITE**

L. M. McDowell-Boyer

Health and Safety Research Division
Oak Ridge National Laboratory

ABSTRACT

Radiological performance assessments are being conducted for the Saltstone Disposal Facility and the E-Area Vaults at the Savannah River Site near Aiken, South Carolina. Saltstone is a solidified waste form which will contain very low levels of radionuclides but considerable levels of nitrate. The E-Area Vaults will contain solid, radioactively contaminated waste. Preliminary results of the assessments indicate that adequate performance will be very sensitive to the degradation scenario adopted for the cover and containment systems for these facilities.

INTRODUCTION

The U. S. Department of Energy (DOE) Order 5820.2A (DOE 1988) requires a site-specific radiological performance assessment for each DOE low-level waste (LLW) disposal facility designed and utilized subsequent to issuance of the order. The purpose of an assessment is to demonstrate compliance with performance objectives for DOE LLW management established in the order. In addition to ensuring compliance with other DOE Orders addressing radiation exposures and U. S. Environmental Protection Agency (EPA) regulations for atmospheric releases, these performance objectives include protecting groundwater resources consistent with federal, state, and local requirements.

Oak Ridge National Laboratory has been tasked with doing radiological performance assessments of the LLW Saltstone Disposal Facility (SDF) and E-Area LLW Vaults at the Savannah River Site (SRS) in a joint effort with the Idaho National Engineering Laboratory and Hanford. The most challenging aspect of these, and perhaps all, performance assessments involves predicting the long-term performance of the various engineered features of the waste-forms, containment, and closure designs over the time period for which significant quantities of radionuclides are present in the facilities. There is no specific regulatory guidance on the length of time for which potential exposure must be predicted nor on the amount of uncertainty which can be tolerated.

THE SRS LLW SALTSTONE DISPOSAL FACILITY AND E-AREA VAULTS

The SRS was acquired by the U. S. government in 1950 and covers approximately 780 sq km in southwestern South Carolina.

The site receives over 100 cm of rainfall annually and thus is classified as a humid subtropical region. As is the case with other sites in the DOE complex, waste management and environmental restoration have come to the forefront of activities at SRS in the last decade.

Both Z-Area and E-Area are on topographic highs which slope toward surrounding creeks. The historic high water table lies at a minimum of 7 m below the existing grade at Z-Area, and 6 m below the existing grade at E Area. The groundwater under both facilities discharges largely to the local creeks, such that off-site contamination of groundwater is unlikely to be significant. A lower regional aquifer is protected from downward migration of contaminants by a thick impermeable zone. Discharge of contaminated groundwater to surface water may carry contaminants off-site, but dilution in streams provides a large amount of protection to potential water users.

The SDF handles disposal of liquid waste streams which are solidified in a cement matrix. Radionuclides of consequence in the liquid waste include H-3, Cs-137/Ba-137m, Ru-106/Rh-106, Sr-90/Y-90, Tc-99, and I-129. A slurry consisting of a high nitrate-content salt solution, Portland cement, flyash, and slag is piped into below-grade concrete vaults. Upon solidification of the resulting monolith of saltstone, the remaining headspace will be filled with clean cement, and the vaults will be protected from infiltration until final closure with various overburden layers. Nitrate is present in the saltstone product at very high concentrations (about 7 wt%) and thus is of potential concern from the standpoint of the EPA's drinking water standard of 10 mg/L for NO₃ as N.

The E-Area Vaults will receive discarded trash, equipment, and machinery that have been contaminated by low levels of radioactivity. Tritium, C-14, Co-60, Cs-137/Ba-137m, Mn-54, Ni-63, Se-75, Sr-90/Y-90, and Zn-65 are the nuclides of potential concern. With the exception of C-14, none of these radionuclides are long-lived. Most of the nuclides will have decayed to stable isotopes by 300 years. Long-lived radioactive isotopes of uranium and transuranics are expected to be present in waste received by the E-Area Vaults only in very minor amounts. Primary containment will be in the form of metal boxes or drums for smaller items. Larger items will be placed directly into the concrete vaults along with the metal boxes and drums. A sloping concrete cover completes each vault. Separate vaults for storage of tritium and waste contaminated by C-14 are planned for this facility.

When all vaults are full at both facilities, earthen covers, designed to minimize infiltration of rainwater and

intrusion by roots or burrowing animals, will be placed over the entire facilities.

ANALYSIS

Demonstration of compliance with DOE Order 5820.2A requires that pathways to potential receptors be identified and potential exposures be predicted over an indefinite period of time. This must be done for three recognized time periods of concern: the operational time period (about 30 years for the SDF and 20 years for the E-Area Vaults), the post-closure institutional control time period (about 100 years), and the post-institutional control time period. Potential receptors fall into two categories: on-site receptors, or inadvertent intruders, and off-site receptors. During institutional control, on-site receptors are not present as the site boundaries are still maintained.

After 120 or 130 years, the possibility of excavation or drilling into the facilities by inadvertent intruders must be considered. Intact, or non-degraded, concrete vaults are fairly robust from the standpoint of external exposure to on-site receptors. The massive concrete buffer (almost 0.5-m-thick vault walls and ceilings) around the saltstone monolith and E-Area waste forms makes damage due to well drilling or excavation highly unlikely.

As stated in DOE Order 5820.2A, the SDF and E-Area Vaults must be designed to meet federal, state and local requirements for the protection of groundwater, as well as satisfy the other requirements for controlling radiation exposures. The EPA's drinking water standard (EPA 1990), which is being applied to groundwater for the purpose of evaluating compliance, limits the annual dose received from groundwater contaminated by radionuclides to 4 mrem and specifies maximum contaminant levels for various chemical compounds such as nitrate. This is the limiting requirement for LLW facilities like the SDF and E-Area Vaults if mechanical intrusion into the facility is not credible.

Over long periods of time, however, it is expected that natural processes may degrade the cover and containment systems so that infiltration into the facilities is increased and the ability of the Saltstone monolith or E-Area waste forms to withstand leaching is increasingly compromised. Erosion of ground surfaces, intrusion by burrowing animals or plant roots, and seismic events are potential sources of disruption of infiltration barriers. Cracks in the concrete vaults and the saltstone monolith may increase leaching to an unacceptable degree, and the concrete vaults may eventually crumble.

Because many of the radionuclides in the both facilities

are relatively short-lived, it is possible that they will have decayed to insignificant levels by the time natural processes have compromised the containment of the facility to any significant degree. Long-lived Iodine-129, Tc-99 and nitrate are, however, of concern for the SDF.

Much of the uncertainty in the results of individual exposure analyses as a consequence of LLW disposal lies not in the wide range in values of quantifiable parameters but in the wide range in credible scenarios describing conditions at the facilities hundreds to thousands of years into the future. There is not an official time cutoff for calculating exposures for DOE radiological performance assessments, and uncertainties become unfathomable after the first several hundred years due to poorly understood mechanisms of degradation of engineered barriers.

CONCLUSIONS

Despite the large amount of precipitation received annually by the SRS, the use of multiple barriers in disposal of LLW at two facilities at the site appears to provide both a workable solution to the common problem of subsidence in waste disposal facilities and a means of radically reducing the leachability of wastes. However, because long-lived radionuclides and non-decaying substances of concern may outlast the lifetime of engineered containment, their presence may adversely impact the performance of these facilities at some time in the future.

Degradation of engineered systems must be addressed in performance assessments. Recognizing that there is considerable uncertainty arising from the limited knowledge of degradation mechanisms and timing, there must be a concerted effort by both technical personnel involved in designing LLW facilities and policy makers and regulators to address this large uncertainty. Design of facilities should acknowledge the inevitability of degradation of protective and containment features. Policy makers and regulators must address the issue of the amount of uncertainty that will be tolerated in performance evaluations and the length of time that should be considered in assessing performance.

D.S.R.E. - Saint-Denis

**GENERAL ORGANISATION OF EDF ABOUT TREATMENT,
CONDITIONING AND INTERMEDIATE STORAGE OF LOW
LEVEL OR INTERMEDIATE LEVEL ACTIVE WASTE**

Managing wastes is a vital activity of EDF

EDF is responsible for managing wastes until the final storage which is done by the ANDRA.

In its management of radio-active wastes, EDF applies the same quality approach as for its other nuclear power plant operations.

The goal is to specify the quality required to comply with fundamental safety rules, to obtain this quality by adequate ways and means at every link in the waste chain and to prove that this quality level is really obtained.

All these actions, supported by powerful computer facilities, contribute to maintain the safety level which was planned at the design stage, and this has made it possible to substantially reduce the volumes and the cost of wastes sent to storage.

1 - AVANT - PROPOS

Le Manuel d'Organisation de la Qualité en Exploitation, document national destiné aux centrales nucléaires a été mis en application en 1977. Il comporte des prescriptions concernant la collecte, le conditionnement, le transport et le stockage de déchets radioactifs solides.

En 1983, le document EDF/SPT - Règles de base et Manuel National d'Organisation de la Qualité - Chapitre 5.2. - traitement des déchets radioactifs - confirme les prescriptions et pratiques du précédent manuel et prend en compte une évolution dans le domaine des déchets radioactifs dont la création de l'ANDRA.

Au-delà de la stricte application des règles, la qualité en exploitation repose avant tout sur l'organisation du travail mise en place et sur la compétence du personnel qui exécute les diverses activités.

2 - ORGANISATION GENERALE

. A partir des principes du Manuel National d'Organisation de la Qualité et règles de base, chaque centrale rédige un ensemble de notes d'Organisation qui constituent le Manuel d'Organisation de la Qualité de la centrale.

. Une note d'organisation définit les responsabilités et les relations entre les différents acteurs impliqués dans le traitement des déchets radioactifs.

. La manière de conduire les tâches élémentaires fait l'objet de gammes d'exécution et de consignes d'exploitation. Les tâches sont réalisées par un personnel dûment formé, habilité et désigné.

3 - APPLICATION

Les différents éléments qui concourent à la qualité d'un colis de déchets radioactifs concernent :

- les approvisionnements des conteneurs et matériaux,
- la collecte des déchets,
- l'évaluation de la radioactivité contenue dans les colis,
- le conditionnement,
- l'entreposage avant expédition,
- l'expédition vers le centre de stockage.

3.1. - Les approvisionnements des conteneurs et matériaux

Chaque approvisionnement est régi par un cahier des spécifications et des conditions techniques (C.S.C.T.) qui définit tous les critères contribuant à la qualité du produit fini.

Afin d'assurer un suivi des approvisionnements entrant dans l'élaboration des colis, E.D.F. a imposé à ses fournisseurs de mettre en oeuvre une organisation de la qualité, qui fait l'objet d'une acceptation puis de contrôles.

Pour chaque matériel ou matériau entrant dans le cadre de cette organisation, une fiche de suivi est ouverte et un numéro d'identification est attribué.

3.2. - La collecte des déchets

A EDF, tous les déchets provenant de zone contrôlée sont considérés comme potentiellement radioactifs.

3.2.1. - Déchets de procédé

Une fiche de suivi est initiée pour tous les déchets de procédé.

3.2.2. - Déchets technologiques

Les sacs de transport de déchets technologiques de faible activité sont étiquetés pour en connaître la provenance.

Pour chaque type de déchets, une fiche de suivi particulière est rédigée.

C'est au moment de sa collecte que la composition radiologique du déchet est déterminée.

3.3. - L'évaluation de radioactivité contenue dans les colis

. La politique mise en oeuvre par EDF, en matière de limitation de radioactivité de l'eau du circuit primaire, conduit à ne pas développer la présence, en quantité significative, de radio-éléments émetteurs "Alpha" dans ce circuit.

De ce fait, hors anomalie grave au niveau du combustible, le respect des spécifications techniques d'exploitation permet de garantir que le niveau d'activité "Alpha" dans les colis est toujours compatible avec les critères d'acceptabilité du centre de stockage et ne nécessite pas de traitement particulier.

En cas d'anomalie grave, le devenir des déchets solides est à discuter cas par cas avec l'ANDRA.

. Détermination de l'activité des différents radionucléides :

- Par calcul direct à partir de spectrométrie gamma,
- Par association d'un spectre type et du débit de dose moyen à mi-hauteur au contact du colis. Dans ce cas, le calcul de l'activité est fait à partir d'une "fonction de transfert". Du fait de son caractère national, il est déposé à l'ANDRA.

3.4. - Le conditionnement

3.4.1. - Préparation

Pour la réalisation de cette phase, des gammes sont rédigées à partir des DESCRIPTIFS DE PROCÉDES.

Chaque type d'activité fait l'objet d'une gamme. Les gammes de préparation des colis mentionnent notamment :

- . la méthode de conditionnement à employer,
- . la description des principales opérations à effectuer,
- . l'habilitation des agents concernés,
- . les contrôles,
- . l'évaluation de la radioactivité contenue.

3.4.2. - Exécution

Le conditionnement est découpé en tâches élémentaires, l'exécution d'une tâche ne pouvant être réalisée avant que la tâche précédente ait été effectuée et contrôlée.

3.4.3. - Fiches d'identification de colis

Afin d'assurer le suivi du conditionnement de chaque colis, une fiche d'identification est instruite. Elle permet d'une part de s'assurer que les actions précédant le conditionnement ont bien été réalisées (collecte du déchet, approvisionnement) et d'autre part de suivre l'état d'avancement du colis.

Lorsque cette fiche a été entièrement remplie et contrôlée, le colis correspondant peut être expédié si aucune anomalie n'est mentionnée.

Les opérations de conditionnement des déchets solides sont placées sous l'autorité d'un responsable habilité et désigné.

Dans le cas où les situations d'exploitation conduiraient à produire un colis hors normes, le responsable de l'exécution n'engage pas les opérations de conditionnement de ce colis et en réfère à un agent de responsabilité supérieure qui :

- . décide de la conduite à tenir,
- . mentionne ses décisions et leur justification sur le compte rendu.

Les fiches d'identification de colis permettent :

- . de garantir la conformité des colis au descriptif du procédé correspondant, et de connaître la radioactivité contenue,
- . d'avoir un état précis et repéré géographiquement des colis stockés en attente d'expédition,
- . de faire une comptabilisation par nature des colis préparés et des colis expédiés.

3.5. - L'expédition

Afin d'avoir l'assurance que tous les colis expédiés au centre de stockage ont été conditionnés conformément aux agréments obtenus de l'ANDRA, ils sont identifiés à l'aide d'une numérotation nationale.

Ces numéros sont attribués dès la confection des emballages chez les fabricants, ceci permet de suivre les colis sur chaque site en fonction de leur état et de leur position géographique et d'être ainsi certain de la correspondance entre les documents qui ont été instruits lors du traitement du déchet, et le colis.

3.6. - Le transport

EDF maîtrise le système de transport de ses déchets et applique les principes et règles d'assurance qualité dans ce domaine. Après enquête et évaluation les transporteurs font l'objet d'une acceptation assortie de contrôles périodiques.

4 - MOYENS INFORMATIQUES

Depuis le 31 décembre 1990, la gestion des colis de déchets nucléaires de toutes les centrales est assurée par informatique, grâce au module DRA du schéma directeur informatique du SPT. EDF dispose ainsi d'un logiciel qui centralise toutes les données permettant la déclaration des caractéristiques des colis de déchets nucléaires destinés à être stockés sur les sites exploités par l'Agence Nationale de gestion des Déchets Radioactifs (ANDRA).

Ce programme permet entre autres à EDF de constituer, par échange de données en temps réel avec ANDRA, un stock de colis validés et expédiables. Il constitue également une base de données de tous les déchets produits sur les différents sites.

5 - CONCLUSIONS

L'organisation de la qualité appliquée depuis l'origine à l'outil de production a été étendue aux activités liées à la gestion des déchets radioactifs au-delà de la stricte application des règles. L'esprit qualité qui anime les différents partenaires contribue à maintenir voire améliorer le niveau de sûreté défini à la conception.

POLITIQUE DE GESTION DES MATIERES DE TRES FAIBLE RADIOACTIVITE

VERY LOW LEVEL RADIOACTIVE WASTE MANAGEMENT POLICY

ABSTRACT

Starting from the different studies dealing with very low level waste management we propose a methodology to improve the present regulation. This approach is presented and limits are proposed.

Les réglementations existantes sur la protection des travailleurs et du public contre les rayonnements ionisants précisent clairement les conditions dans lesquelles doivent s'effectuer les opérations de traitement, stockage, transport et élimination des substances radioactives. Le champ d'application de ces réglementations est défini en fonction de la radioactivité des matériaux exprimée en radioactivité totale et/ou radioactivité massique et/ou radioactivité surfacique.

Les matériaux de très faible radioactivité se situent généralement hors du cadre précédent. Leur traitement, recyclage ou stockage soulève des problèmes réglementaires compte tenu du fait que certaines installations n'acceptent pas de "substances radioactives" alors que tout matériau contient des radionucléides d'origine naturelle et éventuellement artificielle.

Il convient donc de déterminer les limites de radioactivité admissible dans les déchets évacués vers les installations d'élimination, de traitement ou de valorisation(1), (2). Ces limites doivent garantir la protection des travailleurs et des personnes du public.

Plusieurs situations peuvent être envisagées selon que les déchets sont acceptés par une installation déterminée ou par une catégorie déterminée d'installations. Dans les deux cas il est possible d'envisager soit l'absence d'obligations (hormis la contrainte concernant le niveau de radioactivité), soit des obligations légères de types administratif et technique. Ces obligations peuvent porter soit sur des contrôles liés à la radioactivité, soit sur la destination des produits ou sous-produits de l'installation.

La détermination des limites de radioactivité acceptables est obtenue à partir des relations entre la radioactivité des déchets et les doses susceptibles d'être reçues par les travailleurs et le public. Ces relations sont déterminées en étudiant toutes les situations conduisant à une exposition des personnes, en évaluant les conditions de ces expositions et en calculant les doses correspondant à une radioactivité unitaire.

Ces calculs nécessitent la connaissance des pratiques industrielles, des conditions de travail, des caractéristiques des déchets de très faible radioactivité et en particulier du volume attendu par rapport aux capacités des installations de traitement.

Il est alors possible, en se fixant des contraintes de dose, de calculer les radioactivités limites qui permettent de respecter ces contraintes. Les contraintes de dose peuvent être égales à la limite de dose pour le public : 5 mSv sur une période de 5 ans, ce qui conduit à une valeur moyenne annuelle de 1 mSv par an si l'exposition est continue (6) ou à une fraction de cette limite (7). Elles peuvent être différentes selon qu'il s'agit des travailleurs ou des personnes du public ou suivant les caractéristiques des groupes critiques considérés (1).

Les résultats de ces calculs permettent également de décider s'il y a lieu ou non de fixer des conditions sur la destination des sous-produits de l'installation (par exemple cendres d'incinérateur ou scories d'aciérie) ou sur l'utilisation des produits de recyclage.

L'Institut de Protection et de Sécurité Nucléaire a réalisé ce type d'études pour différentes catégories d'installations : décharges de résidus municipaux et industriels, aciérie, cimenterie... (3, 4, 5).

L'ensemble des résultats montre qu'il existe pour chaque radionucléide des limites d'activité massique et surfacique au dessus desquelles les doses aux travailleurs des installations conventionnelles pourraient dépasser 1 mSv par an si aucune précaution n'était prise. Au dessus de ces valeurs les déchets sont dits radiotoxiques et doivent être envoyés dans une installation spécialement conçue pour les recevoir. Remarquons cependant qu'il peut exister des installations où, compte tenu des caractéristiques propres de l'installation et/ou du volume de déchets traité, les doses restent inférieures à 1 mSv par an même lorsque l'activité des déchets est supérieure aux limites précédentes.

Au dessous de ces valeurs les déchets peuvent être envoyés dans une installation conventionnelle à condition que leur radioactivité soit inférieure aux limites d'acceptation dans l'installation considérée. Ces limites sont, selon les radionucléides et selon les installations, soit égales soit inférieures aux limites précédentes.

On a vu que les résultats des études fournissent, pour chaque radionucléide, une limite d'activité massique et une valeur d'activité surfacique. Les résultats peuvent être utilisés tels quels. On a cependant examiné s'il était possible de trouver une présentation plus simple. Une première simplification a été obtenue en prenant la même valeur numérique pour l'activité massique (en Bq/g) et l'activité surfacique (en Bq/cm⁻²).

Une seconde solution consiste à regrouper les radionucléides ayant des limites voisines et à constituer des classes homogènes. Compte tenu du grand domaine de variation des valeurs (8 ordres de grandeur) il est nécessaire de définir plusieurs classes (au moins quatre). Cependant ces classes présentent l'inconvénient de ne pas correspondre à la classification actuelle.

Une troisième solution consiste à trouver une formule générale applicable à tous les radionucléides. Elle doit tenir compte des différentes voies de transfert qui conduisent à l'exposition des personnes. La limite d'activité massique correspond alors à la plus faible des valeurs suivantes :

- $100/n$ Bq par gramme ; n étant la proportion de photons d'énergie supérieure à 0,1 MeV émis par désintégration d'un radionucléide donné
- $100/p$ Bq par gramme ; p étant la fluence énergétique des électrons émis par désintégration d'un radionucléide donné (en MeV).
- $5 \cdot 10^{-2}$ de la limite annuelle d'incorporation par inhalation qui lui est applicable, par gramme
- $5 \cdot 10^{-4}$ de la limite annuelle d'incorporation par ingestion qui lui est applicable, par gramme

Le tableau suivant donne ces limites pour quelques radionucléides

Nucléide	Limite Bq/g	Nucléide	Limite Bq/g
C 14	4 10 ⁴	U 238	1 10 ²
P 32	2 10 ²	Th 230	1 10 ¹
Co 60	5 10 ¹	Ra 226	4 10 ¹
Ni 63	1 10 ⁵	Pb 210	1 10 ¹
Sr 90	9 10 ¹	Po 210	5 10 ¹
Cs 137	1 10 ²	Pu 239	1 10 ¹

Les travaux précédents montrent qu'il est possible pour chaque installation ou type d'installations de définir des critères d'acceptation des matériaux ou des déchets qui permettent de respecter les contraintes de dose.

Du point de vue de l'IPSN la gestion des déchets de faible radioactivité comme celle de tout déchet radioactif doit répondre aux exigences suivantes :

- protection des travailleurs et du public,
- responsabilité du producteur de déchets (connaissance de leurs caractéristiques et de leur destination),
- transparence et information de toutes les parties concernées.

RADIOACTIVE WASTE STORAGE AND DISPOSAL:A THEORETICAL STUDY

Gurinder Singh and H.S.Virk
Department of physics
Guru nanak Dev University
Amritsar-143005(INDIA)

Abstract :-

The application of nuclear energy is especially difficult to grasp and the handling of nuclear wastes is a matter of great concern to an average person. A detailed study is carried out in the field to assure that workers and public are not harmed now or in the future by the effects of radiation from the wastes, that the environment is not polluted and that the financial cost of handling and disposal of wastes is not excessive. The study is particularly important as it involves social aspects such as health and safety, environmental protection, national defence and energy needs.

**OPTIMISATION DU PRINCIPE ALARA EN MATIERE DE GESTION ET
D'ELIMINATION DE DECHETS RADIOACTIFS DE TRES FAIBLE ACTIVITE**

**OPTIMIZATION OF THE ALARA PRINCIPLE FOR THE MANAGEMENT AND
ELIMINATION OF VERY LOW LEVEL RADIOACTIVE WASTE**

The management of low level solid radioactive waste, as proposed by the National Institutions, cannot be applied to waste produced in a University environment. The report from the Université Catholique de Louvain (UCL) states the reasons and the procedure which has been set up by the radioprotection department. It describes the storage facilities and details the quality control tests carried out during the elimination process. The report outlines the difficulties encountered by the radioprotection departments due to the absence of normes for the disposal of solid radioactive waste.

INTRODUCCIION

Le problème de la gestion des déchets radioactifs est devenu l'un des thèmes majeurs de discussion et de controverse en matière de radioprotection. Il est toutefois internationalement admis par les producteurs de déchets et par les Organismes Nationaux, de classifier ceux-ci en 3 grandes catégories : haute, moyenne et faible activité. Il est bien évident que chaque catégorie implique un mode de gestion adapté. En Belgique, une politique globale et cohérente en la matière, a été mise en place à l'échelon national par l'ONDRAF (Organisme National des Déchets Radioactifs et des Matières Fissiles)

La catégorie des déchets de faible activité comprend non seulement, des déchets provenant de l'énergie électronucléaire, mais également, de laboratoires de recherches universitaires, d'hôpitaux (thérapie) ou de laboratoires d'analyses médicales (diagnostic), déchets que l'on peut qualifier de "très faible activité". Le Service de Radioprotection de l'Université Catholique de Louvain (UCL) a estimé, que l'assimilation de ce dernier type à la catégorie des faiblement radioactifs et à son mode de gestion, ne pouvait se justifier tant pour des raisons scientifiques que pour des raisons économiques.

Il paraissait en effet irrationnel de devoir enfouir, dans des installations de stockage définitif, des radioisotopes de courte demi-vie physique (de l'ordre de quelques heures par exemple). De plus, la relation inversement proportionnelle entre l'activité présente et le volume des déchets produits, aurait impliqué des coûts de traitement considérables et difficilement supportables par les petits producteurs. C'est pourquoi il a été décidé, en concertation avec l'ONDRAF, de développer un programme de gestion spécifique à ces déchets solides de très faible activité.

GESTION DES DECHETS A L'UCL

Objectif

Le faible niveau d'activité ainsi que la faible radiotoxicité des isotopes utilisés au sein des installations de l'UCL, ne doivent pas faire perdre de vue, au radioprotecteur, que le but qu'il poursuit est toujours, même dans ce cas favorable, de limiter au maximum les doses d'irradiation délivrées lors des manipulations, du stockage et de l'élimination de ces déchets, ceci afin de minimiser l'impact radiologique sur le travailleur et son environnement.

Principe de base

Le principe fondamental consiste à isoler les déchets dans des installations appropriées jusqu'à disparition, par décroissance radioactive, d'une quantité suffisante de radionucléides pour que le risque potentiel résiduel, lié à l'élimination par incinération, soit acceptable. La Législation Belge impose, en effet, que tout déchet potentiellement contaminé par des agents mutagènes, cancérigènes, tératogènes, bactériologiques, etc. doive, en finalité, être incinéré.

Dispositions pratiques

Pour mener à bien une bonne gestion de déchets, il importe tout d'abord, d'avoir une bonne connaissance de ce que l'on manipule, c'est-à-dire de la nature et des niveaux de radioactivité des isotopes utilisés. En pratique, cela impose de subdiviser l'institution en petites entités codifiées en fonction du niveau de risque rencontré. Une centaine d'entités ont ainsi été répertoriées. On y trouve les accélérateurs de particules et laboratoires de chimie nucléaire associés, différents laboratoires de recherche en agronomie, en biologie et en médecine, ainsi que différents services hospitaliers. Une bonne connaissance des isotopes et activités manipulés impose une centralisation de la réception des colis radioactifs suivie, après contrôle et enregistrement, d'une redistribution aux entités concernées. Outre les installations typiquement universitaires, une série de cliniques et laboratoires d'analyses biologiques bénéficient également de cette gestion des déchets.

La collecte des déchets dans une unité codifiée est effectuée "par badge" c'est-à-dire, l'ensemble des déchets accumulés depuis le dernier enlèvement. Chaque emballage du lot est identifié pour permettre la traçabilité jusqu'à l'élimination. Les lots de déchets sont alors orientés en fonction de leur contenu. Les émetteurs gamma de demi-vie supérieure à 1 an sont systématiquement évacués vers les installations de l'ONDRAF. Les autres radioisotopes sont entreposés, toujours par lot, dans des conteneurs mobiles de 2 m³, eux-mêmes numérotés.

Parallèlement à cette entrée en stock, les caractéristiques relatives à ce lot sont encodées dans une base de données.

- Il s'agit de :
- numéro du lot (badge),
 - date d'entrée,
 - code de l'entité d'origine,
 - numéro du local et du conteneur de stockage,
 - caractéristiques du badge:
 - type d'emballage,
 - nature isotopique,
 - activité par isotope,*

* L'activité prise en compte est l'activité livrée à l'entité depuis la dernière collecte.

A tout moment, le gestionnaire peut obtenir la liste des déchets pouvant être incinérés. Le logiciel effectue ses calculs en se basant sur les valeurs de la base de données, sur les caractéristiques de l'incinérateur (masse journalière de cendres et volume de gaz produits journalièrement) ainsi que sur les tables de demi-vie physique, les limites dérivées de rejet gazeux et une valeur d'activité spécifique maximum fixée dans les cendres.

LOCAUX DE STOCKAGE

Les locaux de stockage situés dans la "zone nucléaire" de l'Université (accélérateurs, irradiateurs, etc...) sont construits en béton et enfouis sous le sol, au-dessus de la nappe phréatique. Les déchets sont ainsi bien isolés de l'environnement, ce qui entraîne un risque quasi nul pour la population et le personnel. Chaque local, d'une capacité approximative de 300 m³ possède un sol imperméable (résine époxy) en pente douce, permettant ainsi de recueillir dans une citerne les eaux d'infiltration ou les liquides provenant d'éventuels conteneurs endommagés. Etant donné le risque non négligeable d'inflammabilité des déchets (matières plastique, papier, solvants organiques...) un double circuit de détection d'incendie et d'extinction automatique au halon est installé. Un système d'extraction d'air fonctionne en continu, est raccordé à la cheminée de 25 m. du bâtiment et est asservi à la détection incendie. Enfin, un sarcophage de 2m³, dans un coin du local permet le stockage des sources irradiantes.

CONTROLE DE QUALITE

Différentes procédures ont été développées afin d'optimiser la gestion des déchets tout au long de leur cheminement. Des spécifications propres à chaque étape ont été établies. Une formation préalable des producteurs de déchets est assurée par le Service de Radioprotection.

Production

Chaque entité est tenue de veiller à :

- un conditionnement sélectif dans les emballages agréés,
- un étiquetage élémentaire de l'emballage (date, isotope et code de l'entité).

Collecte et transport

Les deux fonctions sont réalisées par le Service de Radioprotection. Lors de la prise en charge, les contrôles suivants sont effectués conjointement par le producteur et le transporteur :

- vérification du conditionnement,
- vérification de l'étiquetage,
- enregistrement du nombre de colis.

Le transport vers les installations de tri et de stockage est effectué dans des conteneurs de transport agréés, par véhicule dûment autorisé.

Tri et mise en stock

Grâce à la gestion informatisée des colis radioactifs, une analyse critique des données fournies par le producteur peut être effectuée lors de la réception des déchets. Une rapide mesure physique permet de s'assurer que le type de rayonnement émis concorde avec l'analyse théorique.

Stockage et élimination

Un contrôle visuel régulier permet de s'assurer de l'état des emballages durant la décroissance. Lors du retrait d'un lot pour élimination, différents aspects sont examinés:

- conformité de la constitution du lot avec les valeurs de la base de données,
- contrôle de la concordance du niveau d'activité résiduelle mesuré avec le niveau théorique calculé.

Incinération

En fonction de la nature et de la forme chimique du radioisotope, l'activité résiduelle peut se retrouver dans les gaz brûlés ou dans les cendres. Un contrôle radiologique des gaz rejetés est réalisé par analyse du condensat du barbotage effectué sur les gaz prélevés dans la cheminée. Actuellement, les différents colis du lot sont répartis sur l'ensemble des déchets incinérés durant la journée pour éviter tout effet de pointe. L'installation d'un rideau d'eau épurateur de fumée supprimera ce risque et permettra, d'ici peu, d'estimer le niveau de radioactivité présent dans les gaz à partir de l'analyse de cette eau.

Un contrôle des cendres est réalisé quotidiennement. Il a pour but de:

- contrôler en finalité l'efficacité des procédures,
- s'assurer de la non-contamination de l'incinérateur par des "déchets radioactifs pirates".

Le contrôle des gaz et des cendres permet, de fournir à l'organisme compétent, toutes les données lui permettant d'assurer son rôle de contrôle.

CONCLUSIONS

L'assimilation des déchets solides de très faible activité, aux déchets de faible activité, n'est pas rationnelle. Toutefois, si l'on veut respecter le principe ALARA en matière de gestion, il est nécessaire de disposer d'une infrastructure minimale:

- véhicule de transport autorisé,
- conteneurs de transport agrés,
- locaux de stockage équipés,
- incinérateur propre,
- chaînes de comptages bas-niveaux,
- personnel compétent.

Un centre universitaire disposant de ces facilités peut ainsi assumer efficacement la gestion de ses propres déchets. De plus, sous le contrôle de l'Organisme Public compétent, il peut également remplir sa mission de service au public, en assurant la gestion des déchets des tout petits producteurs (médecins privés, cliniques, laboratoires d'analyses). Grâce à la gestion informatisée et aux différents contrôles de qualité, le respect des normes de rejet gazeux peut être assuré et l'implication sur l'environnement quantifiée. La position du gestionnaire reste toutefois inconfortable en ce sens qu'il est réduit, en l'absence de législation précise, à devoir estimer lui-même le niveau maximum qu'il tolèrera dans les cendres produites par la combustion des déchets.

**COMMENT ELECTRICITE DE FRANCE
A DIVISE PAR DEUX EN CINQ ANS
LE VOLUME ANNUEL DE DECHETS RADIOACTIFS
PRODUITS DANS SES CENTRALES**

J. HERISSON

Electricité de France
Service de la Production Thermique
Paris - La Défense

**HOW EDF, IN FIVE YEARS TIME,
HAS HALVED THE ANNUAL VOLUME OF RADIOACTIVE WASTES
PRODUCED IN ITS POWER PLANTS**

The production of radioactive wastes, expressed in volume of packs of wastes, ready for final storage, from the EDF nuclear plant units, has gone from 380 cubic meters per plant unit per year in 1985 to 180 cubic meters per plant unit per year in 1990.

Other than the technical aspects, this performance has been due to measures taken by EDF in the area of management. These measures are to be supplemented in the medium term by the industrial implementation of centralized treatment techniques such as fusion and incineration.

La production de déchets radioactifs, exprimée en volume de colis de déchets prêt au stockage définitif, des tranches nucléaires d'Electricité de France est passée de 380 mètres cubes par tranche et par an en 1985 à 180 mètres cubes par tranche et par an en 1990. Le progrès est particulièrement significatif pour les déchets de procédés (résines, concentrats, filtres, générés par le traitement des circuits liquides et gazeux), pour lesquels la production annuelle moyenne est passée en cinq ans de $240\text{m}^3/\text{tr}/\text{an}$ à $85\text{m}^3/\text{tr}/\text{an}$.

La production de déchets technologiques (vinyle, papiers, métaux, gravats...) générés par les opérations de maintenance est passée, pendant la même période de $140\text{m}^3/\text{tr}/\text{an}$ à $95\text{m}^3/\text{tr}/\text{an}$ (malgré plusieurs visites décennales).

Cette performance se situe dans un contexte caractérisé par deux données :

- l'envoi systématique (pas d'entreposage sur site) au centre de stockage de l'Agence Nationale pour la gestion des Déchets Radioactifs (l'ANDRA), des déchets produits en exploitation, coûteux mais sûr et incitatif à la réduction de volume,
- l'absence de seuil réglementaire "de minimis" qui conduit à considérer, de manière conservatoire, comme radioactifs certains déchets de très faible activité.

Elle repose, au delà des aspects techniques, sur les dispositions prises en matière de management à EDF. Ces dispositions seront complétées à terme par la mise en place de techniques centralisées de traitement telles que la fusion et l'incinération.

1 - DISPOSITIONS PRISES EN MATIERE DE MANAGEMENT

Les dispositions prises en matière de management autour de la gestion des déchets, s'articulent principalement autour de deux axes, à savoir "responsabilisation" et "organisation".

La responsabilisation :

Elle intègre

- la sûreté qui veut que la production de déchets soit limitée autant qu'il est possible,
- les coûts qui vont dans le même sens que la proposition précédente.

Cette responsabilisation concerne toute la ligne hiérarchique :

- le Responsable national du parc nucléaire qui impulse la politique notamment dans ce domaine et la traduit en objectif dans les contrats de gestion des sites. Ces objectifs sont suivis à l'aide d'indicateurs conçus à l'échelon national.
- le Chef de site qui représente l'exploitant nucléaire et est à ce titre responsable de la production de déchets,
- les Chefs de Service concernés (Service conduite pour l'optimisation des moyens d'exploitation et de traitement, Service maintenance pour la production des déchets technologiques liés aux interventions),
- les Chefs de travaux sur le terrain (préparation et organisation des chantiers, rédaction de modes opératoires et tri à la source des déchets solides).

L'organisation :

Les mesures organisationnelles s'exercent à deux niveaux :

Au niveau local,

Par la mise en place de structures opérationnelles de gestion des déchets et d'optimisation des moyens de traitement, assurant coordination et sensibilisation (par le biais d'indicateurs) de tous les services concernés.

Au niveau du Parc Nucléaire

Par l'existence de services fonctionnels chargés :

- de définir la politique, d'assurer sa promotion et de faire vivre le retour d'expérience,
- de contrôler la mise en oeuvre des politiques et de détecter les "bonnes pratiques".

Ces services orchestrent un retour d'expérience efficace qui a pour objet :

- d'éviter que les "mauvaises pratiques" ou les incidents constatés sur un site ne se reproduisent sur un autre site,
- d'assurer que les "bonnes pratiques" mises en oeuvre à tel ou tel endroit profitent à tous les sites du parc et aux tranches futures.

2 - DISPOSITIONS PRISES EN MATIERE DE TECHNIQUE

En ce qui concerne les déchets de procédés, les progrès significatifs traduisent une bonne maîtrise de l'exploitation des installations et notamment de la gestion et du traitement des effluents liquides. Parmi les pratiques déterminantes pour l'amélioration de ce poste, peuvent être cités :

- la réduction de la production des effluents liquides par une organisation rigoureuse des mouvements d'eau (vidange et remplissage des circuits, contrôle des fuites) et l'optimisation des moyens de leur traitement par une utilisation judicieuse des évaporateurs et des déminéraliseurs,
- l'optimisation de l'exploitation des déminéraliseurs en particulier sur les circuits de contrôle volumétrique et chimique des circuits principaux,
- l'optimisation du remplissage des conteneurs, notamment par le regroupement des filtres,
- le démantèlement et le compactage des filtres de ventilation,
- le rejet des concentrats après décroissance (solution qui dépend des capacités de stockage et des radioéléments rencontrés).

En ce qui concerne les déchets technologiques, l'amélioration de ce poste "déchets technologiques" passe par une double action : réduction des volumes à la source et tri efficace permettant une optimisation de la production et des conditionnements. Les bonnes pratiques identifiées en la matière sont notamment :

- les mesures limitant l'introduction, en zone, de matériaux contaminables (emballages, palettes, bois, etc...),
- la distribution limitée au strict nécessaire des matériaux consommables entrant en zone contrôlée (produits chimiques, de nettoyage, vinyle, etc...),
- l'analyse relative à la présentation des interventions (promotion du confinement dynamique, utilisation de sas décontaminables et recyclables, etc...) et au traitement du déchet résultant (rabotage du bois contaminé, dégainage des câbles, etc...).

3 - LES DEVELOPPEMENTS EN COURS A EDF SUR LE CONDITIONNEMENT DES DECHETS

La recherche permanente de progrès en matière de réduction de volume de déchets radioactifs solides va conduire à terme à des réalisations industrielles de traitement : il s'agit d'une installation de fusion des ferrailles contaminées et d'une installation d'incinération des déchets technologiques de faible activité.

- La fusion des ferrailles contaminées

L'entretien courant des centrales nucléaires produit de l'ordre de 500 t/an d'aciers plus ou moins contaminés. Les opérations particulières que sont les grosses réparations et les opérations de démantèlement généreront des tonnages supplémentaires.

Cette solution passera par une installation industrielle de fusion des ferrailles qui combinera un processus de décontamination surfacique avec un four de fusion proprement dit. Seront alors élaborés différents produits en fonction de l'activité croissante des ferrailles traitées.

Ce projet industriel est un élément du dispositif nécessaire à la maîtrise des déchets, tant au plan économique qu'à celui de la prévention de la dissémination de la contamination.

- L'incinération des déchets de faible activité dits "technologiques"

Actuellement, ces déchets sont évacués des centrales en fûts métalliques et livrés sur les centres de stockage où ils sont conditionnés de manière définitive par compactage pour réduire leur volume et immobilisation dans un liant hydraulique.

Ce procédé de compactage, qui a fait ses preuves depuis de nombreuses années, peut être valablement mis en concurrence tant sur les plans de la qualité du conditionnement que sur le plan économique avec un procédé d'incinération approprié. En effet, l'incinération a pour avantages essentiels :

- de réduire bien davantage le volume des déchets à stocker et donc, pour autant que la capacité radiologique du centre de stockage le permette, de prolonger la durée de vie de celui-ci,
- de transformer les déchets bruts, (constitués en faible proportion de matières organiques), en déchets secondaires minéraux, stables et homogènes.

Le procédé retenu à l'issue d'études et d'essais sur un prototype industriel met en oeuvre une torche à plasma.

4 - CONCLUSION

Les dispositions prises par EDF, tant en management qu'en maîtrise des productions à la source, prolongées par la mise en service à terme d'installations centralisées de fusion et d'incinération permettront d'aboutir à une réduction de volume aussi performante que peuvent le permettre les techniques actuellement industriellement disponibles, et ceci dans un cadre où la qualité et la sûreté des conditionnements des déchets sont parfaitement maîtrisées.

Si les déchets radioactifs sont un des problèmes de société placés en première ligne dans les soucis des opinions publiques, le traitement des déchets industriels en général est une activité en plein développement soumise aux exigences liées à la protection de l'environnement. La démarche et les moyens mis au point pour le traitement des déchets radioactifs peuvent être facilement transposés à celui des déchets industriels pour lesquels des objectifs analogues de réduction importante de volume ou de non dissémination de produits nocifs sont recherchés.

**ASPECTS "DE MINIMIS" EXEMPLES DE
DIFFICULTES RECENTES RENCONTREES DANS LES
CENTRALES NUCLEAIRES D'EDF
POUR LA GESTION DES DECHETS TRES
FAIBLEMENT RADIOACTIFS**

Texte rédigé par Pierre BOUSSARD
et présenté par Jean-Marc DUCOULOMBIER

**CLEARANCE LEVEL (DE MINIMIS) : EXEMPLES OF
DIFFICULTIES MET IN THE NUCLEAR POWER PLANTS OF
EDF ABOUT THE VERY LOW LEVEL ACTIVE WASTE
MANAGEMENT**

ABSTRACT : The absence of a clear reglementation concerning very low radioactive waste management has led EDF to harmonise its internal practices. However plant operators are still confronted with many difficulties for :

- very low radioactive waste which have really been contaminated
- very low radioactive waste whose radioactivity is not due to on a site nuclear practices (natural radioactivity or off-site artificial radioactivity)
- waste which is suspected to be contaminated simply because it has transited through a nuclear plant even outside of all controlled areas.

INTRODUCTION

La réglementation française ne fixe pas de seuil au dessous duquel un corps n'est pas considéré comme radioactif et peut être remis dans le domaine public. La réglementation sur les matières radioactives ne s'applique qu'à partir de 74 ou 100 Bq/g. On pourrait en déduire que, à contrario, au-dessous de ces valeurs un déchet n'est pas radioactif. ELECTRICITE DE FRANCE est en pratique confronté à cette difficulté depuis de nombreuses années.

GESTION DES DECHETS FAIBLEMENT ACTIFS A ELECTRICITE DE FRANCE

Les règles pratiques internes appliquées dans le Service de la Production Thermique d'ELECTRICITE DE FRANCE dérivent du principe de non contact avec une source contaminante ou activante. Elles sont définies par deux documents :

- Une Instruction qui fixe des activités volumiques (3,7 Bq/l en gamma total) en dessous desquelles un déchet peut être considéré comme n'ayant pas eu de contact avec un fluide contaminant et géré comme un déchet classique. Ces déchets sont essentiellement des filtres, résines, huiles et solvants.

- Un Guide Pratique de Radioprotection qui fixe des activités surfaciques (3,7 Bq/cm² pour les émetteurs bêta gamma) en dessous desquelles un matériau ou un outillage sortant de zone contrôlée est réputé non contaminé et géré d'une manière classique.

Ces deux documents servent de fils directeurs pour les centrales, mais de plus, la balise de sortie de site dont le seuil d'alarme est réglé entre 3 et 4 fois le bruit de fond ambiant, sanctionne toute erreur dans l'estimation de l'activité d'un matériau pouvant être rejeté en décharge contrôlée ou recyclé.

DECHETS DE FAIBLE ACTIVITE ARTIFICIELLE

Résidus liquides de lessivage des GV

Les opérations de nettoyage chimique des générateurs de vapeur des tranches REP engendrent des volumes de résidus liquides importants, environ 2000 m³ par GV. Ces volumes, composés d'un mélange d'acide gluconique, d'ammoniaque et d'acide citrique sont peu actifs. Les radioéléments présents, Cobalt 58 et 60, Césium 134 et 137 et Manganèse 54 proviennent des dépôts de magnétite, cuivre et oxyde de zinc retirés des générateurs de vapeur par le nettoyage chimique. Ces volumes peuvent être éliminés par incinération.

Les activités mesurées, pour les 4 GV de la tranche 1 de Nogent, sont :

- 1000 m³ d'activité gamma total < 10 Bq/l
- 800 m³ d'activité gamma total égale à 30 Bq/l.

Les 1000 m³ d'activité inférieure à 10 Bq/l ont été incinérés en 1989 après accord du SCPRI.

Pour les 800 m³ restant, d'activité gamma total égale à 30 Bq/l, un dossier d'impact sur l'environnement a été établi par le CEA/IPSN pour l'incinération de ces résidus. Le SCPRI a donné son accord de principe sous réserve que leur activité soit inférieure à 100 Bq/L et que les sociétés prestataires (Usine d'Incinération et Centre d'Enfouissement) aient reçu l'autorisation préalable des DRIR dont elles dépendent sur le plan réglementaire en tant qu'ICPE. Ces 800 m³ n'ont pu être incinérés faute d'obtenir l'accord de la DRIRE. Ils sont stockés actuellement dans des wagons sur le site de la centrale.

Calorifuge de CHINON A2

L'opération de décalorifugeage des échangeurs et soufflantes de CHINON A2 s'est étendue de Mars 1988 à Janvier 1989. Le calorifuge non activé a été mis en sacs et trié suivant des critères fournis par le SCPRI dans son télex donnant l'accord de principe à savoir :

- Absence d'émetteurs alpha
- Activité < 1 Bq/g
- Contrôle d'activité de la totalité du calorifuge
- Contrôle de débit de dose de chaque chargement
- Tenue à jour d'un registre

L'activité moyenne qui provient du cobalt 60 (naturelle + artificielle) du calorifuge envoyé à la décharge était de 0,3 Bq/g et l'activité totale de 16,8 E6 Bq (0,5 mCi).

56 tonnes de calorifuge ont été évacuées dans une décharge d'ANGERS, le calorifuge dont l'activité est comprise entre 1 et 2,5 Bq/g a été entreposé pour décroissance et le calorifuge dont l'activité est > 2,5 Bq/g a été expédié au SSM après compactage.

Ferrailles d'exploitation

Les déchets issus des zones contrôlées, pièces métalliques venant des circuits en contact avec le fluide primaire ou outillage divers, sont contrôlés et triés ; ceux qui n'ont pas été en contact avec une source contaminante ou activante sont évacués vers des ferrailleurs ; ceux dont la contamination est supérieure à 3,7 Bq/cm² et dont l'activité est inférieure à 100 Bq/g sont stockés sur parc.

Actuellement et pour les 10 années à venir, les déchets métalliques d'activité comprise entre 1 et 100 Bq/g, produits par les centrales REP représentent 300 tonnes d'inox et 250 tonnes de ferritiques environ.

Ferrailles de démantèlement

Les ferrailles de démantèlement pour les 10 années à venir, d'activité inférieure ou égale à 1 Bq/g représentent 7500 tonnes. Les radionucléides présents dans ces ferrailles sont essentiellement, le cobalt 60 pour 97 à 98 %, le manganèse 54 pour 1 à 1,5 % et le césium 137 pour 0,5 à 3 %.

DECHETS DE FAIBLE ACTIVITE ARTIFICIELLE NON DUE A L'EXPLOITATION DES REP

Filtres de dépoussiérage

Les filtres de dépoussiérage de l'air extérieur des ventilations déclenchaient les balises de sortie de site après l'accident de Tchernobyl et ont dû être conditionnés en fût métallique et expédiés à l'ANDRA comme déchets radioactifs.

Détecteurs incendie

Les détecteurs incendie, comprenant des sources d'américium, issus des locaux des centrales sont également conditionnés en fût métallique comme déchets radioactifs (les pratiques sont différentes suivant les entreprises).

DECHETS DE FAIBLE ACTIVITE NATURELLE

Produits de sablage radioactif naturellement

L'utilisation de sable à base de scories de charbon pour la remise en état des portiques du bâtiment réacteur a du être proscrite, car l'activité naturelle présente, de 0,8 Bq/g en gamma totale (hors potassium), déclenchait la balise à l'entrée du site.

Chambres de coupure des disjoncteurs de Chinon A2

Au cours des travaux de démantèlement des locaux électriques de Chinon A2, lors du contrôle, avant la sortie de site, du camion chargé des armoires électriques destinées à un ferrailleur, on a constaté une certaine radioactivité des chambres de coupure en céramique des disjoncteurs (Ra 226 1,50 Bq/g, Th 228 0,25 Bq/g, Ac 228 0,28 Bq/g).

Ces chambres ont été entreposées sur site.

CONCLUSION

En définitive, le Service de la Production Thermique d'ELECTRICITE de FRANCE a fait quelques tentatives pour définir une politique interne pour des déchets bien spécifiques afin de sortir de situations qui se bloquaient ; mais cette politique s'avère de plus en plus inadaptée, notamment pour résoudre les problèmes posés par l'élimination de déchets produits en grande quantité et présentant une radioactivité très faible, voire proche ou inférieure à la radioactivité naturelle et pour définir un critère de tri sur les déchets dits douteux.

Il faut noter toutefois qu'ELECTRICITE de FRANCE a toujours fait la distinction entre les effluents radioactifs qui sont dilués au moment des rejets autorisés par la réglementation et les déchets faiblement radioactifs (résidus liquides ou autres) dont elle s'interdit toute dilution.

Actuellement la situation s'éternise (les ferrailles de Chinon A3 sont sur parc depuis plus de 20 ans) et l'absence de texte réglementaire se traduit par une production injustifiée de déchets dits radioactifs puisqu'on enfûte des matériaux ou des objets considérés comme contaminés par le seul fait qu'ils sont entrés dans une centrale nucléaire (cas des filtres de dépoussiérage de l'air extérieur après l'accident de Tchernobyl). Outre un coût important du conditionnement et du stockage, ceci conduit à encombrer inutilement le centre de l'ANDRA à un moment où le public est très sensibilisé à cette phase du cycle nucléaire.

Il nous paraît donc indispensable et urgent, dans le prolongement des recommandations de l'AIEA et de la CEE, que la réglementation française évolue vers la définition d'un seuil d'exemption en dessous duquel un déchet pourra être considéré comme "non radioactif". Une valeur homogène avec la réglementation sur les matières radioactives nous paraîtrait satisfaisante.

ELECTRICITE de FRANCE est bien consciente que l'adoption d'un seuil d'exemption entraînera une modification de sa politique de gestion des déchets faiblement radioactif, en particulier il paraît évident que les moyens de décontamination, de stockage pour décroissance et de mesure d'activité devront être développés d'une façon importante. ELECTRICITE de FRANCE s'y tient prête et orientera son action dans ce sens.

MOYENS INFORMATIQUES MIS EN OEUVRE A EDF POUR GERER RATIONNELLEMENT LES
DECHETS RADIOACTIFS

M.COMMUNAUX / J.HERISSON

Electricité de France
Service de la Production Thermique
D.S.R.E. - St DENIS

Abstract :

Since December 31, 1990, the management of the nuclear waste packs for all the power stations has been computerized, utilizing the DRA module of the Thermal Production Department data processing master plan.

So now EDF has a software package which centralizes all the data, enabling it to declare the characteristics of the nuclear waste packs which are to be stored at the sites operated by the National Radioactive Waste Management Agency (ANDRA).

Among other uses, this application will make it possible for EDF, by real time data exchange with ANDRA, to constitute an inventory of validated, shippable packs. It also constitutes a data base for all the wastes produced at the various sites.

Depuis le 31 décembre 1990, la gestion des colis de déchets nucléaires de toutes les centrales est assurée par informatique, grâce au module DRA du schéma directeur informatique du Service de la Production Thermique. EDF dispose ainsi d'un logiciel qui centralise toutes les données permettant la déclaration des caractéristiques des colis de déchets nucléaires destinés à être stockés sur les sites exploités par l'Agence Nationale de gestion des Déchets Radioactifs (ANDRA).

Cet applicatif permet, entre autre, à EDF de constituer, par échange de données en temps réel avec ANDRA, un stock de colis validés et expédiables. Il constitue également une base de données de tous les déchets produits sur les différents sites.

Cet applicatif a été développé pour répondre aux demandes suivantes:

- Offrir aux producteurs de déchets radioactifs un outil qui permet une gestion complète de toutes les caractéristiques et de tous les matériels nécessaires au bon conditionnement de leurs déchets.
- Assurer la traçabilité et la sûreté des informations et permettre une transmission de ces informations en automatique et en temps réel entre les producteurs et l'ANDRA.
- Offrir aux services centraux d'EDF un outil d'exploitation et de statistiques permettant un retour d'expérience sur l'ensemble de la production nationale (base de données unique, centralisée).
- Intégrer l'applicatif dans les produits du schéma directeur informatique garantissant ainsi sa maintenance et son évolution.

OUTIL D'EXPLOITATION

L'applicatif DRA est basé sur un gestionnaire de base de données fonctionnant dans un environnement gros système IBM. Sur chaque site producteur de déchets, un réseau local de micro-ordinateurs de type IBM PC dialogue avec un ordinateur central IBM situé à Paris par l'intermédiaire d'un réseau privé EDF basé sur TRANSPAC.

L'applicatif DRA permet la gestion et la traçabilité des différentes données et caractéristiques relatives aux colis de déchets radioactifs depuis le déchet proprement dit, son conditionnement et jusqu'à l'expédition des colis sur les centres de stockage. Il inclut le suivi des conteneurs de conditionnement, des bâches résines et concentrats et des zones de stockages sur site.

Ces données sont saisies et contrôlées par un opérateur, vérifiées par l'applicatif et validées par un vérificateur.

Fonctionnalités :

Réception des conteneurs.

Par lecture codes barres ou par transfert de fichier, les conteneurs livrés sur site sont vérifiés par comparaison avec une liste de référence (utilisation de Terminaux de Saisie Portable équipés de lecteurs laser.) puis transférés dans DRA. L'applicatif assure l'unicité des numéros de conteneurs pour l'ensemble du parc nucléaire.

Gestion documentaire.

Les différentes fiches de saisie papier, fiches suiveuses de collecte de déchets et fiches d'identification de colis, qui doivent encore être utilisées, sont éditées par DRA.

Gestion des déchets.

Les caractéristiques des déchets produits sont saisies sur DRA (fiches suiveuses), les données sont vérifiées par rapport aux différents descriptifs de procédés puis mémorisées (base de données).

Gestion des bâches.

Les caractéristiques des différentes bâches de stockage ou de transport (niveau, activité ...) sont calculées automatiquement en fonction des paramètres des déchets transférés dans ces bâches par l'intermédiaire des données présentes sur les fiches suiveuses puis elles sont mémorisées par cycle d'utilisation des bâches (base de données).

Gestion des spectres.

Les caractéristiques des différents spectres utilisés pour définir les particularités radiologiques des déchets sont saisies, vérifiées et mémorisées (base de données); DRA garantit l'unicité des identifiants des spectres.

Gestion des colis.

Les caractéristiques des colis produits sont saisies sur DRA (fiches d'identification), les données sont vérifiées par rapport aux différents descriptifs de procédés puis mémorisées (base de données); DRA assure la gestion du stock des conteneurs (conteneurs vides, colis en cours, colis expédiables, colis expédiés).

Déclaration à l'ANDRA.

DRA assure la liaison entre les informations déchets, spectres et colis pour calculer les caractéristiques qui sont envoyées automatiquement par l'applicatif vers l'ordinateur de l'ANDRA qui les traite.

La réponse de l'ANDRA, automatique également (temps de réponse de l'ANDRA, traitement compris, inférieur à 15 mn pour les informations de 200 colis) est gérée par DRA, cette réponse est soit une validation (colis expédiable) soit un message d'erreur indiquant la cause du refus de validation de ces caractéristiques.

Expéditions.

DRA assure une aide à la création d'expédition, les opérateurs, sur leur poste de travail, chargent des colis (expédiables uniquement) dans des transconteneurs, ces transconteneurs sont chargés sur des camions ou wagons, qui sont regroupés en expéditions.

Les caractéristiques de l'expédition sont établies et contrôlées automatiquement au fur et à mesure de la constitution.

Les caractéristiques de l'expédition sont envoyées par transfert de données informatiques à l'ordinateur de l'ANDRA de la même façon que les données colis.

Le dossier papier d'expédition est édité automatiquement par DRA et placé dans les différents camions ou wagons (respect de la réglementation des transports).

Gestion géographique.

Les zones de stockage des centrales sont gérées. Le nombre de colis, le type de colis, l'expédiabilité d'une zone entière, le poids et l'activité total des colis de chaque zone sont suivis.

Éditions.

La base de données de DRA (déchets, spectres, colis, expéditions) procure un outil de statistique qui fournit des éditions locales et nationales.

INTEGRATION COMPLETE DANS LES PRODUITS DU SCHEMA DIRECTEUR

Le Schéma Directeur Informatique du Service de la Production Thermique a pour objectif d'offrir aux exploitants des centrales nucléaires des outils informatiques dans différents domaines (maintenance, sûreté, formation, gestion ...) qui présentent tous des caractéristiques homogènes.

Ces produits ont été développés, testés, documentés, mis en service, exploités suivant des normes strictes et communes.

Ces normes garantissent, en particulier, la maintenance à long terme, l'adaptation rapide du personnel d'une application à une autre, l'utilisation d'un matériel commun à toutes les applications.

SURETE ET TRACABILITE DES INFORMATIONS

Sûreté et sécurité informatique

L'application DRA utilise le gestionnaire de base de données CRADLE en environnement CICS IBM ce qui implique l'utilisation des sécurités liées aux applications tournant sur gros systèmes et exploitées dans des centres de calcul par du personnel spécialisé.

La sécurité des accès est garantie à plusieurs niveaux :

- Chaque poste de travail est identifié de façon unique.
- Seuls les postes de travail dont les identifiants ont été déclarés par les exploitants du centre de calcul accèdent à l'applicatif.
- L'autorisation d'accès à l'applicatif est associé à un "user" personnel créé par un administrateur national.
- L'utilisation des fonctionnalités est liée à des habilitations affectées à chaque "user" par un gestionnaire local.
- Chaque "user" est associé à un mot de passe modifiable par son propriétaire.

Tracabilité et sûreté des informations.

Les informations sont "en cascades" (ex: Résines -> Bâche -> colis -> expédition), les liens dans les sens amont-aval et aval-amont sont systématiquement conservés.

Ceci permet, par exemple, de retrouver les caractéristiques de chaque transfert de résine ou de chaque colis conditionné durant un cycle d'utilisation d'une bâche donnée.

La suppression ou la modification de paramètres n'est autorisée que pour certaines habilitations et uniquement si cette modification n'a pas d'impact sur une information en aval qui peut être verrouillée (cas des colis expédiés sur un site de stockage).

Le "user" responsable de la dernière modification ou création d'information est mémorisé.

Toute création ou modification d'information est soumise à approbation d'un vérificateur.

BILAN DE FONCTIONNEMENT

Cet applicatif est en exploitation sur tous les sites producteurs depuis le 01 janvier 1991.

Au terme de dix mois de fonctionnement DRA a assuré la gestion de plus de quarante cinq mille colis, permet la constitution de quatre cent cinquante expéditions contenant plus de vingt et un mille colis.

La mise en service de DRA a constitué, pour EDF, une étape déterminante pour conforter la totale maîtrise de la sûreté et de la qualité de sa production de déchets radioactifs.

PROBLEMES POSES PAR LA COLLECTE ET LA PRISE EN CHARGE DU RADIUM

Philippe KISSEL , Patrice CHARBONNEAU

C.E.A./ Institut de Protection et de Sûreté Nucléaire

Département de Protection de l'Environnement et des Installations

Office d'Assistance en Radioprotection (OAR)

92265 Fontenay aux Roses Cedex . France

PROBLEMS RAISED BY RADIUM COLLECTION AND FINAL PROCESSING

Radium, in its different physico-chemical states and in source form, whether sealed or not, has been the first radionuclide to be used by industry and medicine.

Progressively given up and replaced by other radionuclides providing a more attractive efficiency/safety ratio, waste of radium and compounds are currently often stored in totally unsuitable places.

Considering the 1622 years radioactive half-life of radium, the radiological hazards bound to that natural radionuclide are important enough to start urgently the collection of this type of waste by a specialized organism.

The problems raised by radium collection and final processing, including the on site conditioning and the conveying to the selected storage places, are the subject of the present paper.

1 - INTRODUCTION

Rappelons que le radium, sous différents états physico-chimiques et sous forme de sources, scellées ou non, a été le premier radionuclide utilisé dans les domaines industriel et médical. Progressivement abandonné pour d'autres radionucléides ayant un rapport efficacité/sécurité plus attrayant, le radium et ses différents composés sont actuellement sans emploi et entreposés en des lieux qui ne sont pas toujours adaptés. Compte tenu de sa période radioactive (1622 ans), les risques radiologiques liés à ce radionuclide naturel sont suffisamment importants pour que la prise en charge de ce type de déchets par un organisme compétent et spécialisé, disposant de tous les moyens nécessaires et ayant une structure nationale, soit impérative.

Les problèmes posés par la collecte de ces déchets, incluant le reconditionnement sur le site de leur détention et le transport jusqu'aux lieux d'entreposage ou de traitement adéquat, ont fait, en France, l'objet d'un examen approfondi qui a conduit à une organisation particulière s'intégrant dans l'organisation générale de collecte des autres catégories de déchets radioactifs issus des établissements dits "petits producteurs" : établissements industriels et hospitaliers, d'enseignement et de recherche industrielle ou médicale, et nombre de petites entreprises (fabricants et installateurs de paratonnerres, horlogers,...), de praticiens (médecins,...) ou même de particuliers se retrouvant héritiers de sources de radium.

2 - CONSTITUTION ET SUIVI DU DOSSIER DE PRISE EN CHARGE

Après enregistrement de la demande d'enlèvement établie par le détenteur de radium et ouverture d'un dossier correspondant, la première opération effectuée par l'Office d'Assistance en Radioprotection (OAR) de l'Institut de Protection et de Sécurité Nucléaire (IPSN/CEA) est la vérification des données techniques et administratives portées sur cette demande, ce qui conduit très fréquemment à établir un contact direct avec le détenteur, afin d'obtenir de sa part certains compléments d'information tels que l'identification du fournisseur, la date de la fourniture du radium, la documentation technique d'origine, l'état physico-chimique initial et présent des produits radioactifs, les caractéristiques mécaniques de l'enveloppe des sources et de leur support ou de l'emballage des produits, ... Un examen, sur place, permet de recueillir certaines données techniques, non connues du détenteur, mais considérées comme indispensables en vue d'effectuer une prise en charge du radium qui soit conforme au Règlement de Transport des Matières Dangereuses (RTMD).

Sont notamment effectués dans les locaux du détenteur la caractérisation, par spectrométrie, des radionucléides émetteurs alpha (Ra226, Am241, ...), un contrôle neutronique pour la recherche de sources de radium-béryllium, et le contrôle des équipements ou des lieux du point de vue de la contamination. Accessoirement, des mesures de gaz radon sont effectuées.

Seule la réunion de toutes ces données peut permettre de préparer la stratégie de prise en charge complète et définitive, comprenant toutes les opérations, de l'enlèvement sur place (collecte) au stockage définitif, y compris la fourniture éventuelle d'emballages conformes au Règlement de Transport des Matières Dangereuses et de moyens de manutention appropriés, tels que téléopérateurs mobiles permettant d'effectuer le transfert à distance de sources particulièrement irradiantes.

Dans certains cas, au cours des travaux, des éléments peuvent conduire à prendre des dispositions supplémentaires et onéreuses de sécurité, telles que prise en charge d'autres matières radioactives, décontamination, jugée indispensable, de lieux ou d'équipements présentant un danger immédiat lié à une contamination significative.

Au besoin, une dérogation au Règlement de Transport peut être nécessaire en vue d'effectuer certains transports de radium, car il n'existe toujours pas d'emballage de type B agréé pour le transport de ce radionucléide.

Une fois planifiées les opérations de collecte et autres opérations liées à celles-ci, telles que reconditionnement sur place en emballage de transport et d'entreposage, tous les documents de transport requis sont établis par l'OAR:

- attestation d'expédition de matières radioactives sur la voie publique,
- bordereau de prise en charge chez le détenteur,
- avis de transport au Centre CEA destinataire,
- avis de livraison à l'Unité CEA chargée des premières opérations de prise en charge (entreposage ou traitement)
- avis éventuel de convocation d'une équipe de convoi pour le transport routier.
- au besoin, notification préalable de transport à la Direction de la Défense et de la Sécurité Civile.

3 - OPERATIONS DE COLLECTE ET AUTRES PRESTATIONS ASSOCIEES

Les opérations programmées sur site en vue de reconditionner le radium en emballages transportables sont ensuite réalisées, suivies d'un transport allant de la simple collecte, similaire à celle d'un colis classique de déchets radioactifs, au transport spécial avec convoyage lorsque cela est exigé dans la dérogation ministérielle.

Le radium est ensuite déposé sur une aire OAR d'entreposage de courte durée (<3 mois) ou livré à une Unité C.E.A. se chargeant, soit de son entreposage de moyenne (<5 ans) ou de longue durée (30 ans) en attente de son transfert vers un stockage définitif.

Les éléments de dossier utiles sont remis à l'Unité CEA prenant temporairement en charge le radium et un échange de visas est fait sur des bordereaux de mouvement de matières radioactives .

Une attestation de prise en charge est ensuite adressée à l'ex-détenteur du radium, et un compte - rendu est établi destiné aux différentes Autorités de tutelle ayant à connaître le devenir de toute source radioactive.

Des provisions, destinées à la couverture financière de toutes les opérations dont la réalisation est ultérieurement prévue, notamment celles correspondant au stockage définitif, sont constituées.

4 - ENTREPOSAGES DE COURTE ET MOYENNE DUREES

L'entreposage de courte durée (<3 mois) correspond au nécessaire besoin de transit des colis lors de leur déchargement du véhicule de collecte.

Un tel entreposage, d'une durée maximale de trois mois, a été ouvert par l'OAR pour effectuer certains contrôles d'assurance qualité, notamment en matière de sécurité radiologique, et pour trier les colis en vue de la préparation des chargements destinés aux autres unités du CEA.

L'entreposage de moyenne durée (<5 ans), a pour objet de permettre la constitution de lots de sources radifères de même type, destinés à être, soit traités séparément à des postes de travail particuliers afin d'optimiser les coûts, soit acheminés, après reconditionnement conforme à ses spécifications propres, vers un centre CEA d'entreposage de longue durée.

Un tel entreposage de moyenne durée a ainsi été ouvert à proximité immédiate du poste de traitement des paratonnerres au radium qui, en nombre de sources et en activité globale, pourraient représenter des quantités importantes.

En vue du transport et de l'entreposage du radium, quatre modèles de colis ont été "standardisés" par l'OAR :

le colis "K1" constitué d'une boîte métallique sertie de un litre contenant un petit conteneur de plomb dans lequel est placé le radium ; une gamme de différents modèles de conteneurs de plomb permet d'effectuer le choix le plus approprié en regard de l'activité des sources;

le colis "K2" constitué d'une boîte métallique sertie de deux litres avec conteneur de plomb;

le colis "K20" constitué d'une poubelle étanche alpha de vingt litres, type DTPE A29 de la société "La Calhène", dans laquelle les sources de radium, laissées dans leurs conteneurs d'origine ou replacées en conteneurs appropriés, sont conditionnées dans un mélange, sable sec et grenaille de plomb, dosé pour limiter les niveaux d'irradiation en vue de satisfaire aux normes de transport ; cette poubelle étanche est elle-même calée dans un fût métallique avec couvercle à pattes pouvant être serties;

le colis "K35" constitué d'une poubelle étanche alpha de trente cinq litres, type DTPE de la société "La Calhène", utilisée dans les mêmes conditions que la précédente.

5 - CONDITIONNEMENT POUR L'ENTREPOSAGE LONGUE DUREE

Les spécifications techniques précises relatives au conditionnement du radium en vue de son stockage définitif n'étant pas encore connues, il restera indiqué de conditionner le radium, dès sa prise en charge sur le lieu de détention, de telle sorte que ce premier conditionnement puisse, avec un emballage adéquat étanche au radon, constituer un colis conforme tout à la fois aux règlements de transport (RTMD) et aux spécifications d'entreposage pour une durée de l'ordre de 30 ans.

Un conditionnement étanche pourrait ainsi être réalisé "in situ" avec l'équipement mobile "CORA", qui correspond à un projet élaboré par l'CAR pour la "Collecte du Radium", et qui permettrait la réalisation de colis types K1, K2, K20 ou K35, tels que décrits ci-dessus.

Les spécifications techniques pour l'entreposage CEA de longue durée correspondent à un conditionnement réalisé en fût de 60 litres, placé dans un fût prébétonné de 200 litres; dans un tel emballage peuvent être placés soit "30 colis de type "K1", soit 15 colis de type "K2", soit un colis de type "K20" ou "K35".

6 - RECONDITIONNEMENT FINAL ET STOCKAGE DEFINITIF.

Les spécifications techniques applicables au conditionnement des produits radioactifs destinés au stockage définitif n'étant pas encore fixées par l'Agence Nationale pour la gestion des Déchets Radioactifs (ANDRA), nous avons fait en sorte que tous les conditionnements soient réversibles, afin de faciliter le plus possible une réduction des volumes à stocker, ce mode de conditionnement permettant par ailleurs de procéder à une éventuelle récupération des produits radifères, au cas où de nouvelles applications apparaîtraient ultérieurement.

7 - CONCLUSIONS

L'expérience acquise depuis quelques années a permis de valider l'organisation mise en place et de constater la nécessité, au niveau national, d'un service spécialisé particulièrement qualifié disposant de tous les moyens appropriés pour remplir une telle mission.

THE MIGRATION OF Cs-137 THROUGH THREE DIFFERENT FORMULATIONS OF COMPRESSIVELY STRESSED GROUT

Richard R. Brey and Robert R. Landolt

School of Health Sciences
Civil Engineering Building
West Lafayette, Indiana 47907

ABSTRACT

The effect of uniaxial, unconfined compressive stress on ¹³⁷Cs penetration into grouts containing either flyash, silica fume or no admixture was investigated. Cylinders from three formulations of grout were compressively stressed to either 0, 40, 70, or 90 percent of their construction strength, then placed into an apparatus which produced a hydrostatic pressure head gradient along the cylinder axis of 103 ± 21 kPa using a ¹³⁷Cs salt solution. Cylinders were sliced into thin disks and the relative ¹³⁷Cs quantity in each disk was measured. The use of admixtures resulted in decreased penetration of the ¹³⁷Cs into the grout. Penetration was observed to go through a maximum near the mid-range stress values.

INTRODUCTION

Several design proposals exist for low level radioactive waste shallow land and above grade disposal facilities. These designs include such systems as simple trenches, concrete vaults, and excavated caverns. All incorporate cementitious barriers of some fashion. These barriers will play an important role in enhancing system performance.

It is well documented that microfractures begin to develop in cement aggregate matrices when the composite is stressed compressively to values greater than 40% of maximum strength. These will develop across the matrix and along aggregate boundaries. Microfracturing persists under load until failure. This investigation was intended to observe the effect of stress on ¹³⁷Cs penetration into cementitious grouts.

EXPERIMENTAL MEASUREMENTS

A ¹³⁷Cs salt solution under a hydrostatic pressure gradient of 103 ± 21 kPa was applied to one face of cementitious grout test cylinders (2.54 cm in diameter, 5.08 cm long) for 30d to investigate the effect of stress on penetration. Three formulations of grout varying only in the admixture type used were considered. The first formulation was a mixture of sand, portland type I cement, and water (cement/sand = 0.5 by volume, water/cement = 0.4 by

weight). The second was a mixture of sand, portland type I cement, type F flyash, and water (cementitious material/sand = 0.5 by volume, cement/flyash = 7/3 by volume, water/cement = 0.4 by weight). The last mixture was a combination of sand, cement, silica fume, and water (cementitious material/sand = 0.5 by volume, cement/silica fume = 7/3 by volume, water/cement = 0.4 by weight). After curing at $35 \pm 3^\circ\text{C}$ while submerged in a saturated $\text{Ca}(\text{OH})_2$ solution for 30d the cylinders of each formulation were compressively stressed to 0, 40, 70, or 90 percent of their construction strength prior to the 30d hydrostatic pressure treatment. Construction strength is defined as the average maximum strength at failure minus the standard deviation of the maximum strength distribution. Unconfined compressive stress was applied using a Satec, computer controlled, hydraulically operated, universal testing machine. The load rate used was 185 ± 3 newtons/s. After reaching the desired load level the load was maintained for 30s prior to removal. After the hydrostatic treatment the cylinders were sliced into thin disks in a radiological glove box. The relative quantity of ^{137}Cs in each disk was determined using $\text{NaI}(\text{Tl})$ scintillation crystals and appropriate electronics. Analyses of data followed two strategies. One considered graphical characteristics of plotted data, the other considered raw data corrected for background and normalized by weight. Both strategies used analysis of variance and pairwise comparisons to establish and elaborate on differences between treatments. Figure 1 demonstrates the graphical characteristics analyzed. Figure 2 is an example of a typical semi-logarithmic raw data plot. It is representative of the data obtained from each test cylinder.

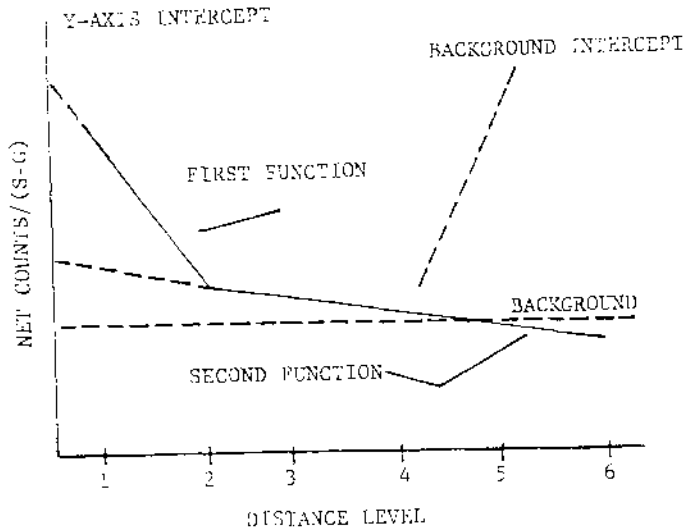

Fig. 1

Fig. 2

RESULTS AND CONCLUSIONS

Cementitious grouts containing silica fume or type F flyash performed better as containment barriers than plain grout mixtures in resisting ^{137}Cs penetration. The total depth of penetration with formulations containing admixtures was about one half that experienced with the formulation without admixtures.

Penetration seems to be governed by two distinct phenomenon as illustrated in Figure 1; one very significant near the surface, the other less pronounced throughout the rest of the specimen. The surface effect was about 20% stronger in formulations containing silica fume or flyash admixtures than in the formulation without an admixture.

The lowest ^{137}Cs penetration was consistently observed at the 0% stress level. Penetration was higher at the 40% and 70% stress levels and decreased at the 90% stress level. A cause of these trends may be a complex interrelation between active exchange sites and available effective surface competing with pore connectivity and size. The density of exchange sites is probably uniform over the surface area but varies among different formulations. The effective surface area available for exchange is expected to increase rapidly with stress. Low penetration at the 0% stress level may be related to the lack of pore connectivity. Increased penetration at the 40% and 70% stress values is attributed to increased pore connectivity. However, this is also accompanied by an increased number of exchange sites. As stress increases further, an increased number of exchange sites associated with a rapidly increasing effective surface area begins to greatly enhance the ^{137}Cs absorption and hence reduce the penetration. The result of this is the decreased penetration at the 90% stress level.

Probabilistic Approach to NDA for Non-uniform Radwastes

Myung C Lee, Duck J Koh, Seung G Ro, and Hee S Shin

Safety Analysis Department
Korea Atomic Energy Research Institute
Taejon, Korea

ABSTRACT

For nondestructive assay of low-level wastes a specific-purpose Monte Carlo code, MCRWA(A Monte Carlo code for Radioactive Waste Assay), was developed to simulate the entire energy spectral response for sources within an assayed container and to analyze the effect of scattered photons from higher energy gammas on the spectrum of a low energy gamma-ray. With the developed code the design optimization of nondestructive assay systems was performed and the probabilistic approach for the data interpretation was discussed.

INTRODUCTION

Non-destructive assay of radioactive wastes produced from nuclear power plants and fuel cycle facilities is required for the purpose of assessing the disposal risks. Such assay is influenced by two distinct facts. The first is the statistical uncertainty of the measurement resulting from randomness in the counting process. The other is the spatial uncertainty due to the random or unknown spatial distribution of the assayed material(analyte) in a waste container. Different spatial distributions of different quantities of the analyte may lead to same detector responses. Thus, such a spatial randomness of the analyte results in a significant source of uncertainty in interpreting the measurement and may require a probabilistic approach^{1,2)}. The probabilistic approach enables one to determine a probability distribution that a certain amount of the analyte is contained for a measured response instead of a single value based on a hypothetical distribution.

The basic assumption in the probability determination is that the loading of waste into the container volume is a random process. And the probability of finding a certain amount of the analyte and matrix materials in each volume element of the container is identical. Having identified various possible spatial distributions of the analyte and matrix in the container's volume, the probability for each to occur can be derived.

MONTE CARLO SIMULATION OF ASSAY SYSTEM RESPONSE.

A key point of nondestructive assay system in the present study is how to obtain the average response of a single point-source of unit intensity with a large volume HPGe detector. In most practical applications accurate analytical models for the point source response are impossible to obtain. In such cases, Monte Carlo simulation offers the only way to generate the point source response, short of doing a large and tedious set of experiments.

A Monte Carlo code, MCRWA (Monte Carlo code for Radioactive Waste Assay) was developed to simulate the entire energy spectral response for point sources located within the assayed sample. The significant features of the developed MCRWA code are that it can be used not only for obtaining the averaged detector response but also for predicting the photon energy spectra of all gammas emitted from multiple radionuclides within the sample. Therefore, the simulated entire pulse-height spectrum with the HPGe detector can be useful for estimating the effect of scattered radiations from high energy gammas on the pulse height spectrum of a low energy gamma ray.

The focus in the study is on the tracking of gamma rays from the source in the sample to the detector. In order to reduce the variance of the output from the Monte Carlo simulation, suitable variance reduction methods such as Russian roulette were used. During the tracking of photons the statistical estimation techniques were used at every collision point to score the gamma-ray intensities detected.

DESIGN OPTIMIZATION OF ASSAY SYSTEM

In a practical case nuclear assay of low- and intermediate- level radioactive wastes generated from nuclear power plants will be done passively using gamma-ray detector responses. In order to demonstrate the use of convexity analysis²⁰ in the assay system design, a cylindrical drum of small size was selected because it has the potential for extension to practical situations. The design procedure developed with this simplified geometry is also thought to be extended easily to practical situations. The sample diameter and height were 16 and 32 cm, respectively. The matrix of sample was polyethylene or cement. The analytes were Pu-239 at 384 keV complex, Cs-137 at 662 keV, and Co-60 at 1,173 keV.

The design problem was to choose the optimum number and deployment of detectors for a given sample shape and size, for a given detector type, and for passive gamma-ray assay. Point source response sets obtained from Monte Carlo simulation was used for calculations of the Relative Mass Resolution (RMR) which is a quantitative measure of the performance of each proposed design. These response sets included the unscattered gamma-ray responses or both the scattered and unscattered gamma-ray responses of detectors. Detail results of optimized assay system design will be given at the presentation time.

PROBABILISTIC INTERPRETATION OF MEASUREMENT

If the spatial distribution of the analyte in the sample is unknown, then this spatial uncertainty will be an additional factor contributing to the measurement uncertainty and the interpretation of measured responses in terms of contained mass will be non-unique. Hence this uncertainty precludes the use of a simple model for design purposes and also precludes the unambiguous calibration of the assayed system based on standardized samples since different spatial distributions of same quantity of the analyte may give different activity readings. A probabilistic approach may be the best solution to these kinds of assay problems.

In this paper two kinds of probabilistic approaches were discussed. One is based on the concept of maximum likelihood. That is, the average response is interpreted as arising from the value of m which maximizes $p(g|m)$ on the set of values of m , where m is the quantity of the analyte and $p(g|m)$ is the conditional probability density of the response given the quantity of the analyte. The other is based on A. Knoll's concept⁴ that analyte and matrix compartments within the sample exist such that within a compartment the material distribution is uniform. The boundaries of the compartment are random variables with probability density functions associated with them. Knoll's methodology was extended and adapted to the data interpretation of the proposed assay system. The comparison of results from two approaches will be given at the presentation time.

SUMMARY AND CONCLUSIONS

The assay system presented in this study is based on a "one-shot" geometry. The spectrometer's angle of view covers the whole examined container. The count rate of the detector resulting from a certain characteristic gamma energy emitted by the source material is referred to as the assay system response. The obtained mass probability curve can be used for distribution characteristics such as first moment, uncertainty within specific confidence level, and most probable mass, etc. The dispersion of the curve shown in Fig. 2 presents the spatial variance for possible allowed distributions of masses.

The averaged entire pulse-height spectral response for sources located within the sample was obtained by the convolution of the Monte Carlo generated energy spectrum with the spectral response function of a large volume germanium detector^{5,6}. The comparison of pulse-height spectrum generated by Monte Carlo simulation and then convolved with the detector response function to the corresponding spectrum measured by using a Cs-137 photon source is shown in Fig. 3. The agreement between the Monte Carlo simulated and experimental results is quite good. In case that the sample contains multiple radionuclides which differ in their characteristic gamma-ray energies and one wants either to assay a radionuclide or to assay whole radionuclides in the drum simultaneously, the response of the detector for each nuclide is required separately. But the measured response may include both the response of radiations from the assayed nuclide and the responses of the scattered radiations from higher energy gammas. One can eliminate the scattered radiation contribution of higher

energy gammas from the measured response by subtracting the complete pulse-height spectra of higher gamma-ray energies from the measured complete pulse-height spectrum sequentially. In this method, however, large accumulated errors will be propagated to final results due to the subtractions. To avoid such accumulated errors, a library least-squares analysis technique⁷ provides better solution to the proposed problem. With this technique one can estimate the detector response for each nuclide in the assayed sample at a time. The specific-purpose Monte Carlo code, MCRWA(Monte Carlo code for Radioactive Waste Assay), seems to be valuable for other assay systems.

ON THE REDUCTION OF ^{222}Rn EXHALATION FROM ^{226}Ra -RICH WASTES
BY COVERING OF SOIL

Y. IKEBE

Department of Nuclear Engineering, School of Engineering,
Nagoya University, Chikusa-ku, Nagoya 464-01, Japan

ABSTRACT

The reduction effect for Rn-222 exhalation from a Ra-226 containing wastes by covering of ordinary soil is calculated. Although the concentration profile of radon in the soil for two layer model is quite different from that for three layer model, exhalation rates are not so much differ between the two models. It is shown that the effective diffusion coefficient of the soil is very effective for radon exhalation.

INTRODUCTION

Recently, concern of peoples about environmental radon is increasing gradually. In some occasions, we shall have to reduce the activity level in air of radon exhaled from wastes such as uranium tailings, excavated Ra-rich soil from various kinds of mine, and so on. In order to reduce the Rn-222 exhalation from such wastes, a covering of normal soil upon the wastes may be practical and useful.

In this paper, the reduction effect for Rn exhalation from wastes by covering of normal soil is evaluated by calculation using various soil parameters such as Ra-226 content, Rn escape-to-production ratio, air ratio, and effective diffusion coefficient of Rn.

MODEL

First, we consider two layer model: First layer is ordinary soil of thickness H_1 . Second layer is wastes of thickness H_2 . Under steady state conditions, the diffusion of radon through soil to surface can be expressed in each layer by the diffusion equation^{1,2)}

$$D \frac{d^2 C}{dz^2} + a - \lambda C = 0$$

where $C(z)$ is the concentration of radon atoms in soil air ($\text{atom}\cdot\text{cm}^{-3}$ of soil air), a is the supply rate of radon atom to soil air ($\text{atom}\cdot\text{cm}^{-3}$ of soil air $\cdot\text{s}^{-1}$), λ is the decay constant of radon (s^{-1}), and D is the effective diffusion coefficient of radon in soil air ($\text{cm}^2\cdot\text{s}^{-1}$).

If we denote δ is the escape-to-production ratio of radon (-), n is the air ratio (=air volume)/(total volume of soil), (-), A is the Ra-226 activity ($\text{Bq}\cdot\text{cm}^{-3}$ of soil), C_g is the

concentration of radon atoms existing in soil air (atom·cm⁻³ of soil), then $C_s = nC(z)$ and $a = \delta A/n$.

The boundary conditions are given by $C_1(0) = 0$, $n_1 C_1(H_1) = n_2 C_2(H_1)$, $(C_{s1}(H_1) = C_{s2}(H_1))$, $\lambda C_2(\infty) = a_2$,

$$\text{and } D_1 \left(\frac{dC_{s1}}{dz} \right)_{H_1} = D_2 \left(\frac{dC_{s2}}{dz} \right)_{H_1} .$$

The solutions are given by:

$$\text{At first layer } C_1(z) = A_1 \exp\left(\sqrt{\frac{\lambda}{D_1}} z\right) + B_1 \exp\left(-\sqrt{\frac{\lambda}{D_1}} z\right) + \frac{a_1}{\lambda}$$

$$\text{where } A_1 = \left\{ \frac{a_1}{\lambda} \left(1 - \sqrt{\frac{D_1}{D_2}}\right) \exp\left(-\sqrt{\frac{\lambda}{D_1}} H_1\right) - \frac{n_1 a_1 - n_2 a_2}{\lambda n_1} \right\} /$$

$$\left\{ \left(1 + \sqrt{\frac{D_1}{D_2}}\right) \cdot \exp\left(\sqrt{\frac{\lambda}{D_1}} H_1\right) - \left(1 - \sqrt{\frac{D_1}{D_2}}\right) \exp\left(-\sqrt{\frac{\lambda}{D_1}} H_1\right) \right\}$$

$$B_1 = -\left(A_1 + \frac{a_1}{\lambda}\right) .$$

$$\text{At second layer } C_2(z) = B_2 \exp\left(-\sqrt{\frac{\lambda}{D_2}} z\right) + \frac{a_2}{\lambda}$$

$$\text{where } B_2 = -\frac{n_1}{n_2} \sqrt{\frac{D_1}{D_2}} \exp\left(\sqrt{\frac{\lambda}{D_2}} H_1\right) \left\{ \exp\left(\sqrt{\frac{\lambda}{D_1}} H_1\right) \right.$$

$$\left. + \exp\left(-\sqrt{\frac{\lambda}{D_1}} H_1\right) \right\} A_1 + \frac{a_1}{\lambda} \exp\left(-\sqrt{\frac{\lambda}{D_1}} H_1\right) .$$

The exhalation rate, E (atom·cm⁻²s⁻¹), at the surface is given by

$$E = -n_1 D_1 \left[\frac{dC_1}{dz} \right]_{z=0} = -n_1 D_1 \left(A_1 \sqrt{\frac{\lambda}{D_1}} - B_1 \sqrt{\frac{\lambda}{D_1}} \right)$$

Secondly, three layer model was treated, in which the third layer corresponds to the basic ground ($H_3 = \infty$). The formulae of $C_3(z)$ and E were obtained analytically using similar boundary conditions to those used for the two layer model.

CALCULATION

The parameters used for the present work are $D_1 = D_2 = D_3 = D = 0.054$, $0.054/10$, $0.054/100$, $n_1 = n_2 = n_3 = 0.1$, $a_1 = a_3 = 1$, and $a_2 = 1, 10, 100$.

Fig. 1 Shows the results for two layer model. In Fig. 1 (1), profile of Rn existing in soil air (Bq·cm⁻³ of soil) is given as a parameter of $D_1 = D_2 = D$ assuming $a_1 = 1$, $a_2 = 100$, $H_1 = 100$

and $H_2 = \infty$. In Fig. 1 (2), profile is given as a parameter of H_1 assuming $a_1 = 1$, $a_2 = 100$, $D_1 = D_2 = D = 0.054/10$, and $H_2 = \infty$.

Fig. 2 shows the results for three layer model. In Fig. 2(1), $C_S(z)$ (Bq.cm⁻³ of soil) is given as a parameter of $D_1 = D_2 = D_3 = D$ assuming $a_1 = a_3 = 1$, $a_2 = 100$, $H_1 = H_2 = 100$, and $H_3 = \infty$. Fig. 2 (2) gives the profile as a parameter of H_1 assuming $a_1 = a_3 = 1$, $a_2 = 100$, $D_1 = D_2 = D_3 = D = 0.054/10$, $H_2 = 100$, and $H_3 = \infty$.

Fig. 1 Rn profile in soil (two layer model)

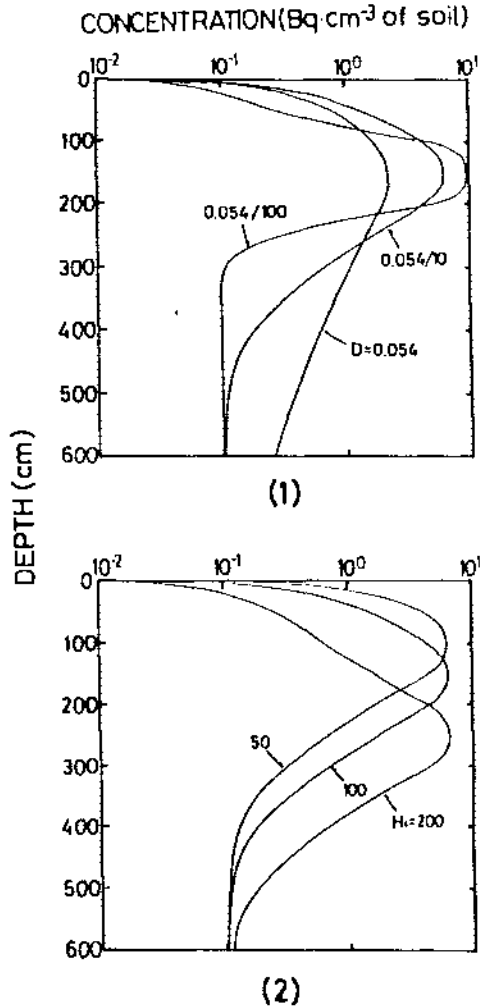

Fig. 2 Rn profile in soil (three layer model)

Fig. 3 shows the calculated exhalation rates, E , for two layer model (broken line) and for three layer model (solid line). In Fig. 3(1), E is shown as a function of H_1 for a parameter of $D_1 = D_2 = D_3 = D$ assuming $a_1 = a_3 = 1$, $a_2 = 100$, $H_2 = \infty$ (two layer), $H_2 = 100$ and $H_3 = \infty$ (three layer). Fig. 3(2) gives E as a function of H_1 for a parameter of a_2 assuming $a_1 = a_3 = 1$, $D_1 = D_2 = D_3 = D = 0.054/10$, $H_2 = 100$, and $H_3 = \infty$.

RESULTS AND DISCUSSIONS

Although the present model is simple and parameters used are assumptive, we may get some informations from the present calculation. Comparing Fig. 1 and Fig. 2, the profile of $D_S(z)$ for two layer model is quite different form that for three layer model. But as is shown in Fig. 3, exhalation rate for two layer model is not so much differ from that for three layer model. It is also seen that D is very effective for the value of E^3 , which suggests that radon exhaled from wastes can be effectively reduced by covering of soil of low effective diffusion coefficient. The present treatment may also be applicable for natural multi-layer soil.

**The Development of Internationally Accepted Exempt levels
of Radionuclides in Solid Materials**

G.S. Linsley
International Atomic Energy Agency, Vienna, Austria

The principles for exempting radiation sources and practices from regulatory control, which were the subject of an international consensus in 1988, have been applied in the waste management area. Guidance has been developed on methodologies for evaluating exempt concentrations and quantities of low level radioactive wastes from industry, medicine and research and of materials intended for recycle and reuse. Recommendations are being formulated on exempt values applicable to all materials and wastes irrespective of their fate after control has been relinquished.

COMPARISON BETWEEN RADIOLOGICAL PROTECTION AGAINST IONIZING RADIATION AND NON IONIZING RADIATION

H.P. JAMMET
Chairman Emeritus IRPA/INIRC and Vice Chairman ICRP
PARIS, FRANCE

INTRODUCTION

Protection against IR and NIR developed in completely different ways because of the very different evolution of the techniques they involve. While as soon as 1928, the International Society of Radiology created the International Commission of Radiological Protection, we had to wait until 1977 to see the creation of the International Committee for NIR (INIRC) by IRPA. To compare protection against Ionizing Radiations and Non Ionizing Radiations we will first carry out a general analysis of its components and then we will draw the general conclusions leading to a quite comparable evolution.

I GENERAL ANALYSIS

The general analysis will be carried out on the definitions, the radiation/matter interactions and the biological effects, the quantities and units, the sources and the exposures, radiological protection itself and finally monitoring and surveillance.

1. DEFINITIONS

The definition of the characteristics of ionizing and non-ionizing radiations is rather complex due to their often heterogenous components.

Ionizing radiation conventionally includes two distinct categories : electromagnetic radiation of photon with energy higher than that of ultra-violet rays (X and gamma rays), and particulate radiation formed of fragments of matter (electrons, beta-rays, neutrons, alpha-rays).

Non-ionizing radiation normally includes electromagnetic radiation with energy less than that necessary to produce ionization : optical radiation (UV, visible, IR) incoherent and coherent (lasers), and waves (microwaves, radiofrequencies, radar, extremely weak electromagnetic fields). Added for various reasons are static electric and magnetic fields, as well as the part of acoustics including ultrasound.

This discussion focuses mainly for comparison purposes on electromagnetic radiation, of which ionizing and non-ionizing radiations cover the entire spectrum from the highest energy cosmic rays to zero frequency electric and magnetic fields.

2. RADIATION/MATTER INTERACTIONS

The understanding of the action mechanisms of radiation is directly related to the penetration of this radiation into living matter, and to its interaction with it.

Parameters associated with exposure : duration and distribution of exposure in time (continuous or intermittent exposure), distance from the source (except for lasers emitted by a source considered as a point), orientation of the exposed subject in the radiation field, and spatial distribution of the exposure (total or partial exposure of the organism).

Parameters related to biological characteristics : cellular and even molecular construction of the exposed tissues, electrical properties, certain physiological properties such as blood irrigation in the event of thermal effects, the dimensions of the organ or the subject, and the functional importance of the tissues or organs affected.

The study of the effects of ionizing radiation on living beings is the domain of two disciplines : one scientific, radiobiology, and the second medical, radiopathology.

Radiobiology is concerned with all the effects of radiation, whether they are beneficial or harmful, and attempts to determine the mechanisms. These are related to the whole organisms, organs and tissues, cells, cell components, or molecular biology.

Radiopathology is concerned only with the harmful effects of radiation.

3.2 IONIZING RADIATION

A number of high general exposures revealed the sensitivity of the haematopoietic tissues and germinal tissues, causing haematopoietic depressions and sterility. A large number of studies have been devoted to harmful rays, namely to death by irradiation due to haematological, visceral or neurological syndromes, treated by brand new methods, such as organ transplants. Attention was then drawn by the induction of cancers : leukemia in radiologists, sarcoma in radium painters, bronchopulmonary cancers in uranium miners, various types of cancer for atomic bomb victims of Hiroshima and Nagasaki. Following the discovery of the genetic action of radiation on the experimental level, an attempt was made, nearly always in vain, to identify the induction of hereditary diseases by epidemiological investigations. The latest induction of manifestations of mental retardation after foetal exposure is between eighth and the sixteenth week of gestation.

3.3 NON IONIZING RADIATION

For the non-ionizing radiation the type, scale and importance of the effects generated are extremely variable, and apparently depend on an even larger number of factors than ionizing radiation. If the energy of the incident photons is vital because it conditions their penetration depth into the tissues and their preferential absorption by a specific type of molecular structure, the field intensity, the radiation emission mode (coherent or non-coherent, continuous or pulsed), the size and geometric configuration of the subject, the cell structure of the irradiated tissues, and often even certain psychological characteristics, such as blood irrigation of the tissues, are equally important factors. In fact, although in recent years interest has grown considerably in the biological effects of NIR, and an increasing number of research projects is devoted to this subject throughout the world, the precise role played by these different parameters, their interference, and specially their quantitative relationships with the biological effect produced, are still very poorly known.

The problems raised and the difficulties encountered by biologists are quite similar to those occurring in the area of ionizing radiation. Apart from the parameters mentioned above, the seriousness of the effects depends on the distribution of radiations (partial or total irradiation), and on the sensitivity and the size of the target organs. As a rule, two types of effects are found here, stochastic and non-stochastic. Certain non-stochastic effects are relatively well-known, as for example erythema and burns of the skin, as well as ocular effects (conjunctivitis, retinal burns, cataract) for optical radiations, effect

resulting from the heating of the tissues, routinely called thermal effects, due to high energy fluence microwaves. It has been possible to determine the occurrence thresholds.

On the other hand, considerable uncertainty subsists on the non-thermal effects that may be produced by microwaves, particularly at the low energy fluence rates. The results obtained appear to show that, in certain frequency ranges, electromagnetic waves can induce biological effects, which are not due to simple heating, at the level of the nerves, endocrine and immune systems, for example. Furthermore, it now seems clear that an energy fluence rate interval exists, called a "window", below which certain effects can appear that are produced by low fluence rate microwaves.

As for the stochastic effects (induction of cancers, genetic effects), while it is well-known that they exist in certain cases (skin cancer due to ultraviolet radiation), we are still in the stage of preliminary research for the other types of NIR.

4. QUANTITIES AND UNITS

The quantities and units employed for ionizing and non-ionizing radiations are quite different in practice for historical reasons, stemming from the compartmentalization of the different disciplines such as radiology, radiobiology, radiopathology, photobiology, optics, telecommunications and acoustics. For ionizing radiation, after having used exposed units such as the röntgen, the units applied today refer to the dose absorbed in the material, such as the gray and the sievert.

For non-ionizing radiation, the conventional units of optics and acoustics are employed. Energy densities in J/cm^2 or power densities in W/cm^2 are used for radiofrequencies. This is the energy through a surface. We are moving towards quantities related to the energy absorbed per unit volume or mass, such as the specific absorption rate.

The International Commission for Radiological Units and Measurements has undertaken a laudable effort to harmonize and standardize the basic concepts of metrology for all forms of radiation.

5. SOURCES

Radiation sources are either natural or artificial, modified or created by man. Natural ionizing radiation sources include cosmic and telluric components causing external irradiation (gamma-rays) and internal irradiation (^{40}K , radioactive families of uranium and thorium). Artificial sources consist essentially of generators of X rays and radioactive substances, sealed or otherwise, used in medicine, industry and research. However, a special mention must be made concerning atomic energy, of which the nuclear cycle ranges from uranium mines to radioactive wastes, including enrichment plants, nuclear reactors and reprocessing facilities.

Natural non-ionizing radiation sources consist essentially of solar radiation (UV, visible, IR), cosmic radiation formed light or radiofrequencies which are extremely weak. Artificial sources are many and varied in the field of optics, waves and ultrasonic acoustics, employed in industry, research, medicine and home appliances. Rapid advances are being achieved for lasers, radar systems and telecommunications.

From the quantitative standpoint, it is interesting to note that raw or domestic natural sources outnumber artificial sources, while the situation is comparable for optical radiation, but is the opposite for radiofrequencies and ultrasound.

6. EXPOSURES

Human exposure to radiation are extremely variable and quite different in method and scale. However, it is closely comparable for ionizing and non-ionizing radiation.

In fact, it can take place in everyday life, on the job, and even during radiological medical practice. This concerns general exposure of the public, occupational exposure of workers, and medical exposure of patients. In compiling an overall balance, it can be observed that public exposure is the greatest, followed by medical exposure, with occupational exposure coming last. However, the individual balance shows that certain workers or patients belong to higher irradiation groups.

7. RADIOLOGICAL PROTECTION

7.1 PROTECTION PURPOSES

Credible protection and acceptability. What are the objectives of radiological protection? From the outset, it has tried to prevent non-stochastic damage, essentially radiological burns and haematological depressions. Subsequently, with the growth of knowledge about the carcinogenic and mutagenic effects, it has attempted to reduce stochastic damage, namely the induction of cancers and hereditary diseases.

Why this diversity of objectives for effects with different correlation? In the first case of non-stochastic damage with a deterministic correlation, thresholds exist below which no radiopathological manifestation occurs. Hence, for doses lower than these thresholds, damage can be avoided completely, and absolute protection guaranteed. In the second case of stochastic damage, prudence has led to the assumption of the non-existence of thresholds, and hence only the ability to reduce the probability of induction of cancers or hereditary diseases. Protection can only provide a relative guarantee.

7.2 APPROACHES TO PROTECTION PROBLEMS

The approaches to the problems of radiological protection has also been the subject of considerable change over the years.

Initially the problems raised concerned a small number of individuals : pioneers in scientific research, practioners in medical applications of radiation. It was normal for the approach to be individual. One was concerned with guaranteeing adequate protection for each worker or for each individual belonging to the so-called critical group of the most exposed persons. Thus standards were progressively established, essentially in the form of individual exposure limits. Subsequently, with the growth of the number of sources and their size, radiological protection was forced to focus on problems associated with the sources themselves. Since a given installation was capable of irradiating a large number of persons, it became indispensable to use a collective approach to the problems arising. The individual exposure limits were gradually supplemented by collective irradiation standards, related to the sources and enabling mutual comparisons between the protection levels.

This is why, in the present phase of radiological protection, the complementarity of the individual and collective approaches is culminating in a set of requirements, some of which concern the individuals subjected to irradiation from several sources, with others related to each source liable to irradiate a certain number of persons.

7.3 RADIOLOGICAL PROTECTION SYSTEMS

The individual and collective approaches to protection problems had the common basis of health and technological considerations. The former concerned standards relative to persons, and the latter those relative to sources. Yet the normal evolution of radiological protection, in the context of the growth of the industrial society, ultimately had to take account of economic and social considerations. The economy had to be quantified in order to compare the respective costs of the risks avoided and the related means of protection. Sociology focused its efforts on the adequate adaptation of protection to the delicate problem raised by the different levels of worker exposure, transborder radioactive pollution, and the spreading of exposure in the more or less distant future. Hence radiological protection proposes protection systems adapted to the foregoing considerations.

The initial recommendations were based on a limitation/minimization system. The limitation of exposure is reflected by maximum permissible doses. Since the exposure of individuals to the limits is undesirable, prudent but arbitrary safety factors were introduced, corresponding to a minimization process. A new protection system was recommended based on optimization/limitation. Optimization is aimed to analyze the various protection alternatives for the exposure sources, and to compare them in order to select the best one. The limitation of individual exposure is the guarantee for each person that the conditions of the optimal solution are acceptable for him.

7.4 PROTECTION AGAINST IONIZING RADIATIONS

In its Publication ICRP 90, the Commission recommends the following protection system :

- non practice should be adopted if its introduction does not realize a net benefit,
- all exposures must be kept at the lowest level that can be reasonably reached, in the light of economic and social factors,
- the dose equivalent for individuals should not exceed the limitations recommended for the circumstances in question

These three components correspond respectively to the principles of justification of the operations, optimization of protection and limitation of individual exposure.

It should be noted that the two principles of justification and optimization are vitally important conditions. The third principle, that of limitation is in fact an individual guarantee, because the distribution in the population of the benefits and costs is not the same.

Dose limitation culminates in protection standards. It is important to draw a distinction between types of protection standards : limits, constraints and levels.

- Fundamental limits

The fundamental limits consist in the primary and secondary limits. The primary limits are dose equivalent limits for the whole organism and the different organs or tissues. Secondary limits are given for external irradiation and internal irradiation. With respect to the external irradiation of the whole organism, the secondary limit applies to the maximum dose equivalent for the organism at more than 1 cm depth. For internal irradiation, the secondary limits are the annual limits of incorporation by inhalation or by ingestion.

. Constraints

The constraints are the upperbounds of optimization and can be established by a competent authority or by the management of an establishment. These constraints are lower than the limits. The minimization process is often employed in setting the constraints, but the optimization process should be used.

. Reference levels

Reference levels are not limits. They are used to determine the conduct required when a quantity exceeds or is liable to exceed the reference level. Exemption levels are fixed for the delineation of the scope of the system of radiological protection, below which it is not used.

Investigation levels can be defined as values of the dose equivalent or incorporation equivalent above which the results are considered sufficiently important to justify supplementary investigations.

Among the most widely used reference levels, ICRP mentions the intervention levels. These are defined as preset levels fixed so that it will be unnecessary to act as long as the value of the quantity measured or evaluated does not exceed this level. Above this level, action must not be automatic, because its timeliness and nature will depend largely on the situation. Furthermore, since action may interfere with the normal progress of operations or, in certain cases, break the normal chain of responsibilities, it should not be undertaken without due consideration.

7.5 PROTECTION AGAINST NON-IONIZING RADIATIONS

The analysis and synthesis of present knowledge on the pathological effects of NIR and the difficulties encountered in the monitoring of individual exposure have led the IRPA/INIRC to establish a protection doctrine based on the following principles :

- Compliance with health protection standards as defined in this document ensures adequate protection for occupationally exposed workers, and for members of the general public, against the hazards which might result from NIR,
- compliance with health protection standards should be guaranteed as far as possible by the development and compliance with performance standards which apply to the design and construction of NIR emitting devices,- when safety cannot be sufficiently guaranteed by construction (performance standards) due to the emitter characteristics or to its use, appropriate operational protection measures must be applied in order to comply with health protection standards.

Health protection standards : They consist mainly of limits that the various quantities defined above should not exceed (except in certain circumstances specified in the text). In the light of present knowledge acquired through animal experimentation and human observation, they are thought to represent the best values to allow the general use of NIR under safe conditions. However, given the limited nature of available data and the progress which will undoubtedly be made concerning the pathological effects of NIR, it can be assumed that these limits might eventually be modified (either increased or lowered) if and when it becomes necessary.

Device standards (Product performance standards) : because of the difficulties encountered in developing individual monitoring of exposure and therefore in ensuring compliance with health protection standards, it is all the more important to make provisions for the appropriate design and construction of the equipment and for the control and approval of the specifications.

The many industrial, scientific, medical and home applications of high frequencies, micro-waves, broad-beam optical radiation, lasers and ultra-sound lead to the design of widely-varying devices. One of the first tasks is to classify them according to the power they develop and to the degree of safety for workers and for the public. For each category of apparatus, design and construction standards must be defined which take into account not only its intended use but also the necessary safety requirements. In particular they should ensure that the device cannot materially deliver a needlessly high power (minimization of the emission), that whenever possible the direct radiation be confined or made inaccessible when the power density exceeds a given value, and that the secondary radiation (scattered or leak radiation) is reduced to a negligible value or even prevented in the proximity of device.

Operational protection : In most cases, technical protection measures applied to the source of the radiation should be supplemented by operational protection measures adapted to each situation.

They cannot all be listed here due to their number and to the fact that they vary considerably, depending on the radiation, the type of emitter and the circumstances. Some of the more frequently used measures are given below. . Measures concerning the selection of an appropriate site for the emitter (antennae of high-power radio and radar installations for long-distance lasers etc).

- . Delineation of controlled, restricted or forbidden areas.
- . Special fitting of the working place : appropriate screens, automatic safety devices etc.
- . Identification of forbidden or controlled areas, operation of the devices etc, such as by warning signs and lights.
- . Development and implementation of safety instructions for the use of apparatus at the various working places, including protection against the associated risks (electrical, chemical).
- . Use, in certain circumstances, of individual protection equipment (special clothes, glasses etc).

8. MONITORING AND SURVEILLANCE

8.1 PHYSICAL MONITORING

Ionizing radiation : The physical monitoring of ionizing radiation has been the subject of considerable research and development activity in recent decades. We are now capable of clearly detecting below the irradiation limits the doses received by the different categories of persons exposed. The methods employed may be direct or indirect.

- . Direct methods involve the measurement of the irradiation at the persons themselves by means of individual detectors (dosimeter film, electrometer pens etc).
- . Indirect methods consist in evaluating the irradiation from the measurements taken in the professional or public environment (irradiation or contamination field).

The dosimetry of ionizing radiation has become a discipline in itself. It draws on an extremely wide variety of measuring methods. It enjoys the availability of a large variety of dosimeters allowing instantaneous and cumulative measurements, with extremely wide ranges of use, very high sensitivity and largely sufficient accuracy.

Non-ionizing radiation : With respect to non-ionizing radiation, the situation is completely different. The dosimetry of this radiation is difficult and has not been the subject of investigations as extensive and intensive as those concerning ionizing radiation. Serious difficulties are encountered in obtaining individual detectors. This means that monitoring for non-ionizing radiation can only be collective in general.

Certain estimates are made from measurements on beams in the immediate neighbourhood of the sources, and other estimates are made at a distance, namely in the vicinity of exposed persons in non-ionizing radiation fields. This duality exists in all fields of non-ionizing radiation : radiation fields that are relatively well measured in the absence of the irradiated individual, but considerable difficulty arises in evaluating the energy absorbed by the individual when he enters the same field, especially if this penetration occurs in unforeseeable conditions, outside a specialized laboratory in this type of measurement :

8.2 MEDICAL SURVEILLANCE

Medical monitoring practices are quite different from one country to another, and this is true, not only for non-ionizing radiation but also for ionizing radiation.

In fact, this is a good thing that the workers exposed to irradiation are subjected to similar medical monitoring as that of other workers when the risks of irradiation are high, it is essential to implement specific medical monitoring of the critical tissues and organs for the radiation concerned.

Hence, for ionizing radiation, monitoring should be carried out on the skin, eye, blood-forming tissues, gonads etc.

As to non-ionizing radiation, and in view of the potential radiopathological damage, medical monitoring should essentially cover the skin and the eye. This medical monitoring should include examinations on hiring to judge the aptitude of the worker, periodic examination in the case of sufficient risks, and post-employment examinations if long-term repercussions are possible. The application of the convention and of the recommendations of the International Labour Organization on the Occupational Health Services is highly desirable.

Epidemiological investigations on workers, members of the public and patients could help considerably to achieve progress in the knowledge required for good protection.

II GENERAL CONCLUSIONS

The analysis that we have just made concerning Ionizing Radiations and Non Ionizing Radiations shows at first sight, important differences and poor similarities. But a deeper exam allows to consider a fast future evolution towards a Similar and General System of Protection.

1. DIFFERENCES

The main differences between Ionizing and Non Ionizing Radiations lies in their characteristics, their interactions with matter, their biological effects, their dosimetry.

The characteristics of the two types of Radiations are distinguished by their nature as well as by their energy. Indeed, they cover entirely the electromagnetic spectrum but there are significant differences according to the energy, between X and gamma photons on the one hand and optic radiations and waves on the other hand. But above all, radioactive phenomena with associated problems of contamination only belong to the field of Ionizing Radiations.

Interactions with matter are basically different because of the energy threshold which allows or forbids ionization. Ionizing Radiations alone are likely to reach the structure of atoms and to ionize them. Non Ionizing Radiations only disrupt the molecular structures and lead to physico-chemical reactions. The biological effects ensue from the interactions of radiations and living matter and thus are very different. Both types of radiation can cause deterministic and stochastic effects. But from the viewpoint of protection, the stochastic effects with induction of cancer and of genetic mutations are dominating for the IR, whereas deterministic effects, in particular thermal are essential for NIR.

The metrology of radiations presents analogies or even similar concepts when the flow and the fluences of photons are being considered. On the contrary, dosimetry is significantly different. The dosimetry of Ionizing Radiations is based on the notion of absorbed dose with its derivatives due to the weightings, linked to their nature (equivalent dose), or to the tissue sensitivity (effective dose), as well as to the spreadings in space (collective dose) or in time (committed dose). Indeed, for waves there is the concept of SAR corresponding only to the absorbed dose, but for the entire Non Ionizing Radiations we are still in front of quantities and units linked to the traditional concepts used in optics or for electrical or magnetic fields.

2. SIMILARITIES

On the contrary, there are many similarities between IR and NIR, concerning the sources, the exposures, the situations and the main parameters for the assessment of their effects.

For both types of radiations, natural sources clearly prevail over artificial sources and this matches specially for radioactivity on the one hand and optic radiations on the other hand.

Exposures involve the same categories of people : workers, the public and patients. For both types of radiations we can speak of occupational irradiation, general irradiation and medical irradiation. Note that in both cases the general and medical irradiations are the more important ones.

Situations are also similar when one wants to clarify the problems posed in radiological protection. For IR and NIR, the foreseeable situations result in usual exposures and potential exposures. In the same way, existing situations cover natural and accidental situations.

Lastly, the parameters involved in the analysis of the consequences of exposures are very similar. Some relate to the characteristics of the sources : dimensions, nature and intensity of emission, frequencies and resonances. Others are associated with the space/time modalities of the exposures : source-person geometrical data, time distribution (rate, fractionation, spreading). Finally, the last ones relate to the characteristics of the tissues and organs exposed : structural, functional or dimensional.

3. EVOLUTION

From these differences and these similarities one could believe that two systems of radiological protection must coexist for Ionizing Radiations and Non Ionizing Radiations. In fact one can think that we are tending towards a unique general system with appropriate modes of application. This optimism is based on the historical background of the two fields, the regulatory organization, the reduction of exposures and the checking of the efficiency of protection.

The historical evolution shows a gap in time between protection against ionizing radiations and non ionizing radiations. Both were first concerned with avoiding the deterministic effects with a threshold before limiting the stochastic effects without a threshold. In the same way, the individual approach preceded the collective approach focusing first on occupational exposures and then on general and medical exposures. Finally, protection against Ionizing Radiations was based for a long time upon the couple Limitation-Minimization before changing to the couple Optimization-Limitation; the same evolution is beginning to be noticed for protection against Non Ionizing Radiations.

The general organization of regulations is almost the same for Ionizing Radiations and Non Ionizing Radiations. It is based upon the definition of the field of application of the system of protection. Circumstances below the exemption thresholds are excluded as well as cases of banning of certain practices. On the contrary, the system of protection is applied thanks to regulations specifying the conditions of notification and registering as well as to the authorization and licensing procedures.

The system of reduction of exposures can very well be designed in a similar way for IR and NIR. These general principles are indeed the same : justification, optimization and limitation.

The justification of the activities carried out rests upon the net positive benefit between their advantages and disadvantages.

Optimization of protection consists in making an inventory of all the possible solutions, selecting them and classifying them according to the increase of the net positive benefit; the optimal solution corresponds to the maximum benefit.

The aim of limitation is to assure to each exposed person that the principles of justification and optimization related to the sources by a collective approach do not lead to unacceptable individual exposures. For this we have three types of standards. First the individual limits of exposure which already exist for IR and NIR and which cannot be over-stepped. These limits apply to foreseeable situations such as usual exposures. With transpositions in risk estimation, this concept becomes applicable to potential exposures which require an important effort of radiological safety for IR as well as for NIR. The new concept of Constraint, recommended in Publication ICRP 60, presents the envelope of the optimized solutions and is adapted to each source or category of sources; nothing goes against the fact of spreading its particularly

rich use for NIR as well as for IR. Lastly, the use of reference levels as guides specially adapted to the existing situations concerning natural and accidental exposures can also be considered for NIR as well as for IR with appropriate simple or double values.

Finally, the checking of the efficiency of radiological protection is essential for NIR as well as for IR. Indeed, the quality insurance of radiological protection rest on the statistics of the real exposure of the workers, the public and the patients. For this, it is right to establish and develop a monitoring of the radiological noxious agents either by an ambient dosimetry, rather easy for IR and NIR, or by an individual dosimetry quite easy for IR, but requiring sustained efforts for NIR. This monitoring of noxious agents must normally be completed by a monitoring of the consequences, carried out at the individual level, for workers by the Occupational Health Services, and at the collective level by serious epidemiological studies related to the occupational, general and medical exposures, for IR as well as for NIR.

x

x x

IRPA who, in 1977, had the merit of creating the International Committee of NIR (INIRC), is considering transforming it into an International Commission of Protection Against Non Ionizing Radiations. May this presentation show that we are moving towards a General System of Radiological Protection similar for NIR and IR. I may be optimistic in nourishing this hope, but I think that it is the demonstration of the success of the continuous policy of the IRPA.

RULES AND REGULATION ON RADIATION PROTECTION IN PERU

Eduardo MEDINA GIRONZINI
Sociedad Peruana de Radioprotección

Abstract

This work details the peruvian experience about application of regulatory criteria for elaborating and issuing technical and legal rules addressed to the man and environmental protection against radiation hazards.

The Peruvian Institute on Nuclear Energy (IPEN) is the state organization, decentralized from Energy and Mines Ministry, commissioned for promotion of application and activities in nuclear energy, as well as for control of all radiation sources and its uses, through legal dispositions that establishes the President of IPEN being the National Authority in the nuclear energy scope, therefore has the power for issuing rules, granting licences and authorizations. This functions are carried out through a staff specialized on radiological and nuclear safety, for performing activities of normalization and inspection in a national level.

The regulation on Radiation Protection has had different stages being prominent that related to the promulgation of Organization Law of IPEN in 1977, and the issuing of the Radiation Protection and Installations of Ionizing Radiation Sources Reglamente (1980) through Presidential Resolutions. In 1989 begin a new stage with the issuing of the Radiation Protection Regulation (second version) promulgated by Supreme Decree 018-89-EM/VME after acceptance of 6 State Ministers entailed with matter. This legal regulation asserit to IPEN as regulatory body.

The technical normative is linked enough to issuing of legal regulation and at present are being developed those considered necessary for regulatory control in this country, where there are around 1500 radioactive installations (90% using X rays in medicine), 2 research reactors and approximately 5000 exposed workers.

The current regulation has been based on international recommendations (ICRP, IAEA, etc) and national experience through 15 years. It is showed the organization for control, applicability of regulations, and the perspective for developing this field.
