The nuclear power reactor accidents at Three Mile Island (TMI) (1979) and Chernobyl (1986) have influenced off-site emergency planning world-wide. Despite very limited environmental radiological consequences of the TMI accident and a limited need of response actions of the emergency organisation outside the plant, the accident caused a higher attention and new conditions regarding the bases for off-site emergency planning. After TMI in many countries more attention was also given to even more severe reactor accidents than so called `design base accidents´, i.e. accidents were now considered which could lead to emergency situations with large scale land contamination's.

The Chernobyl accident some years later made it quite clear that existing national emergency preparedness and international agreements were not sufficient to cope with an accident leading to a large scale radioactive contamination with an impact in several countries. There was an obvious lack of bilateral or multilateral agreements regarding early warning, preparations for exchange of information and measurement data, or shortcomings in existing agreements due to inadequate preparedness and training.

In response to the experience of these two accidents, the awareness and resource spending in the field of radiological emergency planning have increased nationally as well as within the various international organisations. Increased efforts were clearly necessary, and by and large they have improved emergency preparedness considerably.

However, we wish to raise the following questions:

- To what extent could the various planning measures be considered as justified from the radiation protection point of view? Are there instances where public opinions or even `expert opinions´ forced decision makers to take some actions which could be questioned?

- A lot of actions have been taken, and new ones can be expected in the future, to improve emergency preparedness in Central and Eastern Europe and the newly independent states of the former Soviet Union. Currently, there is a need for a co-ordination of all the various ongoing assistance activities, in order to avoid duplication of efforts and waste of limited resources. Which initiatives ought to be taken to make such activities as effective as possible?

1 EARLY NOTIFICATION OF A NUCLEAR ACCIDENT

The IAEA convention on early notification of a nuclear accident and information exchange has got a world-wide acceptance. A communication system for notification and information in case of a radiological accident (ECURIE), which is to some extent parallel to that of IAEA, has been established within the European Union in accordance with a Council Decision of Dec. 1987. For the Member States of EU, these two systems lead to duplication regarding exercises and communication tests. Furthermore, to some extent the two communication systems use different means of communication, thus increasing workload but hardly improving reliability. Communication tests are performed on more or less routine bases in accordance with the IAEA convention and between the Member States of EU through various ECURIE exercises. In this area we believe that there is a need for an extended

international co-operation with common exercises arranged by IAEA and the Commission of the EU. The purpose would be to avoid the use of procedures and formats which are not harmonised. Otherwise, such unaligned procedures can in practice obstruct or prevent the involved Member States from fulfilling their obligations in case of an accident.

2 INTERNATIONAL NUCLEAR EMERGENCY EXERCISES

The accidents at TMI and Chernobyl prompted various international organisations to start or intensify their activities within the field of emergency planning and preparedness during the late 1980s and early 1990s. The reason for that is mainly the different international and transborder aspects in the event of a severe nuclear reactor accident. One of these new activities launched by the Nuclear Energy Agency of OECD was the arrangement of international off-site emergency exercises as INEX 1 (1993) and thereafter followed by the ongoing planning of the INEX 2 regional exercises of which the first exercise will take place in Switzerland 7th November 1996. However, since several years bilateral exercises have been performed on more or less routine bases in different regions where nuclear reactor sites are located close to borders.

With the background of our participation in INEX 1 and our experience in the field of emergency planning we interpret that the overall purpose and the specific objectives of the INEX 1 set by the organiser were reached, even if the final analysis (evaluation report) of the exercises was delayed some years.

It was particularly valuable that the accident scenario considered the two different roles of countries in emergency response , depending on whether the country has a nuclear power reactor site or not. The exercise encompassed both an accident country and a neighbouring country, both of which affected by radioactive fallout. The exercise scenario also covered the post-release phases of an accident, which is an advantage as most exercises only deal with the initial phase of an accident.

Seen from our experience the scenario of INEX 1 was very well developed and useful. For the future we encourage such an international co-operation regarding the development of new exercise scenarios intended to be used in connection with national and bilateral exercises. The development of scenarios in the framework of an international expert group will stimulate participating organisations and emphasise the need to consider the various international aspects involved. It will also give an internationally accepted shaping and quality to the exercise scenarios. Not least for countries with only limited experience and resources in the field of peacetime radiological emergency planning such an international co-operation can be expected to be of great value.

However, we believe that most of the evaluation work of an exercise can and must be performed in the respective countries as many of the aspects considered are very country-specific. Large scale international co-operation in this respect seems therefore not to be of the same priority as the development of exercise scenarios.

3 MONITORING ARTIFICIAL RADIOACTIVITY

In case of an accident which is expected to cause or has caused fallout of radioactive substances the authorities in the involved countries need fast and reliable information on the location and characteristics of the fallout. Therefore most countries have established national strategies to map their territory in case of an inland as well as an accident abroad.

In addition to the IAEA convention on early notification and the ECURIE system, automatic gamma monitoring stations form the most common part of a national early warning system. Concerning the number of these monitoring stations expressed per unit area there are variations between the various countries from 1 station per 100 km^2 to 1 per 10 000 km^2. This means that countries as Germany has thousands of stations, Finland more than two hundred, Norway and

Sweden some tenths. To some extent these numbers also reflect a difference in the resources used for this purpose.
There are also extensive programmes in most countries for field measurements and laboratory analyses of environmental and food samples. Normally such a programme also includes high resolution measurements of airborne radioactivity using air filter stations and resources for airborne fallout mapping.
In accordance with the various international conventions and bilateral agreements an international exchange of measurement data is required in the event of an radiological emergency. To warrant a good quality and a comparability of the data exchanged there is a need for an extended international harmonisation regarding calibration procedures, instructions for the collection of environmental samples an the presentation of the values in connection with reporting of data. Which of all available data will be of most interest to communicate between the countries? To what extent shall data be excluded to avoid overloading of the communication systems or of the emergency response organisations in the various phases of an accident?
As we see it these are examples of questions which need an international discussion to reach some form of international standard or recommendation, in order to express the extent to which different measurement resources ought at least to be included in a national radiological emergency planning. The aim is to achieve a possibility to check whether a national emergency planning can be considered to fulfil an international agreed acceptance level concerning measurement resources. One further purpose with such a standard is to give a background for decisions to what extent a spending of resources can be considered as justified from the radiation protection point of view, including the need to have a background to give reliable information to the public in case of a radiological emergency.

4 CO-ORDINATION OF ASSISTANCE ACTIONS

In recent years a lot of assistance actions have been taken to improve the radiological emergency preparedness for peacetime accidents in Eastern Europe and the newly independent states of the former Soviet Union.
Stationary automatic gamma monitoring stations have been set up. National emergency plans have been reviewed by national teams. Various measurement and communication equipment , including computers, have been introduced to upgrade national laboratories, authorities and organisations involved in the various national emergency response organisations. Workshops on the establishing of a strategy for the information of the public, scientific visits and training courses have been organised.
Our experience is that in this field there is an urgent need to try to co-ordinate all different initiatives for assistance actions which now are going on or planned by international organisations and individual countries. Most of the assistance actions so far seem to have been performed without any co-ordination or attempt to prioritise contributions.
Recently an assessment study regarding the priority of needs for assistance in the field of radiological emergency planning has been done by the Commission of the European Union. Hopefully this study will be followed by an initiative to also co-ordinate future assistance actions to reach an effective use of available resources spended. Our belief is that a better co-ordination in the future of the various assistance actions will be of great benefit to the deliverer of assistance and not least for the receiving country.

ABSTRACT (See instructions overleaf)

The Russian ministry for Civil Defence (EMERCOM) took the initiative of a major exercice played around the consequences of a simulated major release of radioactive matters. This release was supposed to be emitted by the Polyarnie Zory nuclear power plant, in the Kola peninsula. The Nuclear Safety Institute of the Academy of Sciences of the Russian Federation (IBRAE-RAN) was the technical support of EMERCOM for the implementation of all the stages of this exercise.
The Nuclear Safety and Radioprotection Institute (IPSN) provided its assistance to IBRAE all along this process. The exercise was played on May 30th, May 31st and June 1st 1995 in simulating respectively the 3rd day, the 15th day and the 30th day after the release.

The Department of Human Affairs (DHA) of the UN and the IAEA sponsorised this exercise. About fifteen countries participated to it.

IPSN placed its Emergency Center of Fontenay-aux-Roses (Paris region) at the disposal of its Russian counterparts. A real "distant expertise" has been so implemented. Satellite and radio links between Apatity, site of the exercise, and Paris were operated by the French Ministry of Interior. Self sufficient national means for transportation and stay of the experts and the equipement, including a governmental aircraft, have been used. The mission lasted from May 25th to June 3rd, 1995. About fifty French experts contributed to this exercise.

Such a participation is a concrete and operational answer that France could give in the frame of the IAEA Convention on Assistance in the case of Nuclear Accident or Radiological Emergency.

ABSTRACT (See instructions overleaf)

The set of the actors who intervene in the management of a nuclear or radiological emergency varies very much according to the events it can be referred to and the different stages of their evolution. The problems which has to be dealt with are of various nature and require a large spectrum of skills to be solved.

In France, the off-site emergency plans address mainly the decision making and the implementation of the classical short term countermeasures in case of nuclear emergency. The response to the threat phase or to the very early stage after an accidental release of radioactive matters is set up by the centralised organisation of well-known non numerous actors. The efficiency of these plans is reasonably validated by a strong policy of exercises.

Things change when further stages after a release are considered. A lot of other actors will play major roles. Some of them are not really identified. For instance, representatives of the world of Justice or associations of victims have not yet been included in the current attempts of such radiological situations assessment. In addition, new difficult questions, strongly linked between them, can be raised, such as :

- what is "return to normality" ?
- which trust put to which actors ?
- which strategy for compensation ?

All theses issues are currently subjects to concrete debates. Full scale interministerial national exercises are foreseen within the next three years. They aim to strengthen the provisions made by the public authorities. International collaboration overtures are from now on foreseen, particularly with Russia, in some of these important projects.

CURRENT MANAGEMENT APPROACHES IN THE EVENT OF RADIOLOGICAL EMERGENCIES

ABSTRACT

Since the accident at the nuclear power plant at Chernobyl in 1986, most European countries have undertaken major efforts to implement international conventions and recommendations, develop real-time emergency response systems and upgrade early warning/monitoring networks. Despite of these improvements several areas (logistics, hardware, software) are still in need for further R & D.

THE ISSUES

The accident at the Ukrainian Chernobyl nuclear power plant on April 26, 1986, reveiled severe emergency management deficiencies in Europe in the following areas:

- lack of adequate international agreements addressing the transnational consequences of such a major nuclear accident.
- problems with the degree of comparability of information obtained at the local, regional or national levels, describing the environmental radioactive contamination situation.
- incoherent national regulations concerning trade import and export, especially food, food products and animal fodder.
- inadequate public information systems dealing with perceived fears of members of the public as well as dealing with the media.

These issues can be addressed in terms of monitoring networks and communication, emergency response systems, and international conventions and recommendations. In this paper, examples of the international and national responses to improve radiological emergency management in Europe over the last 10 years is briefly described.

MONITORING NETWORKS AND COMMUNICATION

The arrival of the Chernobyl-fallout in Western Europe in three major plumes during 26 - 30 April 1986 resulted in the upgrading of several national early warning- and environmental monitoring networks. In most countries where a large network has been established, the routine environmental monitoring mode (usually gamma dose-rate) will trigger the emergency response operating mode when elevated activities are detected, but in some cases manual operation is still used. Monitoring for atmospheric aerosols and iodine have also been considered to be part of the overall national systems.

If one takes into account the existing (and ready to be deployed) gamma dose-rate and aerosol monitoring coverage per unit population density (persons/km^2), the ten countries that rank highest in Europe are shown in Table 1. The number of stations per population density of the country can be grouped into three general categories of monitoring capabilities of > 10 stations/pop density, between 1 and 5 stations/pop density, and less than 1 stations/pop density. Finland, Spain (when the stations are deployed) and Germany fall into the category with greater than 10 stations per unit population density. Austria, Ukraine, Sweden, France and Norway fall between 1 to 5 stations and leaving Ireland and Hungary with the group of other European countries that have fewer than 1 stations per unit population density.

The density of radiation monitors is irrespective to the size of the national nuclear program (for example France and Germany compared to Austria and Norway), and these results illustrate the importance given to establishment of monitoring networks. This is important due to the relatively small distances between European States leading to the increased probability of transboundary contamination. Further standardization efforts are necessary to improve the comparability of data obtained with these systems:

- hardware: radiation detector systems; measurement conditions (height above ground, collimators, energy response, time-averaging periods, data transmission frequency), early-warning alarm-discriminator;
- analysis: quality assurance and -control of input data and data evaluation systems (e.g. system status, formal and technical compliance with standards or database, consistency between data pools).

At the IAEA (Vienna) a 24 hour-communication centre has been established for the exchange of data in standardized formats. An International Nuclear Event Scale (INES) has been devised. The seven classes of accident scenarios take into account off-site and on-site impacts, worker exposures and degradation of safety systems. It is hoped that with the use of INES misunderstandings can be avoided among all parties envolved in the management of a large scale nuclear accident.

EMERGENCY RESPONSE SYSTEMS

European capabilities for the real-time assessment of accident consequences and emergency response have improved since 1986 due to the development of computer-based support systems, such as: SPADE, MC31 and 3-DRAW for modelling atmospheric dispersion at short-range, mesoscale ($\leq$ 200 km from the source) or long range; STEP and START as feedback-models for estimating the source term and releases; EURALERT as dose assessment programme for different pathways, using data from modelling and measurements.

The RODOS project, funded by the Radiation Fission Safety Program of DGXII of the European Commission, is a major effort to integrate real-time monitoring and emergency response decision-making on a European scale. The large cooperative effort with Eastern European countries adds to the importance of this project.

Despite of these improvements several issues remain to be addressed in the future, e.g.:

- quantification of the uncertainties for the different models, particularly in view of limited respresentativeness of the data available for model validation;
- sensitivity analysis on the significance of contributing factors, such as: topography, agricultural practices or complex meteorological conditions (e.g. deposition in fog; variable wind conditions in stagnant anticyclones), gravitational settling.

INTERNATIONAL RECOMMENDATIONS AND CONVENTIONS

An essential element of confusion during the post-Chernobyl period was the heterogeneous international approach to the **limitation of the radionuclide content in foods**. A major step towards harmonization, thereby facilitating international trade, was the development of the *Codex Alimentarius Commission's guidelines* (1). It is to be noted that only 4 different values for limiting the activity concentration of 10 nuclides in all food, milk and drinking water for general consumption and for infants are used, e.g. 1000 Bq/kg for ^{134}Cs, ^{137}Cs, ^{103}Ru, ^{106}Ru, ^{89}Sr. This results in an increase of the ingestion dose for those countries with previously lower limits (e.g. for ^{137}Cs in milk in the EU: 370 Bq/kg; in Austria: 175 Bq/kg, resp. 12 Bq/kg for infants).

In the area of **early notification and mutual emergency assistance** in a nuclear accident two IAEA-Conventions reduce the shortcomings noticed after the Chernobyl accident (2,3). However, some topics of ambiguity remain, such as:

- what information about the accident is considered „relevant"? What time-period meets the request for information-supply „as soon as possible"?
- what uncertainty is acceptable in the modelling-based forecast whether a release „may occur", whether this „may result" in a transboundary contamination, which State „may be affected"?
- if the resources of a State are insufficient to respond „adequately" to a large accident, can it still refuse external assistance (because of security issues or pride), thereby increasing the radiological consequences in another State?

The issue of timely provision of relevant information about the Chernobyl accident by the former USSR and the adequacy of some European countermeasures were subject to debate. It is foreseeable that divergent interpretations of the above topics can cause further dispute in another large scale nuclear accident.

CONCLUSIONS

Major improvements have been achieved in emergency management since 1986. Nevertheless, comparability of the assessment of the radiological situation and the adequacy of countermeasures are still affected by remaining ambiguities in the interpretation of conventions, insufficient model validation for real-time assessment and lack of standardization concerning monitoring networks. Besides reducing the difficulties that can result in the application of emergency response measures, a more standardized approach would facilitate consistent communication of countermeasures and actual risks to the general public.

EMERGENCY MANAGEMENT IN SLOVENIA

R. Martinčič[1], M. Korun[1], A. Likar[2], B.Pucelj[1], and B.Ušeničnik[3]

[1]J. Stefan Institute, Ljubljana, Slovenia
[2]Department of Physics, University of Ljubljana, Ljubljana, Slovenia
[3]Administration of Civil Protection and Disaster Relief, Ministry of Defence, Ljubljana, Slovenia

Abstract: Accidents may occur during the production, transport, use or storage of the radioactive materials. Experience has shown that advance emergency planning is essential in order to mitigate the consequences of the accidents. The paper presents the general philosophy applied in Slovenia to the problem of emergency response; background information on the Slovene use of nuclear energy; and finally legal, organizational, planning and reviewing aspects of the Civil Protection applying to nuclear or radiological emergencies.

INTRODUCTION

Changes that occurred in Slovenia as a result of independence required a new assessment of the situation in the field of disaster protection, as well as the coordination of policies and goals. Slovenia is at present in the process of reconstructing its system of protection against natural and other disasters.

The system for protection and rescue is organized as an overall system established for the protection and rescue of people, material and other goods in the case of natural and other disasters, in war and in other extraordinary circumstances. The most important points for legal and system-related regulation in the field of disaster protection are determined by the National Assembly. Civil protection and other disaster protection activities are humanitarian and non-military in nature.

In this general context nuclear or radiological accidents fall under industrial accidents which in turn are treated as "other disasters".

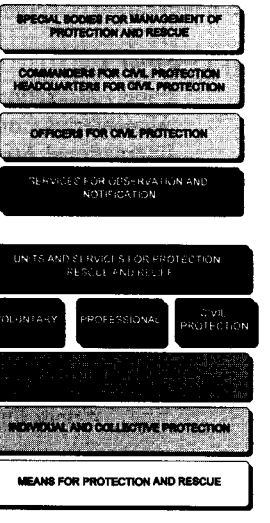

Figure 1. The system of disaster protection

GENERAL PHILOSOPHY AND BACKGROUND INFORMATION

Protection against disasters is undertaken by those bodies, services and organizations, whose regular activities already include such operations. If these are not sufficient, additional forces and means for protection, rescue and relief are brought in. These are mostly forces and means of Civil Protection (CP) which are organized as a special, designated section of the overall safety an protection system in the country. It is obvious that state and local authorities cannot provide sufficient collective assistance during disasters. Therefore the initiative of the local population and their capabilities for individual protection are of vital importance. The Slovenian system of disaster protection is shown in Fig. 1. and disaster protection duties in Fig. 2.

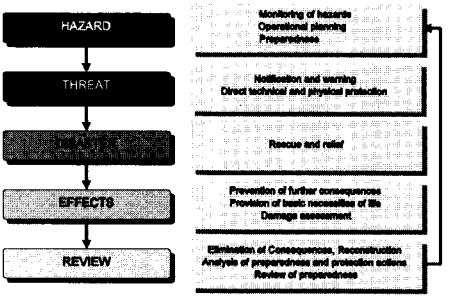

Figure 2. Disaster protection duties

On the basis of the new Constitution entirely new legislation is currently under preparation. Two fundamental laws already exists.

Operational implementation of protection, rescue and relief in the event of natural and other disasters, in war time and other extraordinary circumstances is planned through protection and rescue plans. Protection and rescue plans are based on risk assessments, studies of the vulnerability of the living environment and other studies and investigations relevant to protection and rescue. All of the above information is used to determine which local communities or economic associations or other organisations require protection and rescue plans. Forces of protection, rescue and relief at the state level are shown in Fig. 3.

Slovenia has beside more than 400 radiation sources also one nuclear power plant (a two-loop PWR, 632 MW electric power) and one research reactor. Construction at the Krško site began in early 1975. The plant was synchronized to the national grid in October 1981.

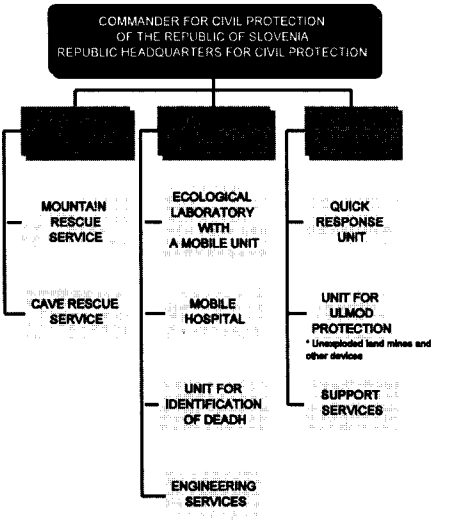

Figure 3. Forces of protection, rescue and relief of the Republic of Slovenia

PLANS OF PROTECTION AND RESCUE IN THE CASE OF NUCLEAR ACCIDENT AT THE KRŠKO NUCLEAR POWER PLANT

Measures to be taken in emergency situations are stipulated in a number of plans, from the national level to the local community level and the plant itself.

According to the law Administration for Civil Protection and Disaster Relief (ACPDR) is responsible for planning and preparedness off-site at the national level. The ACPDR prepared, amended and maintains Emergency Plan in the Event of a Nuclear Accident at Krško NPP. The plan postulates three emergency planning zones (EPZ): (i) urgent protective actions EPZ within 10 km radius, (ii) food-chain and long term protective actions EPZ within 25 km radius and (iii) general preparedness EPZ covering the whole Slovenia.

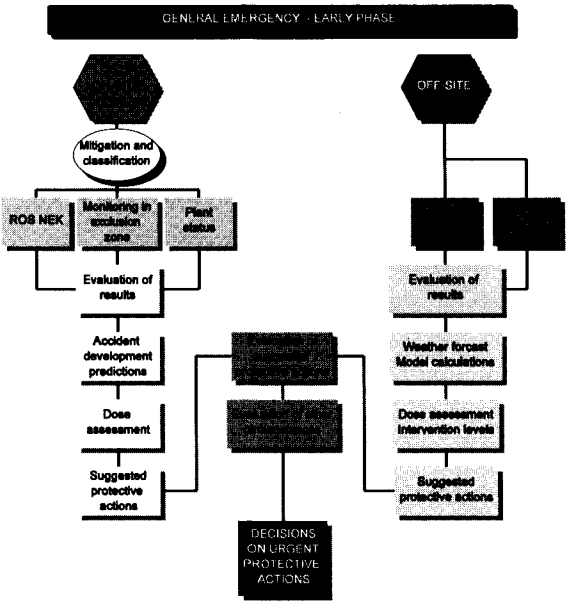

Figure 4. Emergency response in early phase of the accident

The emergency plan at Krško NPP defines an organised and effective response by personnel at the NPP to ensure protection, health and safety and to reduce the consequences of any accidents. Emergency situations in the facility are divided into four categories: abnormal occurrence, abnormal situation, site emergency and general emergency. Appropriate actions are planned for each category.

The Administration of Nuclear Safety (ANS) has its own plan of actions, harmonized with the national plan. In the event of nuclear or radiological emergency the ANS functions as a professional support and advisory body to the Civil Protection Headquarters. Three expert groups are organised for analysis of the accident, dose assessment and for support

and preparation of information for public and the IAEA. The ANS is responsible to notify the IAEA and the countries which could be affected by the accident through international conventions and bilateral agreements. The embassies of neighbouring countries are informed through the Ministry of Foreign Affairs.

Emergency response strategy in early phase of the accident and structure of off-site emergency monitoring are shown on Fig. 4 and 5 respectively.

To test the plans and to remove shortcomings an overall exercise was prepared and conducted in 1993. The exercise showed that the planned on-site and off-site actions form a sound basis for taking emergency actions.

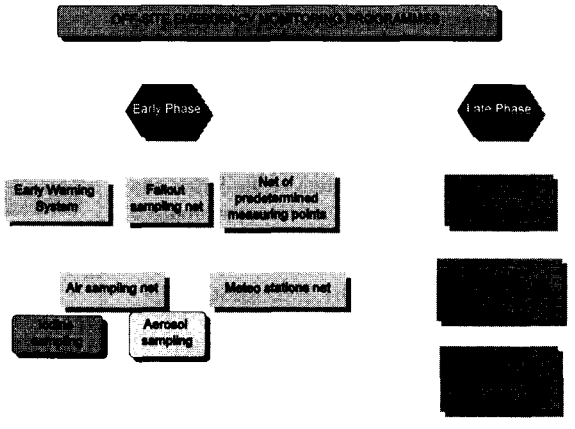

Figure 5. Off-site emergency monitoring programmes

CONCLUSIONS

- Slovenia has Civil Protection for coping with the emergencies.
- The CP Headquarters at national level established highly professional emergency units in different fields of emergency response.
- Additional efforts to increase the preparedness of the CP staff and units to cope with radiological emergencies have paid off handsomely and have led to a general improvements of the performance of CP, also for other types of emergencies.

Finally, a reasonable degree of preparedness has been achieved. However, there always remain some questions and problems yet to be answered and solved. Among these one might choose the following ones. In near future Slovenia has to:

i. complete its own regulations,
ii. implement a new national early warning system,
iii. improve adequate and effective mean for public information and
iv. update the equipment and training of CP in dealing with radiological emergencies.

SOME CONSIDERATION ON DECISION-MAKING IN A NUCLEAR EMERGENCY

Y. Nakashima[1] and H. Wang[2]

1. Suzuka University of Medical Science and Technology, Suzuka (510-02), Japan.
2. China Institute for Radiation Protection, Taiyuan, Shanxi 030006, China.

1. Introduction

In various phases of a disaster, the result of decision-making should finally reach the local public of interest, and the detriment among the public should be minimized/optimized according to the proper response by the public who receive the result. The decision involves the proper selection among countermeasures, and should reach each one of the public. The expression to be informed to the public should be quite understandable in its meaning.

After Hanshin big earthquake (Jan. 17, 1995), the Basic Plan for countermeasures against disasters which is the foundation for the basic law for disasters has been largely revised and reissued in July 1995. For preparedness and countermeasures outside a nuclear facility, there are many useful experiences that have to be learnt from natural disasters. In Japan and China, there have been no major nuclear accidents affecting the public in the environment. However, preparedness for nuclear emergency derived from natural disasters is important.

2. Guide lines for sheltering and preparedness

In Japan, if some trouble occurs in a nuclear facility, leading to serious situation and possibly developing to an emergency, the judgment on whether emergency or not will be made at the Central Committee on Countermeasures and the Nuclear Safety Committee. The result of the judgment will be immediately transferred to the local government of the nuclear facility. The headquarters for countermeasures against disasters will be activated in the local government. And information necessary for countermeasures will be collected. Simultaneously, the experts on nuclear reactor engineering will be dispatched to the facility at emergency and the experts on radiation safety will be also dispatched to the headquarters by the Central Government.

In order to support to the experts, COSTA (a computerized support system for the emergency technical advisory body in Japan) has been developed[1]. In operation (activation) of the system, the commencement of the system depends on the first notification on the trouble in a nuclear facility. And it is assumed that the first notification should not be considerably delayed.

The precise estimation of the reactor situation needs information on the plant 3-4 times every hour [2-3]. Since some uncertainties are accompanied on the estimation of the amount of radioactivity released and prediction of doses to the public, decision-making on countermeasures should pay attention to the uncertainties. [2-3]

The system for prediction of environmental doses is also operated for the

decision of countermeasures, the dose predicted would be accompanied by uncertainty of a factor about 2.

The decision-makers in the headquarters will make decision for selection of countermeasures based on the data from emergency environmental monitoring at first stage, site specific conditions (feasibility for countermeasures, risk in practical case, number of people influenced, avertable dose, and so on) being taken into account. Some flexibility would lay on the decision-makers.

Some uncertainty which will accompany the decision from only predicted dose is listed in the following table.

	situation in practical case
predicted dose: at minimum	• some countermeasures be made unnecessary in real case
predicted dose: at maximum	• at first, a countermeasure be not made necessary in real case. • later, a countermeasure be made, some confusion among the local public would be accompanied in real case.

The delayed countermeasure would be accompanied with some confusion (in allocating buses for evacuation, for example) and with unnecessary detriment among the local public by increasing dose.

3. **Lessons learnt from natural disasters**

Many lessons we should learn from natural disasters. Some of them would be quite useful to nuclear emergency.

1) Information and communication

There are, in general, (a) loudspeaker car and (b) local simultaneous broadcasting system. Their failures in natural disasters are briefly summarized in the following table.

	car speed		information communication on tsunami after an earthquake
	fast	slow	
(a)	local public cannot hear	can hear only in a small area	
	in result, both are not very helpful to countermeasures		
(b)	• misunderstanding by receivers of the information • vagueness in expression of the information • depending on skill by a reporter		

TVs and radios are the fastest communication systems among the mass-media. However, the extent of information arrival to the local public is restricted to an audience rating. There points out the concrete, correctness and appropriate in the expression of information.

2) In obtaining information

At present, telephones are needed as convenient communication means, however there are some overcrowding in communication by telephones in a disaster. Some radio cars are available in a disaster in obtaining in formation on damage. The mass-media use also more powerful radio system, there are happend the sensitivity suppression phenomena on the car local government used in the case of the near radio frequency assigned.

The results from emergency environmental monitoring at first stage are sent to the headquarters via a radio car. There needs some measure in the case where the assigned frequency of a radio car is close to that of mass-media.

3) The public as receivers of information

There found many cases in natural disasters, the receivers did not act after information on evacuation communicated. This is because the receivers have prejudice taking real risk as not so dangerous, namely they would not want to accept psychologically the dangerous situation about themselves [4]. The decision-makers in the headquarters should pay attention to such a problem.

4) Problems about the headquarters

It was a general way to start the headquarters after collecting information on the damage. After Hanshin big earthquake, it is pointed out to be too late for some disasters. The headquarters should function even in the half number of the members, not after all members gathered.

THE IMPLEMENTATION OF THE IAEA ACCIDENT RESPONSE PLAN IN YUGOSLAV PRACTICE

M.Orlić, R.Pavlović, S.Marković, and S.Pavlović
The Institute of Nuclear Science Vinča, Belgrade, Yugoslavia

ABSTRACT

One of the important lessons from the Chernobyl accident is the necessity of existence of operational national emergency response plan. Summarising consequences and experiences after Chernobyl accident, expert groups from IAEA, ICRP and other international scientific organisations, have been extensively worked on reviewing old ones, and preparing new radiation protection and nuclear safety principals and codes. One of the important issue is national emergency response plan for radiological accident.

The nuclear accident response plan in Yugoslavia is presented in this paper. It is essentially based on IAEA model national response plan for radiological accident (8). This model has to be adjusted to the specificity of member states. The optimum society organisation for emergency management in the case of accidents in ionising radiation sources practices is suggested in this paper. Specific characteristics of Yugoslav state organisation relating to accident response are emphasised.

INTRODUCTION

Large accidents at nuclear fuel cycle plants in neighboring states could create big problems for Yugoslavia and other counties. As for prevention, effective protection and lowering the consequences, an accident must be detected as soon as possible. Therefore, the prompt gamma monitoring system is a must. Besides, the population, material goods and environment would be protected to the maximum and the consequences decreased if during the accident people work by appropriate plans.

In Yugoslav radiation protection regulation which is numerous there are several regulation concerning large accident problems. Problems of accident detection, declaration and interventions are dealt with in documents (1, 2, 3, 4). Limits in (5) should be considered as adequate only in accidental conditions. There is three nuclear objects in Yugoslavia, (two research reactors and one temporary radioactive waste storage center). Their monitoring is precisely defined in (6).

But there is still not an appropriate emergency response plan. Instead of the basic act (7) the new one is in preparation. Therefore, the new regulation must be imposed with emergency response plan for radiological accidents including measures for consequences prevention in accordance with the international recommendations (8).

Nevertheless, in Yugoslav practice, especially for Republic of Serbia, exists the response plan (Fig.1) developed by radiation protection experts several years ago (9). In this paper the basic characteristics of that plan are presented. It is in a good agreement with IAEA plan (8). This similarity is discussed too. These two plans will be the basis for developing a new Yugoslav accidents response plan.

YUGOSLAV RESPONSE PLAN CHARACTERISTICS

The subject of the existing response plan (YUPLAN) are:

1. accidents that could happened abroad and endanger Yugoslavia
2. accidents on domestic nuclear facilities which consequences or potential consequences exceed facility bounds
3. accidents at domestic nuclear facilities which consequences or potential consequences do not exceed facility bound but there is not possibility for consequences preventing.

The goal of YUPLAN was a society organisation establishing as well as infrastructure and cadre and instrumentation defining.

Response organisation is defined by:

1. existing state organisation
2. early detection of nuclear accident
3. preventing the consequences in accordance with organisation and possibility of society
4. efficient averting the consequences for people and the environment

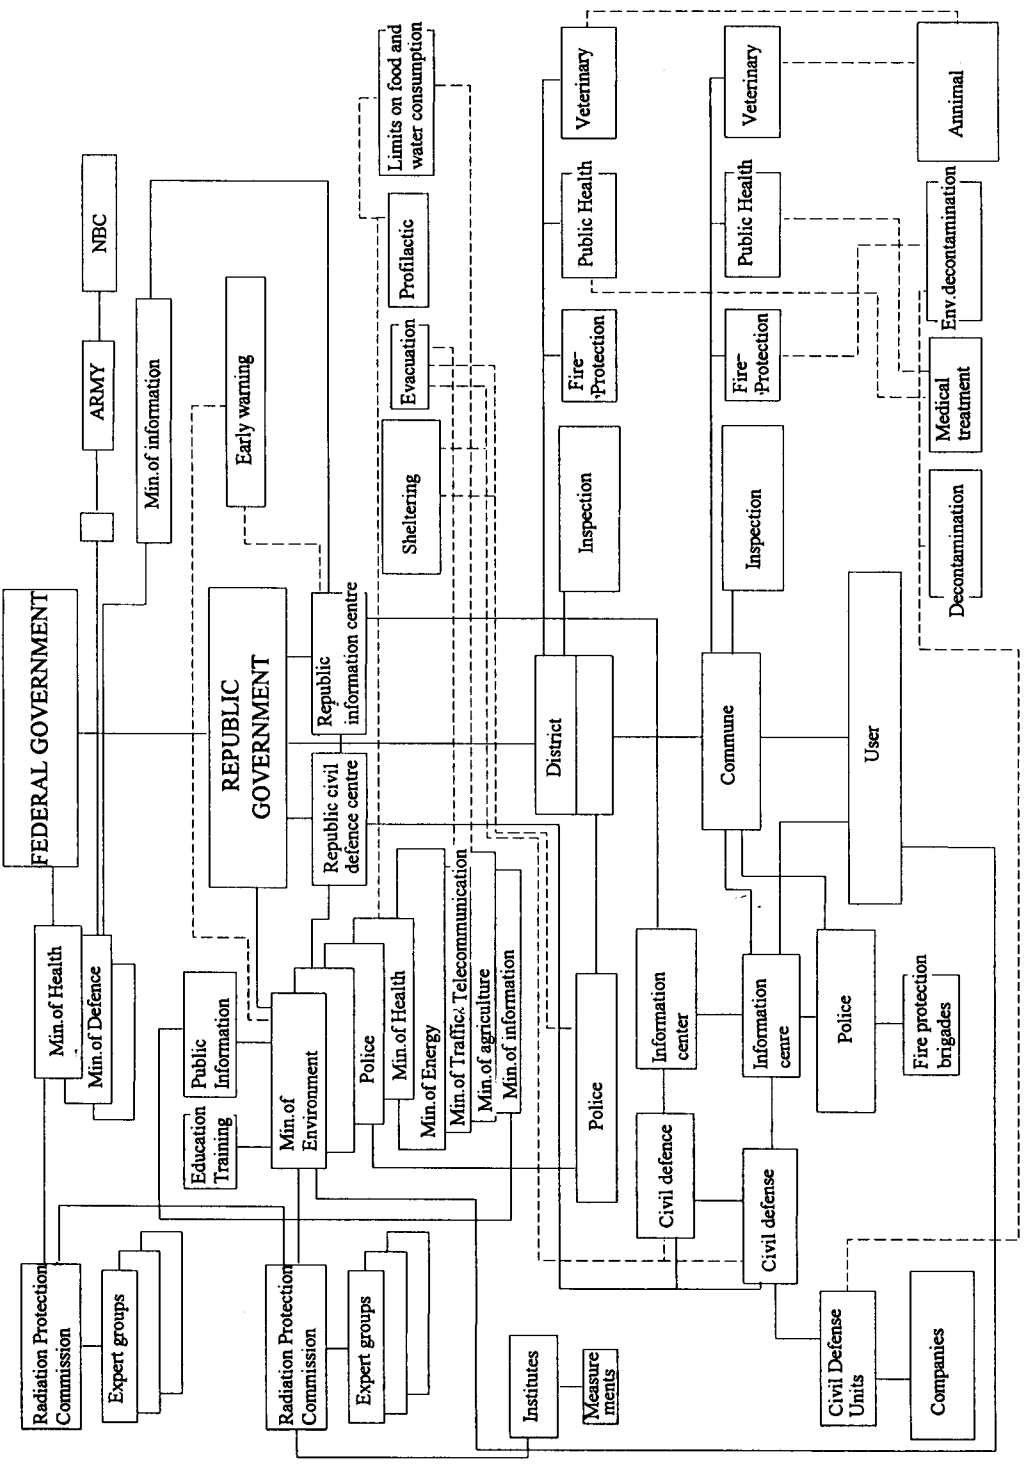

Figure 1. Scheme of the existing Yugoslav emergency response plan

The main organisation subjects are:

1. authority (federal, state, local) with different organs
2. owner of nuclear object (for domestic accidents)
3. prompt monitoring system monitoring
4. measurements (authorised institutions)
5. preventing measures (2)
6. averting the consequences
7. public relation
8. exercise
9. public education

How these organisation works? The system activation begins with nuclear accident notification from the government. The basis for notification is: direct call from nuclear facility authority, prompt system monitoring response, or by diplomatic way. The government activate Radiation protection commission which exist at federal and state level. The commission is well prepared for accidental situation (software, models, measurement). It ascertains the characteristics of the accident and according to severity of accident proposes concrete governmental measures. One of the first measure is environmental monitoring system activation. After those measurements the commission propose the most appropriate measure. One of the most important commission job is defining intervention levels and derived intervention levels for that accident. The commission take care of accidents in all phases and propose the end of accident.

The role of other institution involved in YUPLAN is the same as in other countries and in IAEA plan (8).

YUPLAN AND IAEA PLAN COMPARISON

At the time of the Chernobyl accident, Yugoslav accident detection system was based on absorbed dose rate measurements on several selected locations, manually done in predefined time intervals. Although it was considered as adequate for countries without nuclear power plants, practically it presented itself as very slow and inertial one. Anyway it was very good basement for the implementation of the IAEA Emergency Response Plan. The basic idea is the same in both plans. Some specific elements, concerning political state organisation had to be incorporated.

Differences can be seen in the precision of defining responsibilities of various scientific and technical authorised organisation ivolved in YUPLAN. This differences are naw to be inplemented in new version of Yugoslav Respoce Plan for Radiological Accidents.

CONCLUSION

The Chernobyl accident had significant versatile influence on regulatory changes. One of the aspects is an adequate society organisation in emergency conditions. The necessity of the existence of well co-ordinated plan of action in the emergency is proved, even for non nuclear countries. In the new Radiation Protection Act it has been implemented the governmental responsibility for the existence of the Emergency Response Plan in Yugoslavia. The important task still remained to be done is to make it effective and operable.

ON THE USE OF THE NORMALIZED LEAST-SQUARES METHOD TO RECONSTRUCT THE SOURCE TERM FROM TRACER EXPERIMENTS

Carlos M. Rojas and Alain Sohier
Belgian Nuclear Research Center (SCK-CEN)
Boeretang 200, B-2400 Mol, Belgium

INTRODUCTION

Should an accident in a nuclear power plant (NPP) result in a major release of radioactivity into the atmosphere, a number of protective actions must be issued to avoid excessive exposure of the population to ionizing radiation. Early countermeasures will be based on the current status of the NPP such as burned-up fuel, cooling time, release pathways , etc. However, once the release has begun, off-site emergency actions will strongly depend upon one's ability to collect in a minimum of time enough data to characterize the accident, and to use these data to reconstruct the source term, i.e. the amount and nature of the material being released. New estimates of the source term are then fed into a dispersion-deposition model to obtain an updated view of the affected areas downwind, providing the decision makers with new information.
This paper concentrates on the use of the normalized least-squares method as a tool to reconstruct the source term used during several tracer experiments, as well as on a discussion of its applicability considering the time and data constraints of a real situation.

MATERIALS AND METHODS

Experimental and Modeling

The data set used in this work was generated during several (11) experiments conducted during the early eighties at the location of Mol, Belgium. These experiments consisted of releasing a known amount of a tracer gas (SF_6) from a height of about 2 m. Samples were collected at a number of stations situated downwind on arcs around the point of release, and covering a distance of a few kilometers. For details on the sampling technique as well as on the analytical procedures used to determine the air concentrations, the reader is referred to [1]. The release rate was kept constant throughout the experiment, and the time span between release and sampling was long enough to ensure that the plume had reached the observation point.
A data set of model estimates was computed for each tracer experiment using the segmented-puff dispersion deposition model ATSTEP [2]. This model has been chosen due to its degree of complexity which lies between a simple bi-gaussian model and a particle model, the reduced number of input parameters required, and overall speed, which are all elements of extreme importance in real-time response to an emergency. Model predictions were done assuming a stationary meteorology, i.e. wind direction, speed and atmospheric stability did not change throughout the experiment, and a constant release rate of 1 g s^{-1} .

Normalized least-squares method (NLSM)

This approach does not differ significantly from the one used in [3] for the source term reconstruction using the deposited activity after a nuclear accident, and it is based upon the assumption that the modelled quantities, airborne concentrations in this case, satisfy the equation:

$$L_i = Q\,L_i(P)$$

where the subscript i represents a given point, Q is the source term, and P summarizes all the parameters such as release height, wind speed, atmospheric stability, etc. Bearing this in mind, one can define an objective function F such that,

$$F = \frac{\sum_i (QL_i - Z_i)^2}{\sum_i Z_i^2}$$

with Z_i being the observed quantities, e.g. airborne concentrations and L_i the modelled quantities. The normalization to the sum of the Z_i ensures that all possible values of F are between zero and one, which makes the interpretation of the results somewhat easier. The source term (Q) can be determined by minimizing F, which is a straightforward procedure.

RESULTS AND DISCUSSION

A summary of the results obtained for 11 tracer experiments, is shown in the Table 1 below:

Case	Qreal	Qnlsm	Qinvgauss
1	2.2	1.1	1.2
2	3.2	6.7	6.5
3	3.2	8.0	10.4
4	3.2	3.6	4.1
5	3.4	3.5	4.4
6	3.4	2.9	2.8
7	1.0	0.8	1.1
8	3.3	3.1	4.7
9	3.3	12.0	13.1
10	3.5	1.6	1.4
11	4.2	2.7	3.4

Table 1. Comparison of the real source term (g s^{-1}) with the reconstructed using NLSM and that obtained by simply inverting a bi-gaussian model.

It can be seen from this table that the NLSM procedure yields (cases 4 through 8) an estimated source term that agrees fairly well with the real one, whereas the maximum difference (factor 4) was observed in case 9. In this particular case, the atmosphere was very stable and this resulted in a very narrow plume, as shown in Figure 1, causing that a significant number of receptors did not receive any signal at all. Even in this case (9) a difference of a factor of 4 seems quite acceptable, considering that the meteorological conditions were assumed constant throughout the experiments. Even though this method has proven to be a very useful tool for the estimation of the source term, its applicability to a real situation is very limited, and this is mainly due to the scarcity of observation points during the early phase of the accident. Furthermore, even if several observation points were available, they should be near the plume's center line to avoid situations similar to number 9 above, i.e. when the plume is very narrow.

The last column in Table 1 shows the source term resulting from the inversion of a bi-gaussian model and considering only one point, namely the one with the highest concentration. It is worthy to mention

that this procedure also yields significant results and has the advantage of needing very few observation points. Therefore, the reconstruction of the source term during an accident could be possible if one follows a monitoring strategy that focuses mainly on locating the plume's axis. A number of monitoring guidelines are still under development to achieve this goal.

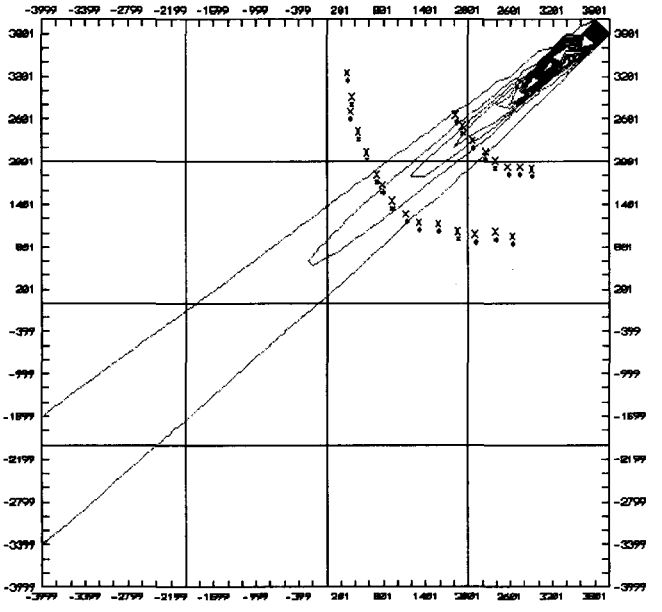

Figure 1. Plot of the resulting plume for case 9. The position of the source in this 41x41 grid has been chosen according to the prevailing wind direction (NE), and the resolution was set to 200m The location of the receptor points is also shown.

REMOVING FOOD PROTECTION COUNTERMEASURES: THE USE OF LIVE MONITORING TO DERESTRICT MUCH OF THE CHERNOBYL-AFFECTED AREA IN CUMBRIA

Michael Segal, Katherine Mondon and Caroline Morris
Ministry of Agriculture, Fisheries and Food, London

INTRODUCTION

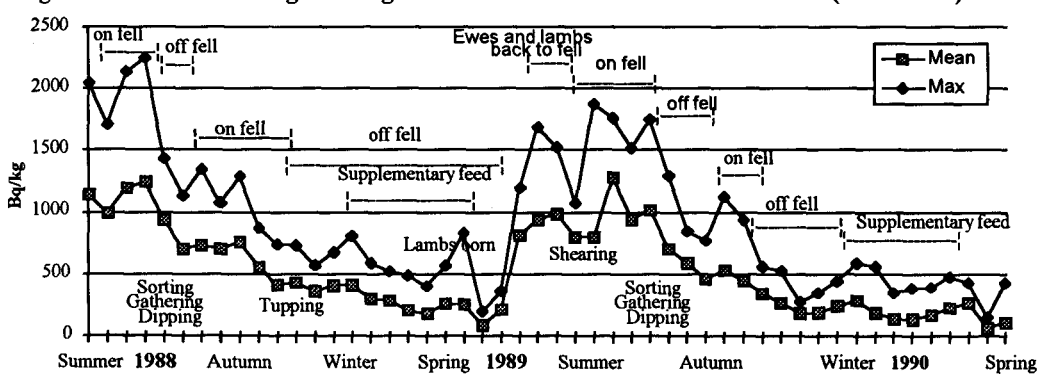
After the passage of the Chernobyl plume across Britain in 1986, some upland areas with peaty soil were significantly contaminated with Cs-137. The main effect on agriculture was the persistence of radiocaesium in sheep grazing these areas. A limit of 1000Bq/kg of total Cs in sheepmeat was introduced to protect consumers, and a system of live-monitoring known as mark-and-release has been applied successfully ever since, ensuring that no animal above this level of contamination could enter the food-chain (1). The level of contamination in the animals has fallen only slowly because of the nature of the soil (2), but over the years it has been possible gradually to reduce the area held under restriction. This paper describes the approach used to determine whether restrictions could be lifted on a farm-by-farm basis in England; similar methods have been used in other parts of the United Kingdom.

METHOD

The essence of all live monitoring is that animals are tested in the field using a hand-held, portable instrument; the calibration curve was established from comparison of live monitoring and accurate determination of activity levels in samples taken from animals after slaughter (3, 4). When animals are destined for the market, in the autumn, farmers in the restricted area are required to present them for monitoring before they leave the area; only those which are below the limit may be moved. A safety margin to bring them within the 97.5% confidence level is applied, because of the natural scatter of the calibration. Failures are then kept on low-lying land where the caesium levels are much lower and within a few weeks can go on to market. The number of animals failing this test in recent years has been minute, less than ten out of tens of thousands monitored each year, partly because farmers generally do not present their animals for testing until they are confident of passing, and partly because of the gradual reduction of radiocaesium in vegetation in the area.

Before removing controls on any farm in the area, it is necessary to be confident that no animal will be contaminated above the limit when it goes to market. A programme of derestriction monitoring has been carried out in the summer of each year since 1989; since 1990 every animal within a selected area was live monitored at a time corresponding to the annual peak of activity. Detailed studies have shown that the peak is reached between June and September each year (Fig 1) (4, 5).

Figure 1. Live monitoring at a single farm in the Cumbrian restricted area (1988-1990)



For this survey, farmers present their animals within 24 hours of bringing them down from the fells, which they can do as part of their summer clipping routine . This approach ensures that the true peak activity in the flesh is measured,as activity falls rapidly once the animals leave the fell, and so if every animal in a flock is below the limit (again with a suitable margin for counting uncertainty) levels will be well below the limit at market time.

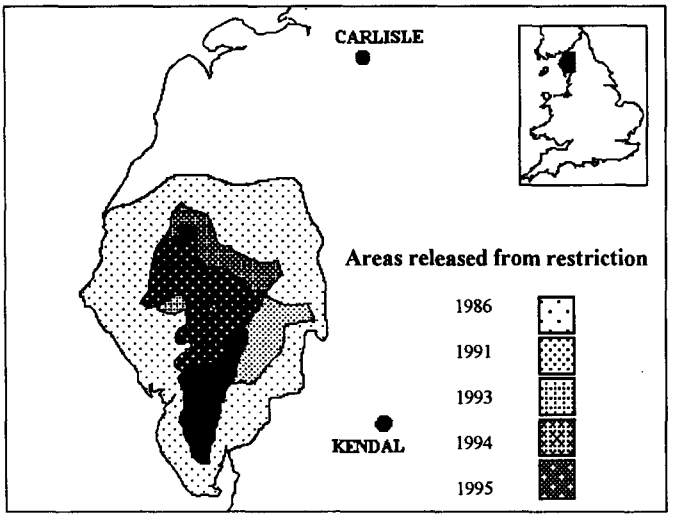
SELECTION OF AREA FOR DERESTRICTION MONITORING

This method is very resource intensive and it would not have been possible to cover the entire restricted area in a single survey. Parts of the area were only selected as candidates for derestriction when there was good reason to believe that many of the holdings tested would pass. Results of each year's mark-and-release monitoring have been an indicator of possible success, but these are mostly a reflection of farming practices. The best indicator has been the soil. Research over several years following the Chernobyl accident showed that within the broad class of organic and peaty soils there are significant differences in caesium retention properties between different soil types (see, eg, 2). Although caesium is recycled and reappears in vegetation each year on many fell soils, the peak level in vegetation falls annually at different rates. These results suggested only deep peat was likely to continue to be a problem in the longer term. Very detailed maps of the soil composition are available (6), and these enabled parts of the restricted area to be selected each year in the expectation that few farms would be likely to show failures.

RESULTS

Figure 2. Sheep grazing areas in Cumbria affected by Chernobyl fallout

In Cumbria, an area of some 197,000 hA, comprising 1670 holdings and containing some 867,000 sheep, was originally restricted in June 1986 on the basis of very cautious assumptions, but1520 holdings with 697,000 sheep were derestricted by September 1986. Fig 2 shows the area covered, and also shows how it has been reduced in recent years following the annual derestriction surveys.



The Table shows how the numbers of holdings under control and the numbers of animals involved have been reduced, up to January 1995. In the summer of 1995 all the remaining area was surveyed; analysis of the latest results is still under way but it is hoped that the number of holdings remaining under control can be reduced to below 20. It is important to recognise that the whole approach is extremely conservative, and a single animal above the limit is sufficient to keep a holding under control. In all cases the vast majority of the animals show very low levels of activity.

Holdings and sheep in Cumbria affected by Government restrictions

Year	Number of Holdings	Number of Sheep
June 1986	1670	867,000
October 1986	150	170,000
December 1991	138	120,000
January 1993	126	110,500
January 1994	112	100,000
January 1995	66	68,819
January 1996	<20	≤ 20,000

Figure 3 shows the distribution of activity measurements for each survey in the last 7 years; although tens of thousands of animals have been below 200 Bq/kg, even at the peak time, the few results above 1,000 Bq/kg have been enough to keep the affected holdings under restriction and require the continuing use of the mark-and-release system.

Figure 3. Activity distributions of sheep in derestriction surveys

Some aspects on improvement of the organizational basis for public protection of those residing under the conditions of chronic "emergency" irradiation.

Vladimir I. Ternov[1], *Irina P. Vasileva*[2]

1,2-National Commission on Radiation Protection
Republic of Belarus

We possess decennial experience of organizing and implementing protective measures for the population in the Republic of Belarus which turned out to be within the sphere of influence of various factors engendered by the Chernobyl NPP accident. It enables us to distinguish some important in essence, from our viewpoint, aspects on radiation protection and safety, whose underestimation might considerably affect adequacy and effectiveness of the entire system of protective measures carried out during different stages of development of a large-scale radiation accident.

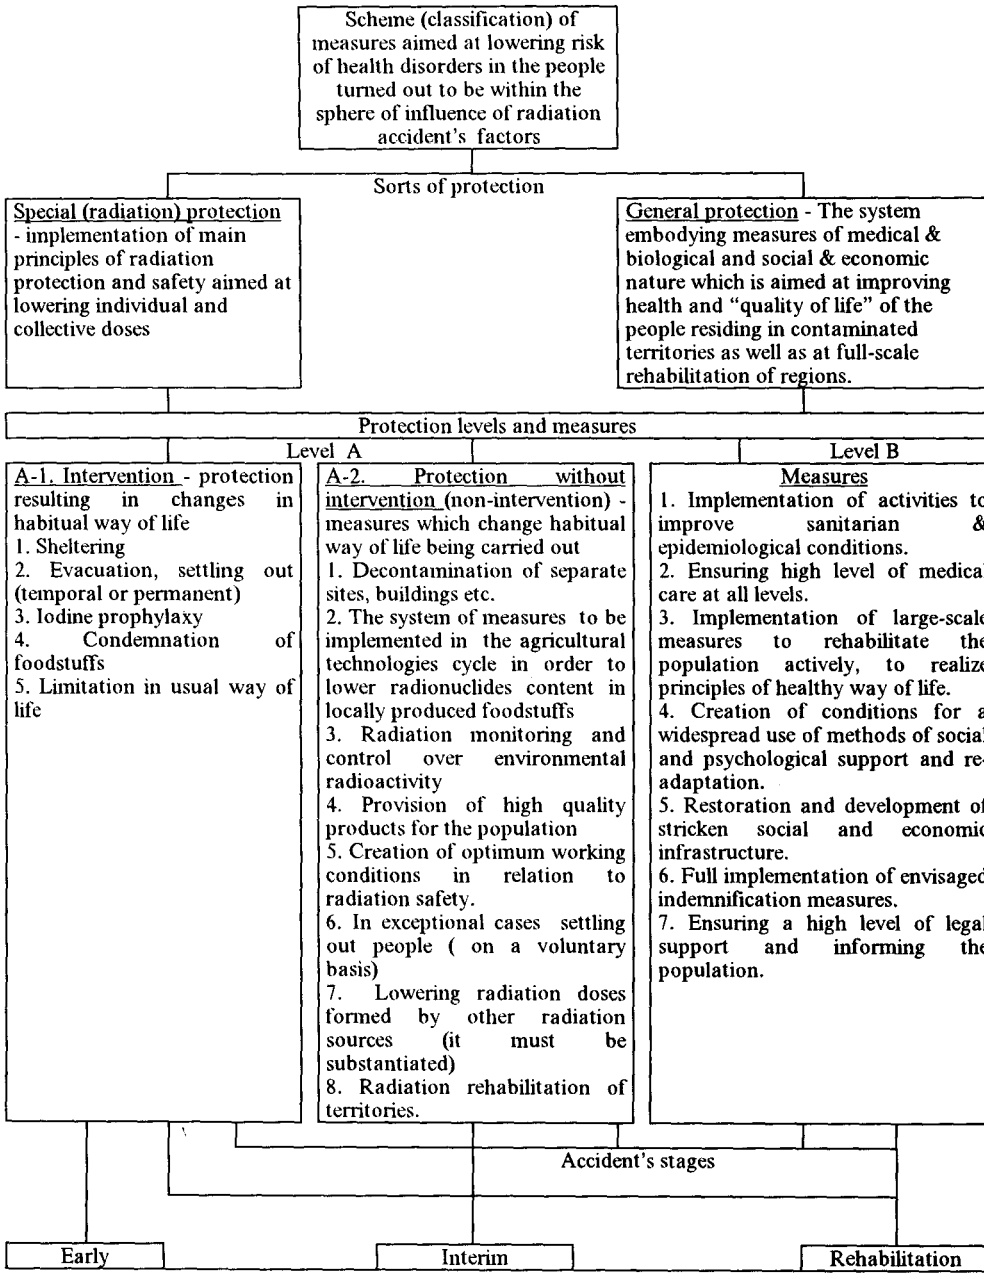
Firstly, definition of separate stages of an accident is based upon methodology which suffers from grave shortcomings. Thus, from the viewpoint of the NCRP, criteria offered to define an accident's stage are not always concrete. A range of reference-points (criteria) for defining a rehabilitation stage is especially broad. There are no numerical characteristics of the stage. It impedes its objectification that, in its turn, does not help to designate conceptual srategical aims and objectives for public protection.

Proceeding from this, we deem that in order to develop methodology of differentiating accident's stages it is expedient to introduce such an additional reference-point (a criterion) as "percentage of a life-long dose formed in people inhabiting radioactively contaminated territories". Doing so and taking into account general appropriateness of dose-forming through "emergency" irradiation, we suggest that one should consider a 50 per cent barrier of a life-long dose to be an upper limit for regarding an accident's stage as a rehabilitation one. It is believed that this approach will help

- to define more exactly time of accident's transition to the rehabilitation stage so that elaboration and implementation of adequate protective measures are underpinned

- to strengthen the system of protective measures since definition of the stage itself can render a positive psychological impact on the population.

Secondly, practice of radiation protection for the population affected as a result of the ChNPP accident convinces one that there is a necessity to draw up a unified international scheme (classification) of protective measures for the people turned out to be within the sphere of influence of an emergency radioactive release. Relying upon international radiation protection principles and experience gained in the republic, Belarus proposes a variant of general systematization (classification) of public protection measures for those affected by radiation accident's factors. Drawing up the given scheme, we proceeded from the fact that from the viewpoint of possible medical and biological consequences a radiation accident can be dangerous not only owing to a radioactive release, but owing to other factors which inevitably arise during any event jeopardizing welfare and health of lots of people.



Scheme (classification) of measures aimed at lowering risk of health disorders in the people turned out to be within the sphere of influence of radiation accident's factors
Sorts of protection
Special (radiation) protection - implementation of main principles of radiation protection and safety aimed at lowering individual and collective doses
General protection - The system embodying measures of medical & biological and social & economic nature which is aimed at improving health and "quality of life" of the people residing in contaminated territories as well as at full-scale rehabilitation of regions.
Protection levels and measures
Level A
Level B
A-1. Intervention - protection resulting in changes in habitual way of life
1. Sheltering
2. Evacuation, settling out (temporal or permanent)
3. Iodine prophylaxy
4. Condemnation of foodstuffs
5. Limitation in usual way of life
A-2. Protection without intervention (non-intervention) - measures which change habitual way of life being carried out
1. Decontamination of separate sites, buildings etc.
2. The system of measures to be implemented in the agricultural technologies cycle in order to lower radionuclides content in locally produced foodstuffs
3. Radiation monitoring and control over environmental radioactivity
4. Provision of high quality products for the population
5. Creation of optimum working conditions in relation to radiation safety.
6. In exceptional cases settling out people (on a voluntary basis)
7. Lowering radiation doses formed by other radiation sources (it must be substantiated)
8. Radiation rehabilitation of territories.
Measures
1. Implementation of activities to improve sanitarian & epidemiological conditions.
2. Ensuring high level of medical care at all levels.
3. Implementation of large-scale measures to rehabilitate the population actively, to realize principles of healthy way of life.
4. Creation of conditions for a widespread use of methods of social and psychological support and re-adaptation.
5. Restoration and development of stricken social and economic infrastructure.
6. Full implementation of envisaged indemnification measures.
7. Ensuring a high level of legal support and informing the population.

Rehabilitation

THE ORGANIZATION OF MONITORING SYSTEM IN THE DISTRICTS AROUND THE NPP TO PROVIDE RADIATION COUNTERMEASURES

Ivan Skuratovich,Ivan Matveenko

Committee for hydrometeorology,Minsk,Belarus

There are created the system of prevention and activities during the emergencies in the Republic of Belarus. This system should provide a detection of the beginning of natural calamities, industrial accidents and disasters, a prognostication of their courses and possible damage and a working up of concrete proposals of protective measures realization and consequences liquidation.

Taking into account how great damage was done to the Republic of Belarus following the accidend of only one of the blocks of Chernobyl NPP, in this system the special place is alloted to prevention and activities with accidents on the nuclear units. To detect beginning of the accident on the nuclear unit it is necessary to create the automatized radiological and meteorological monitoring system especially in the regions adjoining the working NPPs. There is not the own NPPs in the territory of Belarus but the NPPs in operation are in the neighbour countries such as Lithuania [Ignalinskaya NPP], Russia [Smolenskaya NPPs] and Ukraine [Chernobylskaya and Rovenskaya NPPs]. All these NPPs are situated near the territory of Belarus.

A creation of that system on all the territory of the Republic takes substantial capital investments and much time. Therefore the works are realized in stages. In the first stage at the expense of means of the EU Comission according to the project worked up by the firm "Consulting Group" [Great Britain] the firm "Horman Systemtechnik" [Germany] mounted 9 automatic points of gamma-level measuring in the region adjoining the Ignalinskaya NPP. [The siting scheme is added]. Futhermore the automatic points measure availability or absence of liquid precipitation and have possibility to transmit information to the centre of data collection and treatment by radio-line. In addition to the available meteo-stations network [the nearest one is at 60 kilometres distance] is mounted the automatic meteorological station in Drysvyati at the distance of 4 kilometres from NPP. The automatic points work in a continuous rate of measuring, and information is transmitted to the Centre once an hour. In the case of gamma-level raising to the fixed threshold is transmitted an extraordinary report, and the measuring results are transmitted every 10 minutes. By the project GAMMA-1 is envisaged a delivery of the mobile laboratory. This laboratory has a possibility to mount in necessary parts e.g. in the contamination zone 4 additional automatic points with autonomous feeding. It allows to receive the more detailed information from the most polluted regions.

The created network of gamma-level and meteorological parameters measuring allows to detect opportunely a beginning of the territory contamination in the case of the accident on the Ignalynskaya NPP. Futhermore using the data of radiation and meteorological monitoring we can prognosticate what parts of the territory will have different contamination levels and where it necessary to carry out the protective arrangements. The possible protective arrangements include:

- distibution of iodine tablets;
- sheltering of population and animals;
- limitation of polluted food products consumption;
- desactivation;
- evaquation.

It is very important to determine an economic effectiveness of the realized protective arrangements.

CONCLUSION.

An effectiveness of this system using will depend on amount and quality of the measured meteorological and radiological data. It is necessary to create in futher stages the automatic monitoring network in the other regions adjoining the working NPPs and on all the territory of the Republic.

It is necessary to provide the data exchange between the countries of Eastern and Western Europe. Using the automatized meteorological and radiological monitoring network it is necessary to improve the methods of contamination detecting, monitoring data treatment, contamination levels prognostication and regular studying of operational personnel.

The Committee for Hydrometeorology of the Ministry on Emergencies and Population Protection from the Chernobyl NPP Catastrophe Consequences. Minsk, Belarus

The measurement system of the environmental object radiation contamination is the main component part of the radiation monitoring functioned on the territory of Belarus.High sensitivity of the apparatus of the measuring complex allows to receive trustworthly estimation of the environment radiation contamination.

The radiation measurement's estimation of the environmental object (water,earth,air) carries out by spectrometral, radio-chemical and radiometric methods.

The measurement's results accumulated in the automatized data base and uses for estimation and forecasting of radiation situation on the territory of Belarus.

THE DEVELOPMENT OF THE PROMPT SYSTEM OF GAMMA RADIATION MONITORING IN FR YUGOSLAVIA

M.Orlić, S.Pavlović, and R.Pavlović

The Institute of Nuclear Science Vinča, Belgrade,Yugoslavia

ABSTRACT

The needs for and characteristics of the Prompt System of Gamma Radiation Monitoring are analysed. The basic structure of the new system, based on the PC computer is presented. The system consists of the central unit and a number of field stations connected via telephone lines. GM counter is used as a detector. The software is written in Visual Basic. The system is capable of performing a variety of tasks: dose rate measurement (analogue and digital), graphical presentation of the results in the given period of time, data base formation and management, data transmission and preparing reports.

The basic characteristics of hardware and software of the system, performance specifications and future plans are presented in this paper.

INTRODUCTION

Besides large benefit especially as energy resource the nuclear energy represents potential danger for humans and the environment. The main danger is radioactive contamination. In normal working conditions contamination is small, controlled and under regulation levels. But in accidental situations such as Chernobyl accident the situation is quite different. Than we can expect large contamination area and population exposure for a long time.

In situations like those the main task is to protect people from internal and external contamination. There are a lot of possible technical, social, economic and political measures. The cost could be enormous. Because of that, all measures have to be optimised. The main condition for this is very early accident detection. This is the reason why prompt monitoring system must exist. It is very important in the case when accident happens abroad and other systems fails (as it has happened in the case of Chernobyl accident). The information of the prompt monitoring system that an accident have happened somewhere is the basis for the response plan activation.

In this paper basic design goals of prompt system monitoring are analysed as well as the some technical characteristics of the system which is under development in Yugoslavia. An example is given as well.

BACKGROUND INFORMATION GOVERNING THE DECISION ON SYSTEM DEVELOPMENT

Strong regulation demands in nuclear energy applications and rapid technological development in the field of electronics and computers enables qualitative improvements in environmental monitoring systems. Global effects of Chernobyl accident have accelerated the development in this field.

Developed western countries, with strong nuclear industry, are already covered with computerised monitoring networks. There are several commercial possible solutions, depending on selected detector system and requested set of information.

At this time the Yugoslav national system for accidental detection is based on several measuring point, spread over the country. The absorbed gamma dose rate is measured manually every hour and, in the case of exceeding the declared threshold level authorised centre alerted.

Besides those discrete measurements on three selected locations, continual gamma dose rate monitoring by pressurised ionisation chambers (Model RSS-112 Reuter Stokes, USA) is established. Additional two ones have already be planed and they are about to be installed.

Contamination levels and the whole response system in Yugoslavia after the Chernobyl accident practically proved the necessity of the existence of automated monitoring network. Finally, in the process of changing the basic Radiation Protection Act (3) this system is introduced as governmental responsibility.

According to the presented scientific and organisational background information it was necessary to choose further course of action. Taking everything in to the consideration including the finance it was decided to develop one own system. Existing monitors will be incorporated into the developed one.

DESIGN DEMANDS AND GOALS

The main construction demands for the prompt monitoring system are analysed here. The fastest and most convenient way for prompt monitoring is based on gamma dose rate measurement at the background level. It determines the lower measuring range limit. It depends on location characteristics. According to the results of environmental monitoring over years, the value of 100 nGy/h is good enough. If detector enables it is recommended to use a lower value. The upper limit must be above local background variation in the worst case. The isodose lines at Chernobyl accident must be taken into account too. The upper limit of 10 mGy/h is appropriate. But if detector enables it is recommended to use even a higher value.

The measuring error depends mostly on detector and electronics, system function and costs. The compromise leads to standard error of ±20% at ^{60}Co gamma ray energy. The system must measure gamma dose rate in the energy range 0.1-2.5 MeV with energy error of ±30%. Statistical error is in connection with detector efficiency and response time. A value of ±20% is accepted.

Prompt system response time depends on detector response time and transmission time. The appropriate value of detector response time is several seconds and even the value of several tenth of seconds is not critical.

The parts of prompt gamma monitoring system must operate in the field condition. They have to be adjusted to that climatic condition.

Besides of satisfaction of all this demands the goal of Yugoslav prompt system monitoring is to be inexpensive, based on modern electronic components, computers and data transmission infrastructure. At the moment the telephone link is the basic link.

The system consists of a central station and several field stations covering state area. Data transfer between them must be automated. The field station have to send last defined series of measurements on the central station request. Only in the case that the result of measurements at any field station indicate an accident or accident possibility, this station must send measurements results permanently until central station stops it.

Data manipulation and presentation must be at the top level. It means that modern inexpensive PC computers and peripherals as well as its software must be used.

SYSTEM CHARACTERISTICS

According to the above mentioned design demands and goals the prompt gamma monitoring system is developed (1,2). It consists for now of a central station and several field units connected as presented on figure 1.

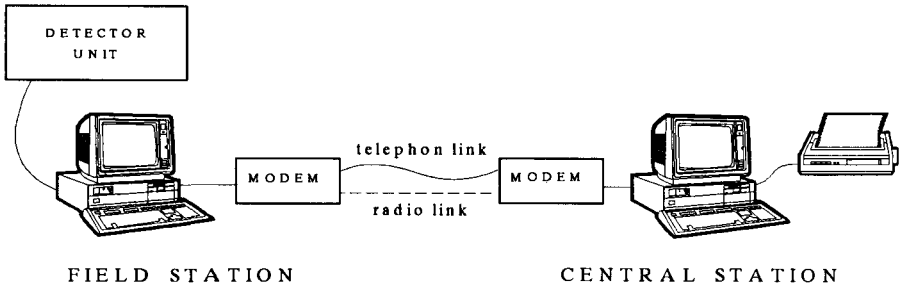

Figure 1 Prompt gamma monitoring system configuration

The detector unit consists of the very sensitive GM counter (ZP1220) with some electronics (high voltage, pulse shaping and forming modules). The pulses are counted in a counter computer card. Ratemeter function is realised by software. By software are realised all other functions as well. One of the important functions is decision making function. Whether the measurement result is a background variation or an accident has occurred ? This function is supported by data base of dose rate measurements at that specific location. This allows the decision function to be self adjusted during the

years and seasonally. The very important software part is communication package. It is based on modern software for PC computers.

Central station have a field station function and an integrating function. All data are here analysed, stored and presented. Decision algorithms are the same as in field station . There is a new software part for area contamination analysing and forecasting. This part is very important in a emergency response plan realisation.

The operation of the prompt system monitoring is very promising on PC computers under Windows™ operating system. So, the program is written in Visual basic™ language. It enables several functions in time: measurement, several types of presentation, data storage, data sending. Besides, data presentation is powerful. Dose rate measurement results are presented in analogue (gauge or bar) and digital form. Analogue form enables easy viewing of full measuring range and alarm levels. Digital form is more accurate. On the PC display a special window is realised for last 24 measurement presentation in a histogram form. It enables daily changes observing. How a PC display looks like during the measurement on field station is presented on figure 2.

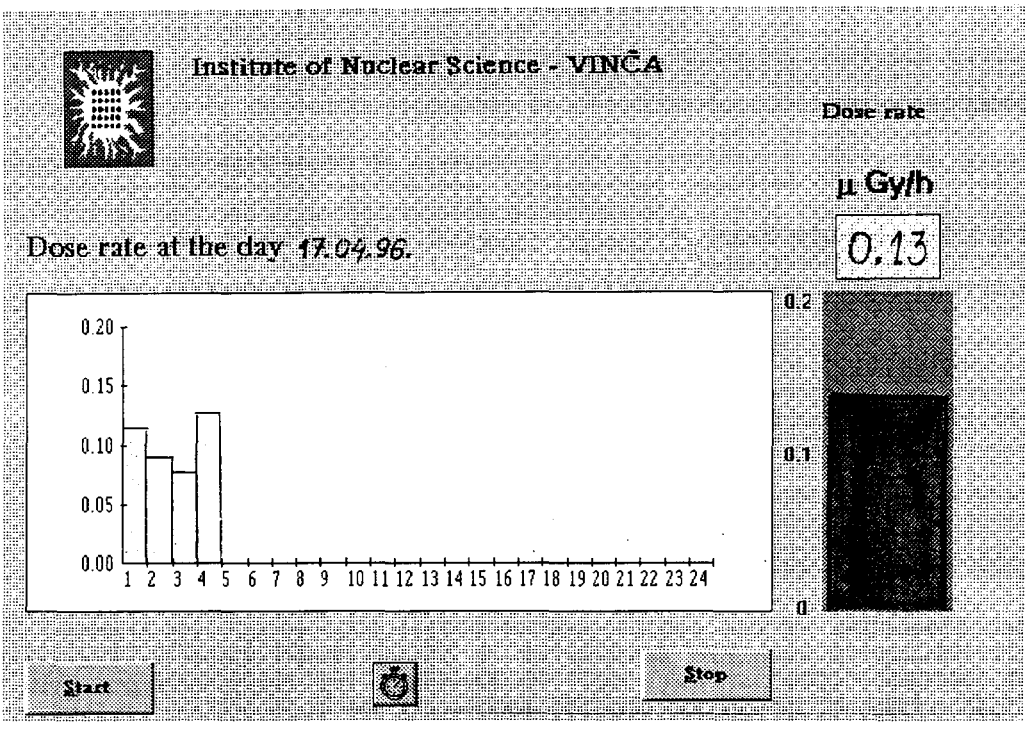

Figure 2. The display of gamma prompt monitoring system during data colection

CONCLUSION

This paper presents new Yugoslav Prompt Gamma Monitoring System for large accident detection. It is based on modern components. Because of this it is cheap, easy for using and with additional capabilities for measurement results presentation, data storing and manipulation and with a appropriate humane-computer interface. It is convenient for small countries.

ABSTRACT (See instructions overleaf)

Radioactive contamination in the Urals region resulted from more than 4 decades of the activities of Mayak Industrial Association (Sourth Urals). A specific feature of radiation conditions on the territory around Mayak is the long-term exposure of the residents due to the presence of Sr-90 and Cs-137 among the radionuclides contaminating the environment. Toprovide informational basis for decision-making about nature protection and environmental safety measures on the territory around Mayak facility a comprehensive radioecological monitoring has been organized. Attention is focused on monitoring natural media, sources of industrial contamination, population's health status, etc. The priority task to be solved by radioecological monitoring is to establish a system of collection and analysis of data on radioac - tivecontamination of the environment, setting-up and updating specialized data bases, assessment and prediction of changes in environmental conditions due to impacts of industrial contamination, infor - tional support to long-term and short-term measures aimed at controlling the environmental situation including emergencies. Nature protection activities are aimed at the solution of the triune task: ensuring safe life conditions for the population, restoration and protection of ecosystems, sustained development of the region's economy.

THE NATIONAL RADIOACTIVITY MONITORING NETWORK OF THE NETHERLANDS

[2] Netherlands Energy Research Foundation, Petten, The Netherlands

INTRODUCTION

In 1988 the Dutch Government decided to integrate the radioactivity monitoring network of the National Institute of Public Health and the Environment (RIVM) managed on behalf of the Ministry of Housing, Spatial Planning and Environment (abbreviated in Dutch: LMR) and a similar network of Ministry of the Interior (BMNI) into the National Radioactivity Monitoring Network (in Dutch: NMR).

After the Chernobyl nuclear power plant accident in 1986, the LMR network was developed within the framework of the National Plan for Nuclear Emergency Planning and Response (EPR) as an early warning and monitoring instrument for future nuclear accidents (1). In March 1990, four years after the Chernobyl reactor accident, the LMR was officially opened. The LMR network consists of 58 stations measuring the natural background γ-radiation level. In 14 of the 58 stations monitors are installed to measure the airborne α/β-radiation level. Because different radioactive nuclides may be released during a nuclear accident the LMR also contains two nuclide-specific monitors which facilitates translation of the measured α-, β- and γ-radiation levels into an effective dose to humans.

The BMNI network is an information system primarily for local management of accidents. This network was designed and built for the Ministry of the Interior by the Netherlands Energy Research Foundation (ECN) in the period 1987-1993. It contains 252 stations measuring the surrounding γ-radiation levels. The network conforms to the management structure of the Ministry of the Interiors Fire Services Department in its hierarchical build-up of four levels: national, provincial, regional and local stations. Measurements are performed at the local level, while the responsibilities for countermeasures during accidents are at the regional level. In February 1993 this network was officially opened.

THE INTEGRATED NETWORK

The integrated network, called the National Radioactivity Monitoring Network, must satisfy the demands of all parties involved. The main objectives of measuring the radiation levels in the Netherlands are to provide:

- early warning against major nuclear accidents
- information on the geographical distribution of radioactive contamination during an accident
- information on the actual radiation doses to the population during an accident
- information on radiation doses to regional, provincial and national authorities
- general information on background levels

The solution was found in maintaining the structures of the existing networks as much as possible and to build an integrating structure, including an overall database at the National Institute of Public Health and the Environment (RIVM) at Bilthoven. In this way the integration is reached by exchange of data, which proved to be much more cost-effective than connecting the different types of monitors and computers using a technical solution.

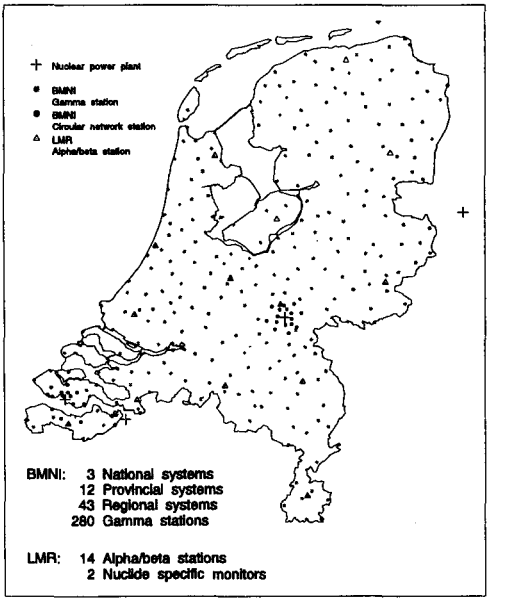

Figure 1. The NMR locations

RADIATION DETECTION

The NMR consists of 280 measuring sites that contain a proportional counter tube (Bitt RS02/1) for the determination of the gamma ambient dose-equivalent rate $H^*(10)$. The distance between sites is typically 15 km. Compared to other European countries, the Netherlands' network, as in Germany and Austria, has a relative high station density (about one station every 150 km^2). A double circular network of monitors has been installed around the two Dutch nuclear power plants: one ring at 5 and one at 10 kilometres from the power plant. These rings immediately provide emission profiles in case of accidents with the nuclear power plants and reduce the necessity for emergency staff to take measurements in highly contaminated areas. Also around the two nearby foreign nuclear power plants some monitors have been installed where the two rings intersect Dutch territory.

An airborne-activity monitor (FAG FHT 59S) determines the aerosol-bound artificial gross-beta activity concentration in air at 14 sites as an indication of inhalation dose. These 14 sites also contain a proportional counter tube to compare artificial gross-beta measurements with gamma radiation levels at the same site. Figure 1 shows all measuring locations of the NMR network.

Two nuclide-specific monitors have been added to the network at RIVM. One, the iodine-monitor, measures the gaseous radioactive iodine concentration in air and the other, the nuclide-specific gamma monitor, identifies the order of contamination of radionuclides by γ-ray spectroscopy.

DATA MANAGEMENT

The special Dutch government emergency telephone network is used for most of the data acquisition. Work stations are set up regionally (sections of provinces, 43 in total at the moment), provincially (12 in total) and nationally (3 in The Hague; a main system, a back-up system and a reserve system in case of malfunctioning of the main system). Acquisition of gamma data takes place once every hour in a hierarchical manner: a regional network calls the sites in its region and collects data, then the provincial work station calls the regional station in its area followed by the national work station, which collects the data from the provincial stations. At the end of a complete upward acquisition cycle, all data are distributed again to the 43 regional work stations. HP9000/340 computer systems, controlled by the regional fire brigades, have been placed in the regional centres. At the National Coordination Centre in The Hague, HP9000/400 computer systems process and store the data. These, as well as the data from the 14 aerosol monitors, are sent to a central database located at RIVM.

NETWORK ALERT

Twenty-four hours a day, every ten minutes, radiation levels are measured at nearly 300 sites in the Netherlands. When the network level is exceeded at one of the sites, the station processor automatically calls the NMR computer at RIVM, which in turn activates a pager carried by specially trained RIVM staff members. The most recent data are sent with the alarm message to the personal computer of the staff member on duty. Ten-minute values of the previous four hours can be examined using NMR presentation software running on personal computers stationed at the homes of RIVM staff. When the alarm level of one of the gamma counters is exceeded, it is followed by an automatic validation procedure: an alarm signal is sent out to the pager (via the NMR computer) only when at least two monitors within an area of 40x40 km^2 have their alarm levels exceeded. The chances of a false alarm due to monitor failure are greatly reduced by this measure.

In 1995 the NMR network performance was tested against the specifications for an adequate alarm response: signalizing an enhanced radioactivity level within 1.5 hours to the central database at RIVM. The tests were performed by simulating a radioactive cloud passing by over the Netherlands. With the help of the regional fire brigades' staff nearly half of the total amount of measuring stations was alarmed during those days. Because of the positive test results the NMR network was declared operational December 1, 1995. It will be officially opened early in 1996.

ACCURACY OF MEASUREMENTS

There are some specific scientific aspects related to the integration of the networks. The reproducibility of the γ-radiation measurements is high (within 3%). As a result, the data can be analyzed to determine and discriminate between the variations in the natural background γ-radiation levels (between 60 and 100 nSv/h) (2). Two γ-radiation measuring stations, one (old station) belonging to the LMR network and one to the BMNI network, are situated at a distance of about 50 metres apart in Bilthoven. The monitors of the LMR are positioned at 3.5 metres height (on top of the measuring station), while the monitors of the BMNI are positioned at 1 metre height (at ground level). Since the monitors are identical, an intercomparison of the measurements is now in progress, which may provide a possibility to separate the different contributions of

cosmic radiation, terrestrial radiation, airborne and deposited radioactivity to the total γ-radiation level. Typical day/night variations in the natural γ-radiation levels were observed for some stations (*Figure 2*). Inspection of the location where the variation was observed showed that for the upper curve (station 01w501 in Kaatsheuvel) the detector was located in the direct vicinity of a shopping centre. During the day a lower γ-radiation level was seen due to the parked cars shielding the emission of γ-radiation from the used building materials in the car park.

For the lower curve (station 22w502 in Heerhugowaard), where an opposite variation in the γ-radiation level was seen, the detector was also located near a car park. However, in this particular case the car park was in front of a block of flats. Assuming the residents to be at home during the night, the γ-radiation level in this period was lower as a result of the shielding by the parked cars. This is confirmed by the measurements in the weekend. The absence of cars in the weekend resulted in a γ-radiation level for station 01w501 without dips in that period. Assuming that the residents in the block of flats also spend some time elsewhere in the weekend, the day/night variations should continue, which was indeed observed.

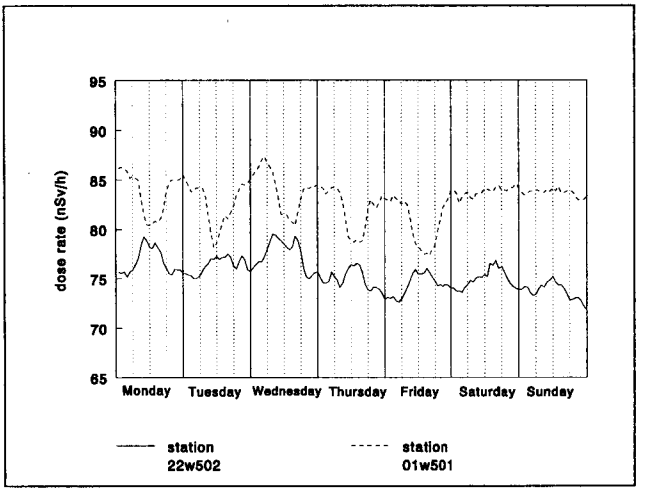

Figure 2. γ-dose rates for a week at two stations in the Netherlands.

These fluctuations and other variations in monitoring levels, with no relationship to an actual accident, can be ascribed to variations in natural environmental conditions. This illustrates that proper scientific judgement should be applied in every activation of alarm levels. RIVM provides this expertise to the EPR organisation.

NETWORK MANAGEMENT

The nuclear emergency response organisation operates on the assumption that nuclear accidents are by definition unpredictable, but do require immediate response. Therefore the network must be permanently maintained. RIVM manages the National Radioactivity Monitoring Network, providing quality assurance, developing and adjusting standard procedures for daily control, providing training of RIVM staff and financial management. ECN is subcontracted to maintain all gamma counters and the work stations. For this purpose a separate maintenance work station is operational at ECN. It is this combined network management that makes the NMR a reliable early warning network for nuclear accidents.

EMERGENCY MANAGEMENT IN NUCLEAR ACCIDENT SITUATIONS THE DISASTER EXERCISE 1995 'NORTHERN LIGHT'

C. Schmitzer, Austrian Research Centre, A-2444 Seibersdorf, Austria

INTRODUCTION

Emergency management does not only start after something has happened. Initially, a feasibility study usually assesses the risk for technologically critical processes and applications. Preventive strategies will be employed both in the administrative and technical field to minimize risk. Technical solutions will increase inherent safety or provide monitoring of critical components. Administrative action would result e.g. in restricted access, training programs, or detailed operating protocols. A final stage would be preparation for remedial action and defining the groundwork for emergency management in cooperation with civil defense forces.

Appropriate precautions will be based on hazard potential, which is inherently substantial when dealing with nuclear accidents. Being the last line of defense, the civil or military defense forces will be involved if a major disaster occurs despite all precautions, overpowering on-site crew capabilities. For major disasters requiring even international assistance, the United Nations Department of Humanitarian Affairs has started to conduct disaster preparedness exercises to improve cooperation and communication among the international relief teams and the local authorities. The EXERCISE '95 was organised by the Russian ministry for disaster management simulating a major accident in an atomic power plant located on the Kola peninsula.

SCENARIO

The technological scenario was modelled as a major accident in a pressurized water reactor (VVER-230/213). After depressurization in the vapor generator a general malfunction of the emergency power systems was assumed, resulting in failure of the emergency core cooling system. As a consequence of pressure build-up and additional failure in the main isolating shut-off, radioactivity was released into the environment through a safety valve for approximately 9 minutes. Then auxiliary power can be restored by the reactor personnel, the safety valve is closed, core cooling initiated, and the reactor attains a safe state. A significant portion of the uncovered core is assumed to be released as radioactive vapor into the atmosphere as a supersonic jet from the stack. Initial assumptions rate the magnitude of the total release up to roughly 10% of core activity, with a characteristic distribution regarding noble gases, iodines, and heavier elements, resulting in major contamination of the surrounding areas. The game-weather assumed predominantly easterly winds, causing trans-border effects as the radioactive cloud is blown towards the Finnish border. Thus international assistance was justified by the scale of the accident.

Preliminary action of the Department of Humanitarian Affairs was geared towards setting up of an On-Site Operations Control Centre (OSOCC) to coordinate the international efforts and serve as a head quarter for communication to local authorities. All participating teams were supposed to furnish a liaison officer to facilitate the communication of requests to the team and results back to OSOCC. International observers were monitoring the results achieved by each team on various missions as well as the recommendations of the expert groups.

OBJECTIVES

Within the exercise different objectives were to be pursued, both on the scale of international cooperation and particular to every team, respectively. An overview of the most important objectives is contained in the following list.

- Checking applicability of disaster preparedness and overall readiness to perform specific missions in contaminated areas (e.g. reconnaissance, decontamination).

- Assessing possibilities of international scientific and engineering support for decision making on matters of radiation protection. Determining the extent of the incident and providing the relevant information for the decision making process.
- Investigating the mechanism of international cooperation in case of a nuclear accident with trans-border consequences. Developing of practical strategies to cooperate in an effort to render urgent help in highly contaminated areas.
- Providing an opportunity of practical work for experts and field teams concerning counter measures in nuclear accident situations. Study of practical experience regarding organisation and implementation of emergency measures.

Among other nations, Austria was present with a team of AFDRU (Austrian Forces Disaster Relief Unit), manned by 30 members of Austrian NBC-forces and specialists from Seibersdorf. Approximately 20 tons of equipment were air-lifted to the affected area on the Kola peninsula, comprising of 3 search troops with vehicles, heavy decontamination equipment, as well as a command post and evaluation centre. Associated ancillary equipment included power generators, sanitary facilities, heating equipment and medical supplies.

The composition of the team was carefully selected to sustain prolonged operation in the field. Medical care, decontamination strategies as well as dosimetric coverage of the personnel were considered, to name just a few items. Experts from Seibersdorf assisted with special tasks regarding radiation protection and scenario analysis. In the preparatory phase much attention was paid to the selection of instrumentation and development of new techniques to implement a successful system concept, a cooperative effort between Seibersdorf and the NBC-division.

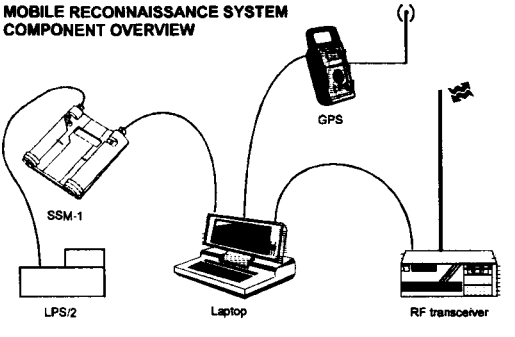
SYSTEM CONCEPT

Seibersdorf was the main contributor in defining the system concept for measuring purposes and situation reporting [1]. A cooperative project was launched together with the NBC-school to define the system requirements, which should allow a self-consistent operation after deployment into affected territory. Basic requirements were considered to be:

- Monitoring of environmental radiation levels at the camp and surrounding areas
- Determination of local weather situation, communication utility for general weather data
- Possibility for measuring of food stuffs or soil samples
- Autonomous mobile reconnaissance system
- Flexible command and evaluation centre
- Scenario analysis and forecasting tool (data interpretation & temporal development)

All of the above functions were implemented to some degree: a satellite telephone and computer hook-up served as communication utility to supplement the local weather information, which was constrained to the camp site; a NaI-based food stuff probe was also used for approximate determination of nuclide composition in soil samples, because a HPGe-detector was not considered feasible for extended field deployment.

The mobile reconnaissance system was a prototype development, based on an Aerial Monitoring System, developed and discussed at Seibersdorf [2]. A laptop computer monitors and profiles ambient radiation levels as determined by a radiation survey meter and high sensitive probe. A satellite based GPS system is used for on-line position detection. The current position is registered on the laptop and all measurements are annotated with positional



and timing coordinates. A RF-transceiver digitally broadcasts position and measurements as well as messages to the headquarter and relays commands to the field team. The headquarter may track up to 3 field teams simultaneously and communicate up to a distance of approximately 40 km. All data are stored internally in case of communication failure.

A scenario analysis tool (MIDAS [3]) was used to correlate the space/time annotated radiation measurement data and interpret them within the framework of the overall situation. Based on current and game-specific weather data, actual reports or projections of the radiation situation could be calculated and for instance heavily affected areas selected for immediate remedial action (evacuation, etc). Hot spots induced by precipitation (rain during passage of the radioactive plume) were modelled based on predefined weather information. These forecasts were used in mission planning for a reconnaissance trip to a heavily affected region on the third day after the accident. Artificial soil samples (provided by the organisers) were then used as corrective inputs to the model calculations, adjusting the assumptions of the source term.

Various inputs simulate the accident (source term, physical properties, local weather). A complex dispersion algorithm tracks individual elements of the release through a 3D wind field. If available, upper air data may be utilized to define wind shear layers aloft. Transfer factors within the model allow calculation such as estimated ground deposition, air-borne iodine, or impact on the food chains. All results are superimposed on a digitized map of the environment, allowing even demographic analysis (population affected, calculation of man-Sv).

RESULTS

The Austrian team and their systems used throughout the EXERCISE '95 were highly acclaimed by the international community. The mission objectives - reconnaissance work, decontamination, medical assistance, decision making support, and expert opinion - could be covered successfully. The scenario analysis - refined with results of simulated measurements - proved to be consistent with Russian model calculations used in preparation of the simulation. The mobile reconnaissance system - and specifically the automatic data acquisition and correlation of measured data with geographical position - significantly contributed to the overall success in forming a clear picture of the large scale situation. This might even be more important in a realistic scenario, where stress and human error can introduce additional problems with data integrity.

CONCLUSION

Emergency management on an international level requires major organisational efforts, in this case furnished to a great degree by the local UN coordination centre. To provide assistance effectively, the international teams have to operate autonomously in the affected territories. This requires not only a high level of training and expertise, but also a sophisticated technical infrastructure. Regarding reconnaissance, results of many different measurements have to be mapped and interpreted to form a comprehensive picture of the overall scenario and its implications. This information might then be used for planning of relief missions to heavily affected areas and in decision support to local authorities. Especially with nuclear accident situations, specific emphasis has to be placed on the future development of the situation. Forecasting capabilities have therefore to be integrated in the decision support systems. Disaster exercises provide a possibility for testing such components under realistic conditions.

ASSESSMENT OF AVERTED FATAL CANCER CASES DUE TO LIMITATION OF RADIOCAESIUM INTAKE WITH MILK FOR POPULATION OF BELARUS AFTER THE CHERNOBYL ACCIDENT

J. Kenigsberg, E. Buglova

Research Institute of Radiation Medicine, Masherov ave. 23,
220600 Minsk, Belarus

After the Chernobyl accident different protective measures for radiation protection of Belarusian population were carried out. As a result, annual reduction of exposure and prevention of significant doses for people of Belarus are registered.

Exposure doses for overwhelming majority of population during all phases of accidental period are conditioned, mainly by the levels of internal doses. For inhabitants of clean and low contaminated territories total doses are formed only by means of internal exposure from consumed foodstuffs, contaminated by radionuclides. For 1.3 million of inhabitants of contaminated territories (with density of radiocaesium contamination more than 37 kBq/sq.m internal doses are higher than external doses in most cases. Only for inhabitants of individual settlements with densities of radiocaesium contamination of territories more than 185 kBq/sq.m, external exposure doses play an important role in total dose formation.

In connection with this, the specific attention during all phases of accidental situation were given to measures, acting to the reduction of internal exposure doses. Internal exposure doses are forming mainly due to radiocaesium intake with ration. Contribution of inhalation component in the total doses of internal exposure is low.

The amount of radiocaesium intake depends on peculiarities of ration structure and caesium transfer by food chain. High specific weight of milk and milk products in daily ration and levels of its radiocaesium contamination are the reasons of main role of milk products in alimentary radioactive intake. As a result of investigation it is known, that for urban and rural population radiocaesium intake with milk can forms 20-24% and 44-54% of total intake with ration correspondingly.

So, establishment of permissible levels for radiocaesium contamination of milk and it revision in the hours of time allows to avert significant part of internal doses.

During intermediate and late phases of accidental situation different permissible levels for radiocaesium contamination of milk were carried out. Since 1986 till 1990 limit for radiocaesium content in milk was 370 Bq/l, since 1991 till 1992 - 185 Bq/l and since 1993 - 111 Bq/l.

Investigation of averted collective doses of internal exposure due to establishment of strict limits in 1990 and 1992 shows the following (table). Averted collective internal dose for urban inhabitants of most contaminated Gomel and Mogilev regions of Belarus forms near 2.2 thousands person-Sv and 1.8 thousands person-Sv correspondingly.

On basis of preliminary estimation it is possible to conclude, that averted collective dose of internal exposure for rural population are similar for those of urban people. But for correct estimation it is necessary to take into account the levels of consumption rate of private milk by rural population. Consideration of this fact can decrease levels of averted internal doses for rural population.

Estimation of averted risks of stochastic effects for urban inhabitants of Gomel and Mogilev regions, that were calculated on the basis of ICRP coefficients, shows that no less than 110 and 88 fatal cancer cases during life and up to 3 cases of genetic disorders among first two generations of descendants of exposed people correspondingly are prevented on a basis of averted doses of internal exposure.

Averted collective dose of internal exposure for urban population of Belarus allows to prevent the probability of occurrence no less than 800 fatal cancer cases and 20 cases of genetic disorders in first two generations.

Data obtained testify that conduction of estimated countermeasure allows to prevent significant part of collective dose of internal exposure and stochastic consequences of accidental exposure for population of Belarus.

Table.

Averted dose of internal exposure and prevented stochastic effects for urban population of Belarus due to establishment of strict limits for radiocaesium contamination of milk.

Region	Averted dose, person-Sv	Prevented fatal cancer cases during life	Prevented cases of genetic disorders in first two generations of descendants of exposed people
Gomel -urban population	2204.6	110.2	2.8
Mogilev -urban population	1758.2	87.9	2.3
Belarus -urban population	16684.0	843.2	21.4

ASSESSMENT OF THE THYROID PROTECTION EFFICIENCY FOR BELARUSIAN CHILDREN AFTER THE CHERNOBYL ACCIDENT

J. Kenigsberg, E. Buglova

Research Institute of Radiation Medicine, Masherov ave. 23,
220600 Minsk, Belarus

During the acute phase of the Chernobyl accident different countermeasures directed on the thyroid gland protection were carried out. The main measures are evacuation and administration of stable iodine.

Evacuation of more than 12 thousands of Belarusian people from 30-km zone at May, 4-5, 1986 provided relative protection of thyroid glands. Besides that, prohibition for consumption of local milk and leaf vegetables were carried out. As far as this measure was established in a few days after the accident, effectiveness of it in reduction of radioiodine uptake by the thyroid gland was low.

The main countermeasure for thyroid protection of no-evacuated people was administration of stable iodine.

It is known, that taking stable iodine is a measure for reducing the uptake of inhaled and ingested radioiodine by the thyroid (1). For guarantee of complete thyroid gland protection stable iodine should be administrated before any intake of radioactive iodine. The uptake of I-131 by the thyroid decreases by 90% if stable iodine is administrated at the time of intake. The effectiveness of the measure decreases with delay, but the administration after the radioiodine intake provides 50-90% of protection depends on the time of taking stable iodine (2).

In case of situation after the Chernobyl accident the criterion of necessity for thyroid gland blocking by stable iodine were dose levels of intervention, expressed in projected adsorbed thyroid doses for first week after the accident: 300-2500 mGy (3,4). These levels are higher than recommended international intervention levels (5). But it is also suitable in case of conduction in time.

For protect of thyroid gland few millions of tablets of stable iodine were distributed among Belorusian people depends on the distance from the Chernobyl station. But there are some reasons to suppose that only 20% of distributed tablets were used for protection (6). In addition, distribution of tablets was begun some days after the accident.

So, it is possible to conclude, that countermeasures for thyroid gland protection of Belarusian people were conducted not in time, that was reason of low effectiveness of thyroid protection. In this situation population of some regions of Belarus and, first of all, children, received the significant thyroid doses. As a result, during years after the accident it was registered the increase of the thyroid cancer incidence rate for Belarusian children (7).

Among children till 14 years in year of accident who were exposed in Gomel region of Belarus 217 thyroid cancer cases were registered during 1986-1994. Administration of stable iodine during first hours after the accident allows to prevent approximately no less than 800 and no more than 2 thousands thyroid cancer cases during life among this group of children.

INTRODUCTION

Due to their relative long half-life and the high transfer factor into foodstuff Cs-isotopes may cause a substantial contribution to the exposure of the population after a fallout from a reactor accident or nuclear weapons' detonations. The reduction of Cs-concentration in foodstuff, therefore, is one of the major goals in proper countermeasures after such a contamination. Ammonium-Ferric-Hexacyano-Ferrate (AFCF), commonly referred to as "Giese-salt", is known to result in a substantial reduction of the Cs-activity concentration in milk and meat when applied with the fodder to the animal. The theoretically achievable reduction in activity concentration under experimental conditions and under scientific surveillance is known and amounts to about 80 - 90 % (1,2,3). Such experiments have been performed up to now on only a few individual animals. The actual reduction, however, which is achievable under realistic conditions is not well known. This reduction depends on such factors as acceptance of application by farmers, knowledge and ability to apply it in the prescribed way, but also on the variability between different animals, etc.

To investigate this question under realistic terms incorporating a large number of animals was enabled by the fact that ammoniumcyanoferrate was applied in an area of elevated ^{137}Cs-activity concentrations in milk in a part of the province of Lower Austria in the first half of 1988 (4). In contrast to the ideal situation of a research farm under controlled and optimized circumstances, the application was performed by several hundred farmers not acquainted to the application before. These had been only trained by members of the local agricultural associations and colleges before application and applied the salt according to their ability and understanding.

Since cyanides are allegedly carcinogenic, prior to application the AFCF was tested for possible long-term effects and in particular for carcinogeneses. The results of these tests shall also be discussed in short.

METHOD

The application of the Giese-salt was performed in an area of about 1000 km^2 involving several thousand cows and some 100 farmers. The region was chosen because of generally higher activity concentrations in milk than elsewhere although samples above EC intervention levels were very rare at the time of intervention. The application lasted for 6 months ensuring that equilibrium conditions were reached (4). The application started only 1.5 years after the Chernobyl event. The reason for this delay compared to ordinary practices after a nuclear fallout was that in the initial phase activity levels in that region were not significantly higher than elsewhere. But, because of the partially semi-natural habitat the long-term decrease was slightly slower than elsewhere in the country. Furthermore, after having realized the higher activity levels in that region, it took some time to get results on the epigenetic and carcinogenic tests providing the basis for approval of the application by the authorities. The application was performed by feeding 2 - 3 g of AFCF per cow each day. It lasted from 1 February to 10 July 1988.

The measurements of the activity concentration in the milk produced were not performed in the milk of individual cows in order to ensure optimum results. Rather the activity concentrations were determined in the milk powder produced in the milk drying plant of that region. By taking milk powder samples each sample averaged about 10000 - 30000 l of milk (5) since the milk is collected in milk collecting tours imploying tanks of about 3000 - 10000 l the contents of which are combined in the drying plant in even larger tanks. Thus, by taking powder samples a good averaging over large feeding areas and a great number of several 1000 individual cows was achieved.

The milk powder samples were measured in 1 l Marinelli-beakers on HPGe-detectors of 20 - 30 % relative efficiency which had been calibrated by intercomparison tests and milk powder standards supplied by the Austrian Research Centre Seibersdorf. Thereby, all measurements, even if they had been from different milk drying plants, are comparable. With a measurement time of 1000 s a detection limit of 5 Bq/kg and an average error of 5 - 7 % with individual samples of typical activity concentrations was achieved.

TESTS ON HARMLESSNESS OF APPLICATION

Ammonium-Ferric-Hexacyano-Ferrate is known to have an extremely low resorption in the body of animals (6). Also practically no transfer into body liquids and particularly milk occurs. Thus no effects in foodstuff should be observed. Despite this low resorption particular attention was paid to possible epigenetic - carcinogenic effects of the substance. Therefore, on behalf of the Austrian Federal Ministry of Health mutagenity tests were performed by the Austrian Research Centre Seibersdorf, Toxicology Departement. They comprised the reverse mutation assay with salmonella typhimurium (AMES) and the micronucleus test (7,8). The micronucleus test was performed on 15 male and 15 female mice in combination with a positive and a negative control group at 3000 mg/kg body weight (7). In the AMES assay AFCF was tested on five different salmonella breeds in two separate tests per breed and at 5 different concentration levels of AFCF with positive and negative controls (8).

AFCF did not show any mutagenity according to AMES nor in the Micronucleus test on NMRI-mice. For health reasons there were thus no obstacles for an application as an additive to fodder in a contaminated area for a limited period of time under restricted conditions (application of 2 - 3 g at most per animal per day)

RESULTS AND DISCUSSION

The weekly average activity concentration in milk powder is given in figure 1 as sum of ^{134}Cs and ^{137}Cs for the period August 1987 (before application) to August 1988 (after application). Obviously, from August to November 1987 the activity concentration decreases only slowly. This is expected due to fixation of caesium in soil and penetration into deeper layers. The effective half-life of this process which was determined for this site in another study over 7 years, amounted to 634 d (9) for ^{137}Cs. This is equivalent to a biological half-life of 672 d. Taking into account that in figure 1 the activity concentration is given as sum of ^{134}Cs and ^{137}Cs, the effective half-life for the sum activity of 540 d is displayed in figure 1. The activity concentration obviously follows this half-life very well during the period August to November.

In December an increase is observed which is mainly caused by feeding of hay which was harvested in summer 1987. The activity concentration, therefore, shows an average value comparable to the hay concentration of that period. This value was also predicted in a study by the Horak et al. (7) in which a large number of grass and hay samples of that region had been measured in summer 1987 and by deploying a transfer factor of 0,004 $d.kg^{-1}$ an average activity concentration of 25.5 Bq/l in milk had been predicted. This activity concentration which should last as long as this hay is fed to the cows (May 1988) is also displayed in fig.1.

With the start of the feeding of AFCF in February the activity concentration in milk rapidly drops to approximately 15 Bq/l followed by a further slow decrease to values around 7 - 9 Bq/l in May and June. The average activity concentration in that period is about 30 % of the value resulting from feeding the hay alone (without application of Giese-salt). Thus, the application of the caesium-binder reduced the activity concentration by about 70 %.

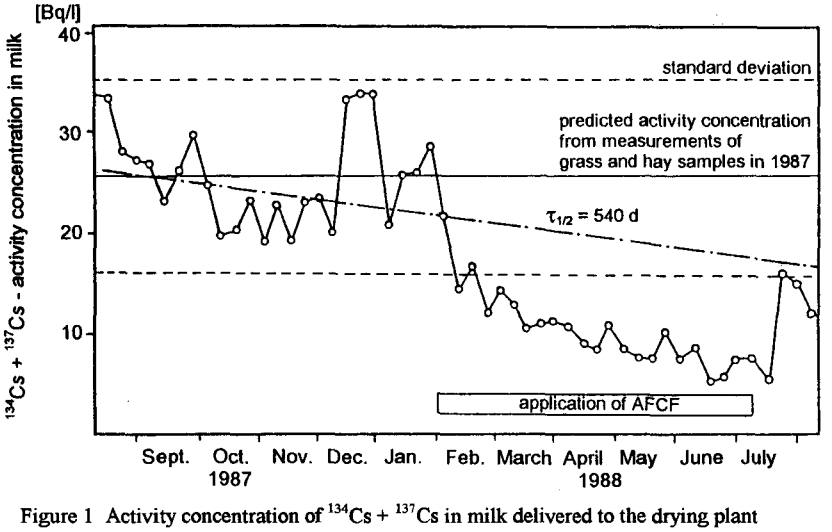

Figure 1 Activity concentration of ^{134}Cs + ^{137}Cs in milk delivered to the drying plant

At the end of the application period (10 July 1988), the activity concentration rises again to about 16 Bq/l. This value would be expected since without application of AFCF and after the winter hay feeding period the activity concentration in milk should be given by the broken-dotted line in fig.1 (resulting from the effective half-life of 540 d as described before). This is well demonstrated by the observed activity levels in figure 1 after mid-July.

Another proof of the reduction effect of activity concentration in milk is given in figure 2 which shows the activity concentration of $^{134}Cs + ^{137}Cs$ in milk in the four major drying plants in Austria in the period January to July 1988. These plants are situated in different provinces in Austria, separated by more than 80 km distance. During the very period all other drying plants show a rather constant value of the activity concentration with plant No.2 and 3 having average milk values of about 10 Bq/l and slowly decreasing to 8 Bq/l on average. Plant No.4 starts off with an average concentration of about 35 Bq/l and stays at this value till about May when the activity levels decrease to about 20 Bq/l. Only in plant No.1 where the AFCF had been applied to the cows, the decrease in activity concentration appears already in February with the beginning of AFCF feeding and stays at this level until June.

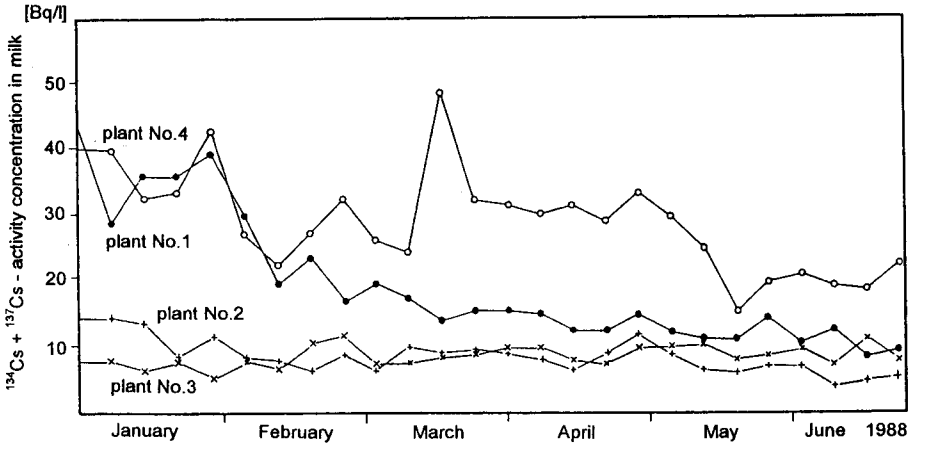

Figure 2 Activity concentration of $^{134}Cs + ^{137}Cs$ in milk in the four major drying plants

CONCLUSIONS

The application of Ammonium-ferric-cyano-ferrate (AFCF), also called "Giese-salt" with reference to its discoverer, may result in a substantial reduction of the activity concentration of ^{134}Cs and ^{137}Cs in milk, even if the drug is applied by farmers not familiar to its application before. Farmers who had been only quickly advised in its application and who had applied the drug for six months, achieved an average reduction in activity concentration by about 70 % during the period of application. This takes into account the variability of Cs-clearance in different individual animals as well as the varying ability of each farmer to cope with the problem.

The decrease in activity concentration is comparable to other efforts to reduce the activity concentration. A reduction by 30 - 80 % had been achieved after the Chernobyl accident in Austria for example by selection of low activity milk in the dairies. The application of AFCF is toxicologically safe and may be satisfactorily performed even by farmers not acquainted with ist application before. It, therefore, is a very valid tool in protecting the public in case of serious ^{137}Cs-contaminations after major nuclear accidents.

INTRODUCTION

Six years after the Chernobyl accident, decontamination actions had been completed in many places, the contamination could be considered as fixed, especially on urban surfaces and the social situation was felt to be stabilized. Under those conditions the efficiency of the « classical » decontamination techniques was under question, it was worthwhile to look at new specific techniques. Besides it was necessary to discuss the interest of new decontamination actions in settlements.
The European Union (EU) sponsored a project ECP 4 in order to look at the opportunities for further dose reduction actions in the contaminated territories of the three republics affected by the accident. The objective was to provide a local decision maker, faced with many alternatives for decontamination, with all the elements for determining what to do according to the various objectives he might pursue. The main results are presented here.

DOCUMENTING DECONTAMINATION TECHNIQUES

The project had a very broad objective. It surveyed usual techniques, techniques that had been designed within the framework of ECP4 (under assumption that they can be made effective at a full scale level), techniques that had been developed or examined by other Programmes, and the « do nothing » option. Exhaustivity was searched for. Actions dealing with all the sources and pathways were considered ; decontamination of urban environment (walls, roofs, yards, roads...), soil decontamination (arable soils and pastures) with chemical and physical approaches, decontamination of forests, protection and decontamination of machines and the decontamination of domestic and industrial food. Laboratory and field experiments have shown that it is still possible to decontaminate walls and roofs on which Caesium remained almost 10 years (for example using water under pressure), or fields in which the fertile layer is too thin for ploughing (e.g. turf harvester), and that modification of cheese making processes can achieve significant decontamination factors (e.g. the Phoenix cheese).
Effectiveness of decontamination has been estimated for about 60 techniques. Figures apply to Caesium, several years after an accident. Some typical results on decontamination factors (Df) are presented here (Table 1).

Table 1: Decontamination yields of Techniques applying to urban objects

Technique	Target	D_f	Constraints	Comments
Turning flagstones manually	Flagstones	6	No	-
Set of tools for dismantling	Houses	∞	No	Need to build a new house
Fire hosing	Roads	1.10	No	Water rinsing
Vacuum sweeping	Roads	1.4	No	Dust close to operator
Roof washer	Roof	2	No	Rot. brush, air compressor
Electric drill, steel wool or sand-paper	Roof (iron), wall (painted)	2-2.3	Possibly scaffolding	Grinding
High pressure turbo nozzle OM-22616	Roof, Wall, Asphalt & Concrete surface	1.3-2.2, 1.7-2.2	No	High pressure water hosing 120 bar
Detached polymer paste	Surfaces (smooth)	4-30	T > +5°C	Transports. Manual work
Sandblasting (dry or wet)	Wall	4 (dry) 5 (wet)	Scaffolding preferable	High-pressure with sand, Whole-body protect/air supply
Polymer coatings	Walls (not wooden)	4-5	T=20-30°C	Humidity <80%
Manual electric cutting machine	Wooden wall	5	Residual nail remove	Upper layer mechanically removed (dust)

Front loader / Bulldozer	Soil	28 / 10-100	No	Scraping top soil (10-30cm) Removes fertile soil layer
Shovel	Garden soil	6	Virgin soil	Digging to about 30 cm depth
Turf harvester (small)	Undisturb. grass. soils,	3-20	No or few stones	Removes the 3-5 cm top soil.
Ordinary plough and tractor	Arable soils	9-12(ext.)	Virgin land	Ploughing to 25-45 cm depth
Deep ploughing	Arable soils	2-4(crop)	Virgin land	Plough soil layer (25-35cm)
Skim-and-burial plough	Arable soils	10-20	Virgin land	5 cm topsoil buried at 45 cm
Liming (special trucks for spreading)	Acid arabic land	1.3-3	Soil pH = 4.5-5.5	Requires K addition, Persistent effect during 4-5 y.
Addition of potassium	Arable lands	1.3-3	No	K addition needed
Organic amendment of soil	Arable soils	1.3	-	Yield and quantity increase
Radical improvement of Pasture (draining, cleaning, disking 3 times...)	Pastures	4-16(peat) 4-9 (podzol)	No	Yield increase
Liming and fertilising	Forest pastures	1.5	Manual	Poor soils enriched by Ca, K
Ferrasin bol or Prussian blue	Cow	2-3	3 bolus/3 m.	Where Cs level > 1000 $Bq.l^{-1}$
Clean fodder to animals before slaughter	Cow	2-3 on meat	2 m. before slaughter	Organisation of special animal feed before slaughter
Phytodecontamination	Soils (mixed)	1.1-1.3.y^{-1}	7 procedures	
Ferrasin filters for milk	Milk	ca. 10	Private farm	If milk contamination> 400 $Bq.l^{-1}$

Other techniques concerning the rehabilitation of forests were examined, as well as techniques for food processing (e.g. alteration of the traditional Tvorog cheese production with a Df of 5).
Techniques have been also documented according the needs of optimisation. Components of the costs were depicted in physical terms: direct manpower and overheads, skill requirements for workers, and needs in education for the public, transportation, consumables, loss of value for products, generation of wastes (solid and liquid volumes, activity and toxicity). Prices were necessary in order to assess costs. A short synthesis was made in order to know the prices of manpower (from 70 to 100 ECUs per month), consumables (e.g. 0.15 to 0.3 ECU per liter for gasoline) and products (e.g. 0.25 to 0.4 ECU per liter for milk). Prices are indeed fluctuant at the local scale but this task was necessary to provide default values and standard values when comparing case studies.

IMPLEMENTATION OF CASE STUDIES

Case studies have been implemented in 4 settlements in order to illustrate a methodology for decision, and to look at cost effectiveness of countermeasures under different conditions (Table 2).

Table 2 : Some features of the case studies.

Cases	Reference Soil contamination ($Ci.km^{-2}$)	Present population	% of pre-accident population	Dominant pathway	Previous actions
Zaborie	66	180	20%	External	Extensive
Kirov	30	500	40%	External	Extensive
Savichi	10	160	20%	External	Limited
Millyachi	5	3200	100%	Internal	Numerous

When dealing with the settlements, no cases were found in which decontamination was desired in order to meet one unique target. The global idea is a desire for a return to a normal life style, by suppressions of interdictions in the formally "evacuated" areas (Savichi, Zaborie) or by alleviation of restrictions in villages in the other areas (Kirov, Millyachi). The need to be less dependent on the restrictions to life style is not a quantified criterion but it is a clearly expressed goal.
Individual doses are a matter of concern that was put forward in the four case studies, but not with reference to the same criteria. Average population dose is a criterion in Zaborie, to be compared with 5 mSv per year. Critical groups of workers have been identified in Zaborie, Kirov, Millyachi, whose doses are still to be compared with 5 mSv (e.g. forestworkers, cowboys,...). Reference to 1 mSv for the average population is also quoted (e.g. Belarus "Passports" on settlements).
It has been said that population stayed or came back in evacuated territories. Direct observations also shown that prohibited land was used either by the people from the settlement or by neighbours.
No objectives were assessed in terms of collective dose. Nevertheless, the gain in collective dose was considered as a good criterion to assess the efficiency of a countermeasure. Cost effectiveness was measured by the « cost of averted Man Sievert ». It was admitted that the most cost effective measure should be applied first in the strategy.
In Zaborie, application of countermeasures was limited by the fact that extensive decontamination took place so that options like ploughing were pointless. However, calculated doses being only slightly higher than 5 mSv (while measured doses are lower), many countermeasures would allow to go below this figure ; cleaning yards, education on mushroom consumption, but combination of agricultural countermeasures. Looking at cost efficiency, actions dealing with yards (Front loader or Bulldozer) or educational programmes yield to a cost of averted Man Sievert below 2000 ECUs, and they would be used first in applying a strategy. The most effective action was the cleaning of the yards surrounding the houses, provided that a local solution for waste disposal is accepted, as was done in the neighbouring settlement of Yalovka. Should generic costs be applied it would be 50 times less effective. Education on mushroom was priced on the basis of one visit per year to each family. Liming, in spite of a poor global impact, has a good cost-efficiency ratio and deserves to be included in the strategy. Both would go along better with a rehabilitation programme. Other options still have interest. Some options yield very high costs for averted Man Sievert, others are limited in their scale of application, because areas fitted for them are limited (e.g. Turf harvester).
Situation in Savichi is such that the effectiveness of countermeasures is usually lower, simply because the contamination levels are lower. Most countermeasures yielded cost of avoided ManSievert higher than 8000 ECUs. Turf harvester and ploughing achieved a cost lower than 1000 ECUs (actually less than 200 ECUs), because there was still room for such countermeasures, so that improving meadows and pastures can be proposed. Cleaning yards remains the most cost effective of the measures dealing with housing. In parallel with the cost benefit analysis, classification of Savichi as a prohibited settlement was reconsidered.
In Millyachi, the importance of internal dose and the high transfer coefficients increase the respective efficiency of agricultural countermeasures. Education for the mushroom consumption remains highly efficient. Many agricultural measures have cost efficiency around 1000 ECU per averted ManSievert, but cleaning yards still remains effective.
Almost in all cases there are actions with a reasonably low cost for averted dose. Should ManSievert be valuated to 5000 ECUs or even 2000, there are indications for application of countermeasures. Besides, it remains true that actions on non disturbed land are among the most efficient and that they are limited in the present case studies.

CONCLUSION

The necessity to undertake new decontamination actions or other dose reduction actions almost one decade after the Chernobyl accident raised serious doubts when the programme was launched. Today, decontamination of all the contaminated territories is still out of reach, but the studies that were undertaken have shown that there are clear indications for action in practical cases. It is believed that this feeling is shared by the local authorities that were involved in the case studies.

MANAGEMENT OF CONTAMINATED AGRICULTURAL ENVIRONMENTS FOLLOWING A MAJOR NUCLEAR ACCIDENT. AN OVERVIEW ON POSSIBLE SHORT-TERM AND LONG-TERM COUNTERMEASURES

Hans Lönsjö

Department of Radioecology, Swedish University of Agricultural Sciences,
PO Box 7031, S-750 07 Uppsala, Sweden

INTRODUCTION

Accidental release of radioelements from nuclear facilities may give rise to severe consequences for the agricultural environment. The deleterious effects will, in addition to the nuclides released and their deposition density, depend on the sensitivity of the agricultural land with respect to climate and soil types and hence the type of agriculture practiced. Another crucial point for the consequences, at least during the first year after the accident, is the point of time in the year when the fallout occurs. In the winter period the deposition mainly will take place on the bare or snow-covered ground sur - face, while a fallout during the vegetation period to a varying extent will be intercepted and retained by growing crops. Depending on the stage of development of the crop and the translocation rate of the single nuclides food and feed can be highly contaminated (the concept of "seasonality", *1*).

CRITICAL NUCLIDES AND EXPOSURE PATHWAYS. DOSE CALCULATION MODEL

With respect to the volatility of nuclides of biological importance, which can be released at a large reactor accident, their abundance will decrease in the following order: iodine isotopes > caesium isotopes > strontium isotopes > transuranic elements. While the radioiodine isotopes ^{132}I and ^{131}I in practice have decayed after one and eight weeks respectively, the effects of radiocaesium (^{134}Cs and ^{137}Cs) and of ^{90}Sr will last for years or decades. Radioiodine and radiocaesium exert both external and internal exposure, while ^{90}Sr (and the relatively short-lived ^{89}Sr) and transuranic elements mainly will be of importance for the internal exposure.

Fallout nuclides in the agricultural environment thus will give rise to external exposure of farmers and others living in the contaminated area and to internal exposure of people eating food with origin from the area. The following general dose calculation model may be used for assessment of the dose contribution from a certain exposure pathway *(2)*:

$$H = C * U * D * P$$

where H means the dose rate to a certain organ or individual, C means the deposition density of a certain nuclide (in *Bq per* m^2) or the concentration of this nuclide in a certain crop product or food stuff (in *Bq per kg*) and U is the utilization rate of this food item or, in the case of external exposure the time of sojourn in a certain environment. D is the dose conversion factor for the nuclide in question (*Sv per Bq*) and P is a dose reduction factor taking into account that the external radiation partly is shielded by soil material, building structures vehicles etc. (as compared with the deposition on a smooth ground surface). In the case of internal exposure P may be considered as a dose reduction factor due to various mitigating actions, which can be undertaken in order to reduce the transfer of the nuclide to a certain crop product or food stuff (as compared with the case where no counter measures have been taken). For calculation of the total dose commitment the contributions have to be summarized for various organs in the body and for all nuclides and exposure pathways integrated over the time and taking a number of natural dose-reducing processes into consideration.

Immediately after a release from a nuclear accident external and internal exposure from the passing plume, and external exposure from nuclides deposited on the ground surface, buildings, vegetation etc. potentially will give doses high enough to cause deterministic effects. After some days decay of the short-lived nuclides the exposure will give rise to stochastic effects only. The external exposure from the deposited nuclides (mainly ^{131}I and $^{134+137}Cs$) will be a dominating exposure pathway, independent of the season when the deposition occurs.

Direct contamination of growing crops will give rise to a number of internal exposure pathways as the nuclides are transferred through the food chains to man. Such a critical exposure pathway is the transfer of radioiodine, radiocaesium and radiostrontium through the chain: pasture grass - grazing cows - milk - man. The effects of a direct contamination will last as long as the crop products are available for feed and food, usually up to one year after the deposition, unless the crop products are condemned.

During the following years the internal exposure will be due to the soil-plant transfer of the long-lived nuclides (indirect contamination). This pathway will usually give much lower nuclide concentrations than after a direct contamination of the crops.

BASES AND STRATEGIES FOR DECISIONS ON COUNTERMEASURES

A number of dispersion models have been calculated for possible reactor accidents, taking various source terms and weather parameters etc. into consideration. The Chernobyl accident in 1986 showed, however, that the dispersion pattern of a radioactive plume can be much more complicated, with respect to variation in deposition density and range of the plume, than can be foreseen in more idealistic models. This fact, in addition to the variation in the radioecological sensitivity with respect to soils and crops, also means that the need for countermeasures in the agricultural environment will vary considerably even between adjacent single farms.

Preparedness planning for the agricultural sector in the case of large reactor accidents includes a number of steps. Besides the basic dose criteria, knowledge of the agricultural environment with respect to soils and crops, population and livestock density etc. will be of importance for predictions of the consequences. Transfer factors for the various nuclides and steps in the food chain, obtained in experimental or environmental studies, will also be a necessary tool. Early warning systems, locally for the environment around single nuclear facilities and on a national or international basis, will be valuable in order to prevent exposure leading to deterministic health effects, but also in such a way that countermeasures can be taken in advance before the passage of the plume. A well established organization for monitoring, sampling and nuclide specific activity measurements will be of utmost importance as a basis for fast decisions on suitable countermeasures. Open and continuing information from the authorities to farmers and others living in the contaminated area will also be important, as any for psychological reasons.

As soon as data on deposition density and nuclide concentrations are available these should be used in prediction models for calculation of the expected nuclide concentrations in crop products, milk, meat etc., as to estimate whether these will be acceptable for human consumption or should be discarded. A continuos following up of the monitoring will be necessary during the vegetation period. All countermeasures should be based on the dose criteria given by ICRP and the cost of an action should be reasonable in relation to the value of the saved dose commitment (*3*).

COUNTERMEASURES FOR THE AGRICULTURAL ENVIRONMENT

A number of possible countermeasures for various situations after an accidental release are discussed and evaluated below. The fallout is assumed to take place just before the first harvest of grass for hay or silage.

A. The acute situation (the first week after the accident).

If the early warning time permits and the trajectory of the plume can be foreseen *evacuation* of persons not involved in the livestock management should be undertaken to prevent exposure from the passing plume and deposited activity. Grazing cows should be installed. Harvest of uncontaminated forage, e.g. by using modern techniques for enwrapped silage, would be an effective countermeasure in such a situation. For persons staying on the farm *sheltering* or *indoor sojourn* during and after the passage of the plume should be recommended as far as possible. *Intake of stable iodine* before or up to 30 min. after the passage of the plume would be an effective mean as to reduce the thyroid dose. After the passage of the plume all field operations should be postponed and the use of food and feed should be restricted until the fallout has been monitored with respect to external exposure and nuclide contents in the crops. (*3, 4*).

B. The intermediate situation (from one week up to one year after the accident)

The restrictions for field operations and for use of crop products should remain until the external exposure has become acceptable and the deposition density and the nuclide concentrations in animal and crop products can be estimated. If the concentrations of critical nuclides in the crop products will not be judged as acceptable as food or feed, *removal and discarding of growing crops* may be a way to reduce the deposition density of the land. A dense crop may initially intercept up to 50% or more of a deposition, why fairly concentrated wastes are obtained. After removal of such a highly con - taminated grass crop the new growth, however, may be acceptable with respect to the nuclide concentration (compare C below). *Removal of contaminated soil* etc. around the farm buildings may be effective for reduction of the external exposure.

C. The long-term situation (one to ten years after the accident)

During this period of time the internal exposure mainly will be due to the soil- plant transfer of radiocaesium and ^{90}Sr. The transfer factors for ^{90}Sr have been shown to be up to one order of magnitude higher than for radiocaesium and for both elements the transfer usually will decrease in the order peat soils > sandy soils > clay soils. The possible strategies for reducing the long-term effects refer to the following categories (*4*): *a. removal of the contaminated soil surface layer; b. deep placement of the contaminated layer; c. application of agrochemicals to the soil* (or application of feed additives) and *d. changing the line of production* (*4* and refs. cited here)

Scraping of the contaminated surface soil for removal and deposition can be a rather efficient method for decontaminating agricultural land, although the costs will be high. For handling the large amounts of soil (350-600 tons per ha) special equipment is needed and the work has to be carried out under ideal conditions. Therefore this method will hardly be realistic for large scale operations. On grassland the use of flail-type forage choppers with equipment for removal of the crop may be a method for the removal of a contaminated crop and the upper part of the contaminated sod

By ploughing the contaminated land the fallout nuclides will be distributed in a 20-30 cm deep soil layer and thus be less available to the crops as compared with a distribution in the uppermost few cm. Ploughing up contaminated grassland, wherever this will be possible, followed by the establish- ment of a new grassland will almost always reduce the nuclide transfer to a factor 5-10 or even more. By deep ploughing or by use of specially designed double layer ploughs a deeper placement of the contaminants can be obtained than after conventional ploughing. However, such ploughs are rare and have a low capacity. All ploughing should be performed under ideal conditions as to be a successful mitigating action.

Application of potassium fertilizers usually will depress the transfer of radiocaesium (by a factor of 2-3 or more at annual applications of 100-200 kg K per ha) and liming acid soils will reduce the transfer of ^{90}Sr and often also of radiocaesium. Generally a well-balanced fertilization, aiming at a positive potassium balance and an optimal pH of the soil, will give a sustainable low transfer of most radioelements.

By changing the line of production of the farm, e.g. from growing crops where vegetative parts are utilized (grassland crops) to cereal or seed crops, a reduced nuclide transfer into the food chain will be obtained. Usually a combination of the various measures will be necessary for the best outcome of the problems.

Practical application of Control Level (CL) distinguishing the production as "pure" (contamination level below CL) and "dirty" (above CL) requires a special analysis of strategies in the field of countermeasures (CMs). It has been shown, that implementation of CM under conditions of inhomogeniety of radioactive contamination (of areas, products) can give non-trivial results, e.g., an increase in collective dose due to differential uses of pure and dirty produce. Based on the analysis of contamination structure before and after CM, it has been shown that, whereas radionuclide removal with dirty produce is decreased, radionuclide content in pure production as a result of CM can be increased, even in unchanging gross production level. Besides, average contamination of pure produce after CM also may be increased. It has been, that CMs such as radical amelioration of pastures and ferrocyne treatment can result in 20-50 fold increase of radionuclide content in pure milk. Therefore, in spite of a general diminishing of radionuclide content in products obtained, population dose can be increased after CM as a result of consumption of pure and processed dirty production. CMs in agriculture give increased percentage of pure production. In this case, it is only based on complex analysis of radiological and economical parameters that effectiveness of introducing the CM can be estimated (e.g., using cost-benefit analysis; the cost-effectiveness analysis is not applicable in this case). A similar approach used for estimation of changes in the structure of contamination of products in the course of time (due to radioactive decay and self-cleaning) also results in a conclusion of possible increase of collective dose during the subsequent years.

ABSTRACT (See instructions overleaf)

We have investigated the influence of incorporated by roots radiocaesium on its uptake processes. 3-day pea seedlings were growing for week on the radiocaesium chloride solutions with specific activity from 0.2 to 519 kBq/l. Stable caesium chloride was added in these solutions in concentration of 1 μM/l to achive the equal chemical conditions for various variants. The all amount of radiocaesium from solutions was absorbed by plants over the week but its distribution within the roots was different for various accummulated doses. Apex radioactivity was equal to 14.9 % from radioactivity of whole root for dose of 0.004 Gy and 1.9 % for 2.475 Gy. That is in the later case roots faster absorbed caesium and redistributed it from root to stem under influence of chronic irradiation. There was an another evidence of it. The root apeces after previous chronical irradiation have accumulated radiocaesium in 4 times greater during 2 hours than control ones. So we could supposed greater level of radiocaesium accumulation by plants in conditions of chronic irradiation on the radionuclide contaminated places. This is especially important for developing of the efficient countermeasures for radiation protection in the environment.

ABSTRACT (See instructions overleaf)

"OPTIMAL SYSTEMS OF COUNTERMEASURES S AND UNIVERSAL ALGORYTHM OF DECONTAMINATION OF RADIONUCLIDE,S CONTAMINATED SOILS" Y.Kutlakhmedov,A.Jouve,N.Zezina,A.Micheev (ICBGI NAS of Ukraine,IPSN CEA,France)(Abstract)

1.We provided of comparative analysis of efficacy methods and means decontamination of soil which were contaminated of radionuclide after accident on ChNPP.It was calculated Cd(coefficient of decontamination)of different countermeasures on criteria of decreasing individual and/or collective doses for population.

2.All possible means and methods decontamination can be divide on the two groups:the first - for ploughed soils(after accident);the second - for unploughed soils and territories.

3.It was created universal algorythm for election of means and methods decontamination of soil for different conditions.

The optimal choice of means and methods of decontamination depends from next circumstances: a) Ploughed or unplouged the soils; b)The characters of distribution of radionuclides on profile of soils ; c) The aims of decontamination (agricultural usage of territories,usage of territories for recreation ,The decreasing of individual and/or collective doses for population); d) The relation of benefit - cost for concrete countermeasures.

USE OF SAPROPELL SEDIMENTS AS A COUNTERMEASURE FOR CONTAMINATED SOILS

ABSTRACT

The objective of this study is the characterization of a set of sediments in terms of radiocaesium specific sorption properties and the development of laboratory tests in order to provide reliable tools for predicting the amendment effectiveness of sapropell sediments in radiocontaminated freshwater sediments. Results for radiocaesium and radiostrontium partitioning between freshwater and sapropell sediments and values of adsorption and desorption distribution coefficient (K_d) for these sediments have been obtained, using two experimental protocols. Results show that: for radiocaesium, significant fractions are irreversibly retained in the freshwater sediments and not involved in the partition process between the two systems; for radiostrontium, the systems are completely reversible. It can be concluded that in the area of terrestrial radioecology the efficiency of the use of sappropell sediments as soil amendment will be confined: for radiocaesium, to soils of very low radiocaesium interception potential; for radiostrontium, for soils of very low cation exchange capacity.

INTRODUCTION

After the Chernobyl accident and the contamination of large areas with radiocaesium and radiostrontium a broad of countermeasures have been tried in order to put a brake on the soil-plant transfer of these radionuclides. In the recent past, such measures were most frequently focussed on liming and mineral fertilizing combinations mainly to radiocaesium. It has been found that the effect of liming and or potassium fertilization can reduce the radiocaesium level in the crop by a factor of 3 to 4 (1). It is generally accepted that these measures operate at the plant level and do not improve the condition of the soil. A number of additional countermeasures which do operate at a soil chemical level was tested in the field. Such measures are based on the addition of a range of adsorbent materials (zeolites and others) to the soils. Sapropell sediments which are characterized by very specific sorption properties for radiocaesium and radiostrontium, have been used in Chernobyl area as a countermeasure for radiocontaminated soils (2). Sapropell sediments are originate from deposits at the bottom of natural lakes in the CIS countries, particulary in Belarus and Ukraine. They are composed of indigested vegetal and animal residues decomposed under anaerobic conditions. The main purpose of this study is the characterization of a set of sapropell sediments in terms of radiocaesium specific sorption properties and the development of chemical tests in freshwater sediments in order to provide reliable tools for predicting the effectiveness of sapropell sediments in soil amendments. Laboratory experiments have been performed with freshwater sediments and a sapropell sediment (used as adsorbent because its high selectivity for caesium ions). Since the mechanisms of radiostrontium and radiocaesium sorption in freshwater sediments are identical with those in soils the conclusions and experimental protocols of this study are also applicable in the area of terrestrial radioecology.

1. PHYSICO-CHEMICAL CHARACTERIZATION OF SEDIMENTS

1.1. Materials and methods

A set of five sapropell sediment samples from Turichanskoje (TL1, TL2), Orechovskoje (OL1, OL2) and Snovskoje Lakes (SL1) (Belarus) and three freshwater sediments T2 (Tejo river, Portugal), A (Tejo estuary, Portugal) and KR-4 (Kiev reservoir, Ukraine) have been characterized in terms of cation exchange capacity (CEC), using the silver thiourea procedure (3), organic matter (OM) content (weight loss at 750°C), pH values (solid/liquid = 1/10 and 10^{-2} M KCl) and specific radiocaesium interception potentials, i.e. $[K_d m_K]$ and $[K_d m_{NH4}]$ values (4).

1.2. Results and discussion

Table 1 summarizes all the sediment parameters determined. It is seen that, CEC values cover a range of 7.5 to 45.0 meq.100g^{-1}. Organic matter contents cover a range of about 10 to 20%. Normalizing CEC values with respect to O.M. content leads to values in the range of 0.8 to 2.7 meq.g^{-1} showing that exchange capacity is to a major associated with organic matter. The $[K_d m_K]$, $[K_d m_{NH4}]$ and ($K_c(NH_4/K)$) values cover a range typical for soils and sediments (4) although the values obtained for samples OL1, OL2 and SL1 are quite low and similar to what is found for podzols and peat soils (5).

Sediments	pH	O.M. (%)	CEC meq.100g^{-1}	[$K_d m_K$] meq.g^{-1}	[$K_d m_{NH4}$] meq.g^{-1}	$K_c(NH_4/K)$
TL1	7.8	15.6	13.5	1.05	0.16	6.5
TL2	7.9	17.0	13.8	1.13	0.16	7.1

KR-4	6.0	16.5	45.0	3.90	-	-

Table 1- Some relevant parameters for sapropell and freshwater sediments.

2. PARTITIONING OF ^{137}Cs and ^{85}Sr BETWEEN FRESHWATER AND SAPROPELL SEDIMENTS

2.1. Materials and methods

Partitioning of ^{137}Cs between one sapropell sediment (TL1) (used as adsorbent) and the freshwater sediments T2, A and KR-4 has been studied according to the following procedure:

Sediment samples (1g, enclosed in a dialyse membrane with 5ml 0.005N $CaCl_2$) and sapropell sediment (1g, also in a membrane with the same solution) were equilibrated with 200ml of a mixed 0.005N $CaCl_2$ and 10^{-4} N KCl solution for 4 days (one-time equilibration). This procedure leaves both systems essentially in the homoionic bivalent ion form. After equilibration, two protocols were followed:

2.1.1. Protocol (a)

The sapropell sediment sample (TL1) was set aside (to be used in a desorption test) and the freshwater sediment was contaminated with ^{137}Cs by equilibration with 50ml of a mixed 0.005N $CaCl_2$ and 10^{-4} N KCl solution labelled with ^{137}Cs (2 days, end-over-end shaking). The values of the distribution coefficient K_d were obtained by monitoring the activities of equilibrium solution and the sediments. The sapropell sediment (in the membrane) was then reintroduced and the systems were equilibrated (end-over-end, shaking). Countings of solution, freshwater and sapropell sediments, were made after an equilibrium time of 3 and 10 days. With these measurements it is possible to obtain the partitioning of ^{137}Cs between freshwater and sapropell sediments, the K_d (adsorption) for freshwater sediment and sapropell sediment (in the desorption process from the freshwater sediment), and the K_d (desorption) for the freshwater sediment.

2.1.2. Protocol (b)

This protocol is exactly identical to (a), except for the fact that the freshwater sediment sample was first removed and the ^{137}Cs was first introduced into the sapropell sediment. This procedure generates K_d (adsorption) for the sapropell sediment and freshwater sediment (in the desorption process from the sapropell sediment) and K_d (desorption) for the sapropell sediment. Protocols (a) and (b) differ merely in the sequence of the addition of reagents, and the entire procedure is a common final state experiment.

The same common final state procedure was used to ^{85}Sr, except that the composition of the liquid phase used for preequilibration of freshwater and sapropell sediments was only 0.005N $CaCl_2$.

2. 2. Results and discussion

Table 2 summarizes all data for 3 and 10 days of equilibration times, in terms of the ratio of ^{137}Cs contents and adsorption distribution coefficients for freshwater and sapropell sediments, for protocol (a) and (b). It is seen that the ratio of ^{137}Cs levels on sapropell (TL1) and freshwater sediments differ significantly depending on the fact if the sediment or sapropell are first labelled (protocol (a) or (b)), showing an irreversibility pattern of radiocaesium in the sediments. It appears furthermore that the ability of sapropell to desorb radiocaesium from freshwater sediments is quite limited, due to the very low interception potential to radiocaesium, and decreases with increasing [$K_d m_K$] values of the sediments (Table 1). Applying the argument developed for calculating the levels of radiocaesium fixation by sediments using clinoptilolite as adsorbent (6), ^{137}Cs levels of about 50-65% (T2), 45-65% (A) and 45-70% (KR-4) were obtained, for equilibration times of 3 and 10 days respectively.

Table 3 shows the results obtained for ^{85}Sr using protocols (a) and (b) and for equilibration times of 3 and 9 days. It is apparent that the partitioning of ^{85}Sr between the sapropell and freshwater sediments is identical in protocols (a) and (b), i.e. the system is completely reversible. Moreover the ^{85}Sr in TL1/^{85}Sr in sed. ratios are in excellent good agreement with predictions based on the sorption distribution coefficient values for the systems. The statistical averages of distribution coefficient ratio (sapropell/sediment) are: 1.2 ± 0.1 (T2), 0.46 ± 0.02 (A)

and 0.34 ± 0.02 (KR-4). These values confirm the reversible nature of the process. Evidently the use of sapropell to reduce radiostrontium availability in sediments, based on ion exchange selectivity, should be restricted to sediments of very low cation exchange capacity.

Table 3 - Radiostrontium partitioning between freshwater and sapropell (TL1) sediments for equilibration times of 3 and 9 days.

CONCLUSIONS

It can be concluded that for radiocaesium, significant fractions are irreversibly retained in the sediments and, accordingly, desorption yields are lower. In the case of radiostrontium, desorption yields from sediments are consistent with complete reversibility. In the area of terrestrial radioecology "practical" results of the use of sapropell sediments as soil amendments can be expected: for radiostrontium, only for soils of very low cation exchange capacity and by using high capacity and high Sr-selectivity adsorbents; for radiocaesium, successful application of such amendments will be limited to soils of very low radiocaesium interception potential.

INTRODUCTION

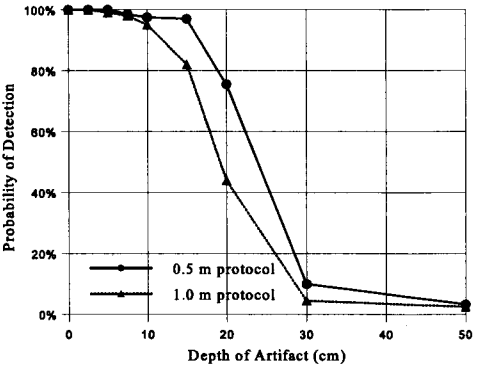
The distribution of contaminants in soil varies from site to site depending on the transport processes that have occurred. Natural transport processes tend to produce a continuous or homogeneous distribution. Human activities, such as earth moving, often result in a discontinuous or heterogeneous distribution presenting special problems for characterization and cleanup. The volume of suspect soil can be orders of magnitude larger than the volume of the discrete particles and pockets of contaminated soil that are present. It is desirable to characterize soil with discontinuous contamination in sufficient detail to allow cleanup of only the contaminated material and to determine with a reasonable certainty, that the material remaining following the cleanup does not require any further action.

In Canada, the Low-Level Radioactive Waste Management Office (LLRWMO) manages historic radioactive wastes that are a federal responsibility. The LLRWMO has developed and refined methods to characterize and verify the success of cleanups of soil with heterogenous uranium mineral and radium contamination. A combination of surface and sub-surface measurements are collected and statistically analyzed to determine the cleanup limits. The LLRWMO has been successful in cleaning up industrial and residential properties affected by heterogeneous contamination. Tens of thousands of cubic metres of uncontaminated soil, from 45 hectares of industrial land in Fort McMurray, Alberta and hundreds of private residential properties in Scarborough, Ontario have been freed from further actions or restrictions. This paper presents the methods the LLRWMO has developed and used for characterizing soil with heterogenous uranium ore and radium contamination, and for verifying the success of environmental cleanups. Examples from LLRWMO projects are described.

METHODOLOGIES

Surface readings are used as much as possible because of the economy of data gathering. The primary method used for surface characterization is the Large Area Gamma Survey System (LAGS) system that has been developed by the LLRWMO (1,2). Gamma radiation data are collected continuously along specified lines (generally one-half meter or one meter lines) of pre-established blocks and read along with location data into a computer. At the completion of each survey block, the collected data are analyzed and the locations of discrete anomalies in the data are identified for followup investigation. This is accomplished by a combination of manual detailed surveys and computer analysis. The computer analysis, called discriminant analysis, is a statistical technique whereby an empirical relationship between the quantitative variables and the classification of an object are established from a calibration set (2). Several different statistical tests are performed on the data, each of which results in a value indicating the probability of the presence of a discrete radioactive source. Several methods of identifying larger areas of possible radioactive contamination have been developed, each relying on the interpretation of a type of site map. The detection limit for a discrete source is de-

Figure 1: Probability of Detection by Depth
(37 kBq cRa-226 Artifact)



pendent on the depth of the source. Figure 1 shows the probability of identifying a 37 kBq eRa-226 source as a function of depth. These probabilities were determined by empirically verified computer simulation assuming a typical background, and using the most sensitive system settings with acceptable false positive rates. It is clear that discrete sources of this activity deeper than 30 cm are not likely to be seen by the LAGS survey.

In areas where the depth of human disturbance is greater than 30 cm, boreholes or test pits/trenches are required to obtain an indication of the presence of contamination. The frequency of sub-surface investigation levels depends on the circumstances at the site, including the original source, the method of dispersion, and the size of the area. For areas of up to several hectares, where earth moving activities have increased the affected area 10-fold, a 20 m grid spacing for subsurface locations has been used. For sites with shallow disturbance (to about 3 meters depth), test pits are the preferred approach unless restoration of landscaped areas prevents their use. Test pits allow a much larger area for inspection and sampling than boreholes. Such shallow test pits can be excavated, inspected for depth of disturbance, the disturbed area sampled and backfilled, cost-effectively. In areas where a review of surface and subsurface data suggests the presence of contamination, carefully placed test trenches can be used to better characterize the area. The trenches can be installed in lifts, each of which can undergo a surface LAGS survey, and each trench can then be inspected and sampled.

APPLICATIONS

During an investigation of an historic uranium transportation network from Port Radium, Northwest Territories to Fort McMurray, Alberta, a number of sites were identified as having been contaminated by spillage of uranium ore and concentrates. This transportation network served mines operating from the 1930's to the 1950's, and carried ore along a 2,200 km water transportation system, through the barge to railcar transfer station in Fort McMurray, Alberta, and on to Port Hope, Ontario for refining. The original spillage occurred at material handling locations such as portages along the route and at warehouses. However, movement of materials on these industrial sites, such as by grading and tracking by vehicles has distributed discrete fragments of uranium ore over a much larger area.

Preliminary investigation in Fort McMurray determined that some 45 hectares of industrial land potentially contained some amount of uranium ore contamination. The object was to establish the area requiring cleanup and to verify both that the cleanup was successful in the areas where cleanup was conducted and that no cleanup was required elsewhere on the properties. As part of the characterization of suspect properties in Fort McMurray, a representative 10% of the surface areas was surveyed using the LAGS system. Part of this LAGS analysis was conducted in trenches that were excavated in lifts that extended to the depth of disturbance. Data were analyzed for small discrete pieces of uranium ore and areas identified by this method were investigated with an intensive hand-held instrument scan. Identified sources were removed and characterized for uranium content to determine whether the cleanup criterion for the project was exceeded. This permitted characterization of the detailed nature of these contaminating particles (volume, mass, composition) and their spatial density (number of contaminated particles per 100 m^2). Following cleanup, a comprehensive verification program was carried out. The program consisted of 100% surface LAGS surveys, both in areas which had been excavated as well as areas where no excavation had taken place. In areas where no excavation had taken place, test pits were excavated on a 20 m grid, the depth of disturbance limit identified, and a sample representating the disturbed material taken. Trenches were excavated in areas where the analyses of surface and test pit data indicated the likelihood of additional buried contaminated material. In excavated areas, soil samples were taken and portable gamma spectrometer readings were made.

As of 1995, approximately 30 hectares of industrial land in Fort McMurray had undergone characterization, cleanup and verification activities. Following successful completion of the verification program, no restrictions on land use were required. Approximately 31,000 m^3 of contaminated soil has been removed from the properties. The area requiring cleanup was 5.3 hectares. The cost of verification in Fort McMurray is approximately $13,000 per hectare or approximately $12/$m^3$ of cleaned up material, and is roughly equal for verifying that a cleanup is successful or verifying that no cleanup is required. The cost of cleanup, restoration and management of waste for this project is approximately $80/$m^3$. Since about 80% of the 30 hectares affected did not require cleanup, the savings compared to cleaning up the entire area potentially affected by distributed contamination may be $10 to $12 million. Table 1 contains a summary of this information.

In the fall of 1980, mildly contaminated soil was discovered in the residential community of Malvern in Scarborough, Ontario. The contaminant was Ra-226 from a radium recovery operation that took place in the 1940s on a farm that subsequently was developed in the 1970s. The contaminated materials included bulk soil contamination as well as discrete sources of radium-contaminated waste. Soil grading and spreading operations during the construction of the residential lots appeared to have spread these small artifacts beyond the limits of the original farm site. In the spring of 1990, a second finding of radium contamination was discovered within Malvern at a site located approximately one kilometre north of the old farm. Investigations of the new site indicated the primary source of the radioactivity to be radium impregnated pieces of plastic tubing similar to tubing found at the 1980 site. During the summer of 1990 a cleanup was conducted and approximately 20,000 pieces of radium contaminated tubing were identified and recovered from 2,500 m^3 of soil.

The discovery of the second site of radium contamination prompted concern that additional contaminated waste may have been discarded at other locations within the Malvern community. The objective of the survey program was to ensure that no additional sites, similar to the two already found, existed in Malvern. From 1992 until 1995 gamma radiation surveys were conducted at more than 1,000 residential properties and 14 schools in the Malvern area covering about 5% of the total area of Malvern. The surveys consisted of LAGS surface surveys with followup surveys for all alarm conditions. No additional sources of contamination were encountered. This extended survey program, which cost about $875,000, provided sound data to release suspicion from several thousand properties in Malvern from possible future restrictions. Summary data are presented in Table 1.

In 1995, a cleanup of some 16,600 m^3 of contaminated soil was conducted at 65 properties in Malvern. As a result of the extended surveys, 25 of these properties, all within a 0.75 km radius of the original source of contamination had been added to the original list. Following this cleanup a verification program was conducted to ensure that the cleanup criteria had been met. The verification program consisted of a LAGS survey over the entire property, soil samples and portable gamma spectrometer readings inside the excavations and perimeter boreholes logged by portable gamma spectrometry around the excavations.

Table 1: Summary Data For Fort McMurray and Malvern Radiological Surveys

	Fort McMurray	Malvern
Area Potentially Affected With Distributed Contamination	30 ha	1,400 ha
Area Surveyed	27 ha	65 ha
Area Freed From Further Action	21.7 ha	1, 397
Area Found Contaminated (Requiring Cleanup)	5.3 ha	3.3 ha
Cost of Survey	$375,000	$875,000

CONCLUSIONS

Techniques for characterizing distributed sources of radioactive contamination have been developed and applied by the LLRWMO. Unnecessary cleanup work has been avoided and restrictions due to possible radioactive contamination are not required on some 1,400 hectares including thousands of residential properties in the community of Malvern in Scarborough, Ontario, and 30 hectares of industrial land in Fort McMurray, Alberta.

MODELLING EXTERNAL RADIATION DOSES IN CONTAMINATED URBAN AREAS: IMPLICATIONS FOR DEVELOPMENT OF DECONTAMINATION STRATEGIES

K.G. Andersson

Contamination Physics Group, Environmental Science and Technology Department, Risø National Laboratory, P.O. Box 49, DK-4000 Roskilde, Denmark

ABSTRACT

The Chernobyl accident in 1986 highlighted the need for contingency strategies for identification and mitigation of the potential long-term consequences of a radioactively contaminated (essentially with ^{137}Cs) urban environment.

To satisfy this need, the PC model URGENT has been developed. The model predicts, as a function of time, the dose rate in urban environments of various population densities. Input parameters for the model, together with associated uncertainties, were derived mostly from in situ measurements following the Chernobyl accident.

The model shows that in the case of dry deposited fallout, indoor surfaces can make a significant contribution to the total radiation dose. This is addressed in terms of 'location factors' which describe potential fractional dose inside the buildings.

In principle, URGENT can be used to describe any decontamination procedure and assess its effectiveness at any time after deposition. Worked examples of how the calculations can be exploited in the development of decontamination strategies are given.

INTRODUCTION

The PC model URGENT for calculation of the time-dependence over longer periods of the dose-rate contributions from different ^{137}Cs contaminated surfaces in the urban environment is essentially based on a set of coupled first order differential equations. However, the time-dependence can not be adequately described by this system for all radiocaesium migration processes. For instance, the weathering processes for roofs, roads, pavements and walls have been modelled by two component functions, as it was clear from the in situ measurement data recorded after the Chernobyl accident, that different fractions of the radiocaesium initially deposited to these surfaces were weathered off with different half-lives (1).

Where possible, the dynamic model has been based on measured data from investigations reported by other workers as well as measurements made by the Contamination Physics Group at Risø. The calculations of the resulting gamma dose rates are currently made using the dose conversion factors presented by Meckbach et al. (2).

The structure of the model, where the various compartments represent different fractions of the deposited radiocaesium on the surfaces in different states (loosely held, fixed, penetrated, etc.) allows a simulation of practically any dose reduction countermeasure by removal of a part of the contents of one or several compartments.

RESULTS/DISCUSSION

In the following is given an example of an application of the model. Consider a scenario, where a dry deposition of ^{137}Cs has occurred in the early spring (when deciduous trees were in leaf) to a highly populated area in the city, consisting of two-storey row-houses, paved areas, roads, and also some green areas with a few trees.

The relative initial distribution pattern of radiocaesium on different surfaces can be assumed not to differ significantly from the typically recorded values for urban dry deposition (3). Based on a limited local Danish poll, the assumption has been made that the average person spends 85 % of the time indoors and 15 % of the time outdoors. The general validity of this assumption has been indicated by the results of a recent state-wide survey of the activity patterns of Californians (4). It is assumed that

the time spent indoors is equally distributed between the two residential floors of the building. However, in detailed strategy formation, the dose rates to people on the individual floors of a multi-storey building should also be considered, as for instance the contamination on the roofs of these buildings may give a large contribution to the dose rate to people living on the top floor, but at the same time give a negligible contribution to the inhabitants of the ground level flats.

Using the above assumptions the URGENT model can be used to estimate the dose rates or accumulated doses to an average person in the considered type of environment at different times following contamination.

Through the years following the Chernobyl accident numerous clean-up procedures have been investigated (5), and the most promising of these were recently investigated in semi-large scale in the Novo Bobovitsi settlement in Russia. Although a strategy certainly may not include decontamination operations for all types of surface, it was found from the field investigations that for environments such as that under consideration, the most cost-effective means of decontamination of the individual surfaces were probably to use a specially developed roof-washer (5) for roofs, high pressure water treatment for walls, cutting of trees and bushes, sweeping of roads and a 'triple' manual digging procedure (5) for grassed areas and bare soil, whereby the top layer containing most of the contamination is buried under shielding layers of soil. These procedures have been simulated by the model.

Table 1 shows the calculated percentage dose reduction achievable by these methods if they are initiated 6 months or 10 years after the deposition took place. Figures are given for both the reduction of the total accumulated life-time dose over 70 years by application of a method and for the reduction in dose-rate at the particular time when the method is applied. Also given is an estimate of the costs of the procedures.

Table 1. Costs and benefits of application of different clean-up methods in an urban row house environment. Percent reduction of accumulated doses over 70 years and of immediate dose rate reduction are given, assuming that clean-up is initiated 6 months or 10 years after deposition.

Surface:	Roofs	Walls	Roads	Trees	Soil
% 70-y dose red. (6 months after)	2.7	1.6	1.1	4.5	63.7
% dose rate red. (6 months after)	6.0	1.3	3.5	28.2	42.1
% 70-y dose red. (10 years after)	0.3	0.4	0.1	0.2	22.5
% dose rate red. (10 years after)	1.2	1.5	0.5	3.9	68.0
Costs (ECU/m^2)	2	1.7	0.1	7	0.5

From Table 1 it is clear that a cleaning of the areas of soil would give the greatest effect, both after 6 months and after 10 years. As the natural reduction of the dose rate from soil areas is rather limited compared to the effects of weathering on most of the other surfaces in the environment, the dose rate contribution from the soil will become relatively larger with time. As the cost of triple digging is relatively small, clean-up of grassed areas would be given first priority in a clean-up strategy for this scenario.

Even if 10 years go by before the garden is dug, it is still possible to reduce the total accumulated dose by almost one-fourth by digging the garden. However, it is clear that in urban centres with smaller garden areas, the other surfaces will be much more dominant. It is therefore important to tailor a strategy for use in a specific type of area. It should be mentioned that recent investigations in Russia have shown that the dose contribution from roofs after 9 years (and certainly earlier) may in some cases be much greater.

Calculations, in which URGENT output for dose rates inside and outside different buildings due to an outdoor deposition has been compared with a semi-empirical indoor deposition/dose model, have shown that in some dry deposition scenarios the indoor deposition may contribute greatly to the average dose-rate. The semi-empirical deposition model was based on the following equation:

$$D_i / D_o = (V_d / V_{dg})\, f\, \lambda_r / (\lambda_r + \lambda_d),$$

where D_i is the average deposited contaminant concentration on indoor surfaces, D_o is the deposited contaminant concentration on a smooth, cut lawn, V_{dg} is the typical deposition velocity to a cut grassed

surface, $V_d = \lambda_d$ v/A (where v is the indoor volume, A is the indoor surface area and λ_d is the rate coefficient of deposition, in other words: the fraction termed λ_d of aerosols in the building deposited per unit time). λ_r is the rate coefficient of ventilation (the fraction termed λ_r of air exchanged per unit time), and f is the filtering factor (the fraction of aerosols in air entering the building which is not retained in cracks and fissures of the building structure). Parameters for ^{137}Cs, which are believed to be realistic estimates, were found from practical investigations (3,6): $V_{dg} = 4.3\ 10^{-4}$ m/s, $\lambda_d = 0.8\ h^{-1}$, $\lambda_r = 0.4\ h^{-1}$, f = 1.0.

It was further assumed that the average indoor contamination level decreases to 70 % in 10 years. The effective dose rates were calculated at 1m above the floor of a room with a ground area of 4m by 4m and a height of 3m. The dose contributions from scattered radiation and deposition on indoor surfaces of neighbouring rooms were not included in the calculations, which were made for three different types of environment, where the essential difference is the shielding provided from outdoor contamination. The results in Table 2 are presented as location factors (defined as the ratio of the effective dose rate received indoors to that received outdoors following a uniform deposit of radiopollutants).

Table 2. Calculated location factors 10 years after a dry deposition of ^{137}Cs to different housing areas, assuming that no indoor deposition occurs and assuming that an indoor deposition does occur.

Location factor (t=10 years)	Without indoor deposition	With indoor deposition
Low shielding building	0.51	0.59
Medium shielding building	0.091	0.14
High shielding building	0.019	0.083

As can be seen from Table 2, the influence of indoor deposition on the location factor in dry deposition scenarios can be great. Indeed, in areas of buildings with a good shielding effect, this contribution may dominate. Similar calculations of location factors at other times after deposition have shown that the relationship between ^{137}Cs location factors with and without indoor deposition does not appear to change significantly with time.

CONCLUSIONS

The role of computer modelling in development of decontamination strategies has been demonstrated by an example of dry deposition to a row house area. It was found that the garden areas contributed most to the dose to people living in this type of area. Even after 10 years it is still possible to reduce the total accumulated dose significantly. A comparison between the URGENT model results and a semi-empirical indoor deposition/dose model has indicated that indoor deposition may in some cases contribute greatly to the average dose.

THE GERMAN CATALOGUE OF COUNTERMEASURES - A SUITABLE AND NECESSARY TOOL IN EMERGENCY SITUATIONS

Helga Zindler, S. Bittner, H. Braun, H. Korn, I. Strilek

Bundesamt für Strahlenschutz, Institut für Strahlenhygiene

1. Introduction

The "overview of countermeasures to reduce the exposure to radiation after events of considerable radiological impact" (here briefly: Catalogue of Countermeasures) is a useful manual for selecting protective measures on the basis of simple calculations. The first version of the Catalogue of Countermeasures was duly submitted in the summer of 1992. A new and more synaptical version of the Catalogue of Countermeasures is currently in preparation.

2. Valid range of the Catalogue of Countermeasures

2.1 Target group

Users of the Catalogue of Countermeasures will be those who need to evaluate the information from an event of considerable radiological impact and possibly resulting consequences. These are experts from competent governmental and state fields of authority and persons belonging to the respective advisory and supporting panels.

2.2 Limits of the Catalogue of Countermeasures

In consequence of the manual-like character of the Catalogue, its universality is considerably limited compared to computer programs.

- For pre-calculation, it is necessary to establish specific model parameters. Under certain circumstances, such model parameters can be changed, if this should result in a better estimation of their actual value.

- By a computer program such essential quantities as contamination and radiation exposure can be determined by one process for all involved sites and points of time. By manual, however, these can be determined for always only one site and one point of time. Therefore, on hand of measurement results it is essential to first gain an overview of the sites and points of time for which estimates are to be prepared.

- A particularly important restriction applies to the reference dose value. In the Catalogue of Countermeasures, the dose that corresponds with the reference dose is assumed to be fully exhausted by one exposure pathway. In practice, however, it must be assumed that next to one pathway there may also be others that play a more or less important role. Accordingly, the derived reference value that corresponds

with the respective reference dose value is generally too high. Nevertheless, this approach seems to be justified by the fact that the derived reference value is calculated by basing it on the lower reference dose value of the ICRP bandwidth concept. In addition, the proportions of the various exposure pathways contributing to the total exposure by one single nuclide may be determined by prepared nomograms.

3. Content of the Catalogue of Countermeasures

On the basis of evaluations taken from literature, measures were compiled in the Catalogue of Countermeasures which are discussed in reference to avoiding or reducing the radiation exposure after events of considerable radiological impact. The necessity for this compilation arose from the consequences of the Chernobyl event.

When using the Catalogue it must principally be presumed that not all of the measures will apply to all situations. Still, an attempt was made to provide a comprehensive overview as a basis for possible argumentation if, for example, a specific measure should not be initiated on account of its low effectiveness.

The main criterion for initiating and executing a protective measure is the radiation dose expected to be received from each of the considered pathways (external radiation, internal radiation after inhalation or ingestion). Since radiation is generally not directly measurable, for practical purposes it is not the radiation dose itself but the derived and directly measurable quantities that are used for decision-making.
To calculate derived reference values, models must be used which e.g. include the circumstances of the release due to the condition of the nuclear installation, the dispersion of radioactive substances in the atmosphere, the radioecology as well as the incorporation-related metabolism of the radioactive substance.

The following derived reference values are used:

- time-integrated air concentration in Bq h/m^3,
- surface and skin contamination in Bq/m^2,
- specific activity in Bq/kg or Bq/l.

On the basis of the derived reference values, the Catalogue of Countermeasures is an aid in deciding on the initiation of measures by indicating the type of effectiveness, the effectivity and the possible problems that may occur from the application of countermeasures.

4. Structure of the revised Catalogue of Countermeasures

The revised Catalogue of Countermeasures will consist of two parts. The first part, in form of models and tables, will allow for shortterm decisions on initiating precautionary measures on the basis of available data and includes:

Chapter 1 Introduction

A condensed description of essential general data on the purpose and use of the catalogue.

Chapter 2 Orientation tables and models

The orientation models in this chapter are serving as guide for the use of orientation tables, including criteria for the selection of required measures. On the basis of actually available information, e.g. measured or prognosed data on the time-integrated air concentration of specific nuclides or tracer nuclides, the measurement table of relevance for these data can be determined from this chapter and identified on hand of a model. For each countermeasure, the table refers to relevant additional information and data contained in other chapters of the catalogue.

Chapter 3 Graphic aids

In this chapter, all measures are graphically compiled. This - in addition to chapter 2, although differently demonstrated - is a rapid means of countermeasure orientation on hand of barred diagrams demonstrating the areas where countermeasures need to be applied.

Chapters 4 to 6 compilation of commentaries on all countermeasures

Based on each area where countermeasures apply, the compilation is divided into respective focal points:

- catastrophe protection measures (chapter 4)
- precautionary radiological protection measures (chapter 5)
- measures in the agricultural area (chapter 6)

The text and tables summarize important information on countermeasures, particularly emphasizing on pre-conditions, feasibility, effectiveness, advantages and disadvantages.

The second part of the catalogue contains supplemental information that may be of use in working with the catalogue. This includes, among others, data on nuclear power plants in Europe and tables in reference to sites and inventories. The second part of the Catalogue of Countermeasures contains also a summary of theoretical principles together with the most important equations on which the catalogue is based. This section should provide the background for a more specific familiarization with the catalogue.

ROLE OF DIFFERENT POTASSIUM CONCENTRATIONS ON ACCUMULATION AND EXCRETION OF RADIOCAESIUM IN A FRESHWATER FISH

Maria Carolina Vaz Carreiro, José Alberto G. Corisco

DGA/DPSR, 2685 Sacavém, Portugal

ABSTRACT

The objective of this study is the role of different K^+ concentrations in water on radiocaesium accumulation and on the biological half-life, in a freshwater fish, in order of its possible use as a countermeasure.

At the temperature of 12°±2°C the accumulation kinetics at K^+ concentrations of 3.5 and 35 ppm are quite similar and CF's at steady state are one order of magnitude lower than with a K^+ concentration of 0.35 ppm. Therefore K^+ concentration in that range seems not to affect radiocaesium accumulation.

The retention experiment lasted for 130 to 260 days and showed increasing radiocaesium excretion rates at increasing K^+ concentrations.

It is suggested, at least for this temperature, that potassium might be used as a countermeasure in lakes of low potassium content.

INTRODUCTION

The transfer of radiocaesium into and outwards the freshwater biota, is affected by several environmental parameters. Out of the most importants are temperature and water chemical composition, mainly the K^+ concentration, as both elements are chemically analogues and K^+ is the non isotopic carrier of caesium.

It is known that in nature, the radiocaesium bioaccumulation shows a large variability, being higher in oligotrophic lakes with low potassium concentrations and lower in freshwater with high potassium content (1); but the influence of different K^+ concentrations in water on radiocaesium excretion is not very well known.

In different lakes it is possible to say that radiocaesium accumulation by fish is directly proportional to the radiocaesium content and inversely proportional to the potassium content in water (2), (3). Other authors obtained significant correlation between ^{137}Cs in fish and K^+ in water (3), (4). More recently, after the Chernobyl accident, very high ^{137}Cs concentrations in fishes were found, mainly in lakes in Northern Europe, with large differences from lake to lake (5), (6). However, it must be stressed that in these cases, the bioaccumulation occurs not only through the water, but mainly through the food webs. On the other hand, some authors stated the above relationship as being inverse, although not statistically significant (7); but they were mainly analysing temporal trends at several latitudes, dealing with a large variability of data.

The balances of radiocaesium and potassium in water have already been studied in laboratory by several authors and an inverse relation was quoted (8), (9), (10).

Concerning radiocaesium biological half-life in freshwater fishes, several values are reported in the literature (11), (12), (13). However, the influence of soluble K^+ on the ^{137}Cs excretion rate, only recently was studied (10), (14).

The objective or this work, was to study the effect of different Potassium concentrations in water (0.35, 3.5 and 35 ppm), on the radiocaesium biological half-life for a freshwater fish species (*Chondrostoma polylepis polylepis*), at the temperature of 12° C.

MATERIALS AND METHODS

All the experiments were performed in 5 litters aquaria, using an artificial freshwater, without water filtration system, but with aeration, artificial light during 8 hours a day, except for weekends (continuos lighting) and the temperature was kept at 12°±2°C. Artificial medium was prepared, in order to get a basic cationic composition similar to the Tejo River water at the site of Fratel dam. Ca^{2+}, Mg^{2+}, Na^+ and K^+ concentrations were, respectively, 36, 11, 25 and 3.3 mg l^{-1}. Only K^+ concentration was changed and the values used were 0.35, 3.5 and 35 mg l^{-1}. ^{134}Cs was in the chloride form, in a 0.1 M solution of hydrochloric acid, with a concentration of 2 μg Cs^+ml^{-1}. Water was changed once a week and the contaminated faecal pellets were daily separated by screening, to prevent their ingestion by fish.

Small specimens of the cyprinid fish *Chondrostoma polylepis polylepis*, aged about 1 year, with a mean weight of 1.8 g, were used and fed 5 days a week, with milled soft parts of bivalves containing 0.9 mg (K^+) g^{-1}, each meal representing about 5% of the total fish weigth. Each group was previously acclimatised to the artificial medium, for 2 weeks, before contamination with ^{134}Cs. Growth rates were evaluated separately for the three groups of fishes and within them, for uptake and elimination period; growth rates for the whole period were low, varying from 0.0011 to 0.0018 day^{-1}. During the uptake phase, fishes were fed in separated aquaria with uncontaminated water, to avoid any contact of food with radioactive caesium.

Radioactivity measurements were made on pre-weighed anaesthetised fishes. ^{134}Cs concentration in the liquid phase during the uptake, was measured in water samples filtered through membranes (0.45 μm). The measuring equipment was based in a well-type NaI(Tl) detector, associated with a multi-channel analyser.

RESULTS AND DISCUSSION

Concentration factor was computed considering the mean value of water radioactivity for all the uptake period. Elimination of the radioisotope was treated by multicompartmental analysis (15), (16).

^{134}Cs concentration in fish, during 4 weeks of direct uptake, has increased in all three groups without reaching a steady state. All the uptake kinetic curves were fitted according to the treatment described in (15), (16), where fish growth, bioelimination, and physical decay of ^{134}Cs are taken into account.

The higher the K^+ concentration in water, the lower the radioactive contamination of fishes **Fig.1**. The evaluated CFs at steady state for K^+ concentrations of 3.5 and 35 ppm are of the same order of magnitude; uptake curves are almost overlapped, as it happens at 20°C (10). As K^+ concentration in water of about 2 ppm seems to be critical (7), it is understandable that 3.5 or 35 ppm has no significant influence on the radiocaesium uptake.

Biological half-life means the time needed for a retention compartment to loose 50% of its radioactive content. Two compartments were evaluated, **Fig.2**, with the following Tb's: at 0.35ppm K^+, Tb_1=21 days and Tb_2=472 days; at 3.5ppm K^+, Tb_1=24 days and Tb_2=254 days; at 35ppm K^+, Tb_1=21 days and Tb_2=136 days.

The elimination of radiocaesium by fish seems to be affected by the external potassium concentration in water. The longer biological half-life (Tb_2) decreases as the K^+ concentration increases.

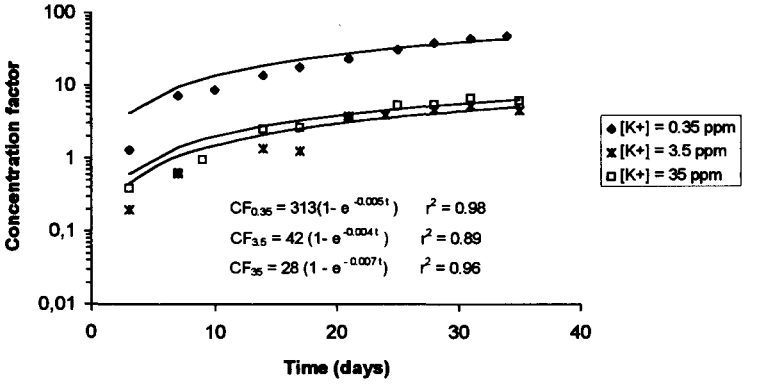

Fig. 1 ^{134}Cs uptake by a freshwater fish from water with different K^+ concentrations.
(CF is the ratio Bq g^{-1} (fish) / Bq ml^{-1} (water))

In (10) the conclusion seemed to be different, however, it needs to be enhanced that it concerned a short-term experiment (about 50 days), while the present one lasted more than 250 days. Retention analysis made at 50 days showed that, in this period, the retention curves exhibited parallel profiles and Tb_1 actually would not significantly differ, but Tb_2 would be very different. A question raises from this data, whether a long-term experiment influences the goodness of the results, although the growth rate will be lower.

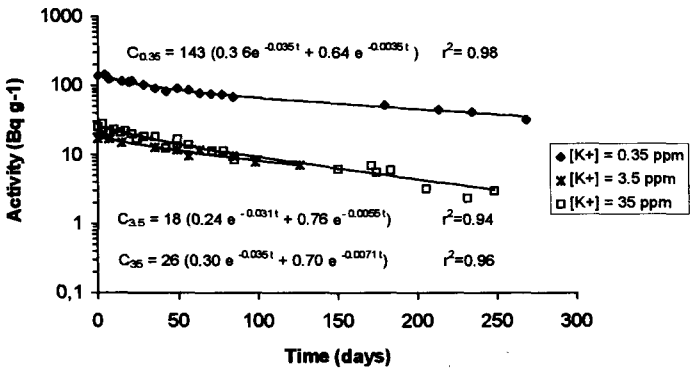

Fig. 2 ^{134}Cs retention by a freshwater fish at different K^+ concentrations in water, at 12°C.
(C is the radioactivity of fishes)

CONCLUSIONS

At 12°±2°C, a long-term retention experiment (more than 4 months), with *Chondrostoma polylepis polylepis*, revealed that at higher K^+ concentrations in water the elimination is faster, i. e., the excretion rate increases with K^+ concentration, therefore the biological half-life of the longer component is shorter.

Relating the interpretation of uptake and loss data, it seems that in water bodies of low K^+ concentration (below 2 ppm), the increase of K^+ concentration might increase the radiocaesium excretion.

SIDE-EFFECTS OF APPLICATION OF MANURE FROM AFCF TREATED ANIMALS

Christian M. Vandecasteele, May Van Hees, Simon De Brouwer, and Hildegarde Vandenhove

Radioecology laboratory, SCK•CEN, B-2400 Mol

INTRODUCTION

AFCF [Ammonium-ferric-hexacyano-ferrate] is a very effective caesium binder. Mixed with the animal feed, presented in the form of salt licks or introduced into the rumen as slow release *boli*, this compound is an efficient countermeasure to limit the gastro-intestinal uptake of radiocaesium by farm animals and wild ruminants (1-3). Less than 1 % of the ingested AFCF is excreted in urine or secreted in milk (2), suggesting that it crossed the gastro-intestinal tract unabsorbed and is finally excreted in faeces together with the caesium bound in the gut. This means that AFCF from treated animals returns directly to pastures while animals are grazing or that it can be spread on fields fertilised with animal manure. Although no toxicological problems have been observed on animals given hexacyanoferrates in the recommended doses, the fate of this molecule in the environment after excretion is not well documented. Except for limited data obtained in Norway and in the CIS (4), practically no information is available regarding its action on the availability of Cs present in the soil, nor concerning potential side-effects of its possible degradation to cyanides and other materials with a concomitant release of bound Cs over long periods of time (2, 3).

MATERIAL AND METHODS

^{134}CsCl and ^{137}CsCl sources were purchased from Amersham and AFCF (Industrial Giese Salt, containing 60-65% AFCF and 35-40% NH_4Cl) was obtained from Riedel-deHaen.

Blank and ^{137}Cs contaminated sheep faeces, with and without AFCF, were successively obtained from the same animal housed in a metabolism cage which was fed 150 g beet pulp per day and mixed grass hay *ad libitum* (fig. 1).

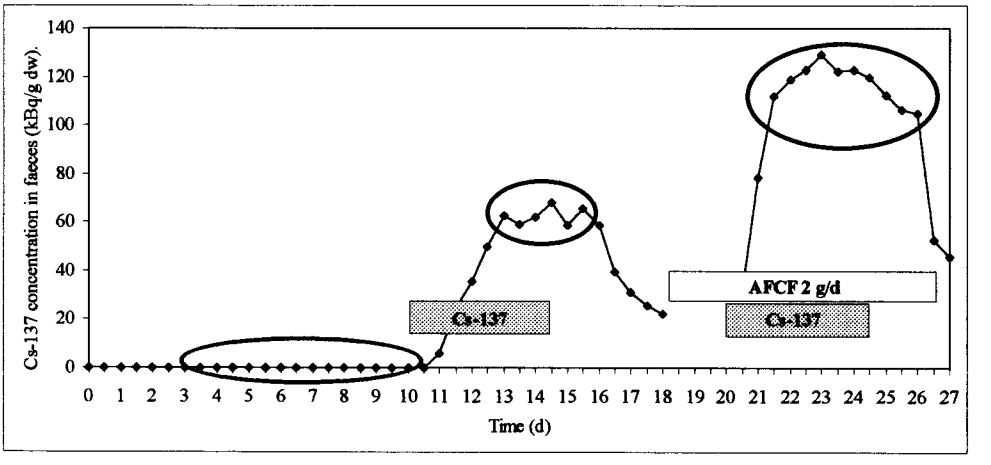

Figure 1: Blank, ^{137}Cs and ^{137}Cs-AFCF faeces production schema. The samples surrounded by an ellipse were pooled to give the different faeces types.

After a period of adaptation to the diet (4 days), Blanca faeces was collected for one week. From the 11th day onwards, the sheep was orally dosed 100 MBq ^{137}Cs.d^{-1} every morning for 5 days, then the

contamination was suspended during 4 days and resumed at a rate of 60 MBq^{137}Cs.d^{-1} for another 5 days' period. Giese salt administration (2 g.d^{-1} given *per os* in the morning, 15 minutes after the administration of Cs) was started two days before the second Cs contamination phase, and carried on until two days after. Both morning and night faeces production was collected. After γ-counting (minaxi, auto-gamma 5000 series, Packard Instrument), faeces with a high and rather constant contamination level was gathered, mixed and ground. Cs-AFCF faeces was diluted with Blank faeces to reach the same radioactivity level as in Cs faeces (i.e. 63 kBq.g^{-1} dw). The AFCF-level of the contaminated Cs-AFCF faeces was estimated from the amount dosed and the faeces dry weight production, assuming that an equilibrium between AFCF ingestion and excretion had been reached when the Cs-AFCF faeces collection was started. After dilution with Blank faeces the concentration was about 0.10 g AFCF.g^{-1} dw faeces. These faeces were mixed with blank and ^{134}Cs contaminated soil. Since 10 g faeces were applied (3.3 t.ha^{-1}), this resulted in a ^{137}Cs contamination level of 630 kBq per container, mixed in the top 0.4 cm layer. The AFCF amount applied with Cs-AFCF faeces was equivalent to 1.0 g AFCF.m^{-2}.

The transfer to ryegrass was studied in greenhouse. Rectangular shaped darkened containers (20x15x11 cm^3) were filled with 3200 g of dry soil (Orthic Podzol). 2 g of Italian ryegrass (*Lolium multiflorum*) was spread evenly over the soil. The seeds were covered with a 0.4 cm moist soil layer homogeneously contaminated with ^{134}Cs (1.0 Mbq per container), mixed with different additives, according to treatment applied. Four treatments were considered:

1. no additives other than ^{134}Cs in the top soil layer,
2. a soil amendment with ^{137}Cs contaminated sheep faeces (3.3 t dw.ha^{-1}) from an AFCF treated animal,
3. a soil amendment with ^{137}Cs contaminated sheep faeces at the same rate but from an untreated animal,
4. the application of an AFCF water solution (30 m^3.ha^{-1}) at a rate of 10 kg Giese salt per ha.

All treatments were set up in triplicate. Pots were watered every two days. Ryegrass was harvested every two or three weeks, depending on growth. Dry weight was determined and activity measured by γ–counting. The ^{137}Cs and ^{134}Cs transfer factors are defined as (Bq.g^{-1} dry plant material)/(Bq.g^{-1} dry soil). After every harvest, plants were given $N_{13}P_{13}K_{21}$-fertiliser (30 ml.dm^{-2} of a solution containing 17 g fertiliser.L^{-1}). In total 19 cuts were harvested over 365 days.

The data were analysed using "Statistica®" as statistical software.

RESULTS AND DISCUSSION

Compared to the control, no statistically significant effect on the biomass production was observed due to the addition of Giese salt (10 kg.ha^{-1}) or animal manure (3.3 t dw.ha^{-1}) (data not shown). The analysis of the variance (two-way anova) underlines a highly significant effect of the time (with an increased yield in spring and early summer), but no difference between the four treatments. The absence of toxic effects on plant growth due to the AFCF applied with faeces is not surprising considering that no effect (visual toxicity symptoms or biomass production decrease) of AFCF has been observed on the same soil type (sandy podzol), after application of up to 1 t AFCF.ha^{-1} in a water solution (5). Such a high dose would only be achieved after more than 270 y on pastures supporting a grazing pressure of 5 cows.ha^{-1}, in so far as the cows are constantly dosed 2 g.d^{-1}, the farm manure produced in the winter period is spread on the grazed pastures and the AFCF molecule is not degraded and its application is thus cumulative.

The availability for plant uptake of radiocaesium excreted with faeces (^{137}Cs) was significantly lower, by a factor 5, in Cs-AFCF-faeces compared to that in Cs-faeces from untreated animal. Moreover, the AFCF brought to the soil (10 kg.ha^{-1}) with Cs-AFCF-faeces (3.3 t dw.ha^{-1}) decreased in the same proportion the bio-availability of ^{134}Cs present in the soil surface layer than that of ^{137}Cs in manure (fig. 2). A comparable effect was obtained by the application at the same rate of AFCF in water.

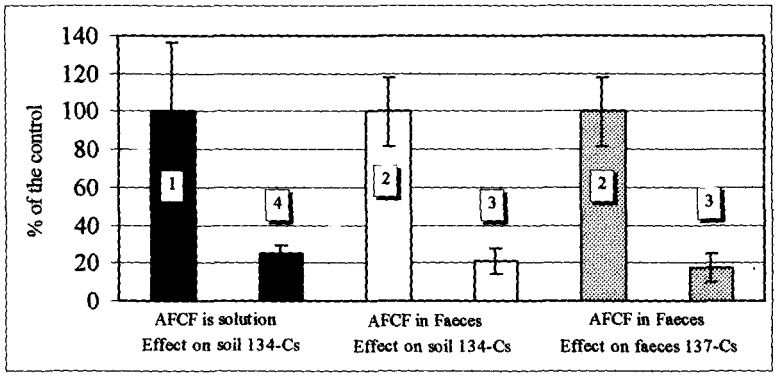

Figure 2: Effect of AFCF applied at a rate of 10 kg.ha^{-1} on the transfer to plants of caesium from faeces or already present in the soil top layer. Average over one year observation (19 successive cuts) for the treatments and their respective control (± mean standard deviation between 4 replicates)

From the comparison of tretaments 1 and 3, regarding the soil ^{134}Cs transfer to plants, we notice that the addition of organic matter can also contribute to decrease the availability for plant uptake of the ^{134}Cs in soil by increasing the soil exchange capacity. In our case, the application of 3.3 t.ha^{-1} of animal manure to a soil containing some 4 % organic matter induces a 20 % reduction of the transfer to plants compared to the non amended control.

CONCLUSIONS

From the results presented here, some conclusions can already be drawn :

- The addition of organic matter (dry faeces) reduces the soil caesium transfer to plants.
- AFCF in faeces from sheep treated with a 2 g.d^{-1} dose limits the availability for plants of the caesium excreted in the faeces.
- The presence of AFCF in the faeces acts also on the availability of the already present caesium in soil, and reduces its bio-availability for plant uptake. This effect lasts for at least one year after the application.
- Taking into account the absence of toxic effect of AFCF addition on plant growth when it is applied on sandy soils as a water solution in concentrations of up to 1 t.ha^{-1}, it is improbable that applying on field or pastures, manure from AFCF treated animals in appropriate doses would negatively affect the biomass production.

However, some attention should be given to the influence of AFCF on the Cs mobility in soil and the risk linked with a potential contamination of the (under)ground waters.

PRESENTING AUTHOR (IF DIFFERENT)

MAJOR SCIENTIFIC TOPIC NUMBER 4.6 (see page 7)

ABSTRACT (See instructions overleaf)

The selection of a near surface disposal site requires a multi-attribute analysis. Some of these attributes deal with the radiological impact.
The first part of the paper describes the most important radiological protection attributes: individual and collective doses, for workers as well as for the general public, for normal evolution scenarios and for accidental situations during the operational and post-closure phases. The post-closure phase includes also an institutional control phase. For potential exposures, one has to consider also the probability of occurrence of the accident.
The second part of the paper identifies the site specific parameters and the relevant scenarios, i.e. scenarios leading to a radiological impact of more than 10 μSv/year in terms of individual dose and more than 1 man.Sv in terms of collective dose or scenarios with a probability of occurrence of more than 10(-8) per year.
The third part of the paper evaluates the relative importance of these site specific parameters intervening in the relevant scenarios.

ANALYTICAL DETERMINATION OF ALPHA EMITTERTS IN WASTE SAMPLES CONTAINING A LARGER NUMBER OF RADIONUCLIDES

R. Biehl and G. Pilwat

Abteilung Sicherheit und Strahlenschutz, Forschungszentrum Jülich, Jülich, Germany

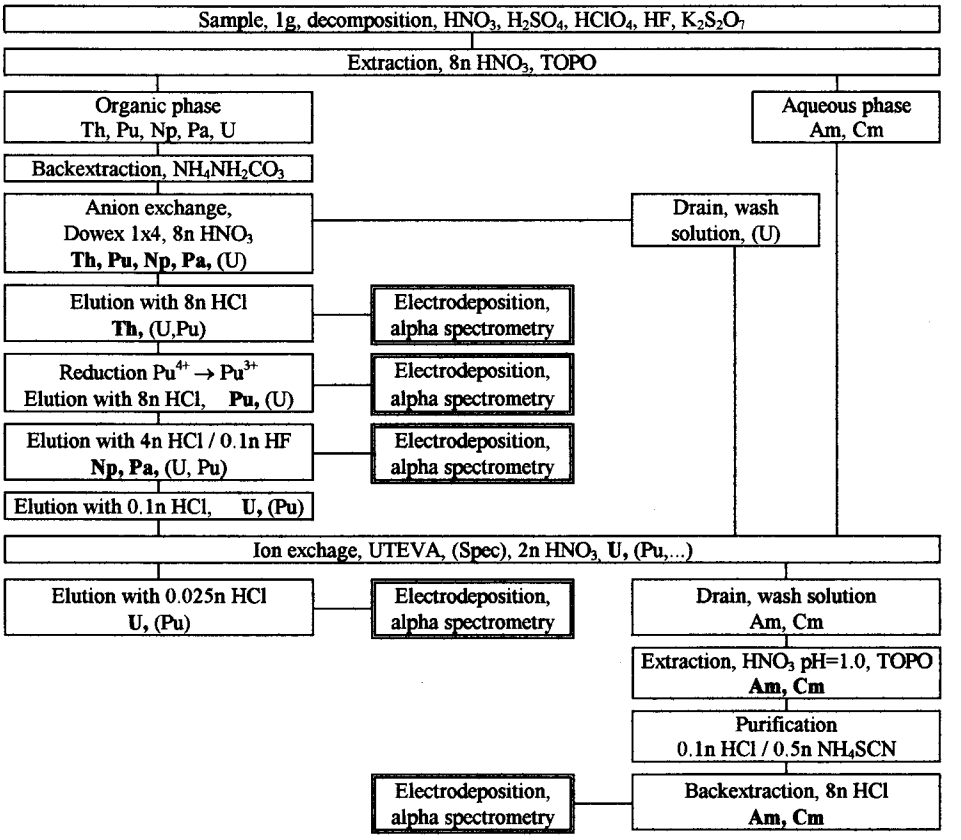
INTRODUCTION

For the disposal of wastes containing alpha emitting nuclides it is necessary to determine the activity of about 20 nuclides of the elements thorium, protactinium, neptunium, uranium, plutonium, americium and curium.
In general, the activity of alpha emitting nuclides is determined by the measurement of samples to be prepared such that the emission of alpha particles takes place largely without loss of energy. However, the separation of the nuclides from sample matrix, purification and preparation of the samples is always connected with losses. Therefore, tracers like U-232, Pu-236, Pu-242, Am-243, etc. which normally are not expected to be present in the sample have to be added in order to determine the yield.
Because of the requirement to determine these isotopes which are used as tracers for yield determination and the determination of very low concentrations in the presence of much higher concentration of other nuclides it was necessary to develop a new analytical procedure.

METHODS

The procedure is schematically presented in Table 1.

Table 1. Schematic survey of the analytical procedure



The idea to perform this complex determination was as follows: The separation of a nuclide to prepare a counting source for alpha spectrometry needs not to be quantitative, if it is possible to detect the residual portions of this nuclide in the other counting sources together with the other nuclides.

Therefore after separation of an element in order to prepare a counting source the following separations have to be performed in such a manner that elements not yet quantitatively separated by previous steps can be detected.

The procedure requires the preparation of up to five counting sources, which give a good energy resolution for alpha spectrometry. Then each alpha spectrum has to be inspected for those nuclides which were not quantitatively separated in previous steps. The activity for each nuclide then results as the sum of activities obtained from the alpha spectra of all relevant samples (see Tab. 2.).

RESULTS

In order to demonstrate the effectiveness of the procedure described above the elements Th, Pa, Np, Pu and U were simultaneously deposited, according to the common radiochemical procedure. Pu-236 was added as tracer. Fig. 1. shows the resulting alpha spectrum. The energy resolution is bad due to the high area weights. The nuclides of interest cannot be estimated with the required detection limit.

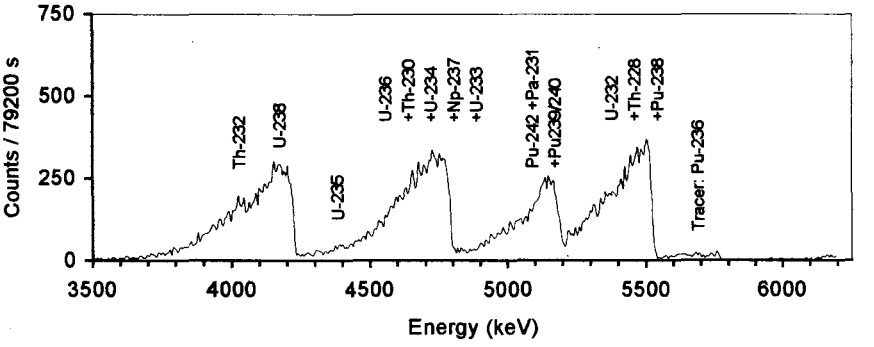


Fig 1. Alpha spectrum of the simultaneously deposited elements Th, Pa, Np, Pu and U. The counting source was prepared according to the common procedure.

In contrast, Fig. 2. shows the alpha spectrum of the uranium fraction obtained by the method described in Tab. 1. All uranium isotopes can now be detected and estimated with required accuracy. As to be expected the counting source contains a portion of plutonium isotopes which are not quantitatively separated in previous steps.

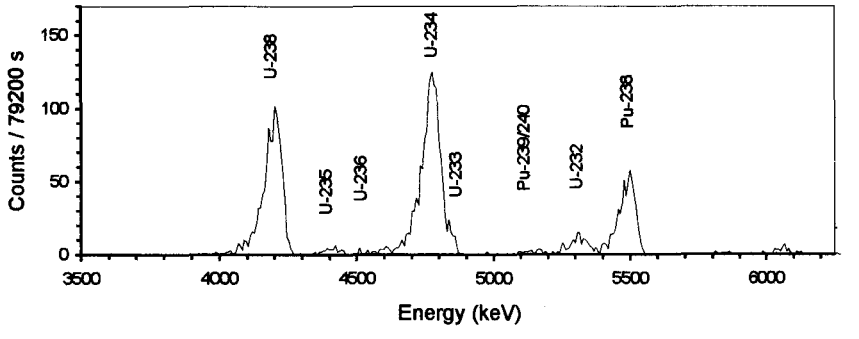

Fig. 2. Alpha spectrum of the counting source prepared from the uranium fraction

Some elements, especially uranium and plutonium appear in nearly all fractions. The activity concentration for the respective nuclide results as the sum of the activities obtained from alpha spectra of all relevant samples. Table 2. shows the nuclide composition of counting sources expressed as the fraction of total activity.

Table 2. Nuclide composition of the counting sources obtained by the method briefly described in Tab. 1.

Counting source	Nuclide composition of the respective sample expressed as the fraction of the total activity						
	Th	Pa	Np	U	Pu	Am	Cm
Th	**96**			6	3		
Pa, Np		**< LD**	**< LD**	**10**	1		
Pu				3	**83**		
U	2			**81**	13		
Am, Cm	2					**100**	**100**
LD: Limit of detection							

In Fig. 3. the resulting spectrum of the sum of the alpha spectra of the Th-fraction, Pa-Np-fraction, Pu-fraction and U-fraction is presented. The resulting spectrum presented in Fig. 3 and the spectrum presented in Fig. 1 represent the same nuclide composition so that they can be compared. It is pointed out that splitting of the counting sources results in a substantial better resolution of the spectra and a lowering of the detection limits.

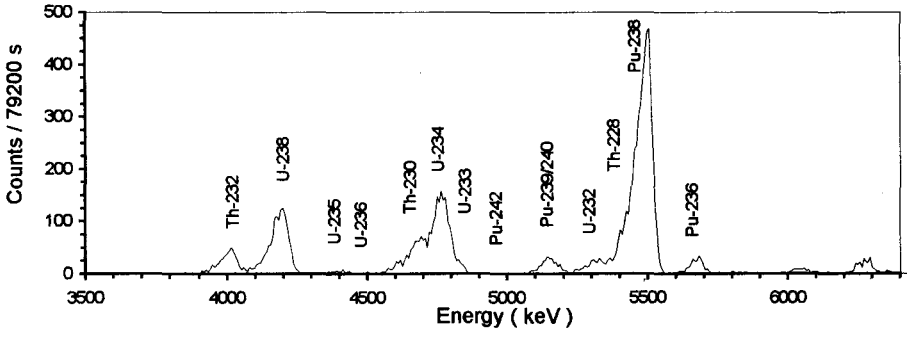

Fig. 3. Sum of the alpha spectra of the Th-fraction, Pa-Np-fraction, Pu-fraction and U-fraction

EDF's "DRA" SOFTWARE FOR THE MANAGEMENT OF RADIOACTIVE WASTE

M. BORDIER
Department of Safety, Radiation Protection and the Environment
EDF/DEPT, SAINT-DENIS (FRANCE)

I - FOREWORD:

In January 1991, the quantities of radioactive waste produced by EDF's nuclear power plants (nearly 13 000 containers per year sent for storage) led to develop a computerised management system for radioactive waste produced by the operation of nuclear units. The development of this computerised system met the restrictions laid down by the ANDRA (Agence National pour la gestion des Déchets RAdioactifs - National agency for the management of radioactive waste), which is responsible for the storage of such waste and which laid down a validation procedure for the characteristics of packages before they are dispatched to the storage centre.

II - OBJECTIVES:

The initial objective was to standardise management procedures throughout all nuclear sites by combining the framework of regulations for the transport and storage of waste with the need to integrate Quality Assurance rules into the software through the use of *"qualification"* which control access to the various functions and provide for an internal check (operator/inspector).

As later developments were included, the following additional objectives were reached:

- automation of radioactivity calculations,
- provision of a powerful statistical tool which provides for the making of comparisons between sites,
- transport planning aid, etc.

III - FUNCTIONS:

The following functions are provided:

- the management of empty containers (metal drums and vessels, concrete containers),
- the calculation of the radioactivity of containers through the use of mathematical tables, which associate:
  - . the dose rate measured with the activity of each radionuclide detected,
  - . the activities of the radionuclides which cannot be measured with the activity of the "key" radionuclides,
- the management of local storage areas,
- the determination of container characteristics (some of which are generated automatically by the application),
- the real time dialogue between EDF and ANDRA sites through the transmission of data files to ANDRA in order to obtain a "Valid" status for the container in return,
- the calculation of the criteria for the Transport of Dangerous Goods Regulations,
- the making up dispatch batches from the stock of "Valid" containers,

- the inspection of containers using bar codes (reception/dispatch),
- the printing of transport documents,
- the retrieval of data concerning radioactivity, stocks, etc.

Additional functions are also available:

• *for operators:*
  - calculation of radioactive decay to optimise transport resources and costs,
  - a library of reference documents for each site,
  - pre-formatted statistical printouts.

• *for central EDF departments:*
  - monitoring of volumes of products and stocks to establish performance indicators (WANO) and for the planning of transport,
  - adding reference documents to the library.

• *for the National Administrator:*
  - updating of tables,
  - specific transactions concerning data bases (change of status) and the interpretation of ANDRA return codes, etc.

IV - RESOURCES:

IV.1 HARDWARE/ARCHITECTURE

Users provided with local PC type workstations which are connected to a host computer (IBM 3090) via a special TRANSPAC 19200 baud links. The IBM 3090 host computer is connected to the ANDRA host computer via a TCP-IP link operating in a UNIX environment. This system provides for on-going communications between the EDF installation which produces the waste and ANDRA.
The software has a CRADLE type architecture combined with the COBOL programming language.
The various container production phases are managed by status.

IV.2 MODULES

The functions described above form part of 6 main modules:
- qualifications,
- radiological spectra,
- bar code readers,
- container characteristics,
- transmission,
- dispatch.

All these modules are specific to each user site which has its own data bases (access controlled by a "site user code"); the tables and operations in the data bases can be updated by the National Administrator in the event of the failure of the application.

The *"Qualification" module* is used to establish the access hierarchy for the various functions according to the authorisation criteria adopted for the user (Operator, Inspector).

The *"Bar Code reader" module* enables container identification numbers to be input using an optical bar code reader (reception and pre-dispatch inspections).

The *"Radiological spectra" module* provides for the input and storage of the radioactivity characteristics of the containers.

The *"Container characteristics" module* is used to establish the regulation statement for storage.

The *"Transmission" module* is used to transmit previous data to ANDRA in the form of computer files.

The *"Dispatch" module* is used for the preparation of the containers to be sent for storage, according to their shape and size and their level of radioactivity.

V - EXPERIENCE FEEDBACK:

By the end of 1995, the software will be used to manage more than 150 000 containers (under construction and dispatched).
Each container record comprising 80 fields, the disk space was approximately 250 Mb.
Availability of the tool is very satisfactory as is the reliability of the transmission system.
The initial objective has been achieved since the automation of the software has led to significant improvements to the following:

- the container descriptions required by ANDRA for the long term storage of data,
- the internal management within EDF.

The next version of the software will involve its modification for the new processing modes for certain types of radioactive waste (fusion, incineration) and require interfaces to be set up with other contractors.

THE FRENCH CENTRALISED LOW LEVEL RADWASTE TREATMENT CENTER NAMED CENTRACO

Charles Barnes, Yann Sixou
SOCODEI, B.P. 92, 95613 CERGY PONTOISE Cedex, FRANCE

SUMMARY

Socodei, a subsidiary company of EdF and Cogema is commissioned to design, finance, build and operate two low level radwaste treatment facilities : a contaminated scrap metal melting unit, and a solid and liquid waste incinerator.

These units frame a low level radwaste treatment centre named Centraco, located near Marcoule in the south of France, and will receive in 1998 waste coming from dismantling, maintenance and operating works of French and foreign nuclear sites.

The decision to create this centre is due to the low density and large variety of low level radwaste which take a volume out of proportion with their activity, specially in the surface storage centre. Up to now, all low level radwaste were sent and stored with no treatment optimisation in surface storage centres.

Socodei proposes in one single site, to optimise low level radwaste management and reduce the volume of ultimate waste to be stored : in a ratio of one to ten by casting ingots coming from melting contaminated scrap metals ; in a ratio of one to twenty by encapsulating earth ashes and ashes resulting from incineration of solid and liquid waste.

This is a centralised treatment centre and that's why Centraco is a new waste management system. Getting together all means in one place reduces costs, avoids mismanagement and risk increase, and allows consistency in safety, environmental impact, transport and personnel radioprotection.

BACKGROUND AND GENERAL FEATURES

Today, low level radwaste generated on nuclear sites are compacted and shipped in metallic casks to the burial French landfill site operated by ANDRA (Centre de Stockage de l'Aube). Waste are coming from nuclear plants (EDF), reprocessing factories (COGEMA) and from labs (CEA) and hospitals.

EDF and COGEMA have ascertained needs to limit low level radwaste volume and environmental impact of waste coming from their sites. Moreover, in July 1992, the French government enacted a law which assigned industrials to enhance value of all their waste in order to get reusable materials from these so that ultimate waste alone are landfilled. SOCODEI has been founded to adress this issue.

CENTRACO holds two low level radwaste treatment units on a 100 000 square meters area : First is the incinerator designed for 3 500 TPY of combustible solid waste and 1 500 TPY of liquid ; Second is the melting furnace designed for 4 500 TPY of scrap metals.

Low level radwaste management is carried out using one of these two process lines, incineration and melting. All waste generated by the process lines - slag, refractory, baghouse filters, earth ashes and fly ashes,... - are encapsulated in order to be sent to the surface storage center.

All packages belong and are allocated to customers in proportion to their inlet processed weight.

WASTE ACCEPTANCE CRITERIA

Low level radwaste containers or packages are accepted if data sheets specifying nature and level of radioactivity, chemical and physical nature are in agreement with Centraco's acceptance criteria. Waste are then oriented to the optimal process and are stored on site to be processed by campaigns.

The main waste acceptance criteria are :

- Alpha activity level has to be less than 370 Bq/g per package and beta-gamma activity level has to be less than 20 000 Bq/g per package (metal melting & incineration),
- Incoming packages can be drums, metallic boxes or containers less than forty feet length. Pieces have to be less than twelve meters long and fifteen tons weight (metal melting),
- Plastic films and wood wedges for loading are accepted but explosive, inflammable and toxic stuffs are prohibited. All metals are accepted except mercury (metal melting),
- Incoming solid waste packages can be closed cardboard drums or metallic drums (incineration),
- Incoming liquid waste packages can be drums or tanks (incineration),
- Metals, aerosols, batteries and explosive and mercurial stuffs are prohibited (incineration).

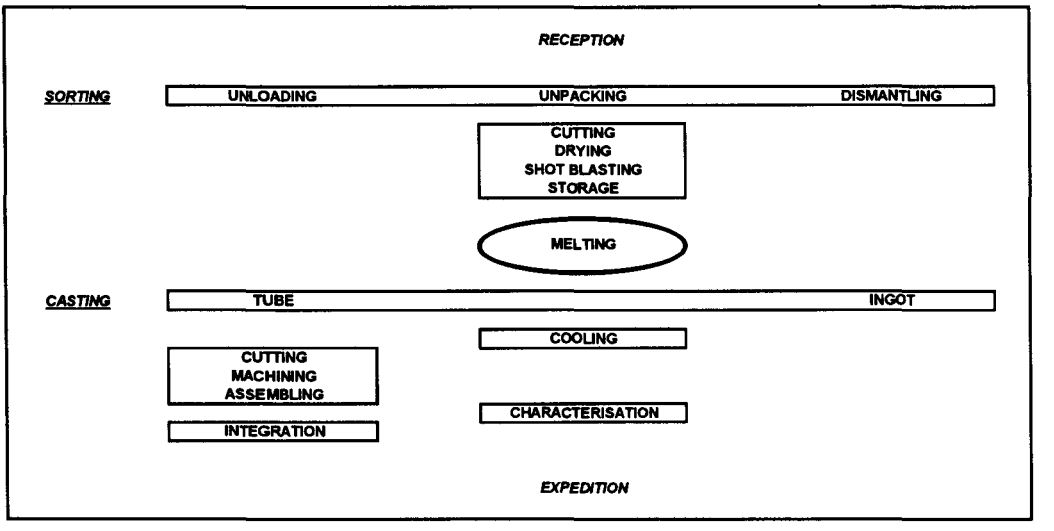
SCRAP METAL MELTING PROCESS

Scrap metals coming in twenty feet containers from the nuclear sites are unloaded and sorted out according to the nature of radioactivity and metal quality - carbon steel, stainless steel and non-ferrous metal. Scraps are first dried out to remove water, then shotblasted to remove painting if necessary.

The high efficiency induction furnace runs at 1 600°C and produces on top of the molten bath, slag with high content of radioactivity scrapped out in specific casks. The molten bath is poured out afterwards in casting casks previously preheated at 850°C.

Molten metal is put either in casts to produce ingots, or in a centrifuge to manufacture tubes. These cylinders are welded with non contaminated disks in order to manufacture shields for casks.

These casks are used to encapsulate and store ultimate waste of high level activity such as spent IER (ion exchange resins) or incinerator ashes.



INCINERATION PROCESS

The twenty feet containers coming in from the nuclear sites are loaded with closed cardboard drums of solid low level radwaste. Drums are unloaded and sorted out according to their heat content and nature of radioactivity, and are sent to the incinerator buffer storage.

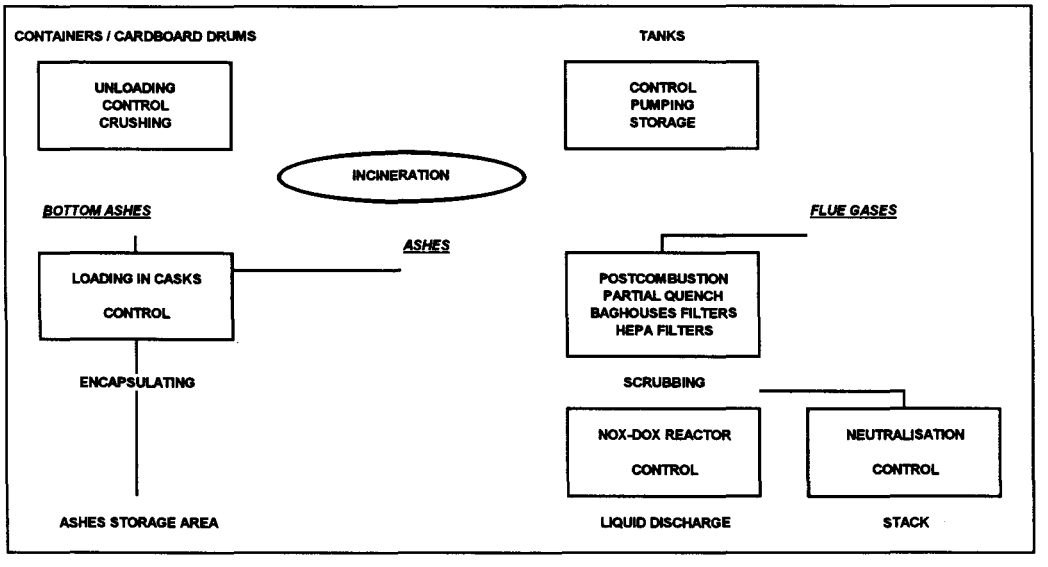
Liquid waste are coming in various containers and are sucked out towards storage tanks specifically devoted to different kinds of liquid. Drums are fed directly without opening through an air lock at the top of the furnace primary chamber at a temperature of 900 / 1 000°C. Liquids are pumped directly out the storage tanks to the corresponding injectors.

While burning, solid waste is moved forward to the end of the chamber by two air-cooled screws, and the resulting bottom ashe is collected by gravity in special high containment casks. Liquid waste is injected through air atomising nozzles in the same chamber.

Support fuel oil is used when the waste heat content is too low. Cooling water is injected on the opposite when the waste heat content is too high. In a secondary combustion chamber, a final combustion is achieved at 1 200°C, in compliance with regulations for incineration.

Flue gases are then cooled down in a partial quench tower to less than 200°C before filtration in series in a bank of baghouse filters and a bank of HEPA filters. Fly ashes are collected in confined casks at the bottom of baghouses filters.

The flue gas treatment consists of two scrubbing towers to remove halogen acids, sulfur dioxide and of a catalytic reactor to remove nitrogen oxides, dioxin and furan. The treated flue gases are discharged through the stack of the site after on-line regulatory control.



COMMENTS

Centraco was asked to be a model plant, and as example has used the ALARA approach right from the early stage of the design. This means that all working stations are optimised to limit the annual dosimetry of the personnel, including both operation and maintenance people.

Centraco will be the link between nuclear sites and surface storage center. The start-up of the melting facility is expected in September 1997, the incinerator will be in operation in May 1998.

MAJOR SCIENTIFIC TOPIC NUMBER 4.6... (see page 7)

ABSTRACT (See instructions overleaf)

A preliminary radiological analysis was performed on core samples from the Hanford Reservation high level waste (HLW) tanks. The purpose of the study was to ascertain the nuclide composition of the HLW, and then determine reference dose rates for determination of shielding requirements for transportation casks. Core samples representative of both single-shell tank (SST) and double-shell tank (DST) waste were analyzed for radionuclide content. The main contributors to the total activity were found to be Sr-90 and Cs-137, for both SST and DST waste; smaller amounts of Tc-99, Pu-239, Pu-240, and Am-241 were also identified. Other transuranics, as well as fission products, were present in negligible activities (< 1.0 mCi).

Radiation doses were calculated for a characteristic 10 ml sample size. In terms of the radiological dose equivalent, the alpha and beta decay of the majority of the constituent nuclides could be neglected. No significant neutron-emitting nuclides were identified in the samples, so it was concluded that beta and gamma radiation would be of greatest concern for an unshielded source, specifically gamma/beta decay of Cs-137 and beta decay of Sr-90. Analytical expressions for gamma and beta dose from an unshielded source were derived. Maximum calculated ranges of beta particles in air and tissue were 220 cm and 0.28 cm, respectively, and it was concluded that although the beta dose rate is greatest in magnitude, realistic shielding by the packaging material would reduce it to negligible values. Specific recommendations for gamma shielding, however, were determined for transportation of Hanford HLW core samples.

EVALUATION OF SECONDARY STREAMS IN MIXED WASTE TREATMENT

Fred F. Haywood,[1] William A. Goldsmith,[1] Douglas F. Allen,[1] and Lance J. Mezga,[2]

[1]Radian Corporation, Oak Ridge, TN 37830
[2]Lockheed Martin Energy Systems, Oak Ridge, TN 37830

INTRODUCTION

The United States Department of Energy (DOE) and its predecessors have generated wastes containing radioactive and hazardous chemical components (mixed wastes) for over 50 years. Facilities and processes generating these wastes as well as the regulations governing their management have changed. Now, DOE has 49 sites where mixed waste streams exist. The Federal Facility Compliance Act of 1992 (1) required DOE to prepare and obtain regulatory approval of plans for treating these mixed waste streams. Each of the involved DOE sites submitted its respective plan to regulators in April 1995 (2). Most of the individual plans were approved by the respective regulatory agencies in October 1995. In many cases, mixed waste treatment that was already being carried out and survived the alternative selection process is being used now to treat selected mixed waste streams. For other waste streams at sites throughout the DOE complex, treatment methods and schedules are subject to negotiation as the realities of ever decreasing budgets begin to drive the available options.

Secondary wastes generated by individual waste treatment systems are also mixed wastes that require treatment in the appropriate treatment system. At large DOE sites, secondary waste streams will be a major influence in optimizing design for primary treatment. Understanding these impacts is important not only for system design, but also for assurances that radiation releases and subsequent radiation exposures will be carefully controlled. Secondary wastes can greatly affect treatment system capacity needs, the types of treatment required, and the health physics program requirements.

MIXED WASTE TREATMENT

Mixed wastes subject to treatment are those wastes that meet one of the following criteria:

- Low-level mixed waste - contains hazardous constituents and radioactivity and is not classified as high-level waste, transuranic waste, spent nuclear fuel, or tailings or waste produced by the extraction or concentration of uranium or thorium from any ore processed for source material.
- Mixed transuranic waste - contains hazardous constituents and radioactive materials contaminated with greater than 100 nanocuries per gram of alpha-emitting radionuclides with atomic number greater than 92 and half-lives greater than 20 years.
- Mixed high-level waste - contains hazardous constituents as well as highly radioactive material with fission products, traces of uranium and plutonium, and other transuranic elements that result from the initial stage of chemical processing of spent nuclear fuel.

A review of some individual site treatment plans indicated that the compounding effects of secondary wastes from these primary treatment processes were not fully understood. The generation of secondary waste was one of several treatment evaluation criteria under the general category, *treatment effectiveness*, and was required to be considered in alternative assessments (3). The importance of this step is realized once the treatment of numerous waste streams begins and secondary waste from one or more treatment modules becomes competitive with primary waste streams requiring the same treatment. We will restrict our discussion to treatment of low-level mixed wastes. Selection of waste treatment technology depends on the physical form and the hazardous constituent or characteristic. With the exception of volatile species such as ^{137}Cs, radiological constituents are generally not considered important for selection of treatment technology. There is a U.S. EPA regulatory requirement to select the best available demonstrated technology for treatment based on the hazardous constituents in the waste.

The design of treatment modules identified during development of the treatment plans requires a thorough characterization of each waste stream. That is, each waste stream must be evaluated completely for physical, chemical, and radiological parameters regardless of its volume (mixed waste volumes range from a few liters to thousands of cubic meters). One obvious benefit from this evaluation is the determination of just how much of the current and projected waste is simply hazardous or low-level radioactive, and how much is truly mixed. Potentially hazardous wastes that do not exceed the hazardous waste treatment standard concentrations listed for wastes prohibited from land disposal may be shipped to and disposed of in existing permitted facilities. Likewise, low-level

radioactive waste that is free of hazardous constituents or characteristics may be eligible for disposal in existing facilities licensed by the U.S. Nuclear Regulatory Commission or a host state.

TREATMENT CAPACITIES

Throughout the DOE complex, a number of permitted systems currently exist for the treatment of hazardous and toxic waste and mixed waste as well. Some of these systems represent the preferred treatment technology for mixed wastes currently stored or being generated at sites other than the host site. Consequently, where the waste streams from these other sites meet the waste acceptance criteria for existing facilities, agreements have been completed or are under negotiation for the acceptance of waste from these other sites. DOE encouraged this practice to the extent it was feasible (3), given the potential constraints of economics and acceptance by the cognizant regulatory authority. Working off the backlog of waste materials at the host site and from off-site locations then becomes a matter of coordination and scheduling.

Mixed waste to be treated on-site (whether generated on-site or from other sites) is subject to milestones included in the site specific compliance order issued by the regulatory authority with jurisdiction for that site. In establishing and then meeting these milestones, consideration must be given to the total capacity needs for any specific treatment technology (primary and secondary streams. During the review of individual site treatment plans, it was apparent that commercially available mobile or transportable treatment modules (4) would be used where possible. For a site with multiple mixed waste streams over a wide volumetric range, rigor must be applied to calculations of the total capacity of a given treatment module. This is especially true if waste stream treatment is to be carried out in parallel.

As an example, one DOE site has a total of 14 individual waste streams in the aqueous liquids/slurries waste category, but the total volume of this category is about 100 m^3, or 86,000 kg. Waste streams ranged from nickel stripping solution, blue print solution, firing range wash water, waste acid and bases, and decontamination wastewater. The preferred treatment technology for this category was physical/chemical treatment followed by recycling of treated water or discharge through a permitted National Pollutant Discharge Elimination System (NPDES) discharge point, and in either case, solidification of residuals. Due to the variety of streams in this waste category, the aqueous treatment module would require, at a minimum, the following capabilities: demusification, oil/water separation, chromium reduction, precipitation (as hydroxide or sulfide), chemical oxidation, alkaline chlorination, sedimentation, filtration, ion exchange, and carbon adsorption. Development of the detailed design or preparation of performance specifications for the aqueous treatment module requires consideration of secondary wastes generated by other treatment modules that will require subsequent treatment in the aqueous treatment module. At the example site above, secondary wastes from the combined treatment of: recoverable metals, inorganic media without arsenic, soils contaminated with chromium, cleanup and spill response residue, mercury-contaminated debris, combustible debris, inorganic metal debris, and batteries, requires 15 times the treatment capacity of waste streams in the aqueous liquids/ slurries alone.

TYPES OF SECONDARY WASTE

Secondary wastes from the primary treatment of mixed waste is a function of the total volume of waste in any given stream. A description of the variety of secondary wastes generated and the respective treatment for each is presented in Table 1. Although these example waste streams are from a single DOE site, a similar situation would be expected at any other site where the same preferred treatment technology is utilized. An example of the impact may be seen here where the required capacity for treatment of existing aqueous wastes is small compared to secondary streams from soil washing, from soft and hard debris washing, from the crusher/shredder, and from deactivation.

RADIOLOGICAL CONSIDERATIONS

From a radiological protection standpoint, special consideration must be given to the handling and processing of secondary wastes. In many instances, for example, where washing/leaching is used as the primary treatment of hazardous constituents, radioactive species may actually be concentrated in the process and thus introduce potential exposure situations that were not encountered in the ordinary health physics program prior to initiation of mixed waste treatment. Expected situations could require the use of shielding material around ion exchange columns where gamma-ray emitters (i.e., ^{137}Cs) have been stripped from aqueous solutions, and around sludge settling basins where gamma-ray emitters were precipitated during primary treatment. Concentrations of ^{3}H, ^{14}C, ^{99}Tc, ^{90}Sr, etc. in secondary streams are very likely to be significantly higher than in the original stream prior to treatment. Thus, special requirements will exist for the sampling and analysis of these secondary streams. Radionuclides mentioned above are beta emitters and are virtually impossible to characterize using in-situ techniques. The laboratory analysis

of secondary stream samples will require significant resources and will require close coordination to ensure that treatment milestones are met.

Managing these secondary waste stream products will present at least some potentially new radiation exposure situations with resulting challenges for the radiation protection staff. Some considerations that will need to be made include the adequacy of training programs for members of the waste management teams and for the radiological control staff, the adequacy of protocols for sampling secondary wastes, the adequacy of and need for additional types of personnel protective equipment (gloves, shoe covers, clothing, respirators, etc.), and the adequacy of portable and installed instruments for monitoring radiation fields in work areas and the environment.

Table 1 Secondary Wastes from the Treatment of Mixed Waste

WASTE STREAM	PREFERRED TECHNOLOGY	SECONDARY WASTES	TREATMENT MODULE FOR SECONDARY WASTE
Aqueous Liquids/Slurries	physical/chemical	sludges oil/grease	stabilize/solidify incineration
Organic Liquids	incineration	ash and bags scrubber sludge	stabilize/solidify stabilize/solidify
Spent Organic Carbon	regeneration	condensed water/organics returned ashes/bags	incineration stabilize/solidify
Recoverable metals	washing/solidification	washwater washwater sludge waste metal oil/grease	aqueous treatment stabilize/solidify stabilize/solidify incineration
(1) Inorganic media w/o arsenic (2) Debris with mercury (3) Batteries	(1) stabilization (2) Acid leach/chemical precipitation (3) recycle	washwater washwater sludge	aqueous treatment stabilize/solidify
Organic Sludge/solids	incineration	ash/bags	stabilize/solidify
Soils with VOCs	incineration/stabilization	scrubber water ash/bags scrubber water sludge	aqueous treatment stabilize/solidify stabilize/solidify
(1)Soils with chromium (2)Spill response residue	(1)wash/chromium reduction/ stabilize (2) characterize/segregate/ treat	(1&2)processed waste (1&2)washwater (1&2)washwater sludge (2)oil/grease	stabilize/solidify aqueous treatment stabilize/solidify incineration

INTRODUCTION

Radioactive sources commingled with metal scrap have become a major problem for the metals recycling industry worldwide (1). Worldwide there have been 38 confirmed reports of radioactive sources accidentally smelted with recycled metal. In some instances, contaminated metal products were subsequently distributed. The metal mills, their products and byproducts from the metal making process such as slags, drosses and dusts from furnaces can become contaminated. In the U.S., imported ferrous metal products such as reinforcement bars, pipe, flanges, table legs and fencing components have been found contaminated with ^{60}Co. U.S. steel mills have unintentionally smelted radioactive sources on 16 occasions. The resulting cost for decontamination, waste disposal and temporary closure of the steel mill is typically USD 10,000,000 and has been as much as USD 23,000,000. Other metal recycling industries that have been affected by this problem include aluminum, copper, zinc, gold, lead and vanadium.

Exposures to radiation from radioactive sources mixed with metal scrap can be significant, even injurious. In Taiwan, steel reinforcement bars that were contaminated with ^{60}Co were used in building construction and may have resulted in doses of 1 Sv or more to individual members of the public (1). Estimates of whole body external doses received by workers and residents in Cuidad Juarez, Mexico, as a result of a ^{60}Co teletherapy unit disposed as metal scrap in 1983 ranged from 0.13 Gy to 5.5 Gy (1). More recently, in Estonia, a ^{137}Cs source that was mixed with metal scrap was detected by an Estonian scrap metal company and transferred to a waste disposal facility. It was subsequently stolen from the facility. One person who handled the source and stored it in his home died as a result of exposure to radiation and another household member suffered radiation injuries (1).

In the U.S. in 1994, an unshielded 14 GBq ^{137}Cs source was found buried at a scrap metal processing site. It is not known when or how this source entered the plant. It is not known what doses workers at the site may have received. The potential for significant doses from such an unshielded source is, however, clearly evident.

The most prevalent preventative measure that the metal recycling industry has undertaken is radiation surveillance of incoming metal scrap shipments to detect radioactive sources. While such surveillance has resulted in detection of radiation sources that were mixed with metal scrap, even the best surveillance systems cannot provide 100% protection because of the shielding provided by source containers and by surrounding metal scrap. The industry in the U.S. believes that the U.S. Nuclear Regulatory Commission (NRC) and the States should take additional regulatory measures to assure that licensed sources are properly controlled by licensees and, when transferred or disposed of, are done so in an approved manner and, thus, are prevented from entering the scrap metal stream (1).

THE PROBLEM

In the U.S. there are approximately 7,000 persons specifically licensed by the NRC to use radioactive materials. Another 15,000 specific licenses have been issued by 29 States under agreements with the NRC. Most of these licensees are subject to routine inspections by the NRC or the States at intervals up to 5 years between inspections. In the U.S., persons may also possess and use certain devices containing radioactive materials under a "general license". Such devices must meet more stringent standards for design so that they may be used safely by persons without special training in radiation safety. There are about 95,000 general licensees in the U.S. Most general licensees are not subject to routine inspections. Thus, there is a significantly large number of licensees and radioactive sources that are under minimal routine regulatory scrutiny.

One of the most common uses for radioactive sources is in industrial devices for "the purpose of detecting, measuring, gauging, or controlling thickness, density, level, interface location, radiation, leakage, or qualitative or quantitative chemical composition, or for producing light or an ionized atmosphere" (2). Approximately 1,500,000 of these devices have been distributed in the U.S. to general licensees but not all contain radioisotopes in forms and quantities that might concern the metal scrap recycling industry. There are about 86,000 nuclear gauges in the U.S. which contain radioisotopes in forms and quantities that could create radiation and contamination hazards if mixed with metal scrap, e.g., MBq and larger quantities of ^{137}Cs. If warning labels on these devices and gauges become obliterated or knowledgeable personnel at facilities that use them leave employment, the devices may become lost or inadvertently disposed of as ordinary metal scrap. About 200 licensed sources are lost or stolen each year in the U.S. (1). Some have subsequently appeared in metal scrap destined for recycling. In 1991, the NRC proposed a rule that would have required general licensees to inventory their devices periodically and report their inventories to the NRC (3). Resource constraints prevented the NRC from finalizing this proposed rule. Furthermore, resource constraints are tightening: For the fiscal years 1993 through 1996, Congress' appropriations to the NRC fell from USD 540,000,000 to 474,000,000, a 12% reduction. The NRC personnel ceiling in this period fell by 5%. Most State radiation control programs are under similar constraints.

FINDING SOLUTIONS

Given these constraints, the NRC decided to seek alternatives to the 1991 proposed rule and in 1995 formed a joint State - NRC Working Group to review the regulatory program for radioactive devices and develop recommendations for changes, as appropriate. The Working Group conducted two public meetings in 1995 and a public workshop in 1996. A deliberate effort was made by the Working Group to inform and involve persons who could be potentially affected by regulatory changes, e.g., the metal recycling industry, vendors and user of radioactive devices, consultants and service companies, the insurance industry and the public. The Working Group's findings and recommendations will be finalized in May, 1995.

Among the issues that the Working Group is considering are:

- Device design - Currently, design requirements for generally licensed devices are more stringent than for other licensed devices. A different licensing method might require different design criteria.

- Retrofit - Should new requirements be applied to existing devices or be limited to newly manufactured and distributed devices?

- Options for disposal - Disposal options are limited by availability of access to waste disposal sites and costs.

- Device identification - Are there ways of enhancing the ability to identify devices that are improperly transferred or disposed?

- Radiation exposure savings - What savings might result from improved regulatory controls?

- Cost and fees - What options should be considered to pay for the cost of implementing additional regulatory controls?

- NRC and State compatibility - To be effective on a national basis, regulatory changes must be adopted by the States which have agreements with the NRC as well as by the NRC.

Lastly, the Working Group is considering methods to determine the effectiveness of regulatory programs to ensure adequate control and accountability of licensed sources.

INTERNATIONAL IMPLICATIONS

The U.S. has a well developed regulatory infrastructure that dates to the 1950's. Nonetheless, there is concern that the present U.S. regulatory regime does not provide adequate oversight of users of radioactive devices insofar as ensuring that such devices are properly controlled and transferred or disposed of and thus do not pose a radiation exposure hazard to workers, the public and the metal recycling industry. Other national regulatory agencies may also need to review their capabilities in this highly important area. It is important to recognize that recycled metal scrap is an internationally traded commodity and that it may contain unwanted radioactive materials. When recycled metal scrap that contains a radioactive source is smelted, contaminated metal products and by-products can result which could become sources of radiation exposure. These, too, may be introduced into international commerce. Therefore, the problem of radioactive sources commingled with recycled metal scrap requires attention worldwide.

Planning for unconditional release measurement

Dr. Bodo Krebs, RADOS Technology GmbH

1. Introduction

The term "unconditional release measurement" is taken to mean the release of residual substances or refuse from the realm of nuclear approval regulations. Here, it must not just be ascertained through measurement that the residual substances are free from artificial activity with regard to the official approval values, but also that all measurements are documented and available so that they can be verified quickly and logically. Often, due to the low amounts of residual substances that are released, manual measurements are carried out which only provide an adequate level of safety if the rules regarding these measurements are properly followed. Increasingly, different nuclide inventories in the residual substances must be considered. This requires special procedures in data processing.

That the unconditional release technique is becoming more and more important is at least partially linked to the fact that the dumping costs for residual substances have, as expected, reached levels which make every other legal possibility of disposal economical. Here, the gross gamma method represents a very economical method.

2. The gross gamma method

The gross gamma method is based on an approximate 4π measurement of gamma activities. The better the background, which may be present at elevated levels in nuclear power plants, can be reduced in the interior of the chamber, the lower the measurement times are for the actual measurement. With systems without 4π shielding, the background can lead to material of high density and large volume being unable to be measured according to the limits of DIN 25482 for unconditional release. In particular, changing fields, such as for example contaminated residual substances which are moved in the vicinity of the system, produce erroneous results.

The advantage of the gross gamma measurement is in the very short measurement time(about 10 seconds). Here, precise knowledge of the activity inventory as the nuclide vector is essential, because it is used computationally to find the total activity. Also with unconditional measurement systems, which measure spectroscopically, the laboratory determination of the nuclide vector is essential, because all radiation sources are to be measured, including those which cannot penetrate the packaging material (e.g. Fe-55 and many more). For residual material containing ^{40}K, differentiation may be possible with correspondingly extended measurement times. The extra amount of time required for this however does not lead in most cases to a positive cost/benefit calculation, because contaminated material cannot be assumed.

Unconditional release measurement systems with a lid can also handle long-format material, e.g. fluorescent tubes. An enclosed measurement is then carried out. The length that can be measured is only determined by the chamber volume.

The system calibration is carried out with different types of measurement material, i.e. different refuse substances are combined to form one type of measurement material and a calibration standard is set up for this material. Different interpretation of influences can lead to a conservative or progressive determination of the activities, but normally over-estimation of the activity inventory occurs in both cases. In practice about 10 types of measurement material are used.

3. Large unconditional measurement systems or manual measurements

The question of whether the procurement of a comprehensive unconditional release measurement system is economical, cannot be answered solely based on the quantities of residual substances that are to be measured. Certainly, the answer to the question would be affirmative for quantities over a few 10,000 Mg/a, such as arise with demolition. However, here the fact is ignored that even large systems have their limits with such large throughputs. Unconditional release measurements can only have a supplementary role here.

Anyway, the question becomes more interesting with regard to lower quantities, such as for example a few 10 Mg/a which would arise in normal power plants, because the cost/benefit calculation is significantly less favourably slanted towards an unconditional release measurement system. Apart from the procurement costs, the servicing and actual operational costs must also be taken into account. If this calculation is carried out over a few years, the procurement costs play a lesser role. The servicing and repair costs are clearly below a few 10k DM/a and can therefore be largely regarded as negligible. The personnel costs therefore remain the main cause of expenditure. Here, two fundamentally different methods can be applied. Firstly, charges of residual substances can be measured with high priority and without delay by using the help of external personnel. This method is needed for modification work or partial demolition, where either no deposition area is available or the costs for the unconditional release measurement arise simultaneously. Secondly, the measurements can be taken using one's own personnel in periods of less workload, so that internal storage capacity is relieved. With this method the personnel costs should not be assigned completely to the unconditional release measurement, because they represent part of the fixed costs. Here in present circumstances, the procurement of a system is worth it even with a few 10 Mg, whereas a positive cost/benefit calculation can be assumed for the first method from quantities above 60 Mg with 70% unconditional release.

Substantial personnel costs, which are often not taken into account, also occur with manual measurements. The advantage of manual measurement is in the clearly higher sorting rates of contaminated residual substances. The disadvantage is in the difficult later management of result documentation and the very awkward and time-consuming execution of the method. In addition, with the throughput of larger quantities, a reduction in the measurement accuracy is to be expected. At first sight, this presents no problem until a serious incident arises.

4. Concept of the unconditional release measurement

A chamber with a volume of at least 300 to 400 litres is used for the unconditional release measurement. A drum with residual substances taken from the charge to be measured is used as a standard for calibration. If slightly different measurement charges are to be measured at a later point in time, it is recommended that a specially developed calibration drum is used, which is able to accommodate radiation sources with any iron equivalent. With this method and with appropriate preliminary measurements, almost all refuse drums and refuse densities can be produced. The calibration is arranged to be as progressive as the approval authorities or the regulations allow. The necessary safety margins should already be included in the calibration. Additional safety margins should be defined by the radiation protection personnel or by the operator applying clearly defined rules. This avoids a measurement result being later interpreted as being just under the permissible limits.

In principle however, all unnecessary safety margins which are only required for the operators' peace of mind should be avoided so that the successive limits are not brought far below the activities occurring in nature.

The calibration procedure is described and documented.

The charges of measurement material are measured drum by drum. The drums which lie above the defined limits are sorted separately. Depending on the personnel capacity and time available, the drums which cannot be released unconditionally can be analysed more closely.Graphical representation of the measurement results enable a preliminary estimation. If possible, individual parts with high activity are singled out after the drums have been opened. Here, a manual measurement is again required. The drum should be measured again immediately after this treatment. Using this method, rates of about 80 to 90 % for sorting out can be achieved. It is not recommended that samples are taken of the charge of measurement material.

The most important data from the unconditional release measurement should be fixed to the drum in the form of an adhesive label. All the required data and results should be documented drum by drum. This can take place by a log printout or by saving data files in a data base or, better still, using both methods. For uncontrolled release projects complete and understandable documentation should be maintained to serve as documentation for the authorities.

With present-day PC technology these are requirements that can be easily fulfilled, even far more than is necessary.

5. Conclusion

In the course of forthcoming demolition projects in the FRG important knowledge about the process engineering involved in coping with large quantities of refuse will be obtained. In particular it will be seen that very large single amounts can be measured for unconditional release.

The available devices must be able to be quickly adapted to forthcoming requirements and to special individual needs. Now that it has been shown that the total gamma method represents a successful concept, the measurement technology can be refined such that even more interpretations are possible with regard to the activity inventory.

Enlargened chamber volumes with improved detector quality will increasingly be a feature of future monitor designs.

The documentation of the results will be more and more matched to the requirements of the individual user and will accompany and support the approval procedure for an unconditional release project more than ever before.

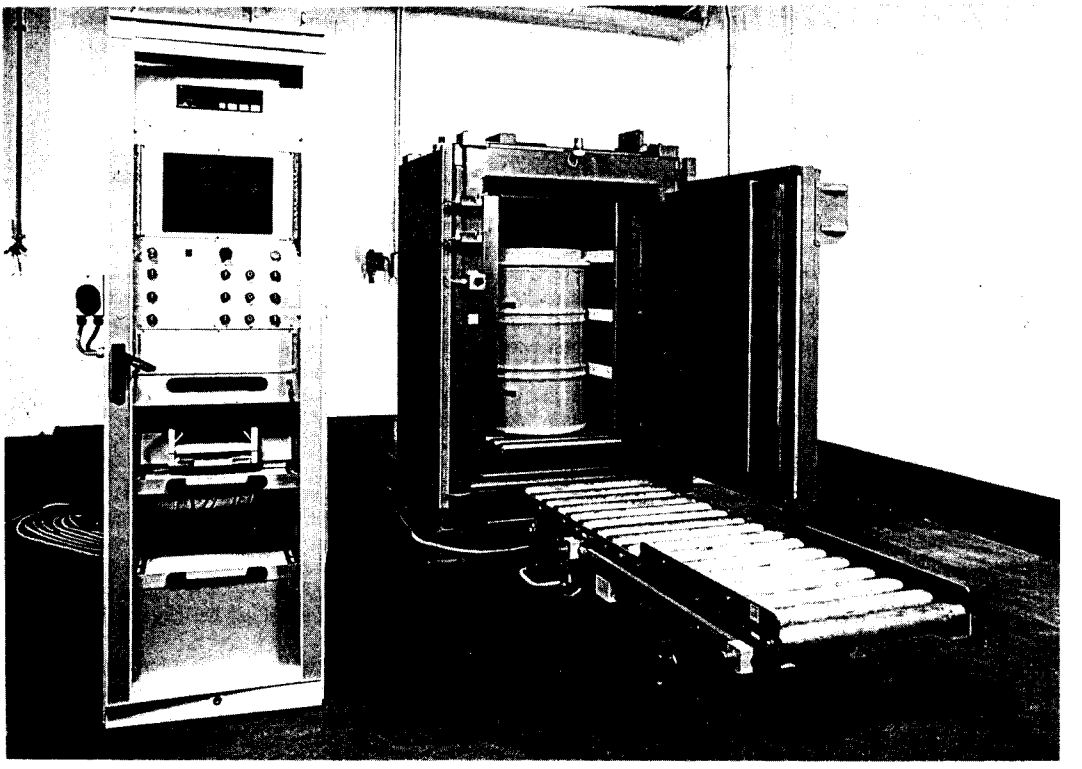

Fig. 1)
Example of an unconditional release measurement system: The RADOS Release Measurement Station H13640 for 200 litre containers. A total of ten separate detectors ensure adequate segmentation. Special design methods in the construction of the frame minimise the effect of the background. The cover and door guarantee optimum charging of the system and the capability of measuring longer objects. With the presence of strong changing fields, a supplementary external detector can be included to take these fields into account.

ABSTRACT (See instructions overleaf)

Quick measurements of objects which are large in size if compared to the detector system, can only be carried out, if the objects are moved past the measurement system. This procedure is to be applied for objects such as vehicles of all kind, waste or recylclates on conveyor belts, or even people.

Especially for large and heavy objects - we like to mention trucks and trains - systems are required, that combine high detector sensitivity with high operation safety. The measurement system must be exact and provide a decision within half a second. Object recognition and measurement start have to be automatic in order not to endanger a smooth operation.

No standardized concepts, for judging the measuement results have been worked out yet. The criteria may be based on dose rate or activity or a combination of both. In many applications these values may have only little to do with each other.

The use of a metal box, in which a defined activity is positioned and with walls that allow to read off a defined dose rate at the outside, has proven to be an optimum for judging the measurement sensitivity of different systems. In practise this procedure rather presents a function test.

WASTE ARISING FROM DISMANTLING OPERATIONS : MELTING CONTAMINATED SCRAP IRON

D. Franquard[1], M. Tachon[2], M.C. Poirier[1]

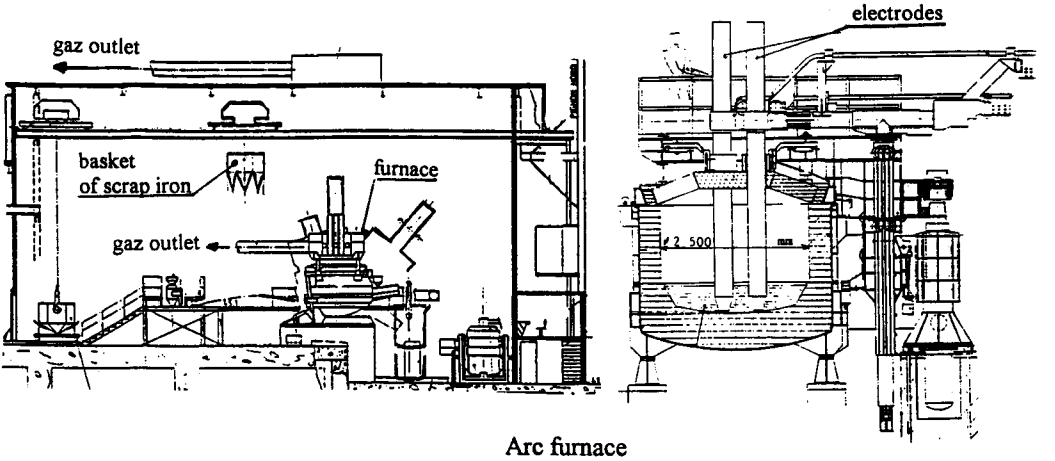
[1]Institut de Protection et de Sûreté Nucléaire, Fontenay-aux Roses, France
[2]CEA, Direction du Cycle du Combustible, Marcoule, France

INTRODUCTION

The « Institut de Protection et de Sûreté Nucléaire » (IPSN) assessed the safety of melting operations for contaminated scrap iron which are carried out in an arc furnace with a capacity of 15 tonnes, located at Marcoule. The « Unité de Démantèlement des Installations Nucléaires » (Unit for Nuclear Installations Dismantling) of the CEA « Direction du Cycle du Combustible » (Fuel Cycle Direction), is responsible for operating this furnace.

To day, more than 5,000 tonnes of radioactive iron have been melted, of which 4,000 tonnes resulted from the dismantling of the coolant systems (CO_2) and the auxiliary equipment of the G2 and G3 reactors. Initially, the iron was cast into 25 kg ingots and into 4 tonne blocks which were placed in interim storage in the G2 and G3 facilities. Then, the scrap iron was made directly into either biological shielding or into cast iron containers for packaging highly radioactive waste.

The radioactive spectrum of scrap iron from dismantling of the G2 and G3 reactors was composed of ^{60}Co (95%) and ^{137}Cs.



Arc furnace

DESIGN OF THE FOUNDRY : LIMITING THE RISKS

The maximum allowable level of radioactivity for materials to be melted was set so that the permissible limits regarding radiological conditions at work for personnel, gaseous discharges into the environment and removal of waste, could be respected.

IPSN took particular care to verify that the dose rates in areas where personnel would be permanently present always remained less than 2.5 μGy/h and that the maximum atmospheric contamination level in the melting room always remained less than 80 times the Derived Air Concentration Limit relating to the radiological elements present.

The arc furnace has a cup which enables very large pieces of scrap iron to be melted. This reduces the amount of cutting, dismantling and handling during preparation of the scrap iron in the foundry. This helps to reduce the overall doses and also helps to reduce the risk of dispersal of radioactive materials during these operations.

This is due to the fact that sections of the pipe-work from the coolant systems of the G2 and G3 reactors, which were 1,200 and 1,600 mm in diameter, could be put directly into the furnace cup which has an inside diameter of 2,500 millimetres. It was not necessary to cut these pipes into small pieces, as would have been the case with an induction furnace which has a much smaller capacity.

To limit the ionising radiation exposures of the workers in the foundry, the majority of the operations are carried out remotely from a control room. The presence of operators in the melting room next to the furnace is limited to rake out slag and to control temperature, i.e. to four workers for 20 minutes per heat.

In order to prevent dispersal of radioactive materials in the foundry rooms, the room containing the furnace is maintained at lower pressure by means of a ventilation system. This ventilation system is also designed to capture the gases and aerosols produced by melting, as close to their emission as possible.

These gases and aerosols (400 kg per heat) are removed at three places : directly from the furnace, from the room immediately above the furnace and from the casting area. The extraction network of this ventilation system, removing around 40,000 m^3/h, is equipped with gas cooling devices and three filtration stages. These are a bag filter, a high efficiency filter that can be unclogged, and a final very high efficiency filter.

Around 99% of the dust emitted is removed by the ventilation system and most of it is captured by the bag filter. The dust which is dispersed in the melting room is removed during the weekly cleaning of the room.

After IPSN had assessed the experience gained from one year of operation and the radiological reports, the maximum limit of radioactivity for the material to be melted was increased, for example, for cobalt from 250 Bq/g to 400 Bq/g.

The main radiation risk in the foundry relates to the complete loss of filtration which could lead to a release of contaminated gases and aerosols by the stack, which could reach 2.7 GBq. However, this accidental condition would have no significant effect on the environment.

REDUCING THE VOLUME OF WASTE

In order to reduce the total volume of dust generated by melting and captured by the bag filter, the dust is returned to the furnace to be melted. Experience has shown that this recycling system does not significantly increase the quantity of dust produced by each melting operation. The number of times it can be recycled is, of course, limited, owing to the increase in radioactivity of the resulting dust.

As regards slag, tests showed that its final volume cannot be significantly reduced by recycling, so it is not.

Melting enables the initial volume of metallic waste to be reduced by around a factor of 10. Furthermore, recycling scrap iron in the nuclear field avoids to use new materials (not contaminated) and, therefore, to increase the final volume of wastes.

FOUNDRY OPERATION REPORT

Radioactive elements are mainly emitted when the scrap iron melts, and not when it is put into the furnace. As this melting phase always occurs when the furnace is closed, and the gases are removed directly from the furnace cup, the dispersal of radioactive materials in the melting room is relatively low. It must be noted that scrap iron is loaded four to eight times during each melting operation.

During melting, the behaviour of each radioactive element depends on its metallurgical properties and on the physical and chemical conditions under which melting is carried out. Therefore, some radioactive elements are systematically lost from the melting bath as aerosols, such as caesium, or as gases, such as tritium. Others are found in varying proportions in the slag and dust. Others, such as cobalt, remain almost totally in the cast iron.

The behaviour of certain radioactive elements such as uranium can vary, depending on the characteristics of the melting bath. Indeed, in the case of reducing conditions (when carbon is added at the beginning of melting), a large proportion of uranium remains in the cast iron. However, during oxidizing melting (without

adding carbon), a large proportion of this radioactive element is found in the slag (70%) and in the dust (30%). Moreover, the addition of oxidizing products during melting increases the amount of uranium recovered in the dust. It is therefore possible to extract the uranium from the cast iron produced by melting.

Experience has shown that radioactive elements remaining in the cast iron, mainly cobalt 60, are uniformly distributed in the material.

Since the foundry started operating in 1992, and until the end of 1995, the total exposure of the foundry personnel was 35 man-mSv. This dose equivalent was shared between around 20 to 25 workers and represented, in comparison, less than 6% of the collective dose equivalent received during all the partial dismantling operations of the G2 and G3 reactors. Finally, the radiological cost per tonne of scrap iron melted in this furnace was on average of 7×10^{-3} man-mSv/t.

OPERATING INCIDENTS

Since the foundry began operation, three significant incidents occurred.

1. Simultaneously loading, for test, sections of pipes and 25 kg bags of manganese compounds into the furnace led to high pressure in the furnace which was channelled towards the top through the sections of pipe, thus lifting a melting room ceiling slab. However, no dispersal of contamination was revealed in the hall outside the melting room. The incident was most likely due to the bags being damp. The adding of manganese is given up.

2. 2.5 tonnes of steel tubes with concrete still adhering to them were put in the furnace which already contained 10 tonnes of molten steel, resulting in a violent reaction. Several slabs of the melting room ceiling were lifted. In this second incident, only the external part of the melting room ceiling was slightly contaminated around the damaged area. This incident was caused by the presence of concrete. The adding of concrete is prohibited.

3. Following one melting operation, a fire was revealed in the bag filter of the gas extraction network. Around 40% of the bags were partially burned. The two other filters placed further down the network were smokelogged, which lead to an increase in their pressure loss and to their deterioration. The quantity of radioactivity released through the stack was less than 540 kBq of ^{137}Cs. This incident was due to the introduction of reactive metals (magnesium, zinc, zirconium, ...). The checking of absence of reactive metals is enhanced.

CONCLUSION

The operating experience of the foundry shows that the risks of dispersal of radioactive material and of exposure to ionising radiation are properly controlled and that the main difficulty lies in acquiring a sufficient knowledge of the chemical composition of the scrap iron so as to avoid introducing materials which could lead to violent reactions during melting. In addition, in comparison with conventional steelworks, the effects of violent reactions are accentuated by the small size of the melting room.

Notwithstanding these incidents, it appears that melting radioactive scrap iron in an arc furnace can be carried out in satisfactorily safe conditions providing their radioactivity and above all, their physical and chemical compositions are known. Setting up a quality assurance programme for the reception of scrap iron at the foundry, systematic analysis of test pieces and rigorous visual monitoring enable the properties of the materials for melting to be better discerned, and thus avoid the presence of materials which could lead to violent reactions during melting of the scrap iron.

Recycling steel in the nuclear industry in the form of biological shielding, containers or other semi-finished products, appears to be an economically viable solution and poses few radiation risks. The mean radioactivity per unit of mass of recycled steel in the plant is about 10 Bq/g.

At last, melting contaminated steel reduces its contamination level and concentrates the radioactive elements into a significantly reduced volume with a better confinement.

RADIATION-HYGIENIC CONCEPTIONS ANALYSIS OF HANDLING WITH REACTOR COMPARTMENTS OF BEING UTILISED NUCLEAR-POWERED SUBMARINES

V.V.Dovgusha, A.Ya.Blekher

Research Institute of Industrial and Marine Medicine
St.-Petersburg, Russia

Elaboration of conception for disjunction and utilisation of ships and vessels with nuclear-powered plants (NPP) removed out of exploitation includes the following main decision:

- Tentative estimation of time-limit after removal of concrete object out of exploitation on the expire of which reactor's compartment (RC) utilisation will come possible, and utilisation technology option;
- The choice of version for RC temporary storage or burial;
- The choice of disjunction and utilisation technology of bow and stern compartments.

The key moment under these questions decision is the radiation state of removed out of exploitation and prepared for utilisation of ship NPP. After discharge of liquid and solid radioactive waste there remain the sources of 2-types radiation in reactor compartment volume: volumetric-radiating-activated material of NPP equipment and superficial-radiating-contaminated by radionuclides equipment's and constructions' surfaces.

Incidentally these sources integral activity with 1-3 years delay time reaches $(1\text{-}2)\cdot10^{15}$ Bq. More than 90 % of long-lived radionuclides are localised in intrareactor constructions that amount to not more of 5-7 % of total radioactive materials mass.

Radiation contamination's level of intrareactor constructions surfaces may reach 2 millions Bq/sm^2, of internal surfaces of the 1-st circuit equipment elements - 100 thousand Bq/sm^2, of the surfaces of the 3-d circuit equipment elements, of desiccation and repair cooling tanks - 20 thousand Bq/sm^2 depending on construction period the surfaces contamination's activity can be conditioned by corrosion products (by Co-60 on the whole) or by radionuclides of fragmentation origin: Cs-137, Cs-134, Ce-144, Ru-106, Sr-90.

Actinide radionuclides activity in the 1-st circuit communications volume of water-cooled ship's NPP can reach $4.5\cdot10^{11}$ Bq.

By 1-3 year delay-time induced activity of construction of exploitation ship's NPP in the places most close to the active zone for reactor casing reaches $2.6\cdot10^{11}$ Bq/kg order value, for reactor caisson - $1.5\cdot10^{11}$ Bq/kg, for steam generator case - $4\cdot10^{8}$ Bq/kg, for pressure hull under reactor - $2\cdot10^{10}$ Bq/kg.

Two conceptions of handling with RC radioactive saturation have been discussed: the first one consists of the absence at present of enterprises with appropriate equipment for disjunction of RC with high-activity equipment and their long-term keeping is necessary for natural activity decay (during 50-80 years) defined by method worked out in our institute. After long-term keeping RC can be disintegrated without large dose expenditures and as a rule - without special remote and protective equipment. Thus for 70 years of keeping the rate of activated gamma-radiation sources will reduce in 1000 times on average.

The alternative conception provides for complete utilisation (remelting) of RC equipment and case.

However RC disassembling immediately after ship's removal out of exploitation is connected with considerable dose loading, heightened risk of environmental radioactive contamination and necessity of using special equipment with remote control. Really, at being

repaired NPS the dose rate in reactor caisson was up to 400 mSv/h, near the reactor case 20-40 mSv/h, in steam generator caisson - 2 mSv/h. Thus, the present conception realisation is possible only after creation of specialised ship disintegrating enterprise, equipped with appropriate technology, that requires large-scale capital investments. Owing to the told the idea of disassembling of RC radioactive equipment before its maintenance did not obtain spreading neither in home nor in foreign practice and in spite of its attractiveness can be regarded only as perspective while keeping in containers ship's NPP equipment of NPS pressure hull and pressurising bulkheads upon its face planes has been realised both in our country and in USA. For normalisation of the radiation situation in conformity with sanitary requirements in the lower part of compartment, in the reactor's arrangement zone, separate areas of pressure hull (container) are covered by proper biological protection. The thickness and configuration in every concrete case can be determined by dosimetric inspection results.

Prepared for burial compartment must correspond to IAEA requirements (1) for type "B" radiation packings (by tightness and impact strength) and PTBRV-73 (2) for the 4-th transport category (by external gamma-radiation levels).

In this case equipment of bow-and stern compartments is disassembled, extracted and either comes for utilisation or is reserved for the second employment. Stage by stage ship's constructions are disintegrated in blocks.

Personnel doze loads under reactor compartment cutting in lower point of external line (without additional protection) average 1 MSv/h magnitude order (under 3-5 years delay). The direct works under reactor's external line require supplementary technological protection, otherwise dose limits will be exceeded in several days or even hours. Our experience indicates that by carrying out factory NPS repairs including opening and decontamination of biological protection tanks, personnel irradiation doses do not exceed 20-30 mSv/year. As well in USA personnel was not exposed to gamma-radiation doses exceeding 20 mSv/year under cutting and preparation for burial NPS reactor compartments (3).

By maintain of main principles of conception various versions of prolonged RC keeping organising can be offered:

- afloat at allocated region of water area;
- inundation in shallow water of allocated region of water area;
- in underground workings-galleries;
- in concrete trenches or on the surface-type grounds protected from precipitation;
- in encirclement of artificially frozen ground, in conditions of permafrost and polar climate (at present thus proposal is being working out in reference to conditions of Novaya Zemlya archipelago).

Afloat storage of ship NPP removed out of exploitation (forming part of NPS, three - compartments blocks or reactor compartments) are of radiation-ecological danger and contradict standards and international recommendations (4-7), being in force forbidding storage of radioactive waste on flooded and waterlogged territories, what is more afloat or under water, in shallow water.

So, this practice should be regarded as forced and provisional. The terms of afloat storage as well as quantity of objects should be reduced to a minimum.

Being in force sanitary regulations and ICRP recommendations exclude the possibility of radioactive waste depots arrangement in flooded and waterlogged places, in regions situated nearer than 500 m from the reservoirs, as well as by ground waters level above 4 m from the depot floor (4-6). Specified requirements should be carried out beyond dependence upon the degree of depot waterproofing, that significantly makes difficult the practical realisation of version NPS' RC arrangement in underground workings-galleries.

The most reasonable and ecologically safe version in organising RC long-term storage of NPS removed out of exploitation is their arrangement in concrete trenches (holes), protected from atmospheric precipitation, or in polar climate conditions in permafrost or artificially frozen ground.

Organising RC storage on the ground surface or in shallow holes (10-20 m deep) and in permafrost ground encirclement also does not contradict with sanitary-hygienic documents requirements.

From the point of view of environmental radioactive contamination the version of storage on specially equipped coast region is of less danger. In this case depot should have not less than two bars on the possible environmental radionuclides route entry. The first includes engineering equipment of storage place for prevention of meteorological and hydrological factors influence, which may break compartment's tightness (covering shield) and engineering system for prevention of radionuclides entry in environment in case RC loss of sealing (spreading shield). Geological formations in depot's arrangement place which must limit radionuclides dissemination are the second bar.

Requirements, similar to arrangement and equipping of points for radioactive waste burial are brought for plot choice.

By execution of all necessary requirements for the storage place the danger of activity dissemination in environment is insignificant and is clearly defined primary by possibility of outward reasons influence (hurricane, whirlwind, aircraft's fall).

As the advantage of version for RC burial in permafrost is the unlimited heat capacity of surrounding rocks and absence of activity dissemination with ground waters as in conditions of frozen rocks of arctic geocryologic region free water completely freezes solid forming so called constitutional ice in which migration process physically cannot be realised.

RC burial in five meters deep from the top part of compartment down to permafrost surface ground satisfy IAEA requirements and home regulating documents for radioactive waste burial (4-6).

The final decision about carrying out of utilisation of equipment materials and constructions of RC removed out of exploitation NPS may be accepted only on the basis of results of materials radiometric examination.

INTRODUCTION

Radioactive-waste materials production in Bologna commune is due almost esclusively to research activity (University, C.N.R., E.N.E.A.) or to hospital assistence activity (Nuclear Medicine). Radioactive-waste products - different for half-life, radiotoxicity, but also chemical and biological toxicity - , can follow different ways of disposal and they can finish incontrollably in the environment.

For estimating the radioecological impact resulting from abovementioned activities , a census of users and main used radioisotopes has been done.

Different methods of disposal has been analyzed and radioactive measures in different samples drawed from city sewer dynamic system - expecially at the entry and at the exit of water depurator. Since the greatest contribute to environmental radioactivity rises from Nuclear Medicine diagnostic protocols, a simple mathematical model that correlates the activity administered to patients with the activity at the entry and at the exit of depurator in different matrix (solid, liquid,and gas matrix) has been created and verified .

A good realiability of model for the most important radioisotopes , like Tc-99m, I-131 ang Ga-137 has been verified . Admissible Maximum Concentration (A.M.C.)has been compared with concentration derived by human activities in water and air.

It has been concluded that the risk for the population is now difficult to point out.

RESULTS

Results are reported in the following tables. Beta-emitter radioisotopes mainly used by laboratories of the University,as H-3, C-14, S-35, P-32, Ca-45 etc., were not foundet at the entry of depurator and not even in other "hot points" in the city sewer system, at least with regard to concentrations higher than 1 Bq/litre. This result is not surprising because radioactive waste products of research laboratories are picked up and treated by authorized firms.

Tab.I shows most important radioisotopes used in Nuclear Medicine, their gamma energy levels (keV),their T(1/2) and the annual amounts administered in Malpighi and Maggiore Hospitals in 1993 (MBq). We can see that more than 95% of activity is imputable to Tc-99m.

Radiois.	En.(keV)	T(1/2)	Malp(MBq/y)	% Malp.	Magg.(MBq/y)	%Magg.
Tc-99m	140	6 h	3,7.10^6	95,5	2,8.10^6	95,4
I-131	364	8,04 d	6,7.10^4	1,75	7,4.10^4	2,5

MATHEMATICAL MODEL

To formulate a mathematical model to value the environment impact starting from the activities administered to patiens we considered: 1) The activities administered to patiens; 2) the half-time T(1/2); 3) the activity distribution in the body; 4) the activity excreted by the patient after three hours since administration; 5) transit time in the sewer city system; 6) activities that,even if escreted, don't reach the depurator (sedimentation, decay, volatilisation).Transit time between the 2 Nuclear Medicine divisions and the depurator was evalued as 3 hours. The treatment of waste waters lasts about 49 hours.

According to the proposed mathematical model, 12% of Tc-99m administered to the patients reaches the depurator and 0,04% leaves the depurator in several ways (ashes,waters,gases).

The final formulation of this mathematical model is :

$$AR = \frac{AS \left(\frac{1}{2^{(TM/T(1/2))}} - K1 \right) \left(\frac{1}{2^{(TT/T(1/2))}} - K2 \right)}{2^{(TD/T(1/2))}}$$

AR = Activity really released in environment
AS = Activity administered to patients.
K1 = (%) not excreted the first time.
K2 =(%) not reaching the depurator.
TM = Average time between administration and 1° excretion (3 h).
TT = Transit time in the sewer city system (3 hours).
TD = Total time required for depuration treatment (49 hours).

Tab.IV reports the good agreement between activities measured each year and values calculated with mathematical model.

Year	Fraction at the entry (%)		
	Tc-99m	I-131	Ga-167
1990	11	21	15
1991	13	22	15
1992	13	22	17
1993	12	72	5
1995	10	23	20
Val.Calculated (Mathem.Model)	12	23	17

ABSTRACT (See instructions overleaf)

The purpose of this study was to devise a treatment method for transuranic (TRU) waste solutions that would remove the TRU elements and concentrate them into a small volume that is suitable for deep geologic disposal. A process that uses magnetite (Fe_3O_4) as a carrier for the TRU elements was developed. This compound is precipitated by adding sodium hydroxide to a solution containing Fe(III) and Fe(II) ions in a 2:1 molar ratio, respectively. It is a very efficient carrier for the TRU elements, and gives decontamination factors (DF, initial amount of TRU element in solution/amount of TRU element remaining in solution after the precipitation) of the order of 10^4 in one precipitation over a wide variety of conditions. The magnetite can be filtered, dried, and packaged for disposal or long-term storage. The remaining solution can be treated as low-level waste since it should contain <100 nCi TRU/gram. If one precipitation does not reduce the TRU concentration to this level, an additional precipitation can be performed. The magnetite can be formed by an *in situ* direct strike (the sodium hydroxide added last), by a reverse strike (the iron solution added last), or by adding pre-formed magnetite to the TRU waste solution.

Among the variables studied were the carrier concentration; the ferric to ferrous ratio; the final pH; the effect of stable anions and cations, including organic complexing agents the precipitate digestion time; initial TRU concentration; precipitation temperature; rate of precipitation; and method of precipitation. The effects of these variables on the decontamination factor will be presented.

REMOVAL OF ^{226}Ra FROM WASTE WATERS RESULTED FROM MINING AND PROCESSING OF URANIUM ORES,WITH NATURAL ZEOLITES

ABSTRACT

The zeolites were of clinoptilolyte type and the used waste waters were: mine drainage waters, waste waters from radiometric sorting and tailings pond waters from a uranium processing plant.

On the basis of experimental results, the parameters of the procedure have been established, wich enables one to obtain a radium removal efficiency higher than 95% at the passage of over 2,000 BEV waste water.

INTRODUCTION

The rasearch was done on laboratory scale and was started to find out an efficient procedure for removal of ^{226}Ra from industrial effluents resulted from exploitation and processing of uranium ores.

For type of zeolitic tuffs from three autochthonous deposits were tested. The zeolite occuring in these deposits is of clinoptilolyte type.

METHODOLOGY

The experiments were done in two steps: in the first step were used synthetic ^{226}Ra solutions to obtain information regarding the removal of the radionuclide by natural zeolites and in the second step using real waste waters resulted from uranium industry.

The experiments were conducted at ambient temperature and atmospheric presure, in dynamics, the ^{226}Ra solutions being passed through sorption columns. The diameter of columns was 10mm, the sorption bed being made up by zeolitic tuff grains of 1-2mm in diameter, previously washed out to remove the fine particles of tuff.

The effluents of columns were collected in fractions having different volumes, depending on the specificity of the experiment. The fractions were analysed for their ^{226}Ra content, being measured the remanent activity of the radionuclide. The radionuclide was measured using its daughter ^{222}Rn.

RESULTS AND DISCUSSION

The experiments were conducted simultanously using the four type of zeolitic tuffs with clinoptilolyte contents ranging between 64 and 77%. The behaviour of the four tuffs was very similar, so that only the obtained average values will be reported.

Removal of radium 226 from synthetic solutions.

Synthetic ^{226}Ra solutions used in the first step of the experiments were prepared by contamination of tap water by Ra Br_2 solution with known activity concentration.

The experiments proved that in the same geometry of the sorbent bed(height-diameter ratio:h/d) the removal efficiency depends on the specific lauding(burden) of the column and implicity on the contact time between the liquid phase and the sorbent. So, passing a solution having 3.7 $Bq^{226}Ra/L$ through a sorption column with h/d=8.4, at different specific burdens were obtained the following results:

Specific burden	Remanet activity	Removal efficiency
[BEV/h]	[10^{-3}Bq/L]	[%]
10	18	99.5
15	18	99.5
20	55	98.5
25	100	97.3
30	174	95.3

It can be noted the very elevated removal efficiency of radium by zeolites, in the conditions when the volume of radium solution passed through the columns was 120 BEV(Bed Equivalent Volume).

The dependance of removal efficiency on the contact time between the liquid phase and the sorbent is shown in Figure1. The optimum time in experimental conditions is of 4 minutes corresponding to a specific burden of 15 BEV/h.

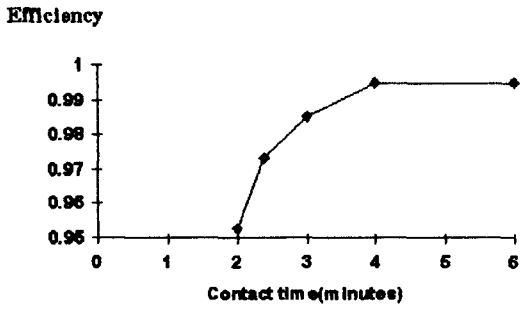

Figure 1. The relationship between removal efficiency and contact time

At this specific burden of 15 BEV/h, synthetic solutions having 0.92, 3.7 and 37Bq ^{226}Ra/L, respectively, volumes of 160 BEV of each were passed through sorption columns having the ratio h/d = 16.8.

The average remanent activities were $7 \cdot 10^{-3}$, $18 \cdot 10^{-3}$ and $451 \cdot 10^{-3}$ Bq ^{226}Ra/L, respectively, the corresponding removal efficiencies being 99.2,99.5 and 98.8%, respectively.Thus, one can note that for a large range of the activity concentrations, the removal efficiency has very high value.

The geometry of sorption columns proved to be unimportant.Thus, at the passing of 120 BEV radium solution of 3.7Bq/L through columns having h/d = 4.2, 8.2, 16.8, and 33.6, at the specific burden of 15 BEV/h were obtained similar efficiencies(99-99,5%).

These encouraging results obtained for the removal of ^{226}Ra from synthetic solutions using columns fieled up with natural zeolites, induced the attempt of using of the same sorbent bed in more cycle after the elution of retained radium. In a test, the same sorbent bed was used in 4 cycle of sorption-desorption , the elution of radium being made using a 5%NH_4NO_3 solution. The specific burdens were 15 BEV/h at sorption and 5 BEV/h at elution, the volumes being 100 BEV for the 3.7 Bq ^{226}Ra/L solution and 20 BEV for the NH_4NO_3 one. In these conditions, even in the fourth cycle, the removal efficiency was over 99%.

Removal of radium226 from true waste waters.

Three uranium industry waste waters were used :mine drainage water, water resulted from radiometric sorting of uranium ore, and effluent resulted from processing of uranium ores.

Due to fact that the activty concentrations the three industrial waters were very low(0.19, 0.56 and 0.17 Bq ^{226}Ra/L, respectively), the sorption test were made using industrial effluent contaminated with 3.7Bq ^{226}Ra/L. So, waste waters having an actual chemical composition and an appropriate activity concentration of radium were obtained. The waste water volumes pased through columns were at least 160 BEV. The experimental results are shown in Table 1.

From the data shown in Table 1 it can be seen that the chemical composition of waste waters has had a negative effect on the removal efficiency of radium, this being the most obvious for the waste water from uranium ore processing. Also, it can be noted that the removal efficiency is not more independent of the columns geometry as for synthetic radium solutions, the decrease of h/d ratio being folowed, generally, by the decrease of removal efficiency.

The detrimental effect of chemical composition of waste waters can be counteract using serial columns, the enhancement of removal efficiency being exactly in the case of processing waste water for which the chemical composition has had the most detrimental effect upon the removal efficiency. Using the same sorbent volume in two columns is more favourable, as for removal efficiency, in comparison to one column.

It can be noted that using the serial column procedure, even at a ratio h/d = 3, the remanent activity concentrations are low, the removal efficiency being over 95% even at specific burdens of 20 BEV/h.

An experiment , using two serial columns with h/d = 3, in which were passed through 2,320 BEV of uranium ore processing waste water, fieled of remanent activity concentration of 0.19 Bq ^{226}Ra/L. Taking into account that in actual Romanian uranium industry waste waters can not be find such high ^{226}Ra activity concentrations, it can be said that in the case of uranium processing effluents it can be achieved an appropriate decontamination using two serial columns (h/d = 3), being able to pass through at least a volume of 2,500 BEV of waste water. These parameters are more assuring for radiometric sorting and mine drainage waters.

Removal of radium from waste waters

CONCLUSIONS

- Clinoptilolyte zeolitic tuffs have a very high affinity for ^{226}Ra, showing high removal efficiencies;
- The chemical composition of waste water can have a detrimental effect upon the removal efficiency of ^{226}Ra by natural zeolites;
- The inhibitory effect of waste water chemical composition can be counteracted using serial columns;
- Natural zeolite column can be used, if it is appropriate, in more sorption-desorption cycles.

DOMESTIC SMOKE DETECTORS - A RADIOACTIVE WASTE PROBLEM?

M W Carter

Mike Carter and Associates, Radiation Safety Consultants,
23 Cassandra Crescent, Heathcote, NSW 2233, Australia.

INTRODUCTION

A common form of domestic smoke detector is the ionisation chamber smoke detector. A small radioactive source provides the ionisation and when smoke enters the sensitive volume the change in voltage is sensed electronically. The use of domestic ionisation chamber smoke detectors is widespread and is recommended by fire authorities and insurance companies. That one million such detectors were imported into New South Wales in 1994 is an indication of the numbers involved. The typical radioactive source in a domestic smoke detector is Am 241, which is regarded as one of the more hazardous radionuclides. If it is such a hazardous material, should it be allowed in the normal household without any control? Or, in a smoke detector, is it in a less hazardous form than assumed in the ICRP recommendations and do its benefits outweigh its possible risks?

In spite of the apparent hazard of Am 241, the possession of the radioactive source in smoke detectors is generally exempt from any form of regulation. Waste regulations, however, set requirements for the disposal of Am 241 and these regulations can be interpreted as applying to smoke detectors. We appear to have a situation where a home owner can legally purchase any number of smoke detectors but when they fail there are Codes of Practice that prevent them being disposed of.

On the other hand, smoke detectors have a direct life saving function and reports indicate that smoke detectors can reduce both injury and property damage by up to 50%. Do these benefits from the use of smoke detectors compensate for any radiological risk?

THE HAZARDS OF AMERICIUM 241

From ICRP Publication 68 (1), the occupational annual limit on intake by inhalation(ALI_{inh}) for an aerosol with an activity median aerodynamic diameter (AMAD) of 1 μm is 500 Bq. The ingestion ALI is 100 kBq. Thus a typical smoke detector with an Americium source of 40 kBq contains about 80 times the ALI_{inh} and about half the ALI_{ing} for an adult worker. Table 1 (based on reference 2) gives the ALIs for inhalation and ingestion for members of the public of different ages. The typical source contains about 2700 times the ALI_{inh} and about 15 times the ALI_{ing} for a one year old.

The majority of Am 241 sources used in domestic smoke detectors are the oxide form. The radionuclide in a gold matrix, sintered at high temperature, is sealed between a silver backing and a thin gold or gold alloy cover, (3). They are robust and can survive quite severe treatment without damage.

Table 1. Am 241 ALIs at different ages.

Exposed person	ALI_{inh} Bq	ALI_{ing} Bq
One year old	15	2.7×10^3
Ten year old	25	4.5×10^3
Adult	26	5×10^3

RADIOLOGICAL ACCIDENTS WITH SMOKE DETECTORS

There do not appear to be any reports of inhalation accidents in the literature.

A case of ingestion by a person who swallowed two Am 241 smoke detector sources of 2.5 μCi (about 100 kBq) each, has been reported (4). The sources were later voided with very little physical damage. The report concluded that the sources lost less than 1 % of their activity and that much less than 1.5 % of the activity released was absorbed into the blood. The authors of the report concluded: "If the sources of Am 241 involved in this incident are representative of those incorporated in domestic smoke detectors, then the most important conclusion that can be drawn is that they are remarkably secure." Current Am 241 smoke detector sources are similar in physical structure, but smaller activities are now used.

CALCULATED RADIATION DOSES FROM THE USE OF SMOKE DETECTORS

External radiation

The OECD (5) has estimated an external dose of 160 nSv from Am 241 to the inhabitants of a protected house.

Inhalation

Table 2. Estimated doses from a fire involving a smoke detector source.

Age	Breathing rate m^3/h	Intake Bq	Dose mSv
1 year	0.35	0.88	0.059
10 years	1.12	2.8	0.11
Adult	3.0	7.5	0.29

For inhalation to occur the source material must become airborne. No inhalation doses will be received under normal operating conditions. The most obvious way for inhalation doses to occur is in a fire. According to the OECD (5) less than 1 % of the Am 241 in the smoke detector source is released in a 925 ^{0} fire. If 0.5% of the material is released and assumed to be distributed in a small room of 20 m^3, then the concentration would be 10 Bq/m^3. ICRP Publication 66 (6) gives an 1 year old child's breathing rate of 0.35 m^3/h during light exercise and a male adult breathing rate of 3 m^3/h during heavy exercise.

Assuming exposure in the small room of no more than a quarter of an hour, the child's intake would be 0.9 Bq and the adults intake would be 8 Bq. Using these values the adult dose would be no more than 0.3 mSv or an child's dose no more than 0.06 mSv. (See Table 2).

If a smoke detector is in a waste stream that goes to an incinerator, there could be a release of the source material if the incinerator temperature is high. Any Am 241 not released will report to the ash and probably go to a municipal tip.

Table 3. Estimated doses from high temperature incineration of a smoke detector source.

Age	Breathing rate m^3/h	Intake Bq	Dose µSv
1 year	0.35	1.75×10^{-4}	1.2×10^{-2}
10 years	1.12	5.6×10^{-4}	2.2×10^{-2}
Adult	3.0	1.5×10^{-3}	5.8×10^{-2}

If 1 % of the source material is released and discharged through a 20 m high stack, and the release occurs over 10 minutes, then the airborne concentration on the ground 50 m downwind would be about 3×10^{-3} Bq/m^3. At that location a child's dose would be 12 nSv and an adult's dose would be 60 nSv. (See Table 3.)

Ingestion

Using the value from Rundo *et al.*(4) for the activity released from an ingested smoke detector source, then the "intake" from a swallowed source would be no more than 400 Bq resulting in an adult dose of 80 µSv or a child"s dose of 150 µSv. A smoke detector disposed of in a municipal tip could leach radioactivity to a local water course. Immersion tests (7) have indicated very slow leach rates. The movement of Am 241, once leached from the source, has been estimated (5) to be 10^{-4} of the ground water velocity. Public radiation doses due to leaching from a tip would be negligible.

Table 4. Estimated doses from use of smoke detectors.

Age	External dose. µSv	Inhalation dose from incinerator. µSv	Accidental inhalation dose from fire. µSv	Accidental ingestion dose. µSv
1 year	0.16	1.2×10^{-2}	59	150
10 years	0.16	2.2×10^{-2}	110	90
Adult	0.16	5.8×10^{-2}	290	80

RISKS FROM THE USE OF SMOKE DETECTORS

Table 4 summarises the possible doses from each pathway discussed above. The once in a lifetime inhalation dose from a fire is the most significant dose. How many people are assumed to be exposed to inhalation of Am 241 in a domestic fire is therefore critical in assessing the overall risk.

THE BENEFITS OF SMOKE DETECTORS

The OECD report (5) indicated that 40 % of fire deaths could be prevented by the use of smoke detectors. Gratz and Hawkins (8) indicated up to 39 % reduction in death and injury and the US National Fire Data Center (9) indicated about 50 %. Similar percentages are reported for reductions in property loss. The OECD report quotes a figure of 18 fire casualties per million population per year, 70 % of which occur in private dwellings. If these data apply to Australia, there are about 13 fire casualties per million per year in private dwellings and about 6 of these could be prevented by the widespread use of smoke detectors.

ALARA

Assuming that each year one adult person in a hundred is involved in a domestic fire inhalation event, one adult person in a thousand is involved in an incinerator fire inhalation event and one 10 year old in a hundred ingests a source, the average annual dose would be about 0.16 μSv. (That is, for the assumptions used, the inhalation and ingestion accident doses have negligible effect on the average dose.)

Using the ICRP (10) probability for stochastic effects of 7.3 % per Sv this would result in 1.2×10^{-2} stochastic effects per million per year. It must be pointed out that natural background radiation is about 2 mSv per year so the calculated increase in annual dose would not result in any observable health effects.

It has been estimated that there are about 13 fire casualties per million per year in private dwellings and that 6 of these could be prevented by the widespread use of smoke detectors. The ratio between probable reduction in fire casualties and possible radiation detriment is 500 to one. This takes no any account of the reduction in property damage.

CONCLUSIONS

The benefits from the use of domestic smoke detectors are at least 500 times greater than the possible harm.

The application of ALARA requires that the radiation detriment be reduced until further reduction is not cost effective. The radiation dose calculated here is so small that any cost to reduce it further would not be cost effective.

If ionisation smoke detectors are the most effective type, and if Am 241 remains the nuclide of choice for domestic smoke detectors then regulators must recognise the fact that the method of construction of the source material makes significant accidental exposure unlikely, the benefits far outweigh the risks, and the exemption that applies to ownership should be extended to the disposal of these sources.

A STUDY OF BPEO IN THE CONTEXT OF LIQUID RADIOACTIVE WASTE GENERATED AT BNFL SPRINGFIELDS FUEL MANUFACTURING PLANT

ABSTRACT

Techniques for establishing Best Practicable Environmental Option (BPEO) in relation to the management of radioactive wastes are undergoing development. Recent experience has been gained via a study at BNFL Springfields fuels manufacturing plant involving identification of options for treating liquid waste, screened evaluation and sensitivity analysis to aid selection. Confidence in the process was such that an interim finding was accepted by the regulators and implemented as the BPEO by BNFL ahead of the finalised work on the study.

INTRODUCTION

Radioactive aqueous waste containing alpha and beta/gamma emitters associated with U-238 and Th-232 decay chains are discharged by BNFL Springfields to the tidal river Ribble in Lancashire under joint authorisation of Her Majesty's Inspectorate of Pollution (HMIP) and the Ministry of Agriculture, Fisheries and Food (MAFF). The dose impact of the discharges amounted to around 0.02 to 0.03 mSv to the critical group during the early 1990s (1). During a review of the authorisation in 1991 a number of options were identified as having potential for reducing further the impact of the discharges and in order to evaluate such options, HMIP and MAFF placed a requirement on BNFL to undertake a BPEO study. This paper describes the methodologies used, the potential difficulties encountered and how they were addressed.

METHODOLOGY

The Royal Commission on Environmental Pollution (2) have provided a conceptual approach for conducting a BPEO study. This approach formed the framework within which the study at Springfields (3) was developed and in essence consisted of option generation, screening, evaluation by multiattribute analysis, initial derivation of the BPEO and confirmation by sensitivity analysis.

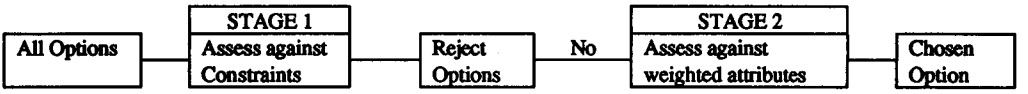
Identification of Treatment Options

Prior to considering specific options, it was considered essential that a full understanding of the waste streams should be obtained, including identification of all sources of contaminants, physical and chemical properties and waste volumes. A fully open minded approach was maintained towards identification of possible treatment options. These ranged from the obvious to the novel including the existing arrangements; options were grouped into common themes, namely (i) limiting impurities in feed materials, (ii) physico/chemical treatment, (iii) hold up to allow radioactive decay and (iv) dispersal by means of discharge. Within these groupings, a total of twenty-one options were arrived at with some options being earmarked as potentially suitable for combining.

Evaluation

In view of the number of options, a two staged approach was adopted in which low ranking options were first eliminated by screening, see Figure 1. This provided an opportunity to target the more potentially fruitful options with more detailed development and costing.

Figure 1. Schematic of Springfield BPEO Methodology



Stage 1 - Screening using Constraints

All options were first assessed against a set of constraints covering statutory obligations, technical feasibility and availability, and financial aspects. It was imperative that implementation of the BPEO did not infringe any legal requirements. Judgements on technical availability were made on the basis that the technique or process had to be accessible, proven or capable of being developed and installed within a reasonable timescale. A six year time limit was used based on a judgement that potentially effective options would not be eliminated due to the development time needed. Costs were an important factor and to avoid bias, all options were sufficiently developed so that they could be compared on an equivalent basis. The detrimental costs following discharges were taken into account and the base line figure recommended by NRPB (4) of £20,000 per man Sv was used together with other health, safety and public concern factors to identify a reasonable level of expenditure. Financial considerations were responsible for the rejection of 52% of the options in the Springfields study compared to 28% for technical constraints.

Stage 2 - Performance against Attributes

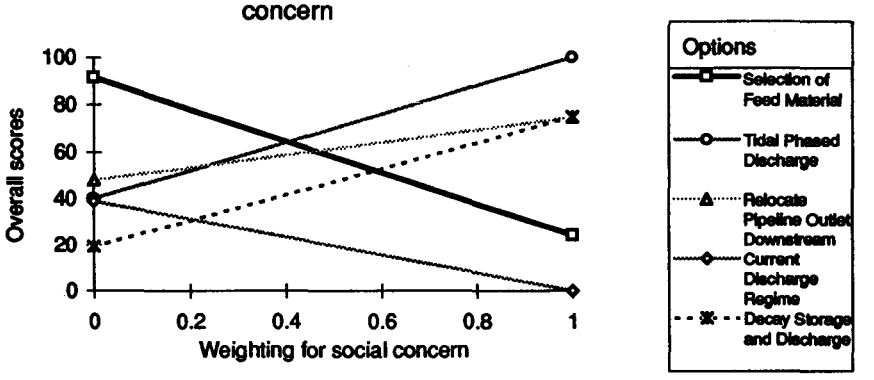
This stage was designed to assess the options which remained after screening using multi-attribute analysis. Attributes were chosen *inter alia* from a review of the constraints. Seven attributes covering quantitative and qualitative factors were arrived at, namely collective dose, skin dose and committed effective dose equivalent to the critical group, timescale, cost, non radiological environmental impact and social concern. For each option in turn, a score was derived according to its performance against each attribute. Linear functions were set by assigning the best performing option (or options in the event of a tie) a score of 100 and the worst performer a zero score. Alternatives to linear relationships were difficult to justify in the present case. A range of weights was chosen for the attributes to take account of their relative importance and the scores were weighted and summed. The highest score was indicative of the likely BPEO.

Assessing relative weights for each attribute is arguably the most difficult and potentially controversial part of the BPEO process. A balanced view can be obtained through consultation between operator and regulators who took account of local and environmental concerns. The outcome of consultation for the Springfields study was that dose was the most important factor with a average relative weighting of 0.4 (85% CEDE, 10% collective and 5% skin), cost was next with weighting of 0.25 and the remaining 0.35 shared roughly equally between all other attributes.

Sensitivity Analysis

The sensitivity of the BPEO to changes in input parameters and assumptions was examined to ascertain that it was reasonably sound. The choice of these parameters depends on how the study was conducted. In this case the weights assigned to each attribute were less well established than the input data for each option and hence the better target for sensitivity analysis. The weights were adjusted by a factor of 4; this accommodated around 90% of the suggested weightings from the consultation exercise and hence was considered to be a reasonable range. This variation did not alter the BPEO arrived at; this was an option under (i) above entailing restricting impurities in the process material. An illustration of this is given in Figure 2 which relates to the attribute social concern and the options remaining after Stage 1 screening. The sensitivity work also indicated that combining the BPEO with the option to change the operating regime in connection with dispersal of radionuclides on discharge could enhance the overall benefit and hence the latter option was earmarked for further evaluation.

Figure 2. Overall scores in relation to weighting for social concern



ISSUES ARISING

A number of difficult issues arose during the course of this study some of which have been already indicated. Some additional issues are highlighted below to assist in future studies.

- A balance may need to be considered between radiological benefits and potential worsening in environmental impact from discharge of chemical species.
- A balance between public and operator doses may have to be addressed.
- Implications for commercial viability and related employment factors may need to be addressed in admitting costly treatment options.
- Public perception stemming from export of waste and hence risks to a different population may have to be addressed.
- There may be a tendency as a result of public or political expectations to implement the best environmental option rather than the BPEO.

CONCLUSION

An open, structured and well documented approach towards BPEO studies with appropriate consultation and demonstration by sensitivity analysis is likely to produce a result which is more universally acceptable. Support for this can be drawn from the present study.

[1].- Instituto de Investigaciones Biomédicas (CSIC), Madrid, España, [3].- ENRESA, Madrid, España. [4].- Hospital La Paz, Madrid, España. [5].- Centro de Biología Molecular (CSIC-UAM), Madrid, España.

This document sets out to provide a guide to the safe handling of radioactive waste produced in medicine and biological research.

Naturally in order to know how to handle radioactive waste properly we must first establish the exact nature of such waste and how it has been produced.

This Guide is basically divided in three parts. The first and main part establishes the correct procedures to be followed in the generation, distribution, manipulation and disposal of radioactive materials.

The second part, which appears in the form of an appendix, offers the norms for protection from radioactivity in the workplace, and refers to methods of decontamination and criteria established in the design of installations as well as appropriate training for employees working directly or indirectly with radioactive materials.

The third and final part describes the process by which the relevant authorities are involved in the disposal and declassification of radioactive waste.

The Guide draws on the experience of professionals working in radiological protection in medicine and biomedical research, and serves to homogenize methods of handling radioactive waste. Furthermore, it offers a new method of characterizing such waste.

In order to manipulate radioactive material, we present operational radiological protection rules, detailing a method to evaluate waste generated in radioisotopes application techniques, based on an analysis of the material used in each technique, its ways of manipulation and quantifying some of the resultant waste. So, by this kind of analysis for each technique, it will be possible to perform a characterization of the resultant products and also a valuation of the total volume produced in the centres.

The radioactive waste management is subdivided in waste that can be declassified directly or after a decay process, and waste that cant be declassified. The latter ones must be managed by an authorized enterprise.

To manage the declassified waste, we propose to carry out an authorization request, to make the pouring by conventional means, to the appropriate organism by comparison between the waste activities and the published international regulations, until the national regulatory organism publishes its own declassified regulations.

We also provide a procedure to control the decay of the waste that must be kept in temporary storage for a period of time until they will be under the limits to perform its management by conventional means.

We establish a control procedure before evacuation to let the user assure that the wastes are under the limits, have the expected destiny and are in accordance with the authorization request.

As in the case of wastes to evacuate by conventional means, we expose a procedure to control wastes before the evacuation by the authorized enterprise.

ABSTRACT (See instructions overleaf)

LONG LIVED, LOW LEVEL RADWASE FORECAST IN SAUDI ARABIA

Samir Abdul-Majid, Ibrahim Kutbi and Abdullah Al-Marshad

Most of the open type radwastes are generated in medical and educational centers in Saudi Arabia; their total numbers are about 15 and 5 respectively, while sealed spent sources are coming from industry. The volume of long lived radwaste was estimated up to the year 2020 for the proper, design of interim storage and radwaste treatments and conditioning facilities purposes. It was anticipated that two main parameters affect the increase in radwaste in the future. The first is the increase of radionuclides use in hospitals in diagnostisis and therapy in the country. The extrapolation of the increase of ^{99m}Tc-^{99}Mo generators over the last few years was used as a growth indicator for this parameter. The second is the increase in population which should be associated with increase in medical services in general. The population is expected to increase about 1.8 times in the year 2020. The annual, long lived waste, that need treatment, conditioning and storage as a function of time is expected to follow the relation, $V = 10 + 0.048t^2$, where V is the waste volume in m^3 and t is the time in years after 1995. The radwaste production rate is expected to be 4 time its current value in 2020. The expected long lived cumulative treated, conditioned and liquid wastes, in that year, if not subject to volume reduction, in m^3 will be: 500, 75 and 100 respectively. Comparisons were made with IAEP waste volume expectations for countries of similar conditions; the results were in reasonable agreement.

Environmental impact of a Very Low Level Waste specific landfill

Ch. BRUN-YABA*, J.M. PERES*, F. BESNUS*

* Institut de Protection et de Sûreté Nucléaire, France
Département de Protection de l'Environnement et des Installations.(IPSN-DPRE)

I - INTRODUCTION

Operating enrichment plants, nuclear power plants and reprocessing plants and the decommissioning of nuclear facilities will give rise to large volumes of waste material (concrete, steel and others metals, technological wastes heat insulators...) and most of them, in term of quantities, will be categorized as Very Low Level Wastes.

This paper deals with the environmental impact of a specific landfill as a final destination for the Very Low Level Radioactive Waste (VLLW) with the aim of providing technical elements for safer workers practices during the operational and the monitoring phases and for a public occupation after closure of the site. This study has been made on the basis of inventories in terms of estimated quantities and spectra of the French VLLW for a set of scenarios which are representative of practices in a landfill.

II - POSITION OF THE FRENCH AUTHORITIES

For very low level wastes, it will be necessary in a near future to define practical rules to achieve a coherent and standardized management of VLLW.

The nuclear regulatory agency DSIN proposes to establish controled disposal channels with a total treacability of all waste produced. In particular, this process will lead to the elaboration of studies on VLLW, the definition of "zoning" in nuclear installations to identify areas having a potentiality to generate radioactive wastes, the definition of adapted channels based on impact studies, for each kind of radioactive waste and the creation of VLLW specific landfills with accurate regulatory controls.

A concrete and approved solution is not finalized, but a specific landfill, concept between an industrial landfill and a low-and-medium level waste repository, seems to be a realistic solution.

III - ORIGIN AND POTENTIAL QUANTITIES OF VLLW

Low specific activity materials can arise during most maintenance activities carried out in nuclear fuel cycle facilities, however the largest potential source of such materials is from the decommissioning of nuclear facilities, especially the commercial power reactors.

Origins of the Very Low level wastes are multiple and theirs specification also. They result especially from :

- operating of the nuclear facilities, enrichment plants, nuclear power plants and reprocessing plants,
- the dismantling of the same nuclear facilities from 1970 to 2090,
- the radioactive wastes from the "small producers" , hospitals and universities,
- the uranium mine and mill tailings wastes,
- the wastes issued from fabrication processes in the classical industry but using radioactive materials.

The three last categories have not been taken into account in this study for the following reasons :

- the radioactive wastes from the "small producers" are incinerated,
- the uranium mine and mill tailings wastes are disposed of at the extraction site because of very large volume and specific nature of the radionuclides,
- the wastes originated from fabrication processes in the classical industry but using radioactive materials are submitted to special treatment case by case.

We consider that in 2050, all French gas-graphite reactors will be dismantled, as well as uranium enrichment and reprocessing plants operating at present time. We consider also that the stage 2 of PWR dismantling will be over. Depending on the delay of 40 years taken into account between the stage 2 of decommissioning and the stage 3 (final phase) for PWR power plants, the VLLW production will drop down for 25 years between 2050 and 2075.

IV - DATA AND PARAMETERS OF THE IMPACT STUDY

IV 1 Source term

The estimated VLLW volumes are 60 000 m^3 for 1994-2015, 128 000 m^3 for 2016-2030 and about 60 000 m^3 for the last period, 2031-2049. The total volume of waste would be about of 250 000 m^3 for a total weight of 866 000 tons.

The drums are put in trenches dug below the original ground level and covered with the concrete and rubble wastes. The dimensions of the landfill are 350 m length, 100 m width and 7 m depth without the ground cover.The mean activity will be of 10 Bq/g with a mean spectrum depending of the origin of the waste.

The main radionuclides likely to be found in VLLW are H3, Mn54, Co58, Co60, Ni63, Sr90, Cs137, U234, U238 and α-total. The spectra are mean spectra, weighted by the potential quantities of the four main materials: concrete and rubbles, metals (steel, copper, aluminium...), technological wastes and heat insulators.

The release of activity from the source to the geosphere is modelled by the Annual Leaching Fraction (A.L.F) for each radionuclide.

IV.2 Description of the geosphere

Calculations have been made for a generic site, the hydrogeological characteristics being quite representative of a surface site disposal [1]. The main outlet is a river with a flow rate of 1.10 m^3/y located at 250m of the nearest landfill boundary. The medium is clayey-argileous, equivalent to a porous medium. The radionuclide transport is slowed up by the sorption of species in the medium and modelled with a distribution coefficient Kd [1].

IV.3 Description of the biosphere

The river water is used for irrigation and for drinking (man and cattle). A conservative diet [1] is defined with meat, fish, vegetables and drinking water comsumption; all these products are coming from the site (autosuffisance). The biosphere data, transfer factors in the differents boxes of the biosphere are taken from litterature and International exercices [2] [3].

IV.4 Exposure pathways

The workers involved in the operating processes will inhale and ingest dust or soil deposited on their hands and face, and will be submit to external exposure from the waste scraps. We considered a driver of handling truck and a chemist who makes measures on small samples of wastes.

We considered that thirty years after closure of the landfill, an individual would live on the site in a house with a garden around (residence scenario). This individual could be an adult, a 10 years old child or an 1 year old baby. The scenario takes into account all the possible pathway exposures.

We have also considered the use of contaminated water, during the operating and post-closure phases, for the irrigation of crops, for fishing areas, by consumption of contaminated drinking water and by consumption of meat from cattle eating pastures and drinking water at the discharge point.

V - IMPACT RESULTS

V.1 Methodology of dose calculations.

The methodology for estimating the individual dose resulting from the exposure pathways described above, is to calculate the impact of a set of scenarios representative of practices using the best-estimate values for related parameters (time of exposure in the practice, inhalation rate, concentration of particles, ingested quantity of dust, human diets,...).

Calculations of the doses during the operational phase of the landfill and for the residence building after closure, are made with the computer code CERISE [4] which determines for various individual exposure situations, the relationship between the effective dose and the radioactivity of a material handled by or located near the person considered, or his radioactivity intake.

Calculations of the radiological consequences from the landfill activity flow rate to the river outlet uses the geosphere GEOS code [5] which estimates the activity flow to an outlet, river or well, coupled to the biosphere ABRICOT code [6].

V.2 Results of dose calculations.

The maximum annual dose occurs in the landfill aera during thethird operational phase where the annual flux of waste is maximum. The total massic dose is of $3.7.10^{-1}$mSv/y for the manual worker, for all radionuclides and all practices taken into account. 65% of this dose is due to Co60 ($2.4\ 10^{-1}$ mSv/y).

For the public scenarios, the maximum dose due to the residence scenario is $2.4\ 10^{-2}$ mSv/y for the adult and 3.10^{-2} mSv/y for the ten year old child. This dose is due for 30% to Pu239 and for 20% to Cs137. The residence has been considered to be built 30 years after the closure of the landfill and the short-lived radionuclides have strongly decreased.

For the river scenario, between 1994 to 2094, the maximum dose of $6.5\ 10^{-4}$ mSv/y is due to Tritium and the maximum occurs very early (about 2040) because of the absence of sorption in the geosphere for this radionuclide. This dose is essentially due to the consumption of vegetable products (~100%), especially cereals (62%) and fruits (21%).

The absolute maximum dose of 5.10^{-3} mSv/y occurs about 6500 years after closure of the landfill and is due in equal proportion to the uranium isotopes U234 and U238. The main pathway is vegetables consumption for 90%, water drinking for 5% and 1.5% for external exposure.

VI - CONCLUSIONS

The deterministic calculations of individual dose were performed for a low isolation capacity. It should be mentioned that it is possible to add engineered barriers to improve the safety of these disposal facilities :

- barriers to make the intrusion of humans, animals or plants more difficult. These include : greater thicknesses of earth cover and reinforced concrete ;
- barriers to prevent the ingress of grounwater, surface water or precipitation. These include : clay covers, synthetic impermable barriers, draining layers and hydraulic bypasses around the facility ;
- barriers to prevent the release of radionuclides from the disposal. This include : impermeable clay or man-made barriers and buffers which let water out but retard radionuclide migration.

Besides the possibility to improve the landfill safety by the implementation of such technical solutions, the generic impact assessment performed shows that the effective doses undergone by persons of the public are well below 1mSv whatever operational or post-closure phase is considered. The highest calculated exposure concerns mainly engine drivers submitted to external irradiation. It should however be stressed that in this case, the range of doses undergone by workers are again low (about one order of magnitude below 1mSv, and mainly due to Co60). Since exposures are only relevent to ponctual operations, they can easily be reduced if necessary by additional temporary protection (such as radiation protected engins or temporary shields above wastes).

According to former results, it is therefore foreseeable that VLLW are likely to be disposed of safety in specific landfills of very simple conceptual design (such as for example the back filling of quarries). Some favorable site characteristics should be looked for but since the radiological impact of the landfill is low, the site selection criteria may not be stringent.

Institut de Protection et de Sûreté Nucléaire, Fontenay aux Roses, France

1. INTRODUCTION

Concerning long lived and high level radioactive wastes, the French Wastes Management Research Act (30th December 1991) has set three ways to be studied : separation and/or transmutation, conditioning processes and volumes reduction, and feasibility of geological disposal. ANDRA, in charge of this last point; has the responsibility to create and develop Underground Laboratories, to elaborate and propose the concept of the future disposal installations with safety demonstration, to be submitted to the French safety governmental authorities (Direction de la Sûreté des Installations Nucléaires). In order to asses these safety demonstrations, to build up its judgement, DSIN will ask technical advice, from Institut de Protection et de Sûreté Nucléaire (IPSN).

To be able to meet these requirements, IPSN is developing, in the framework of its Research and Development safety programs, in situ research concerning the confining properties of geological formations. In order to perform experiments in representative conditions concerning mainly geotechnical and hydrogeological properties of very low permeability rocks, appropriate underground sites have been selected in the past in granite and shale formations. IPSN activities at the Tournemire site are the most important activities regarding specifically research about characterisation of transfers through an argilite formation. This programme is developed in the framework of a cost sharing research contract between IPSN and EC.

2. OBJECTIVES OF THE IPSN TOURNEMIRE TUNNEL PROJECT

2.1 CHARACTERISTICS OF THE TOURNEMIRE SITE

By the end of 1990, IPSN initiated in situ research concerning argillaceous formations, considering the relative lack of knowledge about the behaviour of deep impervious clays. IPSN is studying a geological representative formation constituted by indurated claystones of Toarcian. This site has been selected because of its geological simplicity and also because a former railway tunnel gives access to the centre of the toarcian formation [1]. This is an hundred years old railway tunnel, 1885 meters long, in the close vicinity of the village of TOURNEMIRE (Aveyron), in the South of France, crossing a 200 m thick toarcian clay formation. The overlying limestones are 250 meters thick, so the geotechnical and hydrogeological conditions can be considered as representative of those of a deep repository.

The geological formations of the site are constituted by sub-tabular sedimentary layers of the lower and middle Jurassic Period. The stratigraphic formations involved in the Tournemire environment are as follows : Hettangian and Carixian (limestone, dolomites and interbedded marls), Domerian and Toarcian(245 m of marls and argilites), Aalenian, Bajocian and Bathonian (250 m of massive limestone and dolomites).

The prevailing lower limestone formations of Hettangian and Carixian contain the general lower regional aquifer. At the place of the tunnel, this aquifer is in charge below the impervious domerian and toarcian clays. The limestone layers from Aalenian up to upper Bathonian are the reservoir for the upper regional aquifer : at Tournemire, this aquifer lies in the lower part of the Aalenian and should feed the toarcian clay just below. Taking into account the hydraulic heads of the two aquifers, the fluid transfer through the toarcian argilites, which could behave hydraulically as a semi-permeable medium, is supposed to be vertical downwards.

2.2 WORK PERFORMED

The research program concerns hydrogeological properties in order to determine the characteristics of fluid transfers through the clay formation and it intends to perform modelling of these fluids transfers.

The Tournemire programme includes general geological and hydrogeological investigations, drilling operations for detailed geological studies (information about the depth, lithology, stratigraphy and hydrology), including structural studies relative to paleohydrogeological understanding, development of in situ tests including permeability tests at different level (mainly pulse tests), and boreholes equipment for interstitial water pressure measurement in low permeability rocks, sampling of material for laboratory studies on cores including petrophysical conventional identifications, diffusive characteristics, development of isotopic studies of the interstitial fluid and solid phase (matrix and fractures).

During a first phase, six boreholes have been drilled from the tunnel to the bottom and to the top of the Toarcian formation [1]. From the results of this phase, the programme has been developed thanks to long time hydraulic testings into boreholes specifically conceived for rocks of very low permeability, detailed fundamental studies relative to the possibilities for fluid transfer : diffusive transfer, different fluid potentials and associated

fluxes measurements (chemical, suction...), and a natural isotopes measurement programme on the whole formation surrounding the tunnel aiming to characterise transfers both at the geological time scale and at the time scale corresponding to the perturbation due to the presence of the tunnel itself.

As these developments suppose a good understanding of the structural characteristics of the rock, and the achievement of a very high quality sampling phase of the formation, the on going work is based on a coring campaign of height boreholes around the tunnel [2].

3. MAIN RESULTS

3.1 PETROPHYSIC ROCK CHARACTERISTICS

The argilites appear to be very thinly bedded rocks mainly composed of clay minerals (40-50%) such as mica, kaolinite, illite and interstratified clay mineral close to illite, with about 10 to 40% of carbonates (dolomite, siderite and mainly calcite), 10 to 15% of quartz, and a few amount of chlorite, and pyrite.

The water content is very low : 1 to 3%. The free total access porosity measured with mercury is about 3 to 4%. The determination of the pore volume and the distribution size of these pores thanks to the B.E.T. method has shown that the dominant pore size family was centred on the value of 0.0028 µm corresponding to a total porous volume between 0.0071 and 0.0198 cm^3/g. The mean specific surface is about 10 to 25 m^2/g.

Hydraulic conductivity from laboratory tests with water is between 10^{-13} m/s and 10^{-14} m/s. The very low permeability, and the very small dimensions of the porous space lead to conclude that the fluid transfers in this kind of rock are not governed by convective processes, but by processes such as diffusion or others which have to be recognised and quantified.

Mass transfer studies of fresh tritiated water through argilite sample allowed both the characterisation of diffusive transfers, and those (permeation) under an hydraulic head (15 bars). Diffusion coefficient value is estimated around 3.5 10^{-12} m^2/s (with a total porosity between 8.5 to 10.2 %), and permeation coefficient mean value K_p is about 2.5. 10^{-14} m/s, meaning an average permeability coefficient K_H of 9.5. 10^{-15} m/s. These results seem to confirm that water or humidity transfers are essentially diffusive.

3.2 IN SITU HYDRAULIC CHARACTERISTICS

Many in situ permeability tests at different levels have been performed (mainly pulse tests) as well as geophysical loggings. The in situ permeability of the toarcian and domerian clay formations is very low, between 10^{-11} and 10^{-13} m/s [1]. The permeability of the calcareous carixian and aalenian formations is substantially higher : the Carixian has permeability of about 10^{-8} m/s and the Aalenian of about 10^{-6} m/s.

The aquifer heads, in the carixian and in the aalenian limestone correspond with the values that can be deduced from the hydrogeological regional and local system. But it has not been possible up to now to determine the actual head in the argilite formations because of the very long period to reach the steady state after the perturbation induced by drillings resulting from the very low permeability of this kind of rock.

3.3 CHEMICAL AND ISOTOPIC STUDIES FROM INTERSTITIAL PORE WATER

Isotopic and chemical contents of the interstitial fluids from the Tournemire argilites reveal an high heterogeneity of the fluids into the formation [3]. Due to the very low water content (1 to 3% wt) of this rock and to its high degree of induration. it has been impossible to use the squeezing technique for the extraction of total interstitial water. Thus, attempts to evaluate water chemistry have been made by leaching techniques, but interstitial water was exclusively recovered by distillation under vacuum to measure its stable isotope contents (^{18}O et ^{2}H).

Two fluid families, with different chemical facies have been identified (from absolute ethanol leaching) : (i) one $CaSO_4$-Mg type of fluid, representative of both aalenian limestone and high $CaCO_3$ content levels from the upper toarcian, and (ii) fluids with cationic composition dominated by Na coming from the argilites. These changes in the chemical facies probably result from cationic exchange between fluid and the solid matrix.

Four types of pore water can be distinguished from their stable isotope contents (^{18}O et ^{2}H) : (i) meteoric water which is isotopically similar to that of the overlying aalenian karstic aquifer, (ii) meteoric water whose isotopes content ise modified, probably due to exchange with host rock, (iii) water enriched in heavy isotopes possibly due to an evaporation process close to the tunnel and, (iv) water rich in heavy isotopes which could contain a part of residual connate water. The water types (i), (ii) and (iv) show a "randomly" distribution with depth which could probably be controlled by variations in the accessibility to rock porosity. This point has to be clarified, but the direct influence of both water content and $CaCO_3$ of the rock on these two stable isotopes contents has been clearly identified.

3.4 ISOTOPIC STUDIES FROM CALCITE FILLING IN FRACTURES

In addition to the study on pore water, isotopic measurements were made on the secondary calcite that filled the fractures intersected by the boreholes [1] and [2]. Variations of the stable isotopes content (^{13}C and ^{18}O) of these calcites versus depth appear more « regular » and homogeneous than those observed with pore fluid but the measured values imply that several different types of water have circulated in the fractures. An hypothesis to explain the distributions of ^{13}C and Iron contents with depth in fracture minerals would involve both upward and downward circulations, but it has to be confirmed.

All the secondary calcites are ^{14}C free. Their $^{234}U/^{238}U$ ratio are close to one, but they mostly reflect the contribution of a detrital fraction and cannot be used to estimate the age of the calcite. However, the very high $^{230}Th/^{234}U$ ratio measured from the bottom of the profile, probably indicates a secondary sink of ^{234}U. This suggests that water circulation should have occurred in the fractures at the lower part of the toarcian formation, 600 000 years ago at least.

At this stage of the study, it is impossible to establish any link between interstitial fluids and the « paleofluids » identified from the fractures. It could be possible that interstitial fluids reflect a very long and close interaction with the rock itself; and that paleofluids from fractures could represent fluids with very limited isotopic and chemical interactions with the matrix.

4. MAIN CONCLUSIONS

Some time scale indications can be deduced from the measurements on stable and radioactive isotopes both from the liquid and solid phases of the clay :

- after about one century, a distance of 20 à 30 m around the tunnel seems affected by rock desaturation as it can be seen from heavy isotopes values in the interstitial water;
- the existence of fluid which could include connate water indicates very long residence time into the formation. But these old waters seem to remain in coexistence (at some decimetres of distance) with quasi natural meteoric water;
- ^{14}C and U/Th values from fracture minerals lead to think that the clay formation has not been affected by important circulation for more than several thousand years, but it is possible that solutions percolated through a certain number of fractures less than 600 000 years ago.

On the basis of the available data (aquifers heads and permeabilities of the argilites), fluid circulation simulations through the clay were performed [1]:

- results confirm that taking into account only convective transfer, the transient period to reach the steady state after a significant perturbation is very long (several years), and the value of the interstitial water head at different levels in the Toarcian is close to the value of the topographic level at this point. Combined with the very low permeability of the rock, this means that the flow discharge rate by drainage that can be anticipated, specially at the tunnel level, is very low (below 10 cm^3/h) and very difficult to estimate from in situ tests;
- taking into account only transfers thanks to pure diffusion, calculations indicate that the formation could be leached by meteoric water in less than 2 Ma using an effective molecular diffusion coefficient of deuterium close to the one of water into water, or could not be leached after 130 Ma, using a coefficient corrected from porosity and tortuosity. This proves that such simulation would need a better knowledge of the diffusion coefficient of water through clays.

As a result of the coring campaign corresponding to a circular plan (40 m of diameter) perpendicular to the tunnel axis, the argilite formation in this zone appears to be characterised by the existence of two areas structurally different : a west zone relatively highly fractured, and an east zone without any fracture [2]. In some cases, one can observe fault zones, not only infilled with calcite, but mainly constituted of highly disturbed clay material of less good properties (physical and mechanical). The presence and the importance of such structures into argilite formation should be of great interest regarding fluid transfer possibilities.

PRACTICAL DIFFICULTIES ASSOCIATED WITH INVESTIGATION AND SUBSEQUENT REMEDIATION OF CONTAMINATED LAND

Jon Fowler
AEA Technology, Harwell, Oxfordshire, OX11 0RA, UK

ABSTRACT

This paper reports on the characterisation and subsequent development of a remediation strategy for a seven hectare site in Oxfordshire, England which was used for the burial of waste contaminated with radioactivity and a range of organic and inorganic chemicals.

The method of site assessment is described and any lessons learnt are highlighted. In particular, the shortcomings of various intrusive and non-intrusive site investigative techniques are discussed.

Anyone faced with the problem of developing a site assessment methodology for contaminated land will find this paper particularly useful.

SITE ASSESSMENT TECHNIQUES

In the case under discussion, the purpose of the site assessment was to determine the extent and location of buried contamination within the site, thus allowing identification of an appropriate remediation strategy. The Site Assessment was divided into three main stages:

- desk study (including a preliminary site visit) to identify past usages which may have given rise to contamination and any particular structures or areas where contaminative processes may have been carried out;
- physical investigation of the site using intrusive and non-intrusive techniques to detect and quantify the extent of any contamination;
- data interpretation in order to determine the extent and magnitude of contamination and therefore the likely disposal route for any waste arisings.

DESK STUDY

The desk study is a cost effective way of investigating whether a site has been put to a potentially contaminative use. Typical information sources include:

- site records, e.g. drawings, maps, investigation data;
- company records, e.g. archival information;
- plant personnel, including former employees;
- local literature, e.g. newspapers, local library;
- regulatory bodies, e.g. local councils, waste regulatory bodies, Her Majesty's Inspectorate of Pollution, National Rivers Authority, Health & Safety Executive.

Company records and recollections of former employees indicated that the site had been used as a repository for redundant items of equipment lightly contaminated with radioactive material. In addition, chemically toxic waste, some of which had traces of radioactive contamination, had been buried in unlined, earth-covered pits during the 1950s and 60s. However, there were no accurate records of the nature and quantity of waste deposited in the pits as there was no legislative requirement to record this information at the time of disposal. Recollections of existing and former employees are particularly important in such situations and proved invaluable in this case.

Records confirmed that a preliminary radiological clearance of the site had already been carried out involving the following key tasks:

- decontamination and demolition of buildings;

- decontamination of roadways within the site;
- examination and removal of drains;
- removal of a low level radioactive waste disposal pit;
- trial pitting to confirm approximate locations and contents of the chemical and beryllium burial pits;
- post-clearance contamination and radiation surveys.

However, no attempt had been made to remediate the chemical and beryllium burial pits.

SITE INVESTIGATION

The site investigation forms the major database for the assessment of the degree of contamination and the extent of remediation required. The choice of sampling strategy will depend upon the findings of the desk study and guidance for optimisation of site investigations is given in Reference 1.

1993 Characterisation Programme

The first stage of the site investigation was to confirm the conclusions of the preliminary radiological clearance study, namely that the site is very unlikely to contain any significant burials of chemical or radioactive waste other than those previously identified within the burial pits. This was done via:

- an extensive soil sampling and analysis programme;
- a walkover radiation dose-rate and contamination survey of the entire site;
- general site inspection.

The sampling programme was agreed with the local council prior to implementation and significantly exceeded the sampling density recommended in DD 175 (Ref 1). The main component of the programme was extraction of cores from over 120 locations using a regular grid sampling pattern. A further 70 cores were also sampled where contamination was judged most likely given the existing knowledge of the site. No core samples were taken from the burial pits.

None of the soil cores analysed contained any significant quantities of hazardous material and it was therefore concluded that the site is highly unlikely to contain any disposal sites or areas of contaminated land additional to those previously identified. This was supported by the walkover dose-rate and contamination survey, the findings of the desk study and site reconnaissance which did not indicate the presence of further burial pits.

However, the sampling programme highlighted a number of practical difficulties which may not be obvious to first-time site investigators. Firstly, the importance of ensuring that samples are adequately labelled and logged should not be underestimated. All samples should be clearly marked in indelible ink with the location number and date and time of collection. This allows greater traceability of records and may avoid significant time delays in the future. In addition, the recovered core samples are not discrete and, if particularly accurate data are required, great care should be exercised to ensure that contamination is not carried from one stratum to another. It is also essential to provide analytical laboratories with samples of sufficient size to allow division into representative sub-samples for analysis.

It should be noted that a 'herringbone' sampling regime has since been promoted by some workers in the field in preference to a rectangular grid. This involves the use of four interlocking regular grids and has been shown to be more statistically significant than stratified regular sampling.

Options for Long Term Management of the Hazardous Inventory

An Environmental Impact Assessment of the site identified two potential long term management strategies for the burial pits consistent with modern standards for safety and environmental protection.

- isolation of the pit contents from the environment by the construction of an engineered cap and curtain walls over and around each burial pit;
- removal of the contents of each burial pit and subsequent disposal via an appropriate route.

Either of these options, or a suitable combination of both, would ensure that health risks to members of the public are acceptable and that the environment is adequately protected from hazardous contaminants known to be present at the site.

Trial Excavation of Burial Pit

A trial excavation of one of the chemical burial pits was undertaken in March 1994 in order to demonstrate the practicability of removing the contents of each burial pit. The pit chosen was believed to be relatively free of radioactive contamination and would therefore pose less risk to workers and members of the public.

The trial excavation was performed in accordance with a fully approved safety case and used a combination of manual and mechanical techniques. The pit was found to be significantly larger than indicated by earlier trial pitting investigations and also contained traces of radioactive contamination (i.e. > 0.4 Bq/g). In addition, the degree of chemical contamination was found to be greater than expected and concentrations were generally above typical levels measured in uncontaminated soil.

It was therefore concluded that existing data on the likely size and contents of the burial pits was likely to be inaccurate and that further site investigations should be performed.

Geophysical Survey and Core Sampling of Burial Pits

A geophysical survey of the site was performed and this confirmed the number and approximate locations of the chemical burial pits. The advantage of such techniques is that they are relatively quick and can be used for initial appraisals. However, care must be taken in the choice of technique and the spacing of traverses. It must also be borne in mind that the techniques identify geophysical anomalies which may not correspond to identifiable features upon intrusive investigation.

Once the geophysical survey had confirmed the approximate locations of burial pits, a core sampling programme of the pits was performed in order to provide further information on the nature and quantity of buried contaminants. The results of this programme are not yet available but will be carefully considered when a decision is made as to which long term management strategy should be implemented (i.e. capping or removal). Some general points on data interpretation techniques are given in the following section. It should be noted that the beryllium pits are being characterised as part of a separate DRAWMOPS project.

DATA INTERPRETATION

Once analytical results are available, they must be examined in order to determine the magnitude of any contamination problem. There are a number of documents which can be used in the interpretation of chemical analysis results. For example, the Interdepartmental Committee on the Redevelopment of Contaminated Land (ICRCL) have produced a number of guidance notes relating to the re-use of sites with previous contaminative uses. These are particularly useful when setting action levels above which further more detailed analysis will be performed. In the case of radioactivity, the need to show that soil is below the Radioactive Substances Act 1993 exemption level of 0.4 Bq/g is particularly important although this can be problematic given the level of natural radioactivity typically present in soil.

ACKNOWLEDGEMENTS

This work has been funded under the DRAWMOPS programme of the UK Department of Trade and Industry (DTI). The results of this work form part of the UK Government programme on decommissioning and radioactive waste management, but do not necessarily represent Government policy.

URANIUM MINING AND MILLING BY COGEMA
ENVIRONMENTAL IMPACT COMPARED TO 1 mSv LIMIT

S. BERNHARD [1], JL. DAROUSSIN [2], JP. PFIFFELMANN [2]

[1] ALGADE - Cogema, Bessines, France
[2] COGEMA Vélizy - Uranium Division, Vélizy, France

CEA then COGEMA have been been operating mines and mills in France since 1948. Total production nears 70000 t of U in the concentrate which were contained in some 85 millions tons of ores (pulp and heap leaching). Many sites are now undergoing remediation [1] and impact on the environment has always been a great concern.

RADIOLOGICAL MONITORING

Throughout the life of the operations, monitoring goes on using a complete network on site and in the neighbourhood. This includes geotechnical monitoring (to ascertain the stability and good confinement of the waste), radiological and chemical monitoring. The radiological monitoring implies :

- water sampling up and down stream (Ra, U analyses),
- integrated site dosimeter measuring Potential Alpha Energy from radon and alpha activity of airborne dust particles,
- thermoluminescent dosimeter for external irradiation measurements,
- periodic analyses in the food chain.

For the evaluation of the impact we need :

- the annual radiological measurements of the main pathways during and after remediation,
- similar values for the natural background (a method is described in [2]),
- the complete description of the critical group,
- in order to calculate the Added Total Annual Exposure (ATAE) which is the sum of the different exposures due to the mining with deduction of the initial natural exposure.
- The regulatory value is the sum of these values rated to their equivalent to the maximum recommended value. In France, the maximum recommended value is 5 mSv according to ICRP 26 recommendations. The Added Total Annual Exposure Rate (ATAER - complete formula herunder) must be less than 1.

$$TAER = \frac{gamma}{1\ mSv} + \frac{PAE\ Rn\ 222}{1.68\ mJ} + \frac{PAE\ 220}{0.56\ mJ} + \frac{IE\ dust}{100\ Bq\ alpha} + \frac{IE\ Ra\ 226}{4500\ Bq} + \frac{IE\ U238}{1\ g}$$

ATAER = TAER (station) - TAER (background) < 1

Based on field measures, the exposure and the regulatory value of ATAER of the critical group are evaluated with the following parameters :

- annual residence time : 7000 hours
- standard breathing rate : 0.8 m3.h-1
- daily amount of ingested water : 2.2 liters of the downstream water. This figure includes water ingested through food consumption.

This standard scenario leads to overevaluation as usually people won't stay so long inhouse neither drink water from the river.

RESULTS - IMPACT ON THE ENVIRONMENT

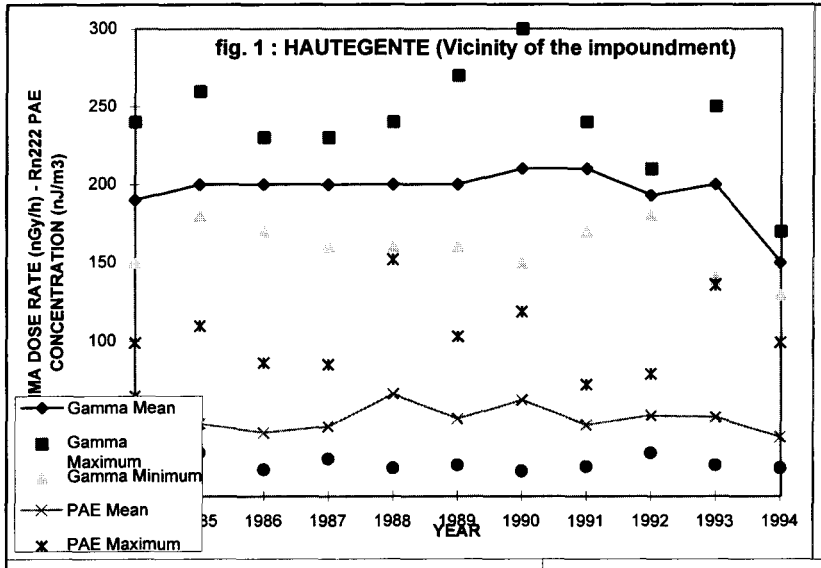
Figures from the area of ECARPIERE (Vendée) are given, as an example, in the following table. HAUTEGENTE is a location where people live, one kilometer from the impoundment. BEL AIR, further away, is considered as the reference in the area and was set up in 1991 to assess the radiological background of the granitic region.

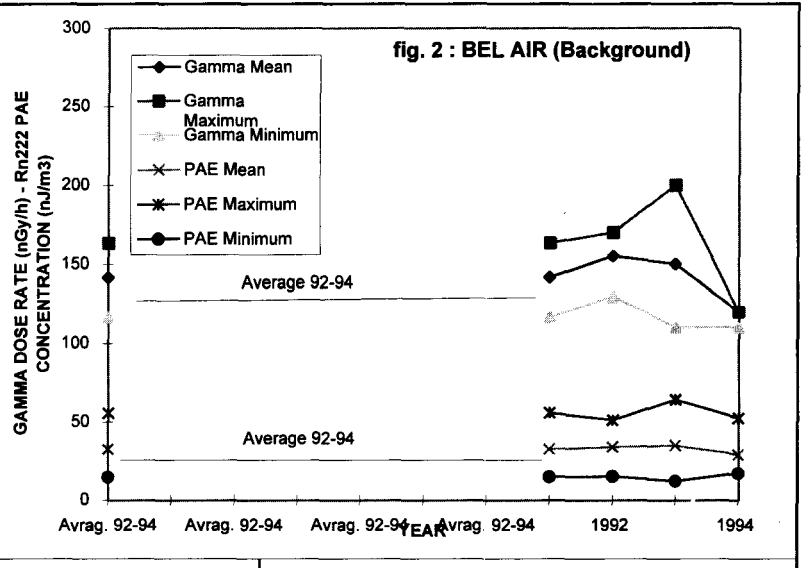
1994	AIR PATHWAY				WATER PATHWAY		ICRP 26 : 5mSv		ICRP 60-5-8 1mSv	
STATION	EXT.EXP	INTERNAL EXPOSURE								
	Gamma ry nGy.h-1	Rn220 nJ.m-3	Rn222 nJ.m-3	Dust Bq.m-3	Ra226 Bq.l-1	Uranium mg.l-1	TAER	ATAER	TAER	ATAER
HAUTEGENTE	150	17	38	1	0,12	0,1	0,42	0,08	1,64	0,33
BEL AIR (Background)	120	13	29	1	0,05	0,1	0,34		1,32	

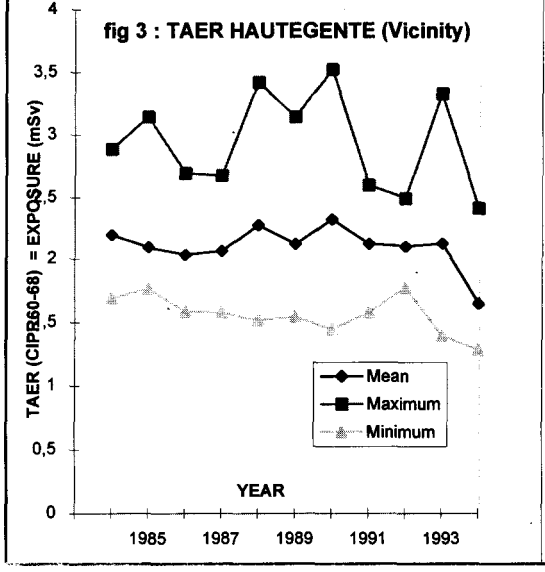
IRPA 9 Vienna 14-19 April 1996 COGEMA/BU/SES/SB, JLD, JPP
Abstract n° 90379 Poster n°P47-2 PPP Session PS- 4b

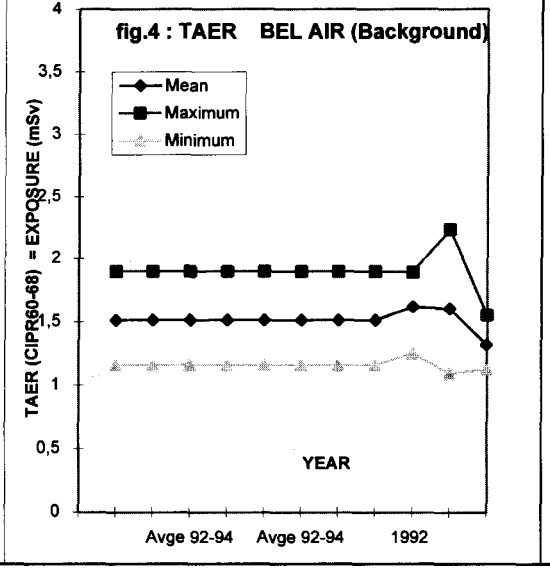
ECARPIERE : fig. 1-2 : MEASUREMENTS

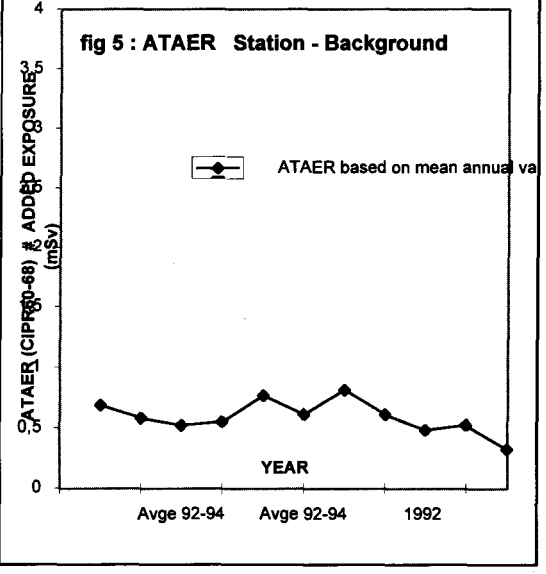
fig 3,4,5 : TOTAL and ADDED TOTAL ANNUAL EXPOSURE RATE (TAER and ATAER)











Although the different measures are slightly higher in Hautegente than in the background, the global impact of the site (ATAER = 0.08 if we consider ICRP 26, 0.33 for ICRP 60-65-68) is limited.
Results and their evolution during the past ten years are plotted on the diagrams for the same two stations :

- figures 1 and 2 show evolution of the measures for the two main pathways : dose rate of external exposure due to gamma irradiation (nGy.h-1) and concentration of Radon 222 Potential Alpha Energy (PAE Rn222 - nJ.m-3). The mean annual value is bounded by the maximum and minimum measurements recorded during the same year.
- figures 3 and 4 display the variation of the TAER using the equivalent to 1 mSv recommended by ICRP 60, 65 and 68. In this case TAER is equivalent to the total exposure.

Evolution of the resulting ATAER is shown on figure 5.

Sets of results concerning different areas are presented on the poster. They show variations of the ATAER up to 1mSv and confirm the following discussion.

DISCUSSION - COMPARISON WITH A 1 mSv LIMIT

Individual measurements (maximum and minimum quarterly or monthly values for respectively external exposure and potential alpha energy) show a great dispersion for both Hautegente and Bel Air. This is due to the natural variability of radioactivity and the uncertainty of the measurements (+/- 20% for Rn222 PAE [3], +/- 10% for external exposure).

Resulting annual TAER (or exposures) range from 1.3 to 3.5 mSv for Hautegente, 1 to 2.2 mSv for Bel Air that is a maximum difference of 2.2 mSv for Hautegente, 1.2 for Bel Air if maximum and minimum monthly or quarterly measures were used to calculate the annual TER.
As plotted on figure 3 and 4, the range is reduced to 1.6 to 2.3 (0.7 mSv difference) for Hautegente and 1.3 to 1.6 (0.3 mSv) if annual means of the different measurements are used for the calculation.

Although use of extreme values for the calculation of TAER is not realistic it confirms that only mean annual values should be taken into account.
In any case all the resulting calculations show that variability of TAE (or TAER) are near to 1 mSv which is the new recommendation of ICRP 60 for a limit to the added total exposure.

CONCLUSION.

- Should the 1 mSv limit be implemented in France, resulting Total Annual Exposure Rate would remain less than 1 in the case of ECARPIERE,
- but we have shown that ICRP 1mSv recommEndation is very difficult to adapt when dealing with natural radioactivity and consequently to the mining industry,
- consequently we think that applicability is linked to :
  - * a special attention to choose the measuring equipments used to monitor environment (active dosimeters)
  - * the use of annual means of the measures (as the seasonnal variability is too much important),
  - * better and realistic definition of the critical group and scenario used for calculation of the total exposure (7000 hours residence time give only a broad evaluation of the impact)
  - * better definition of how to measure, in the natural background, the different parameters used for calculation of the ATAER.

- REPOWER INSTEAD OF RETIRE - A FOURTH ALTERNATIVE FOR DECOMMISSIONING COMMERCIAL NUCLEAR POWER STATIONS IN THE UNITED STATES

James M. Hylko
Roy F. Weston, Inc., 6501 Americas Parkway NE, Suite 800
Albuquerque, NM 87110 USA

INTRODUCTION

The three traditional alternatives for decommissioning commercial nuclear power stations in the United States (U.S.) are as follows (1):

- Decontamination (DECON) - the immediate dismantlement, in which the equipment, structures, and portions of the facility and site containing radioactive contaminants are removed or decontaminated permitting release for unrestricted use shortly after cessation of operations.
- Safe Storage (SAFSTOR) - the station is placed and maintained in such a condition that it can be safely stored and subsequently decontaminated (i.e., deferred decontamination) permitting release for unrestricted use.
- Entombment (ENTOMB) - the radioactive contaminants are encased in structurally long-lived material and then maintained under surveillance for an indefinite period of time.

Of the three options provided, the primary reason for deferring the start of decommissioning is to allow the overall radioactivity to decrease by decay, which in turn, will reduce worker risks, costs of dismantling radioactive components, and shipping large volumes of low-level radioactive waste (LLW). Previous evaluations suggest that a 50-year SAFSTOR deferment provides optimum material and radiation reduction benefits (2). However, during this period of deferment, a utility may need to consider replacement power to accommodate its projected electricity demand profile (EDP). Power generators in the U.S. are expected to order 140 Gigawatts (GW) of new generating capacity and put 100 GW into operation by the year 2003 (3). In addition, the average ages for fossil fuel stations and nuclear power stations are approximately 30 years and 16 years, respectively, with an expected useful life of only 30 to 40 years. Therefore, the projected EDP, compounded with the aging base-load capacity, including the untimely premature closing of a commercial nuclear power station will require the utility to address these concerns concurrently through new construction, life extension, or by repowering an existing station. Surprisingly, the concept of repowering was first recognized in 1974 (4), and is receiving more attention than in the past because of the inherent nature of life extension (e.g., equipment replacement and refurbishment) combined with the benefits of repowering (e.g., reduced emissions, an increase in generation capacity). For the purpose of this paper, repower (REPOWER) is defined as adding a new source of fuel to the existing steam-cycle system of a reconfigured commercial nuclear power station to ensure sufficient electrical generation capacity during the SAFSTOR deferral scenario. This paper reviews the various considerations for repowering, such as previous repowering projects, the gas turbine/heat recovery steam generator (GT-HRSG) repowered station, and the evolution of the non-nuclear station.

PREVIOUS REPOWERING PROJECTS

The W.H. Zimmer Station and the Midland Co-generation Station, both designed initially as commercial nuclear power stations and never operated, were reconfigured as a coal-fired station and a natural gas co-generation station, respectively (5, 6). In 1994, the Fort St. Vrain Generating Station was authorized to repower as a gas-fired combined-cycle steam unit consisting of two GT-HRSGs. Initially, this station operated as a 330 MWe high temperature (helium) gas-cooled reactor (HTGR) from January 1979 until August 1989 (7), and after repowering, is expected to generate approximately 471 MWe. A similar combined gas-steam cycle design has also received particular attention in Europe (8).

THE GT-HRSG REPOWERED STATION

Currently, the most common and cost-effective repowering approach is to use natural gas as a source of fuel, add modern GT-HRSGs, and make use of the existing site and internal components of the steam-cycle system (e.g., turbine-generator, condenser, and cooling water systems). Also, as natural gas prices have declined, utilities have taken advantage of several coinciding market trends to further enhance the rise in the application of gas turbines for electric power generation (9):

- favorable construction economics and environmental benefits provided by gas-turbine-based stations;
- achieving very high combined-cycle efficiencies of 54% to 58% using commercially available technology;
- reliability and availability figures of 98% and 95%, respectively, from gas turbine manufacturers; and
- an EDP requiring large blocks of peaking power; i.e., gas-fired stations are more attractive for peaking applications because low-capacity utilization such as peaking service is often best served by a low capital-cost power station.

The common denominator in these projects is to replace the reactor vessel and coolant system by adding several 100-150 MWe GT-HRSGs (Brayton cycle) to a refurbished nuclear steam-turbine-based (Rankine cycle) station. A gas-turbine-based station consists of a compressor, combustion chambers, and a turbine section. This method of GT-HRSG combined-cycle repowering can improve overall plant thermal efficiency by more than 20%, and in some cases triple the total Megawatt output of the original station (10).

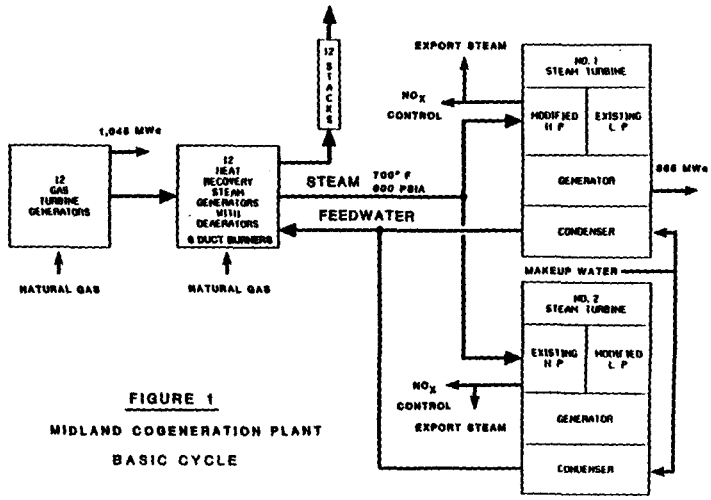

FIGURE 1

MIDLAND COGENERATION PLANT

BASIC CYCLE

Figure 1 represents a general configuration of the Midland Co-generation Venture that was successful in converting two large nuclear steam turbines into a GT-HRSG combined-cycle arrangement (6).

EVOLUTION OF THE NON-NUCLEAR STATION

The containment building will be isolated from the repowered side of the station by installing permanent physical boundaries within the nuclear power block, thereby, enclosing the areas and systems that contain essentially all of the significant radioactive contamination and activated components. The potential of nuclear criticality will have been precluded by transferring the fuel assemblies from the reactor vessel to either the spent fuel pool or an Independent Spent Fuel Storage Installation (ISFSI) (11). Depending on the thermodynamic nature of the repowered system, it may be cost effective to "eliminate and replace" rather than "decontaminate and refurbish" certain components (e.g., pumps, valves, moisture separators). In all practicality, consideration should not be given to decontaminating the small bore piping used for sampling radioactive liquid effluents. In addition, instrument sensors, transducers, and seals having been in contact with steam or condensate containing residual radioactive materials (RRM) will be removed, characterized, and discarded as LLW. Because of the complex geometry of components like the turbine, piping, and associated steam and condensate systems, there will, in all likelihood, be hidden pockets of RRM present creating high radiation dose rate "hot spots" or "crud traps," even following extensive decontamination (12). System perturbations could displace the RRM, that is analogous to a "crud burst" in an operating commercial nuclear power station. Therefore, to ensure that such potential releases are contained, as well as ensure boiler feedwater quality, full-flow condensate ion-exchange polishing capabilities should be maintained for the repowered station. To alleviate stakeholder concerns regarding the potential release of RRM still residing in the steam-cycle system following decontamination, a

modified in-house and environmental monitoring program will be maintained throughout the repowering period. The environmental program will consist of monitoring gaseous, particulate, and liquid effluents continuously, which is no different than monitoring other system parameters (e.g., water chemistry). Nevertheless, the radiation dose to the public from a postulated release of RRM remaining on inaccessible work surfaces (e.g., interior of pipes, drain lines) is expected to be indistinguishable from background levels. Additional station systems foreseen to be required, but downgraded during repowering could include, but are not limited to radiological and security access, the management of LLW, AC and DC electrical power systems, and fire protection/suppression systems.

CONCLUSION

The fourth alternative for decommissioning (REPOWER) focuses on replacing an existing fuel source with GT-HRSGs, and reusing the internal non-nuclear components to yield a combined-cycle power station. In addition, the inherent benefits of modifying the serviceable steam cycle improves efficiency, expands electrical generating capacity up to three times the original station output, while maintaining a favorable environmental profile. Repowering is especially well-suited for stations that satisfy mid-range power demands (e.g., 400-700 MWe), and is expected to have a design life similar to that of a new station (e.g., 40 years). Therefore, the REPOWER alternative allows the utility to accommodate its projected EDP, and reduce the need for new construction by using an existing site already dedicated to the generation of electricity.

MAJOR SCIENTIFIC TOPIC NUMBER 4.7 (see page 7)

ABSTRACT (See instructions overleaf)

Sellafield in Cumbria [UK] has been in use as a nuclear site for number of years. It now contains a 'second generation' Magnox reprocessing plant, modern storage ponds, fuel dismantling facilities, product finishing lines, and the Thermal Oxide Reprocessing Plant [THORP]. It also houses a complex of waste treatment and storage facilities, including a vitrification plant, and the Calder Hall Nuclear power station. Over the years a number of the facilities on the site have become redundant and there is a programme to decommission these areas. A business unit within British Nuclear Fuels plc, UK Group, Waste Retrieval and Decommissioning (WR&D) has been set up to carry out this work. The first strategic objective in the WR&D Business Plan is 'To retrieve waste and decommission facilities safety, cost effectively and within estimated cost and timescale'. This paper will deal with some of the decommissioning work being carried out by WR&D and the dose control strategies, including ALARP which are being used.

DECOMMISSIONING OF WESTERN EUROPE'S OLDEST REACTOR THE GRAPHITE LOW ENERGY EXPERIMENTAL PILE (GLEEP) AT UKAEA HARWELL

Ian P Graham, Jon P Fowler,
AEA Technology, Harwell, Oxfordshire, OX11 0RA, UK

INTRODUCTION

The Graphite Low Energy Experimental Pile (GLEEP) was the first nuclear reactor to be built in Western Europe and was designed to operate at a maximum power of 100 kW, although it was generally run at 3 kW. It is situated on the UKAEA Harwell site in the UK and was a natural uranium graphite moderated reactor which operated from 1947 until it was finally shutdown in September 1990 making it Western Europe's oldest and longest serving reactor. Decommissioning of the Facility commenced soon after closure. All the fuel elements, activated and ancillary items have been removed as part of decommissioning, leaving only the graphite block housed within a 1.52 m thick barytes concrete biological shield. This paper reviews the Stage 2 decommissioning experience. A more detailed description of GLEEP and of the fuel removal process is given in Reference 1.

DECOMMISSIONING STAGES

Decommissioning was managed by AEA Technology on behalf of UKAEA. Following Stage 2 Phase 1 decommissioning, formal hand back of the facility from AEA Technology to UKAEA took place on 9 June 1995.

Decommissioning of the reactor has been divided into three Stages;

Stage 1 decommissioning was completed at the end of August 1994 and involved the removal of fuel from the reactor using specially designed equipment (since fuel changes were not part of the normal operation of GLEEP). The tasks carried out during this stage of decommissioning are described in Reference 1.

Stage 2 decommissioning has been divided into two Phases. **Phase 1** was completed in April 1995 and comprised the removal of activated items, such as the absorbers and control rods, from the reactor. In addition, other preparatory operations for Care and Maintenance were carried out such as altering access arrangements and the removal of the control room, leaving only the graphite block and concrete biological shield. The facility is currently in **Phase 2** which is an extended period of Care and Maintenance scheduled to last until the year 2008 although there are several other options which may become more favourable. No operations within the reactor biological shield are scheduled for the extended period of Care and Maintenance and therefore the number of safety related items is much reduced and all of which are passive control systems.

During **Stage 3**, decommissioning and removal of the remaining reactor structures will be carried out, thus allowing unrestricted use of the area.

DESCRIPTION OF STAGE 2 DECOMMISSIONING TASKS

Stage 2 Phase 1 decommissioning was divided into Parts 1 and 2. **Part 1** comprised the removal of all items within the biological shield other than the graphiite block. **Part 2** involved removal of the remaining items outside the biological shield so that only the graphite block and concrete biological shield remained for the extended period of Care and Maintenance.

The major tasks that were carried out during Stage 2 Phase 1 Part 1 are summarised briefly below:

- all activated items, including the absorbers and their mechanisms, were removed;
- the redundant fuel unload equipment was removed;
- exposed holes in the walls and roof of the concrete biological shield were filled with expanding foam and screeded with concrete.

The major tasks that were carried out during Stage 2 Phase 1 Part 2 are summarised briefly below:

- all loose combustible items were removed from the GLEEP area;

- all Low Level Waste (LLW) and Very Low Level Waste (VLLW) stored in the GLEEP area was disposed of in an appropriate manner;
- the GLEEP standard radium-beryllium source was removed from the vertical storage hole and removed for storage as Intermediate Level Waste;
- redundant reactor instrumentation, such as the area gamma monitors and fire detection systems, were removed and disposed of;
- all redundant electrical cabling in the GLEEP area was removed;
- the GLEEP ventilation system was decommissioned and disposed of;
- part of the steel galleries/walkways were removed and the control block was demolished;
- the GLEEP workshop and offices were cleared;
- 'fixed' spots of contamination on the floor of the general GLEEP area at faces A and B were removed using standard decontamination techniques. This area, which is external to the biological shield, is now no longer a Radiologically Designated Area.

WASTE ARISINGS

The majority of waste generated during Stage 2 Phase 1 decommissioning was below the exemption level of 0.4 Bq/g given under the Radioactive Substances Act (RSA93) and could therefore be classified as 'free release' waste. In total, 244 m^3 of 'free release' waste, including graphite and concrete blocks, was packaged into skips and disposed of in an appropriate manner. More skips than anticipated were required due to practical difficulties associated with packing the waste which lead to less efficient use of space.

There were two disposal routes for items of Low Level Waste (LLW) which exceeded the exemption level of 0.4 Bq/g:

- 5 m^3 of LLW was placed in an ISO container and removed pending disposal;
- 2.9 m^3 of LLW was packaged into 10 litre waste drums and removed for storage pending final disposal.

In addition, 25 litres of Intermediate Level Waste (ILW) was generated and removed for storage until a suitable disposal route becomes available. Routine operational waste was also generated, such as gloves, overshoes and coveralls. No liquid wastes were generated during Stage 2 Phase 1 decommissioning.

RADIOACTIVE INVENTORY

Prior to commencement of decommissioning, the fuel elements were the principal radioactive material within the GLEEP Facility with an activity of approximately 15.5 TBq (i.e. about 99.98 % of the total radioactive inventory). Removal of the fuel elements and activated items has reduced the radioactive inventory of the facility to that associated with the graphite block, its associated steel base and support structures and the concrete biological shield.

A detailed estimate of the radioactive inventory of the structure materials in the GLEEP reactor was carried out in April 1993. The estimated total activity associated with each of the remaining reactor components is given below:

Steel Base and Supports for Graphite Block	2.5E10 Bq
Graphite Block	3.0E10 Bq
Lower Biological Shield	1.8E10 Bq
Upper Biological Shield	6.5E9 Bq

The estimated total radioactive inventory of the facility remaining for the care and maintenance phase is therefore 80 GBq composed of activation products as a result of neutron irradiation of its constituent materials. There is no significant surface contamination present within the biological shield. It should be noted that tritium contributes most to the inventory.

DOSES RECEIVED

No member of the decommissioning staff exceeded any individual dose limit and the team as a whole complied with the group average target of 5 mSv. The following whole body dose equivalents were received during Stage 2 Phase 1 operations:

Collective Dose	1.94 man mSv
Individual Average Dose	0.32 mSv
Maximum Individual Dose	0.66 mSv

A comparison of the estimated and actual collective doses received by operators during Stage 2 Phase 1 decommissioning operations is given below. It should be noted that Phase 1 Part 2 operations were performed outside the biological shield area (i.e. < 2 μSv/h) and therefore no dose allowance was made.

Estimated Collective Dose	3.19 man mSv
Actual Collective Dose	1.94 man mSv

The collective dose received by operators was approximately 60 % of that estimated in the Decommissioning Safety Case mainly because operations took less time than expected and operators minimised the time spent in higher dose-rate areas within the biological shield. The predicted dose budget was also a significant overestimate as it took no account of the general reduction in dose rates as activated items were removed.

WORK PROGRAMME

Stage 2 Phase 1 decommissioning was completed in April 1995 although it was scheduled to last until mid-June 1995. This is because more operators were used than originally anticipated, thus allowing certain tasks to be performed in parallel. It should be noted that the Decommissioning Programme assumed that either two or three operators would be used, whereas up to six operators were used in reality.

In addition, personnel used during Stage 2 Phase 1 decommissioning were familiar with the facility, having carried out the fuel unload operations. This shows the importance of using experienced personnel who are familiar with the facility and do not require significant training and direct supervision.

Another reason for the operations being completed ahead of schedule is that certain contract variations were implemented which increased the efficiency of decommissioning. For example, the GLEEP boundary fence was removed thus facilitating vehicular access for removal of the control block and demolition of the control room, etc. The decision not to completely remove the steel galleries/walkways also saved time. This shows the benefit of adopting a flexible attitude to decommissioning.

CONCLUSIONS

Stage 2 Phase 1 decommissioning of the GLEEP Facility was successfully completed in a satisfactory manner ahead of programme. Decommissioning staff received less than the estimated collective dose and the operations met all Regulatory, Statutory and Authority accident risk criteria, dose limits and targets.

ACKNOWLEDGEMENTS

This work has been funded under the DRAWMOPS programme of the UK Department of Trade and Industry (DTI). The results of this work form part of the UK Government programme on decommissioning and radioactive waste management, but do not necessarily represent Government policy.

DECOMMISSIONING ANALYSIS OF A UNIVERSITY CYCLOTRON

Gilbert X. Eggermont[1], N. Buls[2] and A. Hermanne[3]

University of Brussels (VUB), Radiation Protection Office[1], Cyclotron Department[3], Brussels 1090, Belgium

INTRODUCTION

In the widespread use of some medical nuclear facilities, such as cyclotrons for isotope production, life cycle analysis, including decommissioning, was not taken into account. The structual materials of an accelerator and the concrete shielding of the bunker are activated by neutrons. This could yield a considerable volume of nuclear waste and needs radiation protection concern for occupational workers and the environment during some decennia (1).

At the university of Brussels (VUB) a prospective radiation protection and waste analysis is being made for the later decommissining of their cyclotron (2). Only few similar studies have been published (1,3).

In Belgium future nuclear dismantling operations will be submitted to a radiation protection authorisation procedure. Meanwhile the nuclear waste authorities insist on dismantling planning, including financial provisioning.

An optimisation exercise was made at the VUB-cyclotron, taking into account international trends to clearance levels for low level nuclear waste.

Conceptual prevention opportunities e.g. selective material choice could be identified for future accelerator constructions.

ACTIVATION AROUND A CYCLOTRON

At the VUB a variable energy, multiparticle (protons, deuterons, α- and ^{3}He- particles) cyclotron (CGR-560) is in operation since 1985. The maximal current on target is 120 μA for 30 MeV protons. This machine is used for physics research and for radionuclide production in a shielded vault complex with 4 irradiation rooms (bunkers). The most important contribution to activation is due to ^{201}Tl isotope production at 27,3 MeV protons for radiopharmaceutical companies.

The bunker shielding has a thickness of 2.5 m totalling a volume of 2700 m³ of concrete.

The spectral characteristics of fast neutron beams were determined in different directions, showing an average energy of 12 Mev at 0°. Through multiple reflection on walls and elastic scattering in concrete, thermalisation of neutrons occurs in depth. The activation of trace elements in sand e.g. europium and of particular metals yields medium living radioactive products. They are created by capture reactions with high cross sections and by some threshold reactions with lower yield, as indicated below.

^{151}Eu (n,γ) ^{152}Eu	σ_{th} = 5900 barn	$t_{1/2}$ = 13.33 year
^{153}Eu (n,γ) ^{154}Eu	σ_{th} = 390 barn	$t_{1/2}$ = 8.8 year
^{133}Cs (n,γ) ^{134}Cs	σ_{th} = 29 barn	$t_{1/2}$ = 2.06 year
^{59}Co (n,γ) ^{60}Co	σ_{th} = 37 barn	$t_{1/2}$ = 5.3 year
^{45}Sc (n,γ) ^{46}Sc	σ_{th} = 26.5 barn	$t_{1/2}$ = 83 days
^{58}Fe (n,γ) ^{59}Fe	σ_{th} = 1.15 barn	$t_{1/2}$ = 44 days
^{64}Zn (n, γ) ^{65}Zn	σ_{th} = 0.78 barn	$t_{1/2}$ = 244 days

^{55}Mn (n,2n) ^{54}Mn	σ_{max} = 910 mbarn (18MeV)	$t_{1/2}$ = 312 days
^{54}Fe (n,p) ^{54}Mn	σ_{max} = 590 mbarn (10MeV)	$t_{1/2}$ = 312 days

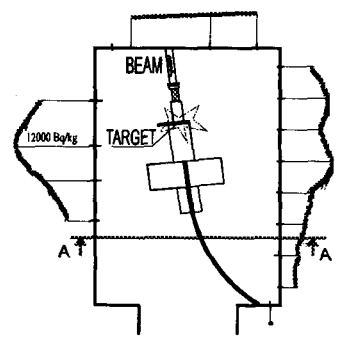

Fig 1 : Spatial distribution of maximal ^{152}Eu in concrete shielding.

The activation distribution was assessed by γ-spectrometry on 5 cm bore samples. They were systematically taken up to a depth of 50 cm throughout the shielding structure presented in fig. 1.

RESULTS OF ACTIVATION MEASUREMENTS

The highest specific activation in concrete occurs laterally near the target at 15 cm depth (fig 2). The iron reinforcement bars in the concrete shielding show maximum activation levels of 32 Bq/g. The activity decrease is exponential for both cases. Prediction of depth profiles could be derived from the measurements (fig 3). The irradiation room infrastructure consists for 70 % of steel. Specific activities up to 360 Bq/g ^{54}Mn and ^{60}Co are measured.

The huge steel accelerator yoke of 80 ton however is showing much lower level activation due to its low ^{59}Co content. These values can be compared with clearance levels of about 0,3 Bq/g (4).

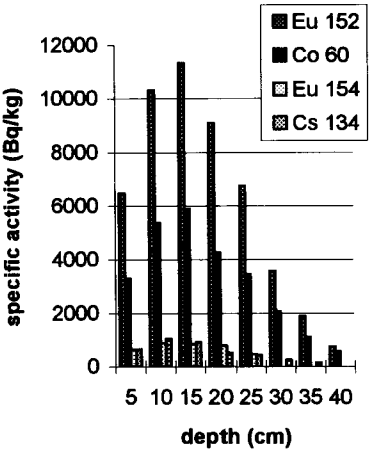

Fig 2 : Depth distribution in a concrete bore sample of specific activity for ^{152}Eu, ^{60}Co, ^{154}Eu, ^{134}Cs

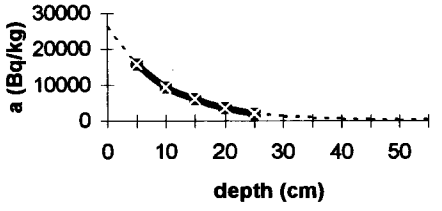

Fig 3 : Measured ^{60}Co activation in iron reinforcement bars

OPTIMISATION OF DISMANTLING SCENARIOS

Dismantling of a cyclotron will be submitted to an authorisation procedure in future Belgian regulations. Waste quantities have to be estimated with specification of their destination. The protection of man and the environment against radiation has to be guaranteed during preparatory work an dismantling operations. Site destination and future use should be specified.

In this preliminary study, the following scenarios were considered :

- Early dismantling of a cyclotron infrastructure, directly after shut-down is confronted with an internal contamination risk by ^{65}Zn. This copper activation product is easily dispersed. ^{65}Zn is detected regularly at acceptable levels in whole body monitoring of cyclotron maintenance workers.
- The waste from metal infrastructures having activities up to 1000 times clearance level could be stored for decay during 35 years in the most activated cyclotron vault. This should be done after the management of the contanimation problems.

- Early decommissioning of the concrete walls to 30-50 cm depths could yield up to 100 m^3 of nuclear waste, applying IAEA proposed clearence levels (4). The dismantling techniques available in nuclear fuel cycle industries allow to remove the activated depths. Since no provisions are made, the cost of this option is too high for an university.
  Dilution techniques, mixing active and inactive crushed concrete and melting iron bars, could be applied in order to arrive at a reasonable cost. The authorisation of such an approach has been given in the UK (5). It is not evident in Belgium, where the obligation of an environmental assessment report could need to take alternative options into account.
- A decay on site of the activity of the concrete rooms and of the metal infrastructures till clearance levels could be performed. Fig 4 illustrates that cooling times of maximum 70 y are necessary for this option.
- Restricted use of cyclotron rooms as controlled areas in the intermediate period was evaluated. Doserates in the documented bunker were calculated from the activation measurements using conservative assumptions. A maximal doserate of 60 µSv/h was derived. Measurements indicate actual doserates up to 15 µSv/h. Occupational use of such rooms yield calculated doses between 6 and 120 mSy/y.
  Surface doses were measured with TLD on concrete samples with a maximum of 2 mGy/y.

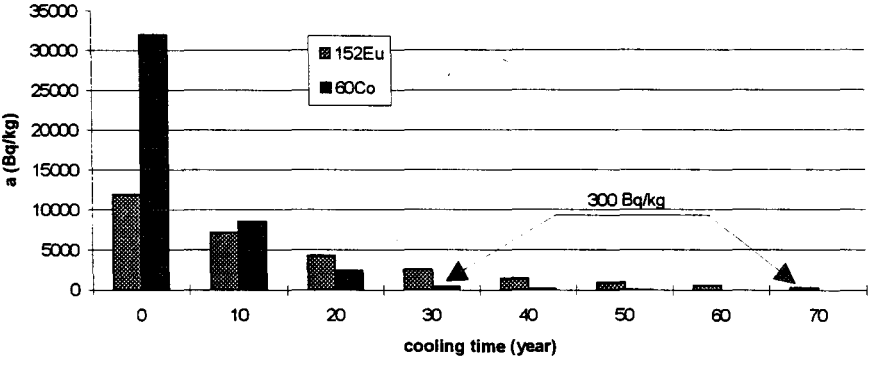

Fig 4 : Decay of Activation of Concrete Bunker

PREVENTION OPPORTUNITIES

The use of iron and scrap metal in the concrete shielding is not recommended for cyclotrons. The use of removable blocks for the inner part of the shielding walls could reduce dismantling costs. Local neutron absorption measures could be taken to reduce the source term. A selection of sand with low europium content for concrete preparation and a preference for low ^{59}Co steel or Al for the infrastructure could be taken into account in cyclotron complex conception.

CONCLUSION

Regarding the high cost of nuclear waste, decay during about 50 years of the infrastructure after shut-down is necessary to allow cooling to proposed clearance levels. Decontamination for ^{65}Zn could be performed after some years.

Considering dose limits for workers and the public, a restricted use of cyclotron rooms as controlled area, seems the most reasonable option. Life cycle analysis techniques should be integrated in the planning of isotope production facilities. It could contribute to reduction of later nuclear waste and to sustainable nuclear development.

RADIATION PROTECTION ASPECTS OF THE DECOMMISSIONING OF THE LINAC-ADONE STORAGE RING

M. Chiti and A. Esposito [1]
[1]INFN-LNF, 00044 Frascati, Italy

Introduction

An e^+ e^- collider, christened DAΦNE (Double Anular Φ factory for Nice Experiments), optimized for operation at a total energy of 1020 MeV, is under construction at the Frascati National Laboratories (LNF) of the National Institute of Nuclear Physics (INFN). The new machine will be placed into the existing buildings which in the past housed the Linac-Adone complex, which definitively ceased operation April 26th 1993 and was at once decommissioned.

The Linac-Adone complex has operated without stopping up to the 26th of April 1993 except for the ordinary maintenance periods.

It was composed by a Linac, capable of accelerating 100 mA of e^- beam peak current to 400 MeV and 1 mA of e^+ beam peak current to 365 MeV, in operation since 1964, and by an e^+ e^- storage ring capable of storing $2x10^{11}$ particles per beam at 1500 MeV, in operation since 1967.

Radiation safety standard and criteria for unrestricted release adopted at LNF

The objectives of radiation safety for the Linac-Adone decommissioning were:

- limitation of personal doses;
- control of radioactive materials either for reuse or for disposal;
- prevention of dispersion of radioactive material during handling and transportation to the final destination.

The limits for personal doses and radioactive material were taken from the recommendations of the Italian National Agency of Environment Protection (1) and from the law in force on the safety and health protection for workers and population against the danger of ionizing radiation field (2), as follows:

- the reference dose for people working in decommissioning areas was 15 mSv/y;
- a limit for unrestricted release for β–γ emitters was set at 1 kBq/m^2 for surface contamination and 1 kBq/kg for mass activity.

Preliminary measurements

Following the shut down of the Linac-Adone complex, the Health Physics Service carried out many measurements to find out the amount of dose rate along e^+e^- beam lines, the specific activity in dust, in cooling water and in metallic components of the machine, in order to obtain useful information for planning the decommissioning itself.

Gamma dose rates, using CaF2 TLD dosimeters (bulb dosimeter mod. 4040 by Harshaw) and a Victoreen ionization chamber mod. 450 P, were measured along e^+e^- beam lines at the distance of about 30 cm from the machine. The results obtained, shown in Figure 1 stress that the dose rate values are higher than the background only near the positron converter and the final part of the e^- beam line before beam dump.

Liquid samples, collected from the primary cooling circuit of the machine supplied with aqueduct water and from the secondary circuit supplied with distilled or demineralized water show (Table I) an appreciable concentration of H-3, as expected, in cooling water of beam dumps.

Tab. I - Measured specific activity in water of Linac-Adone-Leale cooling circuits

Radionuclides	Co-58	Co-60	H-3
Cooling circuits	(Bq/l)	(Bq/l)	(Bq/l)
Linac-Adone primary cooling circuit			3.1±1.3
Linac secondary cooling circuit (5350 l)		1.47±0.07	21.9±1.6
Wiggler secondary cooling circuit (5500 l)		2.00±0.08	21.7±1.6
Adone secondary cooling circuit (5900 l)			20.8±1.6
Leale primary cooling circuit			18.8±1.7
Leale secondary cooling circuit S2 (1500 l)			30.8±1.8
Leale secondary cooling circuit S3 (1000 l)			7.4±1.6
Linac beam dump 1 cooling circuit (2000 l)		0.27±0.03	3.5E04±43
Linac beam dump 2 cooling circuit (6000 l)		1.38±0.06	3.4E04±42

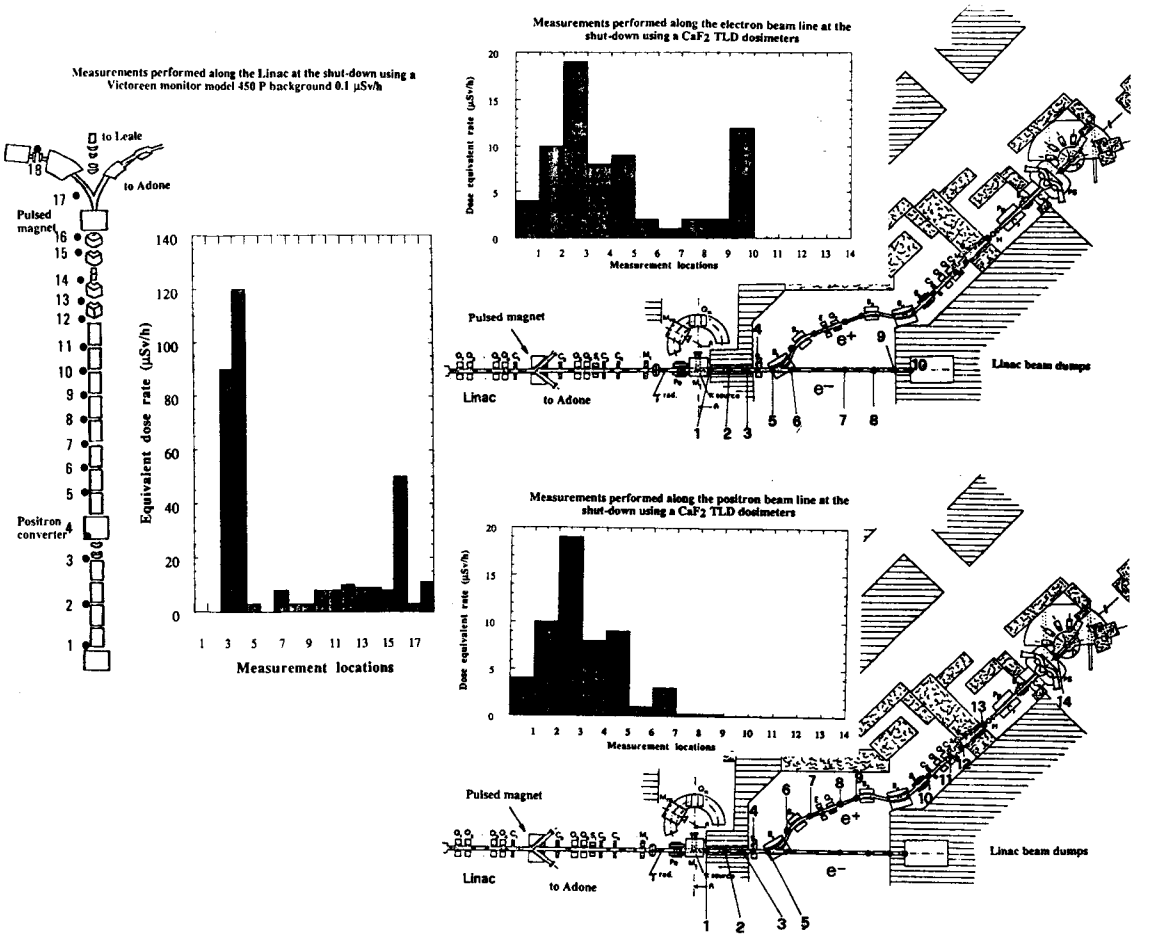

Figure 1 Dose equivalent rate from residual radioactivity

Dismantling of the machine elements and final cleaning

On the basis of the results of the preliminary measurements the decommissioning program, the handling and transportation of materials began and were completed in 3 months without particular protections for people involved except the use of personal dosimeters and disposable dresses used in dusty operations.

During the dismantling the following instruments were used for in the field measurements:

- two portable HpGe EG&G spectrometric systems;
- two environmental Reuter Stokes ionization chambers;
- a Victoreen 450 P ionization chamber;
- a Victoreen Frisker connected with a pancake probe;
- other useful monitors.

Two HpGe spectrometric systems in network with a 486 IBM PC were used for the quantitative analysis of samples.

Materials coming from Linac, including the 12 accelerator sections, the magnetic structures, the vacuum pipe line, the Linac-Adone transfer lines and 43 baskets, filled with remaining materials, were transported to the storage area without any quantitative measurements.

On the basis of the γ rate measurements it was clear that the most part of the materials had a concentration values higher than the clearance levels while the remaining ones not voluminous but very numerous, would have paralized uselessly all Health Physics Service γ ray spectrometric systems. More accurate measurements are foreseen for the future.

TELEROBOTIC DECOMMISSIONING OF THE DIDO HIGH ACTIVITY HANDLING CELL AT UKAEA HARWELL

Sally Forbes and Jane Brown
AEA Technology, Harwell, Oxfordshire, OX11 0RA, UK

SYNOPSIS

This paper reports on the decommissioning of the DIDO High Activity Handling Cell (HAHC) at UKAEA Harwell, focusing on the successful use of a Nuclear Engineered Advanced TeleRobot (NEATER). The use of NEATER achieved a significant reduction in collective dose for the project with a saving of both cost and time, when compared with estimates for traditional decommissioning techniques. The HAHC project has provided a range of experience and awareness of the potential for remote telerobotic operations in decommissioning.

1. INTRODUCTION

The HAHC was used for the handling of irradiated experimental equipment and specimens from the DIDO and PLUTO Materials Testing Reactors at Harwell. The facility was closed in 1984 due to concern over the safety of continued operation of the cell, mainly associated with the deterioration of the ventilation system. The cell remained under care and maintenance until 1989 when a decision was made to decontaminate and decommission the cell and its contents. The decommissioning project started in January 1989 and was undertaken by AEA Technology. The decommissioning project was completed in five Phases, commencing with Phase 1 'Planning and Documentation', with the radiological end point being complete removal of the cell.

2. DESCRIPTION OF FACILITY

The HAHC consisted of the Main Cell (dimensions 7.3m long x 2.4m wide x 3m high) with adjoining Maintenance Bay and Posting Areas located at either end of the cell. The Main Cell was constructed from modules of double walled steel plates, the gap between the plates was filled with sand to provide shielding.

The cell had three pairs of master slave manipulators (MSMs) adjacent to zinc-bromide filled viewing windows. A large power manipulator ran on overhead rails that traversed the full length of the Main Cell and into the Maintenance Bay. A pair of railway lines running the full length of the floor in the facility carried a trolley to allow equipment and waste to be transported into and out of the cell. The major items of equipment in the cell at the start of decommissioning comprised a large steel bench in front of the viewing windows, an auxiliary bench, a set of steel rollers in line with the posting port and a static vacuum unit.

3. INVENTORY

The radioactive inventory of the cell was estimated to be 6×10^{12} Bq cobalt-60 with a small percentage (< 1%) of europium isotopes also present. The majority of contamination was found to be loose, due to large fines and saw cuttings from routine work to cut up cobalt pencils. Radiation levels in the Main Cell were up to 1 Svh^{-1} on contact with parts of the main bench.

4. PRE-DECOMMISSIONING PREPARATION

Phase 2 'Preparation of the Cell for Decommissioning Activities' involved a programme of refurbishment to bring all the systems and equipment required for decommissioning up to modern standards. This included the installation of a new auxiliary ventilation system and a modular containment system.

Specialist foam decontamination techniques developed by AEA Technology at Winfrith were evaluated in Phase 2 during decontamination of the Maintenance Bay. It was found that several applications of foam were required to penetrate the accumulated grease and dirt and that as layers of dirt were removed the radiation levels fluctuated indicating that contamination had been masked.

In Table II are reported, for istance, the results of the measurements carried out on the most radioactive parts of the accelerator.

Tab.II Qualitative gamma-rays spectrometry on Linac components

Material	Dose equivalent rate (μGy/h)	122 keV Co-57 (cps)	321 keV Cr-51 (cps)	810 keV Co-58 (cps)	835 keV Mn-54 (cps)	846 keV Co-56 (cps)	1275 keV Na-22 (cps)	1332 keV Co-60 (cps)
Linac section n°5 at 1 m of distance	750	21			39		1	154
positron converter target at 50 cm of distance	230	8			4		1	170
positron converter flange at 1 m of distance	500	137		1.7	127		197	12

Dose rate measurements carried out with a Reuter Stokes mod RSS112 during the cleaning of the Linac area from the remaining dust and reported in Figure 5, have shown appreciable values in the positron converter area with a maximum of 3 μSv/h .

A quantitative γ spectrometry measurement of a concrete sample, collected from a wall of the positron converter area, stressed the presence of Eu-152, Co-60, Cs-134, Eu-154 (Table IV), due to the concrete activation (n, γ) of the Linac walls (3).

The decommissioning of the Adone area has caused many problems due to the big volumes and weights involved and to the very low value for unrestricted release. The Adone storage ring was formed of 12 identical sectors, each one composed by a straight section, a bending magnet, and a couple of quadrupoles for a total weight of about 35 ton/sector and the concrete shielding weighted about 800 tons. In situ γ spectrometry measurements were carried out on each part of the sectors in order to collect a sample from the most radioactive area. Anyway, the final destination of materials was determined on the basis of quantitative results. All materials coming from Adone were released free except a few vacuum chamber.

Some results of the quantitative analysis, carried out on the most representative magnetic elements and vacuum chamber of the storage ring are reported in Table III. The measurements stress the presence of Mn-54 in the iron of a few bending magnets and Co-60 in the inox steel of a few vacuum chambers, where beams usually were lost (near injection devices).

Tab. III Quantitative gamma-rays spectrometry on some representative Adone components

Radionuclide mass activity	Co-57 (Bq/g)	Co-60 (Bq/g)	Mn-54 (Bq/g)
Sample collected from			
Quadrupol 43		0.00085 ± 0.00007	0.022 ± 0.002
Bending magnet 2		0.0080 ± 0.0007	
vacuum chamber of bending magnet 2	0.011 ± 0.001	0.017 ± 0.002	0.014 ± 0.002
vacuum chamber of quadrupol 43	4.70 ± 0.40	2.14 ± 0.30	9.70± 0.80

Conclusion

The decommissioning of the whole Linac-Adone complex, including radiation protection measurements, has been completed in 6 months.

The continuous survey carried out by the Health Physics Service (1 physicist and two technicians) has obtained two important aims:

1) the movement of the activated material to the area of storage has been carried out avoiding any loss;
2) people involved in decommissioning have received doses, no higher than the background.

5. REMOTE DECOMMISSIONING OF THE MAIN CELL

Phase 3 'Remote Decommissioning of the Main Cell' began in June 1991. The aim of this phase was to achieve radiological conditions acceptable for man-entry into the Main Cell, by remote decontamination and removal of contaminated items from the cell. These conditions were defined as 500 μSvh^{-1} measured as a general background radiation level in the cell.

During the operation to drive the overhead power manipulator out of the Main Cell an oil seal ruptured spilling a considerable amount of hydraulic oil into the Main Cell and work was suspended while a clean-up operation was carried out. It was originally planned that items would be size-reduced in the cell using plasma-arc cutting equipment deployed by the MSMs. However, this technique was prohibited due to the fire risk from residual spilt oil and the MSMs were not strong or rigid enough to manipulate the alternative heavy cutting gear.

An alternative approach was an extensive remote decontamination programme to reduce radiation levels to permit man-entry, followed by manual size reduction. Efforts were made to decontaminate the Main Cell and principally the main bench by remote techniques, however the traditional decontamination methods achieved only limited success in reducing the background radiation level. This indicated that several cycles of cleaning would be required taking a considerable amount of time, inflating the cost and there was no guarantee that this method would achieve the required end point of conditions suitable for man entry.

6. NUCLEAR ENGINEERED ADVANCED TELEROBOT (NEATER)

The opportunity arose to use a remotely operated telerobotic system, the Nuclear Engineered Advanced TeleRobot (NEATER), to continue with the decontamination and decommissioning operations. This was funded partly by the Commission of the European Communities (CEC), who wished to support a proposal to demonstrate and test the capabilities of the telerobot for active decontamination and decommissioning tasks, and the Department of Trade and Industry via UKAEA's Corporate DRAWMOPS Directorate (CDD).

NEATER is based on an industrial telerobot model, modified for use in the high radiation environment found in nuclear decommissioning operations. The telerobot was used for size-reduction of items, monitoring, sorting and packaging of waste, and decontamination of surfaces. Special radiation tolerant tools were developed including an electric saw, pneumatic gripper, foam cleaner and vacuum equipment. A remote automatic tool changing station mounted on the telerobot trolley enabled tools to be changed in the cell.

Computer simulations were performed to demonstrate the feasibility of the proposed operations. Inactive trials were carried out on a full size mock-up of the cell and equipment to train operators and optimise the efficiency of operations, which prove invaluable.

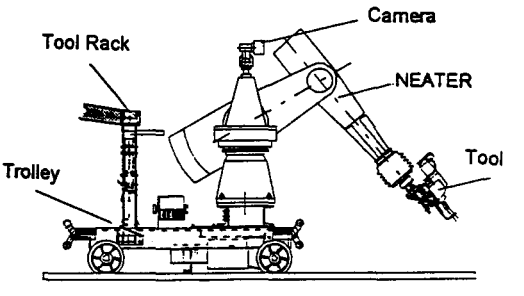

Diagram of NEATER mounted on the trolley.

Installation of NEATER began in July 1993 and the telerobot was conveniently deployed into the Main Cell on a trolley using the existing floor rails. A gaiter and strippable coating were applied to NEATER before it entered the cell to reduce contamination of the telerobot surfaces.

7. EXPERIENCE OF USING NEATER

The use of NEATER for remote decontamination and decommissioning operations is compared with the original plan of using traditional remote techniques (assuming five cycles of cleaning would have been sufficient).

- **Dose**

The collective dose for NEATER operations was 8 man-mSv, an estimated reduction of 90 man-mSv over traditional techniques. Such a reduction will be of increasing value in future projects as regulatory bodies set more stringent dose limits.

- **Waste**

The robot was used to monitor waste in the cell and segregate it for disposal to the appropriate route. The amount of Intermediate Level Waste (ILW) was kept to a minimum by decontamination techniques and by cutting out areas with high radiation levels. Low Level Waste (LLW) was packed directly into half-height ISO containers for dispatch to Drigg instead of intermediate handling and storage on the Harwell site. The elimination of size-reduction and double-handling activities reduced the collective dose for waste handling.

- **Telerobot Reliability**

There was no significant breakdown of the telerobot during an estimated 660 hours of operation. An availability of greater than 90% was achieved, which is considered to be excellent for such a complex piece of equipment.

- **Time Scales**

The schedule for telerobotic decommissioning was for 9 months of NEATER operations in the cell. Actual operations were completed in under 7 months, although the training time had been extended before installation. The actual time from start of planning the telerobotic operations to reach radiation levels compatible with man-entry was 20 months. This time scale can be compared with an optimistic estimate of 40 months for traditional techniques to reach the required levels.

- **Redeployment**

When the telerobot operations had been completed, NEATER was removed from the cell, the gaiter and strippable coatings removed and disposed of as LLW, and the telerobot monitored. Minimal contamination was detected indicating that the protective measures were effective and NEATER could be recovered and refurbished for further use.

8. DECOMMISSIONING END POINT

NEATER was withdrawn from the cell in February 1994 when background radiation levels were below 500 μSvh^{-1} and it was accepted that any remaining areas of high radiation were best decontaminated by manual operations.

Phases 4 and 5 'Man Entry into Main Cell' and 'Achievement of the Decommissioning End Point' were combined in an accelerated programme to complete manual decontamination of the cell, followed by dismantling of the cell structure. The Decommissioning End Point of complete removal of the HAHC, was achieved successfully by August 1994.

9. SUMMARY: BENEFITS OF USING TELEROBOTIC TECHNIQUES

- The HAHC project has provided a successful demonstration of telerobotic techniques for remote decontamination and decommissioning, yielding significant advances in telerobotic decommissioning methodology.
- Use of the NEATER telerobot in decommissioning the HAHC has achieved a significant saving in operator dose, cost and time, when compared with estimates for traditional techniques.
- The extensive use of a mock-up facility for optimisation of telerobotic operations and training of operators proved invaluable in the success of the project.
- The use of a remotely operated telerobotic system reduces the risks associated with projects where man-entry to a facility is restricted and hands-on techniques may not be possible to achieve the required end point.
- The HAHC project has provided a range of experience and awareness of the potential for remote telerobotic operations and it is recommended that telerobotic techniques be utilised in decommissioning operations in radioactive environments.

ACKNOWLEDGEMENTS

This work has been funded under the DRAWMOPS programme of the UK Department of Trade and Industry (DTI). The results of this work form part of the UK Government programme on decommissioning and radioactive waste management, but do not necessarily represent Government policy.

ABSTRACT (See instructions overleaf)

The dry silo at the Sellafield site, British Nuclear Fuels Limited [BNFL] was built in the late 1940s to receive solid intermediate level wastes from the first fuel decanning and reprocessing plants in the United Kingdom. It operated from the early 1950s until the mid 1960s, and the building has been under care and maintenance surveillance from then until the present. The building is a single walled structure, with six internal compartments and a roof superstructure that positioned a transfer flask over the compartment being filled. To minimise external doserates, additional shielding was placed on and near to the silo walls. BNFL has now decided to retrieve the contents of the silo. There has been investigative work to confirm the state of the structure and to confirm the nature of the contents, since contemporary tipping records were not detailed. A remotely operated method for retrieval has been developed and a processing building is to be erected adjacent to the existing silo. Here there will be some initial sorting, identification and processing of wastes to ensure that they are safe for transport to a further building where they will be encapsulated. The poster will outline some of the safety concerns addressed by the recovery facility design such as the potential for fire, the seismic robustness of the silo and the dose reduction measures necessary for construction in the existing doserates from the silo.

ABSTRACT (See instructions overleaf)

The spoils (produced by geological exploration,especially by tunnelling) in uranium deposit contain certain amount of uranium ore, it may have impact on the environment and pose a potential radiation health hazard to the public because of the presence of spoils piles, the amount of spoils at each site ranges from only residual contamination to 92 thousand tons in Eastern China. This paper develops a series of methods for the disposal of uranium spoils, such as applying an earthen cover to control release of radon because radon is the most hazardous constituent of uranium-bearing spoils, building drainage system to avoid water erosion and supporting to maintain the stability of spoils piles, which is based on the summarization of environmental impact analyses in 18 uranium deposits,various factors including health,resource, ecological environment protection and meteorological condition.

By the use of above methods that make the implymentation easily and less costly, we have finished the ultimate disposal of 21 spoils piles and gained ideal results that radon emission rate and gamma radiation are decreased significantly (achieving the demands of pertient standards),natural environment is restored fully, water erosion and misuse are avoided effectively .This paper also presents some data to evaluate the effect of remedial actions.

ABSTRACT (See instructions overleaf)

The use of ^{226}Ra in luminising materials is well known. Even though this work ceased by the 1960s, it continues to have implications for British industry today. This paper looks at the financial and legal problems faced by landowners wishing to sell or develop sites that were formerly used for radium luminising purposes.

The potential liabilities, including the costs of decontaminating the land, are vast and must be considered fully when planning future use of affected land.

CHARACTERISTICS OF GENERATED AEROSOLS AND ESTIMATION OF AIR CONTAMINATION IN DECOMMISSIONING OF THE JAPAN POWER DEMONSTRATION REACTOR

Iwao MANABE and Hiroyuki TOMII

Japan Atomic Energy Research Institute,Ibaraki,319-11,Japan

INTRODUCTION

A decommissioning program of the Japan Power Demonstration Reactor(JPDR) started in order to establish technical bases for future dismantlement of commercial nuclear power plants. Some techniques of reactor dismantling were developed. Various cutting methods were tested during the dismantling of the JPDR, which had variety of structures, materials and contamination level. JAERI developed an underwater plasma-arc cutting system which is capable of effective cutting highly activated reactor components and consequently reducing radiation exposure of workers. The extent of air contamination generated from underwater cutting had been unknown because of insufficient experiences of application of this technique. Methods for estimating the level of air contamination which results from the underwater cutting are necessary to evaluate radiation exposure of workers. A mathematical model of estimating air contamination level was proposed for aerosol generation during in-air and underwater cutting processes. The model was examined and some characteristics of the generated aerosols were investigated.

MATHEMATICAL MODEL FOR ESTIMATING AIR CONTAMINATION LEVEL

The air contamination is caused by the aerosols due to the cutting. An air contamination estimating model for the reactor dismantling is shown in Fig. 1. Formulas to calculate the total radioactivity of material generated during cutting operations were given by Smith et al.(1). The evaluation method of airborne activity resulting from radioactive surface contamination was developed by Shapiro(2). Both methods were applied to our model. The dispersion rate for in-air cutting was defined as activity ratio of material generated during the cutting to dispersed aerosols, and was given by:

$$\lambda a = Ca\,(Vs \cdot S + F)\,T / A \qquad (i)$$

where: λa = dispersion rate for in-air cutting

Ca = airborne concentration for in-air cutting (Bq/cm^3)

Vs = settling velocity of aerosols (cm/min)

S = area of floor (cm^2)

F = ventilation rate (cm^3/min)

T = working time in cutting operation(min)

A = total radioactivity of material generated during cutting operation

The dispersion rate for underwater cutting was defined as radioactivity ratio of material generated during underwater cutting to dispersed aerosols from the water into the air, and was given by:

$$\lambda w(d) = Cw\,(Vs \cdot S + F)\,T / A \qquad (ii)$$

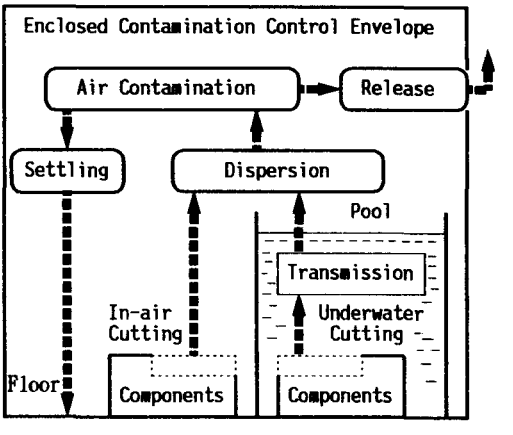

Fig. 1 Air contamination estimating model for the reactor dismantling

where: λ w(d) = dispersion rate for underwater cutting

Cw = airborne concentration for underwater cutting (Bq/ cm^3)

d = water depth at cutting operation (m)

Aerosol transmission factor (P (d)) was defined as:

$$P(d) = \lambda w(d) / \lambda a \qquad \text{(iii)}$$

MEASUREMENTS OF AEROSOLS

The radioactivity air concentration and size distribution of aerosols were measured to investigate characteristics of dispersed aerosols in a thermal cutting process. The reactor internals and pipes connected to reactor pressure vessel(RPV) were cut in the air with oxyacetylene and plasma-arc torches. The highly activated internals were cut contourly at water depths between 1 m and 8 m in the RPV and spent fuel storage pool with underwater plasma-arc cutting systems(Fig. 2). Typical surface or specific radioactivity of contaminated components are listed in Table 1.

Radioactive aerosols generated by the cutting were collected on glass fiber filters with a low pressure cascade impactor and a dust sampler. The aerosols were sampled at an exit of an enclosed contamination control envelope. Radioactivity on the filters were measured with a GM counter and a high purity Ge γ -ray spectrometer.

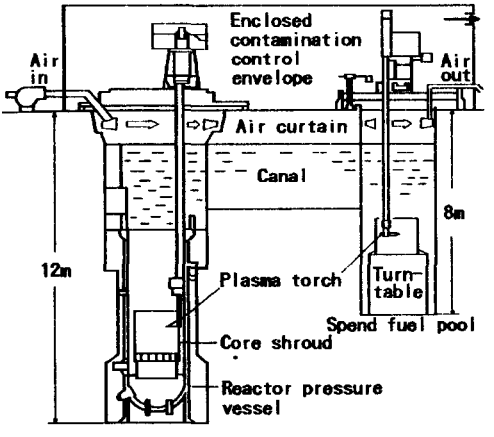

Fig. 2 Schematic view of cutting of reactor components in the water

Table 1 Radioactivity levels in major contaminated reactor components

Code	Component	Radioactivity
a	Pipes connected to RPV	2.9×10^{2} Bq/cm^2
b	Channel box	2.0×10^{4} Bq/cm^3
c	Core shroud	2.9×10^{7} Bq/cm^3
d	Bottom grid	3.0×10^{5} Bq/cm^3
e	Core support	1.5×10^{5} Bq/cm^3
f	Control rod	3.0×10^{7} Bq/cm^3
g	In-core monitor tube	2.0×10^{10} Bq/cm^3

RESULTS AND DISCUSSION

1) Aerosol size and size distribution

Figure 3 shows size distribution of aerosol generated by thermal cutting in the air and in the water. In the case of in-air cutting, bimodal distribution was observed, which has peaks at 0.05 μ m and 3 μ m of aerosol size. On the other hand, in the case of underwater cutting, only a single peak was observed at 0.05 μ m. This property may be explained by the fact that the big-size aerosols in bubbles were easily

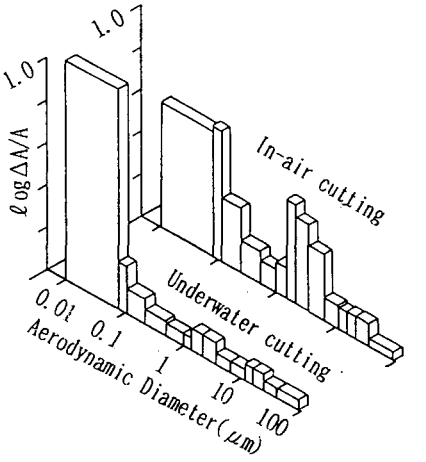

Fig. 3 Size distribution of aerosol generated by thermal cutting in the air and in the water

captured by the water.

2) Dispersion rate during in-air and underwater cutting

Dispersion rates for in-air cutting were calculated by Equation (i) using data measured in the pipe cutting. The results are plotted at 0 m of water depth in Fig. 4. The dispersion rate ranges from 3×10^{-4} to 3×10^{-2}. The geometric mean of the rate is 3×10^{-3}. Dispersion rates for underwater cutting were calculated also by Equation (ii) using data measured in the cutting of internals. The dispersion rate decreases exponentially with the water depth as shown in Fig. 4. The geometric means are 6×10^{-5} and 3×10^{-7} at 2 m and 8 m water depth, respectively.

3) Aerosol transmission factor

The typical transmission factors as given by Equation (iii) are 2×10^{-2} at 2 m, 1×10^{-3} at 4.5 m and 1×10^{-4} at 8 m depths in the water. These results show that the dispersion volume of aerosols depends on the water depth of cutting operation.

CONCLUSION

The characteristics of the aerosols generated from some structure-cutting operations were studied through the dismantling works of the JPDR. A model was proposed to estimate air contamination level due to aerosol generation. The transmission factors of aerosols in the water were obtained and found to decrease drastically with the water depth. The model and accumulated data will be helpful for accurate estimation of occupational radiation exposure and planning of reasonable dismantling methods in future decommissioning of commercial nuclear power plants.

MAJOR SCIENTIFIC TOPIC NUMBER 4.7 (see page 7)

ABSTRACT (See instructions overleaf)

Difficulties with using hand-held survey instruments to quantify radium concentrations in soil became apparent during a recent remediation effort. A major contributing factor was the presence of illite, a potassium-rich clay. Pure illite can have a ^{40}K concentration of 1.8 Bq/gm (49 pCi/gm). The 1.46 MeV gamma ray emitted by ^{40}K has a transition probability of 11%. In illite-rich soils, these gamma rays can obscure detection of the 186 KeV photons emitted from ^{226}Ra. This can, in turn, result in inaccurate field assessments of soil contamination.

Another difficulty encountered was radium contamination at some depth as well as soil overlaid with asphalt. The shielding properties of soil and paving material can lead to serious underestimates of anticipated remediation volumes.

Finally, proper manifesting of shipments from these sites requires activity estimates for each container. Performing such estimates can be done analytically, but in large containers, such as rail cars, it is difficult, time-consuming, and expensive to obtain and analyze samples.

It was found that use of a single-channel analyzer, in conjunction with a 2"x2" NaI(Tl) crystal, overcame most of these problems. An analyze window centered on the 1.76 MeV gamma ray emitted by ^{214}Bi progeny of ^{226}Ra eliminates interference from ^{40}K emissions. In addition, the 1.76 MeV gamma ray is very penetrating. This allows quantification to a depth of at least one meter in soil and within large shipping containers if soil homogeneity can be assured.

LEACHING AND ADSORPTION CHARACTERISTICS OF RADIONUCLIDES IN ACTIVATED CONCRETE WASTE

Shohei Kato[1], Yoshiaki Yanase[1] and Tetsutaro Honda[2]

[1]Japan Atomic Energy Research Institute
[2]Institute of Radiation Measurement

1. INTRODUCTION

Full-scale dismantling of nuclear power plants will come in the near future. In the decommissioning, very large amount of activated concrete waste with very low-level radioactivity will be generated. One of the disposal methods of such kind of wastes is shallow land burial. Radiation exposure to the general public through groundwater is expected to be one of the main exposure pathways in case of the shallow land burial. Leaching characteristics of radionuclides from concrete waste are very important in assessing the exposure due to the shallow land disposal. There are many reports on leaching mechanism focusing on the solidified low-level waste, but not on activated concrete waste (1). Leaching is caused by diffusion, dissolution, ion-exchange, corrosion and so on. The leachability also strongly depends on the environmental conditions, such as form of waste, waste materials, substances dissolved in water contacted with the waste and nuclides of interest. In decommissioning of a nuclear power plant, concrete wastes will be vary in forms such as block, debris, granule and powder. It is, therefore, very difficult to estimate leaching of radionuclides from concrete wastes precisely.

The objects of this study are to obtain diffusion coefficients and distribution coefficients of elements for leaching from activated concrete wastes, to estimate the leach rates of radionuclides from activated concrete wastes by three different models, and to evaluate the leaching models for disposal of activated concrete wastes generated from decommissioning of nuclear power plants.

2. EXPERIMENTAL METHOD AND MATERIALS

2.1 Measurement of effective diffusion coefficients, D_{eff}

The effective diffusion coefficients (D_{eff}) were measured by two methods as follows;

Method 1: Leaching test procedures were similar to the IAEA method(2). A concrete specimen with 2 cm in thickness and 8 cm in diameter (230 g) was activated by a research reactor, and was placed into the distilled water container (500 cm^3). Samples of leachant were withdrawn and analyzed at designated intervals by gamma-spectrometry.

Method 2: Leaching test procedures were the same as IAEA method(2). 10 specimens of non-activated concrete with same dimension as above were placed into water container (5000 cm^3). The concentration of nuclides in leachant were measured by activation analysis.

The leach test results were expressed by a plot of the cumulative fraction of radioactivity leached from the specimen as a function of the total time of leaching thus, $\Sigma a_n/A_0$ versus $t^{1/2}$, where a_n is amount of nuclides of interest leached during the leach interval (Bq or mol), A_0 is total amount of species in test specimen (Bq or mol), t is total elapsed time since start of leaching (day). D_{eff} was delived from the slope using following equation(3): $(\Sigma a_n/A_0)(v/s)=2(D_{eff}/\pi)t^{1/2}$, where s is geometric surface area of specimen (cm^2), v is volume of specimen (cm^3).

2.2 Measurement of distribution coefficients for leaching, K_{dl}

K_{dl}s were measured by different two methods as follows.

Method 1: 50 g of non-activated concrete granule (1.2 - 2.4 mm in diameter) and 200 ml of distilled water was mixed and elapsed for 400 days. The concentration of nuclide in the solution and the concrete was measured by activation analysis. K_{dl}s were calculated by the equation, $K_{dl} = C_m / C_l$, where C_m: concentration in concrete (ppm), C_l: concentration in solution (ppm).

Method 2: 50 g of activated concrete granule(1.2 - 2.4 mm in diameter) or powder(<150 μm in particle diameter) and 200 ml of distilled water was mixed and was elapsed for 400 days. The radioactive concentrations of radionuclides in the solution and the concrete were measured. K_{dl}s were also calculated the above equation.

2.3 Measurement of distribution coefficient for adsorption, K_{da} (4)

10 g of non-activated powder(<150 μm in diameter) concrete were mixed in 200 ml of solution containing ^{134}Cs, ^{60}Co, ^{45}Ca and ^{152}Eu and were shaken for 24 hours. The concentration of the radionuclides in solution were measured. Kda was calculated by the equation: $Kda = (C_0-C)V_S/(CM)$, where C_0: initial concentration in solution (Bq/ml), C: concentration in solution after reaction (Bq/ml), V_S: volume of solution (cm^3) and M: mass of concrete(g).

All samples for leaching and adsorption tests were served from bioshield concrete of Japan Power Demonstration Reactor (JPDR) which is now under decommissioning.

3. RESULTS AND DISCUSSION

Effective diffusion coefficients, Deffs and distribution coefficients Kdl and Kda are listed in the Table 1. Only the Deff of Cs was obtained by Method 1 due to the detection limit. On the other hand, many Deffs of elements were obtained using the method 2. There seems no discrepancies in Deff of each element between two methods. This means that there is no significant difference between the diffusion mechanism of activated elements and that of non-activated elements. The Deffs were Ca > Cs > Co in order of magnitude. Deff of Eu seems to be far smaller.

There were no significant discrepancies of Kdls due to measurement methods. The Kdls measured by both the method 1 and 2 were Ca > Cs > Co > Eu. Kdls for powder concrete were about 10 times as large as that for granular concrete. A relation between Deff and the inverse of Kdl measured by method 1 showed that the Deff increases with decreasing Kdl linearly on the log-log plot. Therefore, these results indicate that a diffusion mechanism is a dominant mechanism of leaching of nuclide from activated concrete waste.

The Kdas measured were Co > Eu > Cs > Ca. The Kdas measured were one order of magnitude smaller than distribution coefficient of equilibrium, Kdls.

In decommissioning of a nuclear power plant, concrete wastes will be vary in forms such as block, debris, granule and powder. It is, therefore, very difficult to estimate leaching of radionuclides from concrete wastes precisely. Following simplified estimation models of leaching are proposed to assess the leaching: a) an instantaneously leach model, the most conservative model, assuming that all activity leaches immediately after disposal, b) an equilibrium model assuming that there is an equilibrium between waste and leachate, this model is apply to the waste in form of granule and powder, and c) a diffusion model which will be apply to the waste in form of blocks.

To evaluate the leach models for disposal of activated concrete wastes generated from decommissioning, leaching amount were calculated by three models using measured data under simplified conditions as follows:

a) Instantaneously leach model: $L = CwV\rho/Q_0$, where L is a leach ratio defined by the ratio of amount of nuclide leached from waste to the initial total amount of nuclide in the waste, C_W is concentration of nuclides in the waste (= 1 Bq/g), V is the volume of waste (= 10^6 cm^3) and ρ is the density of waste (1.0 g/cm^3), and Q_0: initial amount of activity in the waste ($=CwV\rho$).

b) Equilibrium model (5): $L = Kd^{-1}CwPA/Q_0$, where Kd is distribution coefficient ,Kdl or Kda (cm^3/g), P is precipitation (= 10^2 cm/y), A: precipitation area for waste (= 10^4 cm^2).

c) Diffusion model (3): $L = 2(S/V)(Dt/\pi)^{1/2}$, where D is effective diffusion coefficient (cm^2/day), S is total surface area of waste (= $6x10^4$ cm^2, assuming a cubic form waste with side of 1m), t is duration of leaching (= 365 days).

Table 2 shows the leach ratio calculated by different three calculation models under the above conditions. The instantaneous leach model is not based on real physico-chemical process and is the most conservative. The instantaneous leach model is, however, useful when there are no data used for other sophisticated models or the evaluation is for tentative purposes. When the waste form is granule or powder, the equilibrium model is more reasonable than the instantaneous model. Table 2 indicats that the leach ratios calculated by the equilibrium model are several order of magnitude smaller than that by the instantaneous leach model. For example, leach ratio of Co from powder concrete was $3x10^{-4}$ times as large as that by instantaneous leach model.

Estimation of leaching using the distribution coefficients for adsorption (K_{da}) is an alternative method when distribution coefficients for leaching (K_{dl}) are not available. The results, however, shows that the leach ratios calculated using K_{da} are one order of magnitude larger than that using K_{dl}.

Table 2 shows that the leach ratio of elements from cubic concrete waste estimated by diffusion model was 10^{-4} to 10^{-6} times as large as that by the instantaneous leach model.

4. CONCLUSIONS

1) Leachability of nuclides from an activated concrete is Ca > Cs > Co > Eu.
2) The leaching amounts from granular concrete waste estimated by equilibrium model are 4 to 5 order of magnitude as large as those by the instantaneous model.
3) The leach amounts calculated using Kda are one order of magnitude larger than that using Kdl.
4) The Leaching amountsestimated by diffusion model are five order of magnitude as large as those by the instantaneous leach model.

COLLIMATED IN-SITU GAMMA SPECTROMETRY: A NEW METHOD FOR FAST CLEARANCE MEASUREMENTS OF LARGE AREAS OR BUILDING STRUCTURES OF NUCLEAR FACILITIES UNDER DECOMMISIONING [1]

Lothar Hummel; P. Guglhör; K.H. Lehmann
Technical Inspectorate of Bavaria (TÜV Bayern Sachsen, München)

INTRODUCTION AND MOTIVATION

The ideas in the late sixties which led to the use of bare spectrometric radiation detectors like NaI(Tl), Ge(Li) or nowadays high-purity germanium detectors (HPGe) for field measurements (in-situ gammaspectrometry) were to get easy and rapid informations about the radiological state of outdoor grounds after nuclear weapon tests or to estimate dose rates created by natural radioactive nuclides in the soil. In this cases, it was assumed, that there was no disturbance of the source-detector geometry for many hundred square meters around the detector. After the nuclear accident in Chernobyl in 1986 these advantages focussed strong scientific interest at the in-situ technique and in 1993 it was established in the german regulatory for immision surveillance after significant radioactive emissions. For unrestricted release in decommissioning "in-situ gammaspectrometry may be the only method of achieving validation of the release criteria, particulary for large areas outside the buildings" [1].

In a late phase of the decommisioning of a nuclear power plant all components containing a significant inventory of radioactivity are removed, leaving large surfaces with often poorly known contamination levels. Taking in account only buildings of restricted areas in the next 50 years in Germany 7E3 Mg activated and 5E6 Mg contaminated concrete must be released from facilities under decommisioning. Before the ground and the building structures of the facility can be conventionally pulled down, the remaining radioactivity must be determined in order to check the radiological relevance of the concerned part of the plant and to decide the possible path of material release. The basis of assessment may be the so-called "10 μSv-concept" [2].

Today the mainly used strategies are analysing samples, taken from the surface or measuring the surface activity via large proportional counters. In both cases we meet severe systematic problems.

1) A commercial contamination monitor meets a minimum detectable activity of 0,1 Bq/cm² Co 60 or Cs 137 on a surface two to ten-times faster than a collimied in-situ spectrometer. On the other hand shielding layers coming from decontamination coatings or migration of the radionuclides in the surface lead to relative small errors performing in-situ measurements whereas contamination monitors are completely inappropriate in the most cases to determine the remaining activity.

2) Taking and analysing samples leads for the single sample to more exact results than in-situ measurements caused by the not completely known source geometry and the measuring time which is in the latter case normally much shorter because of the large number of measurements.

The main problem of the analysis of samples in the laboratory is the estimation of the representativity of a collective of samples. Comparing the results of in-situ measurements and laboratory analysis we noticed substancial differences which could be attributed to strong inhomogenities in the spatial distribution of activity. These were not overcome by sampling.

The importance of this problem can also be shown theoretically. Ferguson [3] determined the number of samples to meet a defined statistical significance for finding an existing contamination. As an example ~200 samples are necessary to find a circular contamination with a diameter of 35 cm on a relative small area of 10 m² with a safety of 95%.

[1] This work was financially supported by an international EC R&D-contract ("Measurement of Spatial Distribution of Contamination on Concrete Surfaces and Build-up of Dusts for the Improvement of Scenarios for Material Release" / CEC Contract FI2D-CT94-0086), which is coordinated by us.

Errors arising from this sort of problems do not appear by measuring with a collimated high-purity germanium detector directly in the regions of interest ("in-situ"). There are only two problems left.

1) The vertical distribution of a contamination may be not known well enough. This fact creates a uncertainity which can reach a factor of two. On the other hand this systematic error may be solved and is furthermore small, compared to errors which can affect the quality of the results of traditional techniques.

2) A formal problem e.g. in the german radiation protection ordinance is, that the value of a surface contamination has to be achieved by a measurement averaging over 100 cm^2. Such an averaging area is obviously not adequate for clearance measurements of thousands of square meters of probably contaminated walls, floors, roofs or soils. At the moment this subject is discussed in Germany.

Apart from this the collimated in-situ gamma spectrometry allows to get very fast informations about the radiological state of large areas and -if one takes in account the high quality of these informations- for low costs.

DEVELOPMENT OF AN COLLIMATED IN-SITU SPECTROMETER

Despite the strong worsening effect to the minimal detection limits, it was obvious that for using such a device for clearance measurements it had to be collimated to reduce the field of view. Reasons therefore are that

- possible contaminations must be locateable,
- there must be a well defined averaging area (e.g. some m^2), and
- contaminations outside the measured area must be effectively suppressed.

So we designed and constructed a prototype of a high-resolution in-situ spectrometer on the basis of 41% p-type HPGe-detector, surrounded by an optimised collimator made out of brass and a low natural activity lead-bismuth-tin-alloy. As a compromise between portability and shielding effect a attenuation mass per area of ~53 g/cm^2 was realised for radiation which reaches the collimator in an angle of incidence parallel to the investigated surface. Furthermore the detector is shielded for radiation from the rear hemisphere. Depending on the collimator used and the height of the detector above the surface our spectrometer averages over areas between 0.4 and more than 10 m^2 in one measurement.

To get quantitative values of contaminations the system had to be calibrated. This needs much more work than for gamma spectrometers in laboratory, where reference sources with relative small volumes for a reduced set of geometries and chemical compositions exist. Performing in-situ gamma spectrometry one has to deal with large sources and any horizontal and vertical activity distributions. They can only be simulated numerically or experimentally. We use three approaches to verify the calibration factors between the full-energy-peak count rate and the specific activity level;

- a modified standard method for uncollimated systems suggested by Beck et al [4] in 1972,
- an experimental calibration by recording a great number of spectra with small sources in different positions and superimposing them as a function of the source geometry and
- a complete numerical simulation modelling the source and the entire detector-collimator-system

All commonly used yield curves with calibration factors based on the standard method have already been verified experimentally. According to our current experience, the two yield curves generally do not deviate from one another by more than 10% in the region of higher photon energy (662 keV and above). Differences of more than 30% have not occurred below 186 keV. These tests make the individual calibrations very reliable, as the two methods are in no way related to one another and the occurrence of identical systematic errors is thus ruled out.

PERFORMANCE OF THE SPECTROMETER

It could be shown that our calibrated prototype is able to meet the maximal activity limits for unrestricted release in Germany in some minutes of measuring time, if the proportionate activity of a strong gamma emitter like Co 60 or Cs 137 is sufficiently high in the nuclide vector. Examples for minimal detectable activities are:

- Under rigid conditions (maximum collimation, some migration of the nuclides in concrete) and normal dose rates due to natural nuclides detection limits of 800 Bq/m^2 for Co 60 and 1400 Bq/m^2 for Cs 137 in three minutes are reached.

==> A contamination with a nuclide vector containing only 20-30% of these nuclides can be detected with the requirements of the german radiation protection ordiance.

- For the relatively difficult to measure activity of U 238 (via Pa 234m) a detection limit of 150 Bq/kg is reached after 15 minutes.

  ==> Uranium can be measured on piles with any enrichment.

  ==> The observance of exemption values for deposition of waste contaminated with the more difficult to measure nuclides of the nuclear fuel cycle can be proved (f.e. [5])

- In the same time a surface contamination of 500 Bq/m² U 235 is detectable and can be discriminated from the natural Ra 226 and U 235 186 keV background in concrete containing 1 Bq/kg U 235.

Furthermore disturbing radiation from outside the interesting field of view is strongly suppressed. For low and medium energy gamma radiation (<700 keV) from nuclides distributed vertically and horizontally homogeneous in soil 90% of the total photon flux appear from an angle of ±48° relative to the detector axis in the collimated case. Without collimator this value would rise to 82°, so it would be impossible to localise a source.

APPLICATION OF THE SPECTROMETER

Aside from the development of such a spectrometer we made experiencies with our prototype inside the restricted area and outside the buildings of several nuclear power plants unter decommissioning like KKN, KRB-A and VAK in Germany and G 3 and RAPSODIE in France by painting a grid over the area of interest and measuring at each grid point. Measurement campaigns in facilities of the nuclear fuel cycle were performed in NUKEM-A, HOBEG and WAK in Germany.

Up to now with this campaigns new knowledge about the lateral distribution of contaminations, the variability of its composition or -by comparing with other measuring techniques- their systematic uncertainities could be quantified. The description of the results of these campaigns would exceed the scope of this compact. As examples we

- mapped the short distance variability of the Chernobyl Cs 137 fall-out by scanning 1500 m² grassland completely with 3 m² surface area per single measurement,
- showed for a contaminated floor for one room in the restricted area of a nuclear power plant that the Co 60 / Cs 137 ratio was completly indefinite (variation over more than three orders of magnitude) and
- investigated large deviations in the measured surface activity via proportional counter and in-situ for several surfaces with different histories and contamination scenarios.

DELICENSING OF NUCLEAR SITES IN THE UK

J S Griffiths [1], P H Burgess [2]
[1] Nuclear Safety Division, Health and Safety Executive, Bootle, Merseyside
[2] National Radiological Protection Board, Chilton, Didcot, Oxon.

INTRODUCTION

In the UK, the operation of nuclear facilities is regulated under the Nuclear Installations Act 1965. This Act requires the issue of a licence for a number of prescribed activities. Once a licence is issued the licensee's period of responsibility continues until the Health and Safety Executive (HSE) gives notice in writing that there has ceased to be any danger from ionising radiations. This requirement applies whether the licensee wants to remove part or all of the site from his responsibility. Both of these processes are often referred to as delicensing. As with any other licensing function under the NIA65, the Nuclear Installations Inspectorate (NII) carries out this process on behalf of HSE.

Since the inception of the original Act in 1959 there have been a number of occasions where licensees have sought to end their period of responsibility or exclude parts of the site. As current facilities age and enter the decommissioning phase of their operations it is likely that there will be an increase in the number of requests NII receive to end the period of responsibility. It is therefore important that the process under which delicensing takes place is understood and that there is a suitable mechanism on which a judgement can be made regarding the suitability for the period of responsibility to be ended. This paper sets out some views on this process from a regulatory standpoint and discusses some practical aspects of how suitability may be demonstrated.

REGULATORY PROCESS

In the UK the licensee is responsible for safety until the period of responsibility ends. In seeking to end the period of responsibility similar procedures to those undertaken for an operational plant are expected. The work will have to be planned and managed safely and the regulator would expect that appropriate safety cases for the various stages leading to this end point are prepared. Before delicensing can proceed a safety case would need to be submitted for NII's consideration. Such a case will need to address a number of aspects, which could typically include:

History and use of the land

Type of work undertaken

Arrangements for preserving records, appropriate to the licensee's obligation under the licence, i.e. records relating to site operations which may be used as evidence in any claim resulting from such operations.

The state and maintenance of the plant in the shutdown condition.

The necessity for any dismantling of the plant or buildings and for any subsequent cleaning-up operations.

The management and disposal of radioactive waste.

Reason for excluding from a nuclear site licence.

Evidence that no leakage of radioactive matter has occurred into the land, or if such has occurred how it was dealt with.

Evidence that no radioactive contamination has been deliberately sealed or fixed into structures that will remain after the site is declared free from danger.

Information concerning natural background radiation in the vicinity.

Site survey information that compares measured levels with local background.

NII will be looking to establish that, to the degree necessary for the purposes of the Act, remaining levels of radioactivity are indistinguishable from those which would naturally occur in the area.

TECHNICAL EVALUATION

The previous discussion sets out the type of information that NII would expect the licensee to provide for its consideration. It is clear that there are a number of aspects against which such a safety case can be assessed and there will be site specific features. There will therefore be a mixture of qualitative and quantitative judgements depending on the site. An important aspect is to be able to interpret the monitoring undertaken and to form a judgement on whether it is appropriate for the circumstances and whether further monitoring is reasonably practicable. Monitoring approaches may include direct radiation monitoring and soil sample analysis. To help NII's judgement some technical investigation of the available techniques for the former and the detection capabilities has been undertaken in conjunction with NRPB. All currently available instrumentation has an inherent instrument background. This limits the level of radioactivity which can be measured with any degree of certainty and sets a detection threshold. In addition, there is a limit to the discrimination between a response due to natural background and any contaminant found. These are generic aspects which will apply to all delicensing cases. There is a very real practical need to establish whether it is possible, with current instrumentation, to easily monitor low levels of environmental radioactivity and to know the limitations of the measurements.

RESULTS

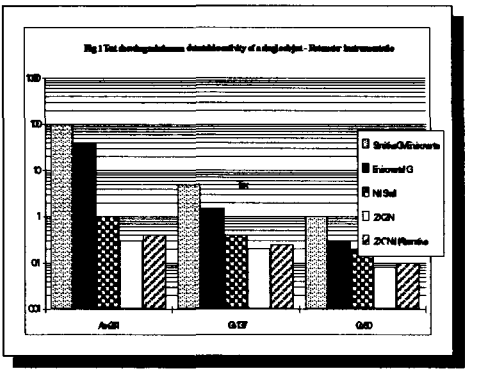
A range of possible monitoring instrumentation is available in the UK. Some commonly available instruments currently in use for directly monitoring levels of radiation were selected with the view to performing the following tasks;

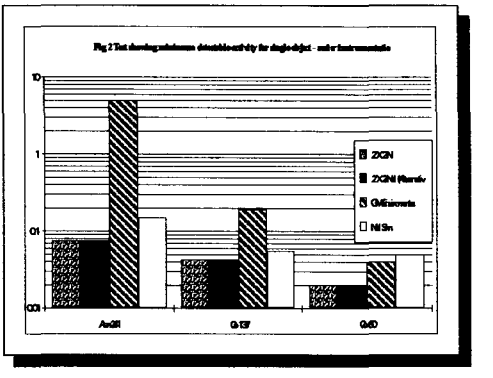
Determine the minimum detectable activity assuming a single object in the ground.

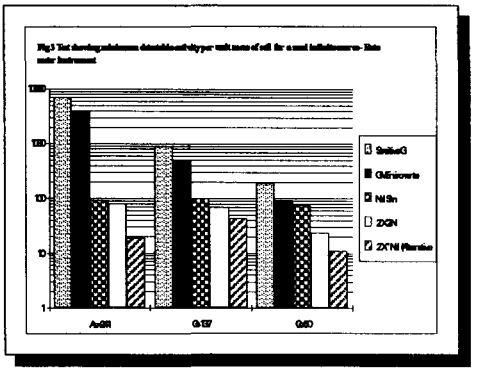
Using instrument in a scaler mode with a 30 second counting time assess the minimum detectable activity.

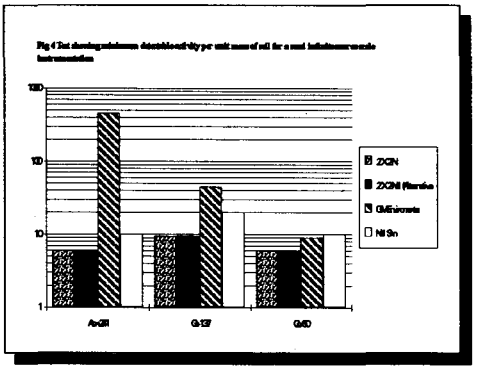
Relate each minimum detectable activity to a concentration in soil.

For each task a range of single nuclides was assumed (Co-60, Cs-137 and Am -241)









The results show that in general a lower level of detection can be achieved with instrumentation in a scaler mode. Figures 1&2 indicate that some instrumentation has the capability to measure levels at 10 M Bq in ratemeter mode and 1 MBq in scaler mode for a number of nuclides. These results illustrate the level of activity, in a single object, above which there is a high degree of confidence that the measurement is due to presence of radioactive material. (Full details of the arrangement and tests are provided in ref 1.) It should be pointed out that this is an implied level of activity and could be due to natural radioactivity or the presence of artificial radionuclides. To clarify this would require further determination, probably using gamma spectroscopy equipment to compare with the natural background spectrum. The initial monitoring is a first step and provides valuable information to enable regulatory decisions about the need for and type of more detailed monitoring programmes.

Turning to figures 3 and 4, they provide information which relates to what the instrumentation response means in terms of a minimum detectable activity in the ground. This is useful in terms of comparison with criteria under other UK legislation and again for comparison with natural background levels for the area. The results illustrate that it appears to be possible to monitor for levels of 1 Bq per gram for a range of nuclides. The investigations have shown that it is possible to carry out such measurements in reasonable timescales using standard equipment.

Some scoping work was done to extend this technical evaluation to examine the effects of shielding due to normal building materials and depth of buried objects. The difficulties of measuring for Plutonium was also investigated as was the use of portable gamma spectrometry equipment as part of the overall task. The latter aspect can be important due to the variation in the natural radioactivity content in building material. The basic conclusion of this scoping work was that for artificial isotopes it is reasonable practicable to achieve low limits of detection.

CONCLUSIONS

The process by which a site can be delicensed requires a range of information to be provided to the regulator. The experimental work undertaken has shown that it appears to be technically possible to monitor low levels of radioactive material using portable instrumentation which can subsequently be compared with current regulatory levels for below regulatory concern and natural background. The paper has also illustrated that judgements on delicensing need to be made in empirical and quantitative terms.

The views expressed in this paper are those of the authors and do not necessarily represent those of their respective organisations.

The authors wish to gratefully acknowledge the assistance of Mr M Bacon and Mr I Robinson of NSD for their assistance in preparing and reviewing the paper.

RADIATION MONITORING AND QUALITY ASSURANCE IN DECOMMISSIONING OF NUCLEAR FACILITIES

Huang Zhijian
(China Institute for Radiation Protection)
(P.O.Box 120, Taiyuan, Shanxi, China ,030006)

1. Introduction

Radiation monitoring in decommissioning of nuclear facilities is a major part of the entire decommissioning engineering. Quality of radiation monitoring has a direct influence on the quality of decommissioned work. Decommissioning due to poor engineering quality will result in not only great economic loss but also poor social impact. Therefore, it is not difficult to understand in decommissioning of nuclear facilities the radiation monitoring quality is of special importance. The paper is intended to present the characteristics of radiation monitoring in nuclear facility decommissioning, quality assurance system, quality assurance requirements and the related issues.

2. Characteristics of radiation monitoring in nuclear facility decommissioning

Radiation monitoring in decommissioning of nuclear facility involves the dismantlement, decontamination and cleaning of equipment, facilities and buildings as well as radioactive waste disposal, including source term survey, decommissioning monitoring, termination survey, and verification inspection survey[1-4], etc. The work amount of various monitoring categories varies greatly with the different stages of decommissioning. Decommissioning monitoring requires the large amount of work to be done, lasting long time throughout the full process of the decommissioning. the termination and verification inspections are to check and certificate the quality of decommissioning monitoring. So issues on radiation monitoring quality discussed in the paper is mainly focused on decommissioning monitoring.

3. Radiation monitoring quality assurance system

Radiation monitoring quality assurance system is shown in Fig. 1. The decommissioning project is contracted by licensee or contractor(s). The licensee sets up Decommissioning Office (DO) and Quality Supervision Office (QSO). Radiation Monitoring Leading Group (RMLG), led and supervised by decommissioning office, include Radiation Monitoring Group (RMG) and Quality Assurance Group (QAS), which is also guided and supervised by the QSO. The RMG consists of decommissioning operating monitoring, radiation protection monitoring, and environmental monitoring, which are also guided and supervised by the QAG according to decommissioning plan. The QAG is responsible for preparation of monitoring program, preparation and provision of quality assurance documents, organization of personnel training, selection of monitoring instruments, determination of measuring and analytical methods, determination of sampling and sample preparation methods, review of monitoring data and report. The QAG is also responsible for organization of post-decommissioning termination radiation survey and providing of termination survey report. These monitoring groups separately exert interior and exterior quality control measures according to quality control requirements. Termination verification inspection survey for decommissioned nuclear facilities should be undertaken and carried out by the inspection survey group entrusted by competent authority.

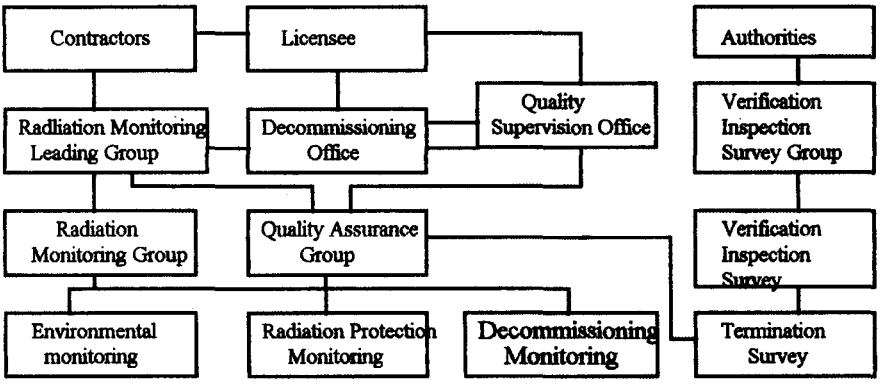

Fig.1. Radiation monitoring Quality Assurance System

4. Quality requirements for radiation monitoring

It is the final quality target of radiation monitoring during nuclear facility decommissioning to enable the residual radioactive contamination level of decontaminated equipment, facility, building, field, and site to meet the standards required by decommissioning project, and to identify these items can be open for the public to use on a restricted or unrestricted basis. After decommissioning, radioactivity inventory and desposal must be clear. Thus, in preparation of nuclear facility decommissioning programm, the quality requirements for the process of monitoring should taken into account.

4.1 Quality requirements for source terms survey

Source terms survey at the preparatory stage of nuclear facility decommissioning mainly involves two factors: residual radioactivity and radioactive contamination. The former means the amount of radioactive materials left within the decommissioned nuclear facility while the latter means the extent to which the decommissioned object is contaminated and the related contamination amount. In principle, the quality requirement for source term investigation is to give accurate or comparatively precise magnitude for the large while contamination source survey is to discriminate contaminated objects, types, and extent, giving the estimates of contamination.

4.2 Quality requirements for decommissioning monitoring

4.2.1 Training

Scope of training includes basic features and properties of decommissioning project; types, distribution and magnitude of contaminating nuclides; underlying know-how and regulations of radiation protection; contents and requirements of decommissioning monitoring; control limits of nuclides of concern; monitoring methods; performance of monitoring instruments; operating procedures; sampling requirements; analytical methods; target and requirements of quality assurance; format of records and monitoring report.

4.2.2 Selection and use of instruments

Detectable lower limit of instrument should meet the specified decommissioning standards. Probe surface area of surface contamination monitor should perferly be same with that specified by decommissioning standards.

Reference standards used for calibration of monitoring instrument and sample analysis should be traceable to the national standards. All of monitoring and analytical instruments should be confirmed to be steady and reliable.

4.2.3 Quality control in decommissioning monitoring

Quality control in decommissioning monitoring requires conducting full-range scanning mohitoring with view to not omitting hot points and above-standard points. So the extent of decommissioning monitoring should properly larger than the contamination extent indicated by source term investigation. In the process of monitoring, decontaminated area and volume of items should be given, and magnitude of radioactivity decontaminated should be estimated in a timely manner, so as to sort contaminated parts and determine where the decontaminated contaminants are located. Parameters, such as types of nuclides and inventory of radioactivity, should be presented during packaging of radioactive waste into drums.

5. Implementation and control of standards

In decommissioning of nuclear facility, the objective of radiation monitoring is to identify whether or not the residual radioactivity level on the decontaminated or cleaned equipment, facility, building and field meet the specified standards or limits. In implementation and control of standards, there would be an issue that is: what is above standard or above standard point. Because any of specified standards or limits is a absolute value. This can be reflected in instrument reading, or measuring data or analytical results of sample, where there will exist a variety of errors. There should be a confidential interval in implementing standards: $A \pm k\sigma$, where A is a number value specified by standards, σ is total error of measurement and k is a coefficient related to confidential level. In decommissioning radiation monitoring, standard can be implemented in terms of $A \pm k\sigma$, $k=1$, with relative error 30%. This means that standards is implemented in terms of 2/3. However, for termination survey and verification inspection survey, standard should be implemeted in terms of $A \pm k\sigma$.

GENERAL PROBLEMS OF RADIATION MEASUREMENTS IN DECOMMISSIONING OF NUCLEAR FACILITIES

Huang Zhijian Ten Huijie
(China Institute for Radiation Protection)
(P.O.Box 120, Taiyuan ,Shanxi, China, 030006)

1. Introduction

Radiation measurement in decommissioning of nuclear facilities is a major part in the entire decommissioning work, being involved in source term survey prior to decommissioning, decommissioning monitoring, termination survey and verification inspection survey. These measurements are dependent upon the nature of decommissioning engineering at different stages. They have their own respective specialty and complexity in spite of much similarity with each other[1]. Additionally, radiation measurements in decommissioning of nuclear facilities include radiation protection monitoring of personnel and environmental monitoring. This paper is confined to monitoring of the decommissioned objects of nuclear facility.

2. Source term survey prior to decommissioning

2.1 Aims and contents of source term survey

Source term survey before decommissioning belongs to preparatory work of decommissioning, and is to provide basis of preparation and implementation of decommissioning programme by determining the state of a nuclear facility to be decommissioned, such as source location, nuclide type, contaminated object, scope of contamination and determining radioactivity inventory. To achieve these objectives, the contents of source term survey include (1) major workshop to be decommissioned, accountability, classification and registration; (2) investigation and estimation of residual radioactivity magnitude; (3) level of contaminated workshop, equipment, parts, place, and scope, and their estimation; (4) radiation field distribution in nuclear facility: (5) accounting and registration of licensee-own radiation sources, (6) determination of decommissioned objects and decommissioning work area.

2.2 Source term survey method

There are two methods for source term survey: (1) estimation according to technological process and (2) estimation according to radiation measurements. The magnitude of residual radioactivity within nuclear facility, which is related to technological process, should be given by operating department, but in some circumstances, accurate data are difficult to be obtained from the operating department. Thus the needed data can be acquired through radiation measurements.

Contamination source term survey is much larger than residual radiation investigation in area. In addition to installations, equipment, parts, and building plant, and site, the former involves environmental issue, varying with type of nuclear facility. If there exist many types of contamination nuclides and complex equipment, and even more all of currently developed measurement methods are employed, there still would be some problems difficult to be tackled with that are needed to be studied according to decommissioning object and given the optimal investigation programme.

2.3 Estimation of radioactivity magnitude

As indicated previously, source term investigation involves two magnitudes: the residual radioactivity and radioactive contamination within facility. Magnitude of residual radioactivity is larger generally than that of radioactive contamination. Both are different in order of magnitude.

Source term survey should firstly focus on the accurate estimation of residual radioactivity and secondly on radioactive contamination. Currently it has not been specified what accuracy is needed in estimating radioactivity magnitude in source term survey.

3. Decommissioning monitoring

3.1 Objects and tasks of decommissioning monitoring

Decommissioning monitoring is the continuation of radiation measurements in source term survey. The primary objects of decommissioning monitoring are equipment, parts, building plant, field, and other location and position contaminated during dismantling. The task is to indicate decontaminating and cleanup position and extent to ensure them kept below control level after decontamination. Heavily contaminated parts should be estimated for their radioactivity level, together with their disposal method and site. Of course, decommissioning monitoring should incorporate radiation protection monitoring of personnel. Dose to individuals should be controlled below the specified limits and as low as reasonably achievable.

3.2 Decommissioning monitoring method.

Decommissioning monitoring must be made with attendance of decommissioning personnel. If possible, Decommission personnel may be equipped with monitoring meters for self-monitoring. Owing to non-homogenous contamination, decommissioning objects should be given full-scanning measurement, without any leak of hot point. samples taken for cleanup should be of representative, and number of sample should be estimated by stratified sampling method. Prior to packaging of wastes into drum, radioactivity should be measured on drum by drum basis to provide radiological data.

4. Termination survey

4.1 Aim of termination survey

Termination survey is conducted made after completion of dismantlement, cleanup, disposal. It is conducted by licensee and contractor for decontaminated equipment, parts, field for the purpose of identifying whether termination survey is qualified. Verification inspection survey can be made only after termination survey is confirmed to be qualified and decommissioning monitoring report and termination survey report are submitted.

4.2 Contents and requirements of termination survey

Termination survey is firstly to measure the terminal state of decommissioning work, aiming at providing statistic data for termination survey programme. Termination survey objects are (1) decontaminated and cleaned up facility, equipment, parts, plant building, etc., for which surface contamination and radiation field are to be measured; (2) cleaned up soils and fields, for which sampling and analysis of soils, water, sediments are necessary in addition to surface contamination an radiation field measurements. Termination survey should give reliable data because they have direct relevance with standard and control level. Meanwhile, It should be noted that background, or close-to-background, data given by termination survey is also important to same extent, that must be completely recorded.

5. Verification inspection radiation survey

Verification inspection radiation survey is a important part of decommissioning quality inspection, independent on licensee and radiation monitoring personnel participating in decommissioning and not being affected by administrative management. Verification inspection is only based on the national radiation protection regulations and specified decontamination and cleanup criteria.

Verification inspection group staff should be designated or commissioned by regulatory authorities. Verification inspection organizations should be established with consultation with the licensee and local authorities, and the inspection staff should be from the various relevant departments under the approval of the higher competent authorities. If there is no need to sponsor national-level verification inspection, then verification inspection is only technical acceptance of decommissioning work. If national-level verification is necessary, then, such verification inspection is awaiting for the verification inspection by the national authorities. The termination verification inspection radiation survey report is required to be submitted for review by national authorities.

The differing parts between verification inspection radiation survey and termination survey are that the data provided by licensee shall be audited at the stage of verification inspection radiation survey, such as decommissioning procedures, methods, quality assurance documents, measures, remedial actions, records and reports of decommissioning monitoring and termination survey, data processing and evaluation.

6. Conclusion

Radiation measurements in decommissioning of nuclear facilities may involve many issues and can be reflected in decommissioning work at different stages. The quality of decommissioning work can be ensured only each of them is carefully tackled with. High attention should be paid to quality of radiation measurements in decommissioning work at different stages. Integrated quality assurance system should be established, checked and perfected on step by step basis. On the other hand, special radiation measuring apparatus or devices should be developed according to the types of nuclear facilities in our country to meet the needs of nuclear facility decommissioning. This is a task to be undertaken jointly by research units and nuclear facilities.

BASIC PRINCIPLES OF FEDERAL POLICY FOR REHABILITATION OF TERRITORIES AND POPULATION EXPOSED TO RADIATION (ILLUSTRATED BY THE SITUATION IN THE URALS, RUSSIA)

V. Ya. Voznyak, V.V. Panteleyev

The Urals region is known to be one of the most unsafe territories of the Russian Federation both in terms of radiational and general ecological conditions. An emergency radiational situation arose mainly due to the activities of the Mayak Industrial Association (MIA) subordinated to the MinAtom of Russia. The facility's operation has become a source of radioactive contamination of the territory, radiation effects on the population. Besides, it may potentially lead to major radiation accidents.

Radiation exposures of large populations in the Urals resulted from uncontrolled gas-aerosol routine releases which were going on from 1948, discharges of radioactive wastes into the river Techa in 1949-1956, an explosion of a storage tank with high-level wastes in 1957 which led to the formation of the East-Urals Radiation Trace (EURT), downwind transfer of activity from the shores of the drying-up lake Karachay (a depot of medium-level wastes) in 1967, on-going discharges into the bypassing canals from which the activity enters the Techa due to seepage through dams constructed on the river. As a result of only the first three incidents large territories were contaminated in three oblasts (provinces): Chelyabinsk, Sverdlovsk, Kurgan. About 23,000 sq km were contaminated with long-lived radionuclides and 437,000 people were exposed to radiation. Within first years of exposure the maximum absorbed effective doses received by the population due to different radiation accidents were as follows: 170 cSv for the residents of the upper reaches of the Techa, 60 cSv for the EURT residents. In a proportion of exposed population and Mayak workers cases of chronic radiation sickness (CRS) were observed. Over 2000 cases of CRS were diagnosed in Mayak personnel and over 900 cases in off-site population.

The radiation incidents in the Urals inflicted considerable damages on the population's health and the socio-economic status of the entire region. On the whole, economic losses were estimated as 9.5 billion (calculated on the basis of the prices operant in 1990) for Chelyabinsk Oblast alone. The destruction of the social-production infrastructure on these territories, exclusion of the contaminated lands from agricultural use resulted in deformed demographic, migrational and other social processes. The majority of the population of the region developed a persistent radiophobia and anxiety which resulted from living in the locality characterized by increased radiation risk.

In spite of the steps taken before 1992 to minimize the impacts of the radiation exposure on the population and the damage inflicted by the territory contamination the results of such steps proved to be inadequate. The health measures did not encompass the entire exposed population, measures aimed at radiation protection, economic and ecological rehabilitation proved to be ineffective too.

In 1992 the Federal Program for radiation rehabilitation of the population and environment restoration in the Urals region was adopted. It specified the economic, engineering and social tasks which had to be achieved in the period from 1992 through 1995. The dose from accidental exposure was assumed to be the main criterion for decision-making about the necessity of carrying out protection measures on the contaminated territories, the character and scope of such measures, as well as compensation of damages suffered by the population. The effects of radiation exposure on human health were considered in combination with other confounding factors, such as chemical pollution, endemic and biogenic factors characteristic of different rayons.

The principal objectives of the Program were as follows:

- localizing the sources of radiation contamination and preventing further spread of radiation contamination in the Urals region and adjacent territories which may result from further waste accumulation and re-distribution of radionuclides currently deposited in the environment;
- nature restoration in the areas designated as sanitary-restricted zones;

- further development of monitoring the radiation conditions on the territory contaminated with radionuclides;

- improving the standards of medical assistance to the exposed people, especially to the critical population groups, safeguarding the population's health, minimizing the exposure to non-radiation polluting factors;

- development of social and industrial infrastructure, diminution of the socio-psychological tension.

The achievement of each of the tasks listed was based on the implementation of a complex of corresponding measures.

The period of the implementation of the Program coincided with a very complicated phase of the country's economic development. Because of inadequate funding many important tasks of the Program related to social, medical and radiation rehabilitation of the population could not be realized in full measure.

The social-economic and radiation conditions determined the necessity of the development of a follow-on comprehensive Federal Program for social and radiational rehabilitation of the Urals population exposed due to MIA operation for the period 1996-2000.

BUILDING STRATEGIES FOR RESTORATION OF CONTAMINATED AREAS AFTER A NUCLEAR ACCIDENT : IMPLEMENTATION OF RELATED STUDIES AND FIRST ORIENTATIONS

F. Besnus, J.M. Peres, P.Santucci

Institut de Protection et de Sûreté Nucléaire (IPSN), Fontenay-aux-Roses, France

INTRODUCTION

The widespread contamination resulting from the Chernobyl accident has lead IPSN to implement a program, aiming at building strategies for environmental restoration after an accident potentially occurring in a reactor or a fuel cycle facility. Establishing optimized strategies requires to consider the incidence of all remediation operations, from the collection of the contaminated material to the final storage of the wastes issued from decontamination. Most of the decontamination strategies actually consist in shifting the polluting substances from the environment to a controlled and safer system, i.e. a storage or a repository, which result in the overall decrease of hazards undergone by the various groups of the population exposed. The usefulness of the treatment of contaminated material against the direct storage of the latter will therefore strongly depend on the ability of applied technologies to transform the material in an innocuous product or reduce significantly the volumes of wastes to store, so that doses and costs are globally spared. The incidence of storage will therefore be of great importance in determining optimized strategies. Another important aspect of remediation relates to the feasibility of the industrial implementation of technologies. Some considerations on the above issues are given in the present paper. As a starting point, only rural environments contaminated after a major Nuclear Power Plant accident were considered.

HYPOTHESES ON ACCIDENTAL SITUATION

Making prognosis on the radiological situations resulting from a potential accident is a difficult task considering the numerous parameters involved, such as the nature of radioactive releases, the meteorological conditions and the environmental components that may be touched. A good example of the variability of contamination distribution was given in the Chernobyl area where rainfalls during the period of the accident occasioned a deposition of radionuclides in spots and where the levels of activity were found to vary strongly with the distance according to the physico-chemical nature of the nuclides released, i.e. released in gaseous forms or included in fuel particles (1). The hypotheses presented below must therefore be considered only as rough estimations of what could be an « homogenous » radiological situation in rural environments after a severe accident in a French Nuclear Plant.

First estimations were made through a simulation exercise considering reasonable assumptions on a major accident that could occur on a French 1300 Mwe PWR plant (a S3/10 scenario was chosen for this exercise). In such case, deposition of released activity would lead to levels of the range of 10^4 Bq.m^{-2} for ^{90}Sr, 10^5 Bq.m^{-2} for ^{134}Cs and ^{137}Cs and 10 Bq.m^{-2} for ^{239}Pu at 2 km from the plant. If the site remediation objective was to bring the levels of public exposure down to recommended limits of 1mSv/year, this would lead to remove soils within a zone of 2 km radius around the plant during the first year after the accident, according to effective dose calculations carried out by mean of the ABRICOT code (developed for the modelling of nuclide transfers into the biosphere (2)). Considering a penetration depth in soils of about 5 cm for the major radionuclides, as could be observed in most sites of the Chernobyl area (3), a volume of about 7 10^5 m^3 would have to be removed. This is considerably less than for the Chernobyl case for which the fulfilment of a less stringent remediation criteria (2,2 mSv/year after 4 years) would lead to remove about 10^9 m^3 of soil (4). As a base for studies on the feasibility of site remediation, a contaminated area of 10 km radius around the plant was considered to be conservative (scenario S3 for which public exposures are estimated in most cases to be negligible outside the 10 km zone). Such scenario implies the treatment of about 10^7 m^3 of soil and 3 10^3 to 3 10^5 t of dry vegetation depending on seasonal conditions. If the treatment was to be completed within 2 years, which we propose to be a working assumption , the removal and the treatment of 2 ha/h (1500 t/h) of soil as well as the treatment of 1 to 100 t/h of fresh plants would be necessary to ensure 24 hours a day. Such figures illustrate that besides the decontamination yields necessary to obtain, the industrial constraints of remediation are of key importance in determining strategies for site restoration.

FEASIBILITY OF INDUSTRIAL TREATMENT

A review of existing standard techniques commonly used in clean up industry was made, in addition to already published information (5). The techniques of heap leaching were at first examined. Preliminary investigations show that heap leaching does probably not allow efficient treatment of large volumes of soils contaminated after an accident of Chernobyl type. Besides the very large number of heaps and volumes of reagent needed for treatment, it is very doubtful that a substantial amount of Cs (which is predominant in

contaminations resulting from NPP accidents) may be removed within the time recommended for treatment. Simulations have been performed in order to evaluate the efficiency of leaching for ^{137}Cs. The results are given in figure 1.

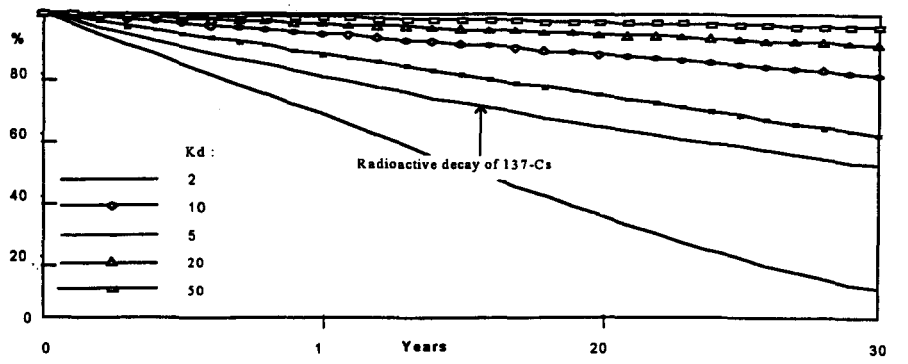

Figure 1. Simulation of the fraction of ^{137}Cs removed (in %) by leaching at a rate of percolation of 0.1 $l.h^{-1}.m^{-2}$ save for radioactive decay

It appears that for a percolation rate of 0.1 $l.h^{-1}.m^{-2}$, which seems a maximum for heaps of about 10 m height, no significant fraction can be removed within two years even for a distribution coefficient (Kd) of 2 ml/g. For smaller heaps of 3m height where larger percolation rates may be obtained (1 to 5 $l.h^{-1}.m^{-2}$), better results can be achieved but still, a very low Kd value is needed. The laboratory tests made on samples from the Chernobyl area show a very strong sorption of Cs on soils which does not allow significant removal by leaching with standard acid reagents. Even if a very efficient reagent was available, the industrial constraints would still remain since enormous amounts of reagent would be needed for efficient leaching (up to 16500 m3/h). It appears therefore that leaching techniques cannot be applied to the treatment of contaminated soils in large volumes. It may nevertheless be remembered for smaller amounts of material contaminated with soluble species.

Other standard techniques used in clean up industry follow principles of separation and sorting of material according to their physico-chemical nature so that adapted treatments can be applied to each component of the contaminated media. In rural environments, one would therefore recommend the separate collection and treatment of vegetal cover and soils.

The collection of vegetal cover at the rates indicated in the previous section appears feasible. Several types of engines adapted to the collection of many kinds of cultures and fields at rates ranging from 20 to 40 ha/day are already available at moderate costs. The economical incidence of radioprotection depends on the choice of designing special engines or « nuclearize » existing ones. This choice and the level of protection required for workers are highly related to the time passed before collection since it has been shown that exposures from atmospheric pathways decrease by several orders of magnitude after a few months. The protection required after such period would therefore concern only external exposure from soils. The methods of treatment of the collected vegetation are based on the potential of the latter for volume reduction. A reduction of a factor 10 can easily be expected when using standard techniques of drying and incineration of collected fresh material. Operations can be conducted in units of moderate sizes, easy to set up in a short time scale, or even in mobile units able to treat 60 to 300 m^3/h of material. The techniques of treatment of secondary products, such as steam and smoke are well proven and can probably easily match safety requirements through the use of high efficiency filters. Drying and incineration techniques are however demanding in energy. An appropriate supply of fuel or electricity on site must therefore be anticipated. The investments and operational costs (without manpower) were roughly estimated to be of the range of 600 FF (French francs) per ton of treated material. Above operations would lead to the production of a maximum of 30000 m^3 of ashes, which is close to the annual volumes of wastes received by the « Aube » repository (low level waste repository operating in France at present). According to predicted levels of activity deposition presented in previous section, the storage of such material (as well as the direct storage of contaminated soils) should be compatible with the overall amount of activity allowed to be received in LLW repositories (« radiological capacity »). These wastes may however have to match other requirements (such as massic activity limits, immobilization and chemical passivity of product) in order to be accepted for disposal in such facilities.

As for vegetal products, the collection of contaminated soils is feasible at moderate costs and submitted to the constraints that were mentioned above. The principles of treatment of collected soils is based on the separation of mineral and organic particles in a first stage, followed by the removal of polluting substances driven in solution by use of a reagent. The resulting effluents are then decontaminated by standard techniques (concentration by evaporation, co-precipitation, elution in ion-exchange resins, etc.). The separation techniques

are mostly based on gravitational sorting. « Dry » and « wet » processes of sorting can be applied. The dry techniques can consist of a sedimentation of particles in a column blown by an upward air stream, or by sieving on rotating meshes. Nevertheless these techniques have been seldom used for industrial purposes and their ability to treat large volumes of material still needs to be assessed. They are furthermore probably extremely demanding in power supply. The wet techniques are much more frequently used in clean up industry and consist in the decantation of particles in a water stream or the flotation of the small fraction driven to surface by injection of compressed air in water. These operations are often simultaneously completed by the addition of reagents for removal of polluting species. As mentioned before, processes of decontamination using the chemical properties of the polluting species are not promising for contaminated soils of Chernobyl type, since the major radionuclides they contain have shown a very strong affinity to the substrate. On the other hand, it has been shown that the major part of the deposited radioactivity was always contained by the small grain size fraction of soil. The separation processes based on size fractioning could therefore act as decontamination techniques for soils contaminated by a PWR accident. However, the efficiency of former techniques for decontamination purposes still needs to be assessed and must allow the separation of sufficiently fine fractions to provide significant reduction of the volumes of material to be stored. Furthermore, the wet separation techniques need heavy infrastructure and are extremely demanding in water supply (up to 8 m^3/s) so that their implementation requires delay and appropriate siting. An optimistic estimation of investments and operational costs for the treatment of the overall 10 km zone (based on the assumption that decantation and flotation can treat a load of 100 g/l of suspended material which is probably a maximum) would be of the order of 3 10^8 FF, but the manpower needed for building the facilities and the transport of material to the treatment plant may considerably increase this cost.

CONCLUSIONS

The studies carried out on the ability of standard industrial techniques to treat very large volumes of contaminated material from rural environments have shown that it is certainly possible to treat a contaminated vegetal cover within a short time without undergoing major industrial and economical constraints. The drying and incineration of collected plants may allow a reduction of the volumes of wastes to store by at least a factor of 10. Some investigations on the nature of the wastes produced are nevertheless necessary in order to assess if additional conditioning is needed to match safety requirements for disposal. The optimization of the treatment of vegetal cover raise the question of the time necessary to leave before beginning operations. An early collection may potentially allow the removal of most of the deposited activity but present higher risks of exposure for workers. The question of finding a balance is, in other respects, also raised for the implementation of some early counter-measures of agricultural type (ploughing, planting) which enable an immediate reduction of exposures by dilution of deposited activity but involve additional difficulties in achieving total decontamination (increase of the volumes to treat). The treatment of soils in large volumes is much less promising, because of heavy constraints of industrial implementation (large infrastructures and very important needs for water and power supply). Furthermore, all the reviewed techniques have to be calibrated with respect to their ability to achieve significant decontamination for soils contaminated after a NPP accident. The technologies based on size fractionating seem the most interesting to test since they may allow good decontamination and a reduction of the volumes of wastes to store. But their efficiency must be assessed at industrial scale and the constraints of implementation still remain for the treatment of large volumes. From above considerations, we would recommend to address the following issues : treat vegetal covers and soils separately ; look for a reduction of the volumes of soil to treat by methods of radiological sorting ; calibrate and improve technologies based on size fractionating ; examine the ability of wastes produced to meet safety requirements for disposal. Finally, optimization should be made by considering, in particular : the balance between the doses spared for people living on decontaminated sites against the doses received by workers as well as by people exposed to the secondary products of decontamination ; the balance between the benefit of early counter measures against total and long term decontamination ; the balance between the radiological and economical costs of the reduction of the volumes of wastes to store against direct disposal of all collected materials.

These conclusions concern of course only rural environments contaminated after an accident of Chernobyl type (NPP accident). We believe that a real optimization must consider together all the categories of environments touched (rural, forests, aquatic, urban). Other types of accidents must also be addressed.

EFFECTIVE DOSES FROM DIAGNOSTIC MEDICAL EXPOSURE IN ROMANIA

Olga Iacob[1] , C. Diaconescu[1] , C. Milu[2]

1-Institute of Public Health and Medical Research,Iasi,RO-6600
2-Institute of Hygiene,Public Health,Health Services and Management, Bucuresti,RO-7000

INTRODUCTION

It is well known that medical applications represent the most important man-made source of radiation exposure for population. Certainly, the diagnostic radiology is by far the largest contributor to the annual collective dose arising from all medical exposures. A relatively small contribution comes from diagnostic nuclear medicine procedures that involved a much smaller fraction of the population than X-ray examinations.

The purpose of this paper is to reassess in terms of effective dose(1) the magnitude of patient exposure from both diagnostic X-ray examinations and diagnostic nuclear medicine procedures,performed in Romania.

Knowledge of the real level of patient dose is an essential component of quality assurance programs in diagnostic radiology and in diagnostic nuclear medicine.

METHODS

Effective doses to about 5900 patients undergoing 20 most important type of X-ray examinations were derive from entrance the surface dose or dose-area product measurements carried out in 42 X-ray departaments,selected by their averall annual workload throughout the country (2), and the appropriate conversion factors calculated for a mathematical phantom by Monte Carlo techniques (3).

Effective doses to patients receiving diagnostic nuclear medicine examinations were calculated from the mean administered activity of the most frequently used radionuclides (4) and the dose factors (for adult patient) published by ICRP (5).

The collective doses, necessary to estimate the average annual effective doses per patient and per capita from all diagnostic medical exposures, were calculated using the frequency data provided by our 1990 national study, included in UNSCEAR 1993 Report (6).

RESULTS AND DISCUSSIONS

Table 1 summarises our results regarding diagnostic X-ray examinations performed in Romania : the entrance surface doses as patient-wieghted averages and the corresponding individual and annual collective effective doses.
Barium enema was associated with the highest effective dose (8.12 mSv) and the annual average effective dose per patient was estimated at 1.55 m Sv. The annual collective effective dose resulting from all X-ray diagnostic examinations was evaluated at 14300 man x Sv. Unfortunately, fluoroscopic examinations have a contribution which accounts for more than 60% of this collective dose. The high values of the effective doses due to traditional fluoroscopy might be reduced by improvements in the techniques and equipment, as well as by lowering the fluoroscopic time.

The annual effective dose per capita was of 620 μSv representing about 24% from the natural radiation background.

The average administered activity and the resulting effective doses both

MEDICAL EXPOSURE IN ROMANIA

Cornelia Diaconescu , O. Iacob , D. Davidescu

Institute of Public Health and Medical Research,Iasi,RO 6600

INTRODUCTION

Medical exposure and in particular diagnostic radiology represents in Romania the largest manmade source of public exposure (about 14,200 man Sv/y).

METHODOLOGY

The annual frequencies of 32 different types of X-ray examination by age and sex distribution were estimated from radiological registers of 45 medical units (25 hospitals and 20 ambulatory care units) from 20 districts. As representative for country they were selected on the reported annual workload of their X-ray departments.

The sample of X-ray exams consisted of all radiological examinations carried out in a specified week (2^{nd}) of the middle month of each quarter in 1990 in every medical center taking part in this survey.

The details recorded included age and sex of patients,type of examinations as well as technical factors such as the number of films or the fluoroscopic screening time.

Sample's data (213,675 patients representing 2.86 % from the annual total) were extended to the annual number of X-ray exposures reported to the Ministery of Health by local district Health Statistic Departments [1].

The grand annual total for all types of medical and dental X-ray examination was 7,471,235. This coresponded to 495 exams per thousand head of population [2].

The size of population concret by the medical services was 15,084,146 people. The population of Romania in 1990 was 23,2 million [3]. Local population details such as age and sex distribution (1990) were taken from local Offices of Population Censuses.

In order to assess the tendency of medical exposure in Romania, present results were compared with those obtained in the earlier surveys (1970, 1980) [4].

RESULTS

The annual numbers of diagnostic X-ray examinations decreased between 1970 and 1990, as shown in Table 1,from 1010 exams per thousand inhabitants in 1970, to 495 exams in 1990.

Romania, like other few countries of health-care level I, showed downward trend [2]. The calculated annualy decrease rate for the last ten years was 2.2 per cent. This tendency was manifestly in all age groups as the following data show (Table 2). Also, these data indicate the 16-30 years old as the most frequently examined.

Although particular examinations such as fluoroscopy or mass miniature chest radiography were dropping between 1980-1990, as showed previously, they still have a frequent utilisation. For example, comparing the frequency of fluoroscopic examinations it

was evident that 63 - 74 per cent of all 1990's fluoroscopic examinations were performed for chest (lung, heart) (Table 3).

Table 1. The annual average numbers of radiological examinations per thousand population in Romania (1970-1990)

Type of examination	1970		1980		1990	
	number	%	number	%	number	%
Fluoroscopy	320	31.68	264	42.17	178	35.95

*) = 1980 **) = 1990

The values of table 3 point out that the children under 15 , are the population group where this X-ray procedure has been most frequently carried out.
In the last survey (1990) also digestive examinations were more common in older patients, the children had an unexpected high frequency of bowel examinations (10.9 per cent).
Detailed quantitative data on the frequencies of different types of X-ray examinations conducted in 1990 are given in Table 4.
As table data show, the thorax is the most irradiated anatomical region, either by fluoroscopic or by mass miniature chest radiography; their cumulated annual frequencies ranged between 37.9 (for 0-15 years old) and 65.9 (for 16-30 years old) from all X-ray examination carried out in a specified age group [5].Digestive barium examinations increase with age,males having a small higher frequency than females (4.71 v 4.45).

Table 4. The frequency of the radiological examination by age and sex (1990)

Type of examination	Age group (years)				Sex

Spine(+lombo-sacral joint)	1.51	2.48	5.45	6.32	2.42	2.50
Skull,facial bones (+dental)	9.82	9.38	10.54	8.54	4.92	4.85
Arm,hand,leg,foot	18.98	6.79	9.49	10.07	5.44	3.83
Pelvis	3.51	0.49	0.82	1.11	0.56	0.58
Abdomen: - plane	1.53	0.71	1.44	1.65	0.68	0.60
- colecistography	0.05	0.44	0.99	1.27	0.28	0.50
- urography	0.65	0.56	1.22	1.58	0.76	0.83
-hysterosalpingo-graphy	-	0.37	0.31	0.09	-	0.21
Angiography	0.92	0.60	1.33	1.75	0.20	0.15
Mammography	0.01	0.30	0.59	0.35	-	0.34
Others	2.62	1.84	2.57	3.35	1.21	1.32
TOTAL	100	100	100	100	53.38	46.62

Some specific X-ray examinations as computed tomography have had a very low annual frequency and were reported as "others exams". Mammography was used only for diagnostic, not in screening programmes.
It is possible that spectrum of medical exposure in Romania will be changed for the next years due to extensive use of ultrasounds, after 1990.
So, it will be interesting to compare this last "clasic-radiological picture" with that of the end of century.

INTRODUCTION

The unnecessary radiological examinations and their implications referring to medical exposure and benefit against detriment problems represent an important subject of a great part of the literature. The evaluation of these is very important in the ex-communist countries, where such publications are almost completely missing. Our study follows to establish the number of unnecessary examinations in three roentgendiagnostic departments and their contribution to medical exposure.

MATERIAL AND METHOD

The study has been done during three months in three different radiological services: Unit A - a hospital of 315 beds, Unit B - a hospital of 147 beds and Unit C - an outpatient's department with 30 000 persons belonging to it. All the three X-ray installation has been in average 20 years old, without image amplifier.

The number of unnecessary examinations varied among 6 - 25 %.

TABLE 1

Unit	Nr. fluoroscopic examinations	Nr. radio-graphs	Nr. all examina-tions	Nr. unnecessary fl. ex.	Nr. unnecessary rad.	Nr. unnecessary at all
A	760	1 125	1 885	28 (3,6 %)	85 (7,55 %)	113 (5,99 %)
B	1 035	791	1 826	43 (4,1 %)	104 (13,1 %)	147 (8,05 %)
C	842	758	1 600	190 (22,5 %)	210 (27,7 %)	400 (25 %)

The causes of the unnecessary examinations were:

1. Factors exterior the X-ray department:

- the general practitioner, who recommended the X-ray examinations (insufficiency or lack of clinical examinations; the X-ray examination is not relevant for the prognosis; unknowing or carelessness of some examinations algorithm; unjustified controls; lack of utilisation the information's of the X-ray examination by the clinician)
- subjective recommendation elements (the patient's pressure; some financial interest of the physician; medico-legal or insurance purposes)
- patients insufficiently prepared for the examination
- the circuit of the examination's results and the films

2. Factors belonging to the X-ray department:
- professional training (radiologist, radiographer)
- the performance of the X-ray installations
- the quality of the materials used (films, developer, cassettes, follies)
- the way of the editing of the results

The number of the repeated radiographs is variable depending on pretension the radiologist about the film's quality. The most frequent repeated radiographs in the studied units were: chest, lumbar spine, cervical spine, skull, extremities, intravenous urography.

The mostly repeated fluoroscopic procedures were: chest, barium meal and barium enema. The reasons: unnecessary recommendation and improper p[reparation of the patients.

To appreciate the patient's exposure during the most frequently repeated procedures we could not apply any direct measurements: entrance surface dose per radiograph and dose-area product per examination because of lack of correspondent instruments.

We measured the exposure dose in the air, using a spherical ionisation chamber and keeping the same conditions of the real X-ray procedures. We investigated in this way 4 radiographs and 2 fluoroscopic procedures.

TABLE 2

RADIOGRAPHS	**REFERENCE DOSE/FILM mGy (average values)**	**COMMENTS**
Lumbar spine AP LL	24,59 57,63	Very different values depending from the X-ray installation
Cervical spine AP LL	16,3 17,3	Similarly.
Pelvis AP	23,37	Similarly.
Urography	97,49	Differences from number of films required
FLUOROSCOPY	**REFERENCE DOSE/EXAMINATION mGy (average values)**	**COMMENTS**
Chest (average duration of examination: 1,5 min.)	24,14	Different values depending from the X-ray installation and radiologist
Barium meal (average duration of examination: 6 min.)	96,54	Similarly.

CONCLUSIONS

The study of the reasons of the unnecessary X-ray examinations have a great importance in such countries, where the use of the old X-ray installations, the frequent use of fluoroscopic procedures, the lack of systematically organised quality assurance in X-ray departments, the lack clinical leaflets and diagnostic algorithms contribute to the growth of the medical exposure of the population and it is only partial controlled. As the replacing of the X-ray installations on national level is a slowly and very expensive process, it seems to be for great importance to put aside or improve the other reasons that lead to unnecessary examinations and irradiation, as follows:

1. Introducing a personal card for the X-ray examinations evidence
2. The responsible involvement of the clinician or general practitioner in recommendation of the radiological examination, with good knowledge of benefit against detriment of this
3. Transforming the radiologist from a simple executive into a decision taking factor; introduction of examination algorithms
4. Informing the patient about the implications of the X-ray examinations
5. Establishing of any criteria in order to editing of the results
6. Improving the education prócess and the training of the radiologists and radiographers
7. Implementing an organised form of the quality assurance in radiological departments.

RADIATION EXPOSURE OF THE GERMAN POPULATION FROM X-RAY DIAGNOSTIC PROCEDURES

J.H. Bernhardt, R.Veit and B. Bauer
Institute of Radiation Hygiene, Federal Office for Radiation Protection
D-85764 MUNICH-OBERSCHLEISSHEIM

INTRODUCTION

The following provides an overview of the frequency of X-ray diagnostic procedures in Germany, the effective dose per examination type, the collective and per caput effective doses, trends in frequency and effective dose and the risk evaluation, based on age-dependent risk coefficients.

FREQUENCY OF X-RAY DIAGNOSTIC PROCEDURES

During the years 1990 to 1992, an average of nearly 100 million X-ray examinations per year were carried out in West Germany with 65 million inhabitants, resulting in an average of 1,500 examinations per 1,000 inhabitants per year. The most frequent X-ray examinations were those of the extremities (302/1000), followed by chest radiography (275/1000) and dental examinations (270/1000) (1). All numbers represent complete examinations, i.e., partially consisting of several single radiographs.

More than half of the X-ray examinations are performed by practicing physicians on out-patients. Nearly 25 % of all X-ray examinations are performed by dentists and only about 20 % of all examinations on in-patients in hospitals (2).

At present no relevant data are available from the new federal states (former GDR).

DOSE ASSESSMENT AND EVALUATION

Mean doses per examination type

In order to determine the average radiation exposure of the patient for the various examination types in diagnostic radiology, more than 5000 measurements of the dose-area-product (DAP) have been performed in the years 1992-1994 by our institute and medical phycisists in other parts of Germany (3). Large variations of the DAP up to 2 orders of magnitude have been found for the same examination type due to the great variability of the patients (age, size, weight etc.) and the equipment and technique used (number of exposures, fluoroscopy time, film/screen combination, grid, kV, filter etc.).

From these data mean values of DAP were calculated for more than 30 examination types. Mean values of effective dose E were determined by using examination type-specific conversion factors obtained from Monte-Carlo simulation of the relevant examination with anthropomorphic phantoms (4). Effective doses for computed tomography (CT), mammography, dental examinations and examinations of the extremities were estimated seperately. The mean value of E vary between 0.01 mSv for dental examinations and nearly 30 mSv for CT of the abdomen.

Collective effective dose

The annual collective effective dose from X-ray diagnosis for West Germany (1992) of approximately 114000 manSv was obtained by multiplication of the estimated mean E per examination type with the corresponding annual frequency and summation over all types of examination. This rather high value, equivalent to an annual per-caput value of ca. 1.8 mSv, is mainly caused by the rapid increase of angiography including interventional radiology (ca. 9% of the collective effective dose) and even more of CT, which alone is responsible for about 35% of the collective effective dose.

TRENDS

In spite of the introduction of alternative examination techniques such as sonography, mainly for parenchymal organs, and endoscopy, mainly for esophagus, stomach and large intestine, the number of X-ray examinations has altogether increased,

namely by about 10 % between 1988 and 1992. The frequency of some types of X-ray examinations is very strongly increasing, i.e computed tomography by +80 %, angiography by +54 % and mammographie by +42 %. Other examination types are markedly decreasing, i.e. mainly those of the GI-tract by -32 % (2).

Since dose intensive examinations such as CT and angiography, including in particular interventional radiology, significantly increased and their absolute number is larger than that of GI-tract examinations of decreasing frequency, the collective effective dose increased between 1988 and 1992 by about 14,000 manSv or 14 % from 100,000 manSv in 1992. The annual per caput effective dose increased by only 8.5 % during this period, since the population also increased from about 61.5 Million 1988 to 65 Million 1992.

However, the per caput value is purely computational, since it includes also those fractions of the population where no X-ray diagnosis was performed. The per caput dose may not be used for calculating individual risks. The value is only suitable for comparison of countries with different medical care systems.

QUALITY ASSURANCE AND QUALITY CONTROL

The legal provisions concerning diagnostic radiology prescribe that all radiological equipment must be thoroughly inspected by the manufacturer and an expert prior to starting up and afterwards every 5 years (5).

Another quality assurance measure concerns the qualification of the staff. Only physicians with a special qualification in both the medical field and radiological protection are permitted to use X-rays and are eligible for establishing the indication. All other physicians as well as radiographers and auxiliary medical staff are allowed to take action only upon instruction and under supervision. However, they must also possess medical knowledge and are obliged to attend a course in radiological protection, albeit on a lower level.

Quality control of all X-ray machines is achieved with so called " constancy tests" performing phantom exposures once a month. The performance of the film-processing machines has to be controlled daily.

Important institutional panels for acceptance auditing are committees which request X-ray films of patients subjected to all types of diagnostic procedures from all physicians and hospitals and are offering advice on the improvement of image quality (1).

The Federal Medical Board of Germany has published guidelines for quality assurance describing medical and technical requirements how to conduct standard examinations of conventional radiology and computed tomography (6-7).

By all these measures it is intended to optimize the radiation exposure of the patient in diagnostic radiology.

ASSESSMENT OF RISK AND BENEFIT

It is shown in annex C of ICRP 60 (8) that the lifetime probability of radiation induced fatal cancer varies with sex and predominantly with the age at the time of exposure. For the multiplicative risk projection model, which is prefered at present by the ICRP, the lifetime mortality risk decreases with increasing age at exposure.

If the collective risk from diagnostic radiology needs to be assessed, one must use an adequate average risk coefficient for patients to be applied to the collective dose. Since the age distribution of patients is generally very different from that of the whole population, the ICRP average risk coefficient of 5.2 % per Sv (8, Annex C) is not applicable to patients.

Based on a representative trial in West-German hospitals of 1990 the age distribution of in-patients representing about 20% of all patients was determined for all X-ray diagnostic procedures and classified for 7 types of examinations, making about 86 % of the collective effective dose of in-patients. About 45% of all in-patient examinations are performed on patients older than 65 years, further 30% on patients aged between 41 and 64 years. From the age distribution per examination type mean risk modifying factors for in-patients per examination type were derived. For the 7 examination types the risk modifying factors vary between 0.38 and 0.51. The weighted mean, finally gives a mean risk modifying factor for in-patients of 0.47. In other words: the stochastic radiation risk of in-patients is only about half of that of the population. The mean risk modifying factor for out-patients (ca. 75 % of

all X-ray examinations) surely must be higher due to their younger mean age. Therfore a risk modifying factor of 0.6-0.7 for all patients of diagnostic radiology seems to be quite reasonable.

These factors take into account only the different age structure between patients and population, but no other possible differences in risk related to the different health status of patients. The mean life-expectancy of patients with severe diseases is shorter than for the average of the population in the respective age class and also shorter than the latency period. Since a considerable part of the collective dose is used in the diagnostics of such patients the overall radiation risk coefficient is reduced.

However, assessments of the radiation risk in diagnostic radiology are of no value if the risk is considered separately from disease and therapy related risks and if the benefit for the patient from the radiological examination is not taken into account. The difficulty is, of course, to quantify the benefit because it is not easily definable. The benefit could, for example, be measured in years of prolonged life expectancy, which again are difficult to assess. According to other conceptions, the benefit is identified by those portions of radiological diagnoses that lead to - positive or negative - therapeutic decisions because they are the only ones of importance for the patient. Therefore the most important question before performing an examination should be: Will I get an information which really influences the therapy of the primary disease?

When ionizing radiation is applied in medicine, the benefit to the patient should always be the main priority. This benefit is an integral part of the risk-benefit-evaluation together with the individual radiation risk for the patient and other individual risks from the examination. For the assessment of the individual radiation risk from a specific examination, the age-dependent cancer mortality risk coefficient of that patient may be used together with the average effective dose of the respective examination type. Additionally must be taken into account that the age-dependency of cancer mortality varies for different tumors and also that a very different individual presdisposition exists for the development and survival of a cancer disease, which, in part, could be of genetic origin. Added to this, for the exposure of young patients, the genetic risk must be considered which can largely be disregarded for older patients.

INTRODUCTION

The medical X-ray exposures due to radiological examinations are responsible for the largest contribution to the population collective dose as result of the normal use of artificial sources of radiation.. The relative impact of the medical exposures to the total dose received by the population from all kinds of radiation sources varies from country to country and in some cases within the same country (1). The dose variations observed for a specific type of examination are in general associated to several factors i.e. the type of film-ecran combination, the choice of the appropriate physical parameters of the x-ray generator (Kvp, filament current, exposure time) and finally to the film processing conditions.

At the present moment the data available in Brazil are scarce and scanty to allow a complete analysis of this question so needed by the health authorities to justify the implementation of a quality assurance and dose reduction programs. In addition, it is desirable to establish a cost effective operation based on simple administrative concepts in order to reduce the number of films retake, then increasing the life expectancy of the equipment and the number of radiological procedures.

The aim of this work was to assess the typical doses of an PA and LAT chest wall X-ray examinations in five different public hospitals (a University Hospital, a Cancer Hospital, a Navy Hospital, an Emergency Hospital and a State General Hospital), as representative of the city of Rio de Janeiro, and compare the results with the international data and recommendations available.

MATERIALS and METHODS

Chest X-ray examination was selected for this study since by far is the most frequent type of procedure requested as part of a normal medical routine in a hospital or as part of the admittance procedure for a new job.

The experimental methodology adopted for this work is very similar to the one developed by the Institute of Physical Sciences in Medicine (2) and accepted by the Common Wealth as well as by several countries in the European Community.

In-vivo measurements were conducted using chips of Lithium Fluoride (TLD-100) thermoluminescente dosimeters, manufactured by Harshaw. A conventional thermal treatment was applied to the TLD's (400°C/1h + 100°C/2h) and then they were exposed several times to a reference Co-60 gamma beam in order to group them in accordance with its relative response. A calibration factor adjusted for its well known energy dependence was assigned for each group. As result of this procedure, the typical overall random uncertainty for a dose of 1 mGy is 4% (1 σ).

For each measurement, the dosimeter was placed on the patient skin at the center of either the PA or the Lateral radiation fields, and immediately after stored in a lead box for subsequent evaluation. A minimum of 10 patients were selected in each hospital (average height of 1.6 m and 65 kg of weight) and further identified by age and sex. No changes or suggestions were made related to the selection of the radiographic parameters during the radiological procedure in each place.

RESULTS and DISCUSSION

The Fig.1 gives an overall view of the average entrance dose measured at the surface of the patients for the PA and LAT projections for all the examination rooms evaluated. By looking at the results individually by machine or institution, one is tempted to believe that the homogeneous distributions are an indicator of consistency of the operational procedures. However, when the individual patient records were analyzed, severe inconsistencies were clearly shown related to the choice of the machine parameters(kVp and current) for a

particular dimensions of the patient (height and corporal mass). This observation might be strongly related to the general level of training of the radiographers or his lack of attention to a specific machine. It is a normal practice in our Country to have the radiographer working on shifts, and as result of that, they tend to work on several different places and different machines, not being able to develop familiarity and a professional feeling about the performance of a machine.

The Table 1 shows the average dose values for this type of examination published by national (2) and international organizations (1,3) together with the values obtained by this study. It is clear that the measurement results obtained at the hospitals # 1, #3 and #5 are in good agreement with the recommended values also shown in the same table.

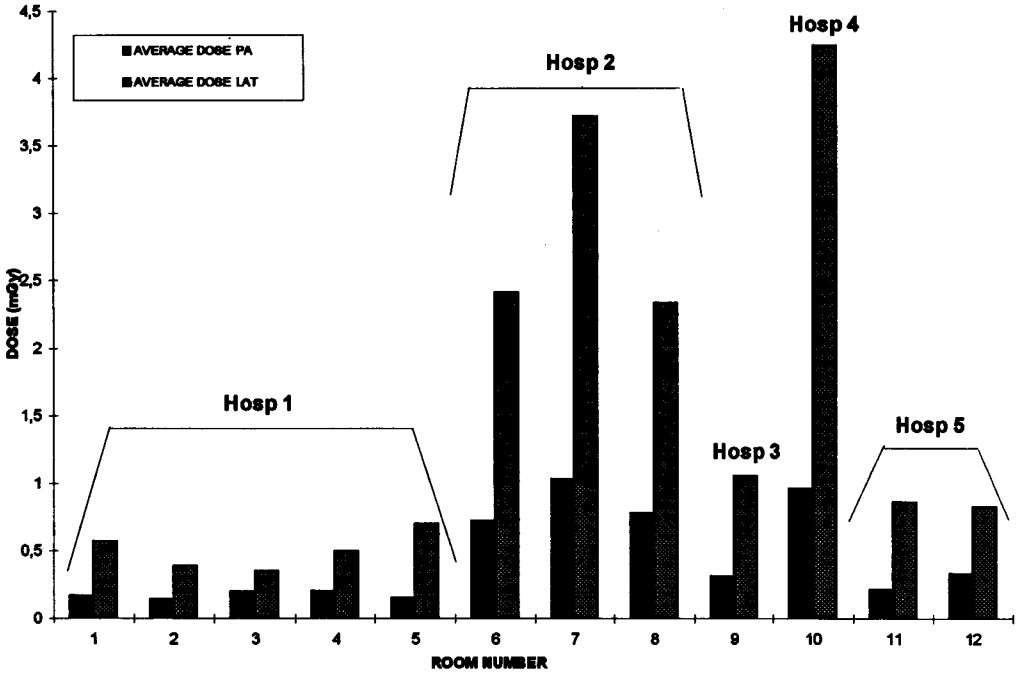

Figure 1: Average entrance dose values for the entire set of data.

However, the same positive considerations cannot be made for the results presented by the hospitals # 2 and # 4. The measured values are two times greater than the reference values presented in Table 1, as result of problems observed in the operational procedures presently adopted i.e. consistently wrong choice of physical parameters for a particular patient size, old ecrans still in use, filament current indicator and timer both running out of the specifications, dark room with light leakage without any quality control and last but no least insufficient training of the radiographers

Table 1: Comparison between the values obtained in the present work with the recommended values published by the UNSCEAR, IPSM-UK and IAEA.

INSTITUTION	AVERAGE DOSE- PA mGy	AVERAGE DOSE- LAT mGy
IPSM-UK	0.18	0.99
UNSCEAR	0.4	1.5
IAEA	0.4	1.5
PRESENT WORK	0.43	1.49

CONCLUSIONS

1 - The use of thermoluminescent dosimeters, TLD-100 to measure the entrance doses of chest X-ray examination has shown to be adequate if the necessary care is taken in its selection and a good and consistent methodology is followed for the storage, irradiation, thermal treatment and the read-out of each chip.

2 -The results tends to show that the average entrance dose for the chest x-ray examinations measured in five typical hospitals in Rio de Janeiro are very similar to the world average value published by UNSCEAR and the IAEA reference value as well. However, the results obtained in two of those hospitals strongly indicates the immediate need of a quality assurance program in order to optimize the radiological procedures generating a positive impact in the dose reduction for the population, in the operational costs and set a example for other institutions as well.

ABSTRACT (See instructions overleaf)

The diagnostic X-ray units in Poland were subjected to the analysis. The air-kerma on the X-ray table was measured for the X-ray parameters used routinely during lumbo-sacral spine radiography of standard patient. The measurements of air-kerma were performed using TLD made of lithium-fluoride.

The dose received by patients in different X-ray departments can be more then two orders of magnitude from 0,14 mGy up to 72,11 mGy, for the same X-ray examination. The dose can be significantly reduced if the cassets with amplyfying foils made from components of rare earth are used.

EVALUATION OF RADIOLOGICAL DETRIMENT FROM NEGATIVE RADIOLOGICAL EXAMINATIONS

Ileana Frómeta Suárez, S.F. Jerez Vegueria

Institute of Occupational Health, Calzada de Bejucal Km 7 1/2 Ap. 9064 CP Havana CP 10900, Cuba.

ABCTRACT

The individual doses of radiation due to diagnostic radiology are usually low, though their contribution to the collective dose is very important given the large numbers of people exposed to these. This paper presents an analysis of the number of negative radiological examinations in a major Cuban Hospital, and their contribution to the collective dose of radiation.
The reports of each individual radiological examination are classified according to the type of examination, and recorded as positive or negative according to the criterion of clinical indications. The absorbed dose by irradiated organ and tissue, effective dose equivalent, collective dose, and radiation risk (expressed as severe hereditary effect and the occurrence of fatal and non fatal cancers) are all evaluated.
The total contribution of negative examinations to the collective dose are found to make up 52.9 % : 11.35 Sv-man in the studied population.

INTRODUCTION

The rapid development reached in medical radiology and increase medical irradiation of patients during the last years, has made possible that the diagnostic radiology and radiotherapy are now considered the biggest contribution to the collective dose, because large numbers of people are exposed; consequently the majority radiation exposure from artificial sources.

This situation has given place to the fact that the expert scientific groups in radiation protection consider the necessity for the protection of the patient and promote the aplication of the concept of rational use of diagnostic radiology and the justification of its practice, if it really produces sufficient health benefit to the exposed individuals (1-2).

In our country during the last years it has been reported significant increment of radiological examinations and using the criterium that a large percent of these examinations, in its clinical indications were not justified, we decide to know the incidence of negative examinations, evaluate its contribution to the collective dose and estimate the health detriment associated to these expositions in a big hospital in Havana.

MATERIAL AND METHOD

This study was carried out in the important Hospital "Manuel Fajardo" in Havana City. All patients with radiological examinations performed, in the emergency services, hospital admission and out-patients services, during four months in 1993, were recorded. We individiualized information for each patient, and examinations were classified by type of X-ray examination and number of exposures.

Based on the justification criterium of clinical indication of the radiological examination, Its were classified into positive or negative examinations. The positive examinations were considered those in which the

clinical indication was confirmed with the diagnostic information obtained or by diagnoses where a new disease was unexpectedly found. The negative examinations were those radiografic studies without clinical diagnostic or no useful radiografic because of use of unsuitable radiografic technique: improper film and defect in the film pocessing card.

An analysis of frecuency distribution for each examination type, according to classification, was carried out. The absorbed dose has been obtained according to the organs and tissues irradiated in correspondence with the radiografic techniques taking into account the technical factors employed per examimation (3).

The equivalent dose, the effective dose and the collective effective dose for each study group in the exposed population. were estimated. The contribution to the collective dose of each examinations, was evaluated. The comparative analysis of the contribution dose of the negative and positive examinations. was presented. The radiological risk was expressed through the probability of ocurrence of radiation induced fatal cancers, non fatal cancers and serious heriditary effects as a result of medical X-ray exposure (4).

RESULT AND DISCUSSION

In this paper 5486 patients with X-ray examinations, were recorded. From them 2249 (41%) resulted negative examinations and 3287 (59%) positive.
The distribution and percentage of each type of examinations according to classification is presented in Table I.

TABLE I
DISTRIBUTION OF RADIOLOGICAL EXAMINATIONS

Examination Type	Positives No	%	Negatives No	%	Totals
Barium enema	101	38.9	158	61.0	259
Urography	133	46.6	152	53.3	285
Single Urinary t.	150	43.8	192	56.4	342
Digestive tract	399	57.4	295	42.5	694
Spine	435	59.5	295	40.4	730
Chest	2019	63.5	1157	36.4	3176
Totals	3237	59.00	2249	41.00	5486

Chest examinations represented a high average in relation to the remainder of the X-ray examinations reported. The high average for negative examinations in three examination types: barium enema, single urinary tract and urography, was obserbed, though these examinations require the specific clinical criterium for indication and they are the most complex studies in conventional radiography.

The contribution to the collective dose according to the examination type is shown in table II. The collective effective dose estimated for all examinations was 21,58 Sv/man. The contribution of negative examinations to the total collective dose constituted 52.9%. The contribution to the collective dose due to negative examinations such as barium for enema, simple urinary tract and urography examinations, is significative because they

represent 86,1% of collective dose resulting from all negative radiological examinations, although these examinations represent only 16,1% of all examinations. These results are similar to those reported in the literature (5).

TABLE II
CONTRIBUTION TO THE COLLECTIVE DOSE

EXAMINATION TYPE	COLLECTIVE DOSE (mSv)	
	Positives Exs.	Negatives Exs.
Barium enema	1,72	2,69
Urography	5,14	5,87
S urinary tract	0,91	1,17
Digestive tract	0,39	0,29
Spine	1,29	0,87
Chest	0,76	0,43
Totals	10,26	11,32

The risk estimate for the studied population showed the probability of occurrence of one case for fatal cancer induced by X-ray examinations. Probability of ocurrence of non fatal cancer and hereditary disorders was not estimated. The mathematical expectancy of probability of occurrence of radiation induced cancer in patients with negative examinations was not estimated, because the influence of low level doses reported in organs, sample size and recent values of risks factors recommended in the ICRP 60(4).

CONCLUSIONS

The significant average obtained of negative examinations in this study showed that it is necesary to establish the justification criterium for the clinical decision of radiological study.
Contribution of the collective doses associated to the negative radiological examinations gave significative values to the collective effective dose.
The matematic expectancy due to negative radiological studies discarded the possibility of estimate quantitatively radiological risk, however we is not discard occurrency of health effects in exposed individuals.

DOSE DISTRIBUTIONS OF PATIENTS FROM CHEST FLUOROSCOPY, UPPER GI-TRACT RADIOGRAPHY AND CINEMATOGRAPHY IN JAPAN

Tomoko KUSAMA[1], Michiaki KAI[1] and Katumasa OHTA[2]

[1] Department of Radiological Health, Faculty of Medicine, The University of Tokyo
[2] The Nagano College of Nursing

INTRODUCTION

The per caput dose from medical exposure in Japan is several times higher than in other developed countries. There are no dose limitations for medical exposure. Then, the appropriate applications of radiation diagnosis/treatments (justification of practices) and the quality control of diagnosis/treatments(optimization of protection) are needed to reduce the doses from medical exposure. It is well documented that patient doses from a X-ray diagnosis are distributed in the broad range. Recently, the IAEA introduced guidance levels for some typical X-ray diagnosis and in vivo nuclear medicines. We carried out the investigation of dose distribution of patients from the X-ray examinations of chest, cardiovascular cinematograph and upper GI-tract X-ray examination in order to give the basic information on the quality control of each X-ray diagnosis. These X-ray diagnoses are performed frequently in Japan, and especially chest X-ray examinations are carried out periodically to all population more than 18 years old as legal health check and GI-tract X-ray examinations to the persons more than 35 years old. The cardiovascular cinematography and the upper GI-tract X-ray examination bring higher effective dose for patients. More information is, therefore, needed for the reduction and quality control of medical exposure in Japan.

MATERIALS AND METHODS

We estimated the student doses from the chest fluorography as legal health examination, the adult doses from the upper GI-tract X-ray examination as periodical health check from a part of the occupational health service and the child doses from cinematography of cardiovascular. The doses from the chest fluorograph were estimated by a phantom experiment on the condition of the specific voltage and current of X-ray tube. From these result, each dose was calculated on other condition, which were given in our nationwide survey for all national and prefectural universities and colleges. The doses from GI-tract X-ray examination were estimated from both phantom experiments and the direct measurement of 105 patients with TLDs (Mg_2SiO_4 and $CaSO_4$). The time of fluoroscopy and the numbers of exposure during GI-tract X-ray examination were counted for 417 subjects. The doses from the cardiovascular cinematograph were measured with TLDs (Mg_2SiO_4) worn on the body surface of 9 children.

RESULTS AND DISCUSSION

The dose distributions of lung from chest X-ray examination are shown in **Fig.1**. The doses of lung from chest X-ray examination were broadly distributed from 0.1 to 1.5 mGy in spite of one exposure in all the examination. Some of the doses from chest examination were over the guidance levels of typical X-ray examinations recently proposed by the IAEA. In chest fluorography, many types of X-ray machine, old and new one, were used. The higher doses were brought by old X-ray machines in which lens cameras were frequently used as fluorescence screen. In the optimization of chest fluorography, it is necessary to consider an appropriate X-ray machine. The range of the skin dose from the upper GI-tract X-ray examination was from 8.9 to 210 mGy (**Fig.2**). This is due to the variability of time of fluoroscopy and the number of exposure. According to our survey, the time of fluoroscopy in upper GI-tract examination depended on radiation technicians as shown in **Fig.3**. The time per one examination for technician was broadly distributed from 32 to 331 seconds. In addition, **Fig.4** shows that how to increase of the time per exposure with the number of exposure is different between fluorography and radiography. It was evident that the optimization in GI-tract examination depended on the technical control of a technician. In this case, education for the technician is essential for optimization in upper GI-tract X-ray examination. The skin doses of children treated with cardiovascular cinematography are shown in **Fig.5**. The doses were ranged in 206 to 995 mGy. The difference of doses in cinematography depended on the clinical

condition of each patient. In medical exposure, it is suggested that there are high possibilities of the dose reduction from technical aspects of machines and technicians.

ABSTRACT (See instructions overleaf)

During 1994-1995, a national survey was conducted in Canada to assess equipment imaging performance and radiation doses of Canadian mammography facilities. The survey was a cooperative effort of the federal Radiation Protection Bureau, all ten provinces and both territories. The Bureau provided the survey instrumentation, data assessment and overall coordination, while the provinces and territories carried out the actual site surveys.

A random sample consisting of approximately 200 facilities and stratified by province was initially selected. As the survey progressed, however, several provinces used the opportunity to conduct census surveys of all of their facilities. As a result, the final total number of facilities surveyed was over 300, which represents approximately one-half of all Canadian mammography installations.

The survey followed the Nationwide Evaluation of X-ray Trends (NEXT) protocol, which was developed and used by the US Food and Drug Administration for a similar 1992 survey of 400 US installations. Since one aim of the Canadian survey was a comparison with these earlier US results, care was taken to ensure comparability of the data. Accordingly, survey instrumentation was calibrated and film scoring was done using identical methodologies and, where possible, was carried out by the same individuals.

Participating provinces and territories will use their individual results as a baseline for the comparison of the performance of mammography facilities within their jurisdiction with those of Canada and North America as a whole.

The aggregate national results, including a comparison with the US survey of 1992, will be presented.

ABSTRACT (See instructions overleaf)

A survey has been performed to investigate typical radiation dose levels for children undergoing the most frequently radiodiagnostic examinations. Data analysis of radiographic techniques and measured entrance surface dose using TLDs were performed. Determination of effective doses and collective effective doses from different types of radiodiagnostic examinations were calculated. The result of this study emphasize the necessity for the improvement of pediatric radiologists training and urgent need for quality assurance guidelines.

SLOVENIAN NATIONAL SURVEY OF DOSES TO PATIENTS UNDERGOING X-RAY EXAMINATIONS

Tomaž FORTUNA, Urban ZDEŠAR
Institute of Occupational Safety, Ljubljana, Slovenia

ABSTRACT: In 1994 Slovenian national survey of doses to patients undergoing X-ray examinations begun. Results of the survey of lumbar spine examinations in both projections are presented. Entrance skin doses per radiograph were measured with TL dosemeters. Measurements were peformed on adult patients of both sexes. The median of entrance skin doses is calculated and compared to guidance levels from Basic Safety Standars. Effective dose is also estimated.

INTRODUCTION

The population of Slovenia is estimated to about 2.000.000 inhabitants. There is about 300 X-ray machines in medical use. In 1991 the x-ray diagnostics was covered with 87 radiologists and 318 radiological engineers. The number of x-ray examinations in 1991 was estimated to about 1.200.000 including a little more than 430.000 sceletal examinations (1).

However, till 1994 when national survey of doses to patients begun, little was known about doses to examined patients. Due to relatively high frequency of sceletal examinations, the first phase of the survey was focused to X-ray examinations of lumbar spine.

MATERIALS AND METHODS

According to Slovenian regulations each X-ray machine has to be controled at least once a year by a qualified expert. The collection of patient doses data was carried out during these regular checks. $Li_2B_4O_7$ TL dosimeters (Panasonic UD-807HA2) sticked on the patient skin were used for entrance skin dose (ESD) measurements. Dosimeters were calibrated to measure entrance skin dose with Co-60 source Capintec ionisation chamber PR 06 and Capintec electrometer WK 92.

For X-ray examinations correction factor for energy dependance was used. Aditional data concerning exposure technique (tube potential, total filtration, FFD, image receptor size) and examined patient (sex, age, height, weight, patient thickness in the centre of the beam) was also collected.

Effective dose calculations were carried out using X-DOSE software, developed by John Le Heron from National Radiation Laboratory of New Zeland and is based on normalised conversion factors from ESD to organ doses calculated in NRPB using Monte Carlo techniques (3).

RESULTS

From the total number of our X-ray nachines only on about 10 % X-ray examinations of LS spine is performed and about one half of them were checked during the survey.

Statistical parametres caracterising patient sample are listed in Table as well as the corrensponding measured and calculated values for doses.

Median values of entrance skin dose measurements per radiohraph are well belove the guidance levels (4).

CONCLUSIONS

1.The number of "counts" was small. (See Table!)
2.Estimated mean effective doses for X-ray examination of LS spine for both prejections were for males 1,9 mSv and for females 1,5 mSv.
3.Higher doses were due, (mainly) , to improper film processing.

AGE AS A FACTOR IN ASSESSING RISKS TO PATIENTS FROM THE USE OF X-RAYS

John Le Heron

National Radiation Laboratory
Ministry of Health
P.O. Box 25099
Christchurch
New Zealand

INTRODUCTION

Any use of ionising radiation carries with it a risk of harm, and it is often necessary to estimate this risk for groups of irradiated persons, or for individuals. Such persons include patients in diagnostic radiology. In diagnostic radiology effective dose has become widely used as the preferred index of patient dose. This is primarily for two reasons - effective dose is linked to a useful definition of radiation detriment and, because it converts an actual irradiation into an equivalent uniform whole body dose (in terms of detriment), it is able to cope with the partial body irradiations characteristic of diagnostic radiology. But while effective dose has these attractions, it is based on assumptions that could impose limitations on its use for risk assessment. Effective dose is an index that has been averaged over populations and risk projection models, and its application to individuals or specialised groups of the population may not be appropriate.

In this paper the collective risk from the use of diagnostic radiology in a large New Zealand teaching hospital is assessed using an age-specific approach, and this is compared with the collective risk assessed using the coefficients given in ICRP Publication 60 (1) for the general public.

METHOD AND RESULTS

Age- and sex-specific risks of stochastic radiation effects have been calculated by using the health effects model developed at NRPB for a UK population (2) . In applying the model, ICRP 60 values were used for cancer lethality fractions and for weighting factors associated with hereditary effects. These age- and sex-specific lifetime risks of total radiation detriment were then used to derive age- and sex-specific tissue weighting factors. The age- and sex-specific tissue weighting factors vary considerably since the relative contributions of the tissues to total detriment strongly depend on age at exposure and to a lesser extent sex. For example, the gonads, while dominant early in life, assume little significance later on. Conversely the lungs' relative importance increases dramatically in the middle years, while the red bone marrow's importance increases throughout.

The age- and sex-specific tissue weighting factors were used to derive age- and sex-specific "effective doses" for x-ray examinations that were considered significant in terms of contributing to collective dose. These "effective doses" were derived from the Monte Carlo based normalised organ dose data of the NRPB, UK (3,4). "Effective doses" for most x-ray examinations were smaller than the ICRP values, generally reflecting the reduced significance of the gonads at older ages. Notable exceptions were examinations of the chest region, where "effective doses" exceeding twice the ICRP value were obtained for some adult age bands. Differences between males and females were small compared with the differences due to age at exposure, hence a sex averaged age-specific "effective dose" was assigned to each x-ray examination.

Assessment of lifetime risk from an x-ray procedure was performed by multiplying the age-specific "effective dose" by the age-specific total risk coefficient. When these results were compared with the estimate of risk obtained by using effective dose and the risk coefficient for the general public significant differences were obtained. For example, with skull x-rays, the age-specific risk was about two to three times greater than the ICRP estimate for children, but fell to below the ICRP estimate for older adults. For chest examinations the age-specific risk was above the ICRP value for ages at exposure up to about 60 years. And for the abdomen, the age-specific risk was about double the ICRP risk for children, but less than half for most of adulthood.

X-ray examination statistics were obtained for a large New Zealand hospital for a six month period, giving patient numbers for males and females in 5 year age bands. To illustrate the very different make up of the patient population compared with the New Zealand population, a comparison of proportions of patients in age bands versus the general population is presented in Figure 1 for three x-ray examinations.

Age-specific collective risk to the patient population was determined using age-specific "effective dose", age-specific risk coefficients and the age-specific frequencies of the x-ray examinations. For comparison the ICRP estimate was obtained using effective dose, the risk coefficient for the public and total frequencies for the x-ray examinations. The relative results are presented in Figure 2 for simple radiographic examinations, barium studies, IVUs and CT examinations. The age-specific collective risk assessment for each of these examinations is about one-half that of the ICRP estimate, with the exception of chest and skull examinations (both conventional and CT). In the case of the chest age-specific risk estimates, this is a result of the relative importance of lung doses in the older age groups, for the skull examinations, it reflects the relatively large number of these examinations performed in the younger age groups and the higher risks at these younger ages.

The estimate of total collective risk to the patients from the practice of diagnostic radiology in this hospital, using the age-specific risk approach, was approximately three-quarters of the ICRP estimate. The large proportion of CT examinations being performed in the hospital meant that the contribution from CT chest and CT head examinations had the effect of bringing the age-specific total collective risk estimate closer to the ICRP estimate.

DISCUSSION

The estimate of collective risk using the age-specific approach was less than the simple ICRP estimate. However the age-specific approach necessitates many sets of tissue weighting factors, and the potential confusion of age-specific "effective doses" for all the x-ray examinations. In addition, given the large uncertainties in the nominal risk coefficients for radiation detriment, it must be concluded that the additional "accuracy" of the age-specific approach to collective risk is not justified.

For estimating individual risks or risks to particular age groups it would be desirable, from a practical perspective, to retain the single ICRP set of tissue weighting factors but to obtain a more specific estimate of risk. NRPB have looked at this in the context of simple radiographic projections, and concluded that sufficient accuracy was obtained by adhering to the ICRP approach, but if a particular age group was of interest, then applying scalars of 1.8, 0.8, & 0.15 for paediatrics, adults and geriatrics respectively to the ICRP risk estimates would suffice (5). Applying this approach to the data in this study (which included CT examinations and fluoroscopic examinations) gave a collective risk estimate within 10% of the age-specific estimate, thus giving support to this simple solution.

CONCLUSION

While patients in diagnostic radiology may be unrepresentative of the general population, assessment of their collective risk can be assessed with sufficient accuracy using effective dose and the risk coefficients for the public given in ICRP 60.

QUALITY ASSURANCE PROGRAM IN DIAGNOSTIC RADIOLOGY

Alejandro Yacovenco Arguirópulo
UFRJ/COPPE - CNEN/IRD

INTRODUCTION

One hundred years after the discovery of X-rays, they continue being nowadays part of physicians' daily activities, and the diagnosis throughthe use of X-ray equipments is one of the most important fields in clinical medicine, thus becoming the most important cause of human exposure to artificial sources.

For this reason, in the last twenty years, most of the developed countries did the utmost to establish programs which could warrant the quality of the radiographic image. Aiming the protection of human being against the harmful effects of ionizing radiations, in December 1980, World Health Organization decided to form a group of professionals highly experienced in medical radiology, and initiate an inspection and quality control program. In September 1988, the Group of Studies of the Program Related to Radiological Protection of the Commission in the European Communities, prepared a working paper in which guidelines were set up regarding quality of images, dosage to patient, and associated radiographic factors, necessary to obtain acceptable radiologic performance.

In Brazil, efforts driven in this direction, guided by some equipment testing, starting in 1990, began to be more known. When the Director and the Head of Radiology in the Military Police Hospital of the State of Rio de Janeiro (HPM) learned about these efforts, they decided to contact the Institute for Radioprotection and Dosimetry (IRD) of Comissão Nacional de Energia Nuclear and submit the problem of low radiologic performance and increasing rates of rejection.

Thus, with the coincidence of interests and needs, along with a proposal from the Commission of the European Communities (CEC), IRD decided to offer the author laboratory support to elaborate a Quality Assurance Program (QAP) to be implemented in HPM.

METHODOLOGY

The first step for implementing the QAP was setting the objective, that is, setting a methodology which maximizes the probability of obtaining good diagnostic quality images, allowing to reach high performance level of the radiology service.

In order to reach this objective, some administrative goals were fixed, such as improving patient's care, improving qualification of professionals, and creating a working environment based on shared responsability and solidary participation; and inspection goals, such as obtaining and maintaining high quality standards in each step of the radiographic process. All this aiming improvement of the quality of the image, optimizing dosage of each examination and reducing costs.

After establishing the objective and fixing the goals, there was still the problem of how to determine the more adequate way of implementing the QAP. Obviously, everything could not be changed overnight, nor could changes be imposed, without misorganizing in force proceedings. Thus, in view of the need to face all steps of the radiographic process, and considering that QAP should aim also patient's satisfaction, from the clinical standpoint, where the first issue is care, a methodology was worked out in such a way that it can be seen from an administrative standpoint (set up conditions to implement QAP; motivation and adoption of a working system aiming changes in values and attitudes; creating and bringing into practice flow control tables and tables for analysing film losses), and from a technical standpoint (set up of procedures to interpretate lost radiographies, and to get quality inspection and administration; data collection regarding radiographic techniques, size of patient, dosage on surface entrance and quality of image; refresher course and set up of image criteria). Finally, it was considered the adoption of corrective measures for each step of the program, analysis of images before and after set up of image criteria, and establishment of economical advantages of the QAP in diagnostic radiology.

RESULTS

Reduction of Rejection Rates

Rejection rate of radiographies ocurred in a radiology service is an indication of the constancy with which the quality of the approved image is obtained, and therefore, is related to efficiency. The first step when QAP was implemented was the control of this rate that suffered successive reductions as shown in figure 1.

Causes of Rejection

The advantages of QAP are highly dependent of the correct interpretation of the causes that lead to repeating examinations. In order to identify these causes, the technique of repeated exploitations was adopted, which can be described as a critical evaluation of radiographies which are produced by the radiology service during the activity of image production, but that, however, do not contribute for the process of diagnosis.

This analysis produced a large range of information about the efficiency of image production activity of the radiology service, and demonstrated when a certain area served by a particular process of the film had an elevated rejection rate. As shown in figure 2, one should first identify whether the cause of rejection was due to equipment, the film, the patient, or to film development, by studying in depth within each group, and doing a more detailed study of the causes of error.

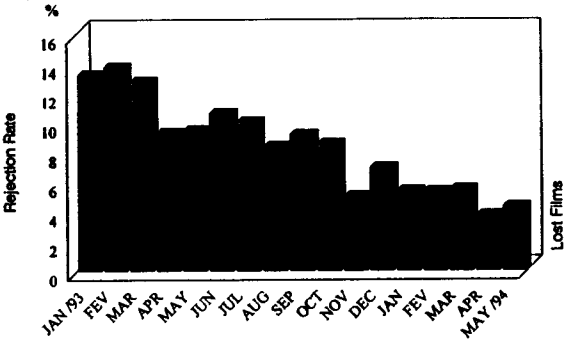

Fig. 1 - Reduction of rejection rate of radiographies

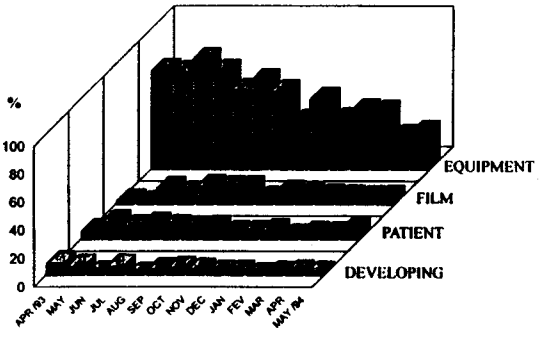

Fig.2 - Evolution of film rejection causes

Cost Reduction

To get a picture on how cost evolution was progressing due to lost films, as shown in figure 3, we calculated the average cost of each square meter of radiography produced in the department, and the amount of square meters lost every month.

Optimizing of Dosage

The dosage absorbed by the tissue in a certain examination depends mainly of the technical factors employed in the radiography, of the characteristics of the equipment, of the X-ray beam, of the number of exposures, and of the delay of exposure. Comparing dosage obtained before and after applying quality criteria, as shown in figure 4, one can notice a significant reduction of dosage in all examinations. Amongst the factors that contributed to this reduction, is the utilization of a radiation field of smaller dimensions, and the type of radiographic technique that was used.

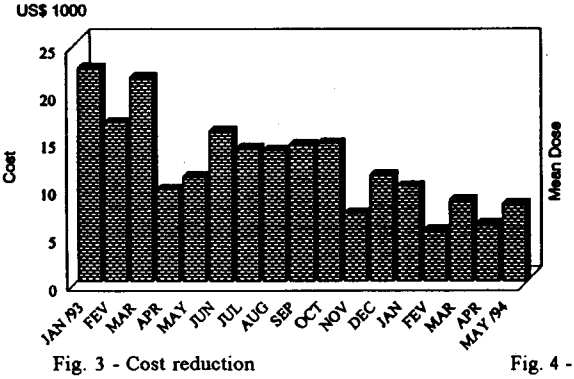

Fig. 3 - Cost reduction

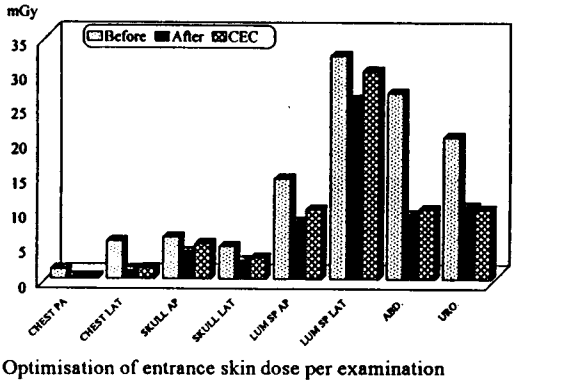

Fig. 4 - Optimisation of entrance skin dose per examination

Improvement of Radiographic Image

Based on criteria made up by the CEC, and having the support of one of their specialists, specific criteria for each of the normalized projections were created. In a comparative study between images obtained before and after

QAP, radiographies were observed by radiologists from HPM itself, acting as judges, attesting and quantifying the visualization of anatomic details of interest, according image criteria. As an example, the result of this evaluation in the PA chest examination is shown in figure 5 and 6. Generally, the results show that little distances focus-film, low V and high mA.s lead to contrast defficiency, lack of light and medium tones in important area, details mildly expressed, no clearness, images of low density, and excessive magnification of the object in the radiographies, all this before utilization of QAP.

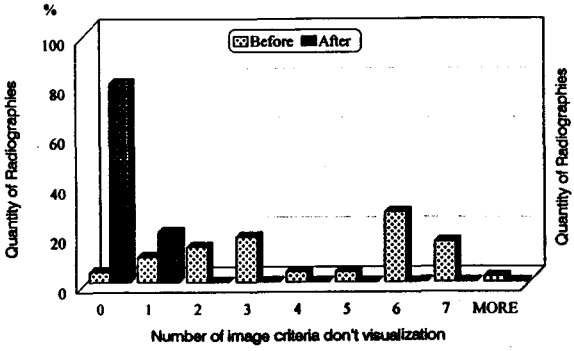

Fig. 5 - Visualization of imge criteria in the PA Chest examination, before and after QAP

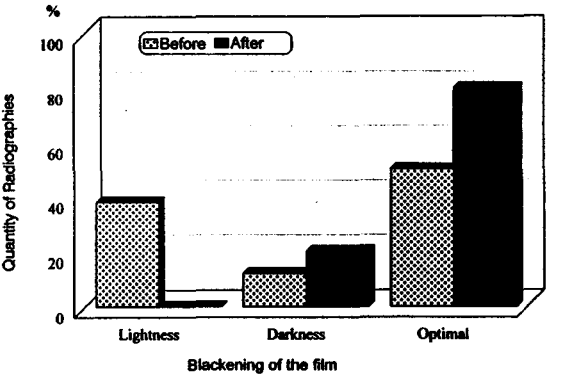

Fig. 6 - Evaluation of blackening of the film in the PA Chest examination

CONCLUSION

It is pertinent to mention that during the period of implementation of the QAP, there was always the intent to exercise a kind of leadership which aimed motivation of professionals, through friendly methods of consciousness, orientation and capability. To solve problems, new ideas were stimulated and took advantage of creativeness, resulting in a positive relation between the degree of participation and the feelings of satisfaction, responsability and compromise. The analysis of films rejection, besides allowing an evaluation of problems which lead to a poor quality image, also was useful as a tool to improve technicians' performance and as a basis for overall guidelines for the improvement of image quality.

The lessons that were given fully achieved their objectives, motivating people and contributing in a decisive way to the quality of the image, to optimized dosage, and reduced rejection rates and costs. They were also useful to incline professionals to like the changes, as much as they rejected them in the past, starting to think of the need of training, self-improvement and constant changes.

Settling quality criteria, besides allowing a uniform evaluation of radiographies, also forced radiology doctors to make a more complete and detailed evaluation of final images.

A significant reduction in dosage was found in all evaluated examinations, reaching 80% in the chest examinations, and 30 to 60% in the other examinations. It was also found a reduction of 70% - from initial 14% to below 5% - in the rejection of films, and a cost reduction of about 75%.

In the evaluation of the gotten images, before and after of QAP, all established criteria could be seen in a high percentage of radiographies obtained after the use of the new techniques, demonstrating an effective improvement in the quality of images.

It was confirmed that, with serious and persistent work, one can offer to patients services and products within their expectation, even in a public hospital. Therefore, such programs should have the support of related authorities, not only because of its economical and technical aspects, but also because of the social ones.

As a final comment, it must be mentioned that many things were made correctly, but some errors were made. But, above all, there was persistence. And, if good results were achieved, these are due, with no doubt, to hard work.

PROPOSAL OF DOSE CONSTRAINT VALUES TO THE PATIENT IN DIAGNOSTICC RADIOLOGY

Leopoldo Arranz[1], J.M. Sastre[1], E. Guibelalde[2], B. Tobarra[3], G. Madrid[4] N. Ferrer[1], J.C. De Andrés[1].

INTRODUCTION

A dose constraint is the value of an individual dose not to be exceeded in the individual dose distribution considered in an optimization process. The objective of a dose constraints is to set a ceiling to the doses to individual from a source, practice or task which are considered acceptable in the optimization process at the design stage. Implicitly, as C. Zuur (1) states, dose constraints are below the relevant dose limit and usually should be established as local or national levels. Exposures for medical purposes are not subject to dose limits and hence dose constraints were recommended by the ICRP just for occupational and public exposures. However, as an effective tool for optimization for medical exposures, ICRP-60 in §180 (2) recognizes the value of applying this concept to patient diagnostic radiology with some peculiarities: "Considerations should be given to the use of dose constraints, or investigation levels, selected by the appropriate professional or regulatory agency, for application in some common diagnostic procedures. They should be applied with flexibility to allow higher doses where indicated by sound clinical judgement".

As B. Wall indicates (3), there is some interesting features in this recommendation: it suggests that for diagnostic medical exposures the dose constraints are to be used retrospectively as investigation levels for checking existing practices an not at the planning stage, as is the case for occupational and public exposures. In this practical application of ICRP concept of dose constraints to medical exposures of patients, the term reference level (4) or guidance level (5) have been indistinctly used. Unless justified by clinical judgements, appropriate action should be taken by the centres to improve practice; this could involve changes in technique or equipment to reduce doses to values below the reference level without compromising the quality of diagnostic information. When used in this manner, this has the same function as the "dose constraints".

National and sometimes local reference dose levels usually are set towards the top end of the observed range of typical practice, i.e. defined at a certain percentile such as the 75, to identify where corrective action is most urgently required. This concept is usually used at the first stages of optimization in diagnostic radiology as a level that should be obtained, however, measured doses at any other optimization stages should be clearly below, so that, new *constraints* should be imposed.

This paper analyses retrospectively the dose levels imparted to patient in some common examinations (chest, lumbar spine and mammography) at different optimization stages of different facilities to propose some local constraints for diagnostic examinations. Dose values have been obtained under routine working conditions. Centres included in the survey have been chosen all over Spain, classifying them with particular attention to the following aspects:

- Organizational aspects of the diagnostic radiology service, i.e., operational, technical and clinical criteria, as well as quality requirements.
- Evaluation and revision of routine medical protocols.
- Quality control of the radiological equipment.
- Quality criteria for the surveillance of the working procedures, with requirements of proper training of the technical staff.

MATERIAL AND METHOD

The examinations included in the survey were of the chest (postero-anterior and lateral projections), lumbar spine (AP and lateral) and mammography, since they are representative of simple examinartions (4) and hence coul be considered as *common* diagnostic procedures. Patient entrance surface doses were mainly estimated

from DAP (dose per area product) measurements carried out with transmission ionizing chambers. Alternatively, some data were obtained with thermoluminiscent dosimeters placed at the centre and on the surface of the patient field. A previous chambers and electrometers intercomparation among the participating centres were carried out to ensure that all measurements were comparable. Data are obtained from samples higher than 10 patients in each facility. Paediatric patients were not included in the survey. Third quartile values are shown in tables.

RESULTS

Tables summarize dose levels of the aforementioned examinations and the characterisctics or degree of implementation of quality assurance programmes in each facility. First level (which correlates with the highest dose reference values) corresponds to data obtained by the Medical Physics Group of the Complutense of Madrid (6) at an early optimization stage of radiation protection in diagnostic radiology. This group conducted a research proyect in the community of Madrid during the period 1986-1992, partly supported by the Eropean Community, and carried out in several health centres. Those first data could be representative of the dose reference values without any implimentation of quality control programmes (most data were obtained before 1989). Rest of data included in table came from services with different degrees of quality assurance implementation. Lowest local reference values could be considered representative of a facility in which all organizing aspects of the radiological services have been taken into account, also staff training on radiological protection topics and equipment quality control.

OPTIMIZATION LEVELS	L1	L2	L3	L4
1. Quality criteria for the surveillance of the working procedures, with requirements of proper training of the technical staff		X	X	X
2. Quality control of the radiological equipment.		X	X	X
3. Organizational aspects of the radiodiagnostic service i.e. operational, technical and clinical criteria, as well as quality requirements			X	X
4. Evaluation and revision of routine medical protocols				X

MEAN VALUES OF PATIENT SURFACE ENTRANCE DOSE (mGy) CLASSIFIED ACCORDING TO LEVELS OF OPTIMIZATION

Examinations	L1	L2	L3	L4	EU [1]	UK [2]
Chest PA	0.50	0.35	0.18	0.12	0.30	0.20
Chest LAT	1.60	1.20	0.56	0.70	1.50	1.50
Lumbar Spine AP	20.00	11.10	7.51	3.28	10.00	9.20
Lumbar Spine LAT	45.10	22.70	17.90	8.53	30.00	22.80
Breast	13.90	5.60	4.48	-	7.00	10.00

[1] CEC reference values [2] Ref (7)

CONCLUSIONS

The proposals of the introduction of dose constraints in diagnostic radiology could be a solution to ensure that patient doses do not exceed the level considered has optimum for each examination.

Each facility according to the different optimization levesl that could be achieve, should be adopt their own constraints values as presented in this paper, however, it is important to be account that the imposed levels could be improved while getting new optimization procedures.

Until now the best level of optimization (L4 in table) achieves was due to the good practice of the complete radiological process, including all from the moment an examination is asked to the final clinical report is issued.

ASSESSMENT OF RADIATION DOSE AND QUALITY ASSURANCE IN MEDICAL X-RAY DIAGNOSIS.

M. BROȘTIUC ,"EMERGENCY" HOSPITAL,RADIOLOGY DEPARTMENT
CALEA FLOREASCA str. no 8 , 71406 ,BUCHAREST, ROMANIA

ABSTRACT. The intensive employment of X-rays in diagnostic radiology,represent so far the largest man-made source of public exposure to ionizing radiation."The aim of radiation protection of the patient has gradually shifted from a concern about population exposures and hereditary effects, to the ambition of limiting the risk to the individual patient" (1).

Key words:patient doses,radiation protection, quality assurance.

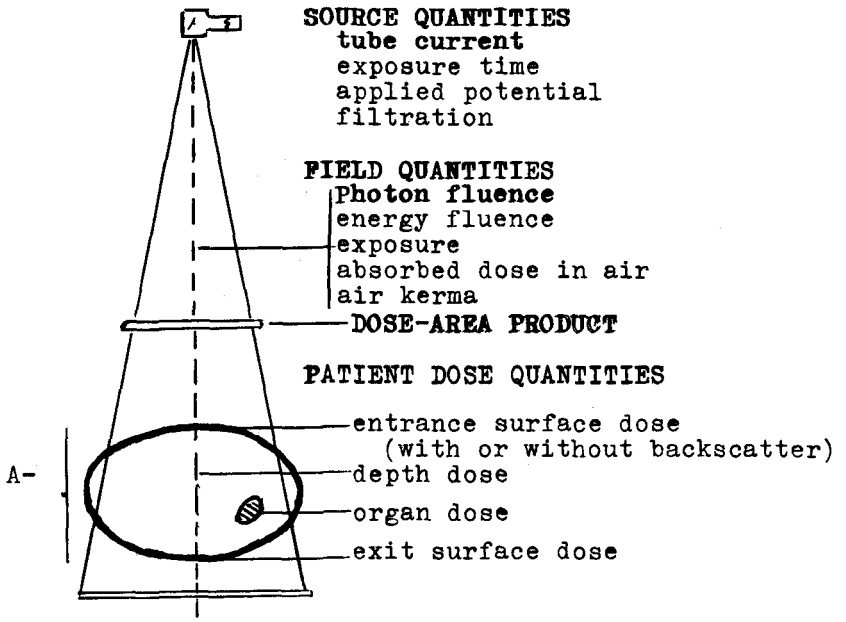
INTRODUCTION

By measurement of radiation is known the cause ionization within matter.Are used the general units of mass and volum. The concept of a give dose of radiation producing a particular effect is no different from that which applies in the medical administration of drugs.The radiation dose is an electrical phenomenum and is measurable using appropriate instrumentation e.a. various types of detectors available such as film badges,geiger counters,scintillation counters etc.Readings from these instruments may be translated into a dose of radiation absorbed by a unit mass of tissue (2).

MATERIALS AND METHODS

In order to be able to assess patient doses are necessary the equipment characteristic of X-ray examinations, dosemeters,tissue-equivalent phantom,water phantom and the competence technical personnel.

Include details of technical medical procedures by the EUROPEAN GUIDELINES of radiation protection of the patient. The biological damage of ionizing radiation,stochastic effect,which implies a single "hit" or repeatedly doses, effect which can be visible tardy,for all technical practical procedures in X-ray examinations impose respect of potential exposure by the justification of a practice, the optimisation of protection -ALARA principle-,and used of individual dose and risk limit for reducing doses without loss of diagnostic information (3).For each patient, individual -specific sex,age group- the radiation dose should be applied with flexibility and combined with dosimetric quantities,data on field size,field position,



A-**energy imparted**

focus distance and beam quality -KVp,filtration=the radiation quality- .

Patient dosimetry (4)

EXPOSURE contents ions which are generated in air,as a consequence of radiation.Ions can be mesured with an ionization chamber,which is an air space between two conducting plates coupled to the positive and negative poles of a voltage source.The exposure,means,the number of ions with negative or positive charges divided by the mass of air in the ionization chamber.

SOURCE QUANTITIES-that are selectable and often indicated on the equipment.

FIELD QUANTITIES -some of which can be measured with suitable instruments.

PATIENT DOSE QUANTITIES -which are mostly incapable of direct measurement,but which are the quantities that we realy want to know to assess the level of harm.

The quality and quantity of the radiation emerging from an X-ray tube,is a function of the tube current,exposure time,applied potential and filtration which give rise to a radiation field propagating through air that can be specified in term of the photon or energy fluence.

Radiation intensity,as well as light intensity,decreases in inverse proportion to the square of the distance from focus.Dose decreases also without matter,even in air.

The photons interact with the air to produce measurable values of air kerma or dose absorbed in air,at any point in the X-ray beam or integrated over the beam area -dose area product-.These "free-in-air" doses can be measured with ionisation chambers of typically between 3cm and 60cm volume for "point" dose measurements and of a large area,typically 400cm,for dose area product measurements.

PATIENT DOSES

By attenuation the interaction of X-ray beam with patient produces a non-uniform distribution of absorbed dose within the body,since the beam is localised to the area of interest and is attenuated as it passes through the body.In conventional film-screen radiography,the size of the patient will be influenced patient doses,since larger patients require higher entrance doses for the same dose to the image receptor.Measurable quantities during X-ray examinations are (5):
-entrance surface dose per radiograph,with termoluminescent TLD stuk directily to the patient's skin,in which case the measurement will include radiation back-scattered from the body.Entrance surface dose is called incident dose.
-dose area product per examination
-effective dose,concept which describes the probability of damage to different organs with their weighted sum,which are the radiosensitive,such as gonads,bone marrow,lungs,colon, brest etc.The sum of the weighting factors equals to 1.
The relative depth dose values strongly depend on radiation quality and geometric conditions.Parameter influencing organ doses are:patient size,tube voltage,filtration,field size, field position,focus-skin distance,scatter-gruid,sensivity of the film-screen combination.Dose calculations for organs and tissues are normally carried out in two steps:
1.calculation of dose free in air by dose measurements,dose calculations can be base on source data -source concept,or on the known or estimated dose at the image receptor -receptor concept,which is preferably used in those cases where the mAs prodoct is not known.
2.conversion of dose free in air to the dose in organs or tissue.

QUALITY ASSURANCE PROGRAMME IN DIAGNOSTIC RADIOLOGY

The quality assurance is a strategie for increase quality of diagnostic images and keeping patient exposure at adequately low level (6),after German regulations QA programme means the acceptance tests for X-ray machine and film processor, the acceptance constancy tests -the result of consecutive constancy checks can be compared,and supervised by committees established by professional medical organizations.

INTRODUCTION

Medical X-ray examinations in Romania give rise to a large annual collective dose equivalent of about 14,200 man Sv (90% of all manmade sources) [1]. The extent to which the unnecessary medical radiation contributes to this collective dose was not investigated and on a national scale the response is very difficult to obtain.This work is an attempt to estimate, even rough, the current extent of unnecessary exposures due to repeated examinations and of those with poor image quality.

METHODOLOGY

Twelve X-ray diagnostic departments from seven medical centers were selected on their annual workload basis for the audit. Because the rejected radiographs are not recorded separately, we have chosen a four month period (the middle month of every quarter) during 1993, to make an analysis of these spoilt films. The annual repeat rates of radiographic examinations were calculated on this basis, for each hospital. A random sample of 800 films from all X-ray departments was separately viewed by three radiologists. According to their own opinion, the examinations divided between the following categories of a three step scale: very good for films having no errors of exposure,positioning or processing; good or diagnostic acceptable for films with some errors of exposure, positioning or processing but which do not detract from the diagnostic utility of the radiograph and unacceptable for films having such errors that made than unsuitable to diagnostic. We used this last category of radiographs or spoilt films to make an evidence of clinically unhelpful X-ray examinations because the probability of obtaining an useful information for patient management is extremely low.

RESULTS

The four month sample involved 11819 patients which had a X-ray examination; the overall number of films used was 21330 and the percentage of patients with a repeated exposure ranged from 0.53 to 5.70. The main causes of a repeated film which form part of a X-ray examination are divided into the following categories (A-D) :

A - faults due to personnel (radiographer) : positioning or processing ;
B - machine faults : overexposure, underexposure (errors of exposure) ;
C - films with faults of manufacture : stains and traces revealed by development ;

D - consultant's request.
The annual frequency of repeated examinations with their causes in each medical center is presented in Table 1.

Table 1. Annual frequencies of repeats with their causes

Hospital	Main causes for a repeated film (%)			
	A	B	C	D
1	6.2	79.3	6.2	8.3
2	41.6	41.6	-	16.8
3	100.0	-	-	-
4	5.9	29.4	64.7	-
5	14.8	59.3	25.9	-
6	16.6	16.6	66.8	-
7	23.1	61.5	15.4	-

The exposure errors seem to be the major fault accomplishing the higher percentage of repeated films (up to 79%) in almost all hospitals. Radiographic films with faults such as stains and traces which appeared by processing the film are another cause for a repeated examination.
The faults in positioning included also the selection of wrong beam limiting cone or diaphragm. Except one hospital (for lung diseases) where all repeated examinations were due to this kind of error, the radiographers'faults had a lesser effect on repeat rates. From the eighteen commom X-ray examinations observed, only five had relevant repeated rates : lung, heart (21.2%); lumbosacral spine (16.9%); i.v. urography (21.1%); gastric series (21.2%) and extrimities (8.5%). The frequency of rejects by cause and type of examination is present in Table 2.

Table 2. Frequencies of repeats for some examinations

Examination	Categories of repeats causes (%)			
	A	B	C	D
Lung,heart	22.9	54.2	20.0	2.9
Lumbosacral spine	7.1	78.6	14.3	0
I.V.Urography	30.0	25.0	35.0	10.0
Gastric series	0	80.0	0	20.0
Extremities	14.3	35.7	50.0	0

These data reveal that the examinations with higher patient exposure such as lumbosacral spine or urographies , having an important contribution to collective dose, have been repeated mainly due to machine faults, a kind of systematic error which cannot be avoided, because the radiological equipment is very old. On the other hand, the repeated examinations by cause C are easiest to eliminate. But apart the repeats, the most unnecessary medical irradiation arises from clinically unhelpful examinations [2,3]. In this category we have included the examinations appreciated by radiologists as unacceptable having such errors that cannot contribute to diagnostic decisions. Radiologist's impressions are summarized in Table 3.

Table 3. The radiologists'impressions on the radiographs (%)

	Image quality		
	Very good	Good	Unacceptable
% of the original sample	19.7±5.4	49.6± 3.2	30.7± 2.7
Type of examination			
Lung+heart	24.2±7.2	48.0± 5.5	27.8± 5.4
Lumbosacral spine	16.0±5.4	35.8±10.2	48.2±13.4
I.V.Urography	12.5±4.0	47.8±13.8	39.7±13.0
Gastric series	20.0±5.1	50.4± 7.8	29.6± 5.2
Extremities	28.9±8.3	53.4± 9.3	17.7± 5.9

There is an evident discrepancy between the percentage of repeats,as nowadays registered in radiology and the percentage of daily performed radiographs of poor quality,never recorded like that,but in fact as unhelpful to diagnosis as the former ones. Our results make an evidence for the need and the importance of a register of reject radiographs, a very simple and useful mean to control the radioprotection standards [4]. Estimates of the extent of the unnecessary component of the collective dose due solely to clinicaly unhelpful X-ray examinations and the repeated ones, are given in Table 4.

Table 4. Annual collective dose and potential dose savings

Type of examination	Effective dose/ film	Annual collective dose	Potential annual collective dose savings from :		
			Poor quality exams	Repeats	
	mSv	manSv	manSv	manSv	%
Lung,Heart	0.25	17.0	5	0.13	30.2
Lumbosacral spine	2.0	50.0	24	0.90	49.8
I.V.Urography	2.5	40.3	16	0.35	40.6
Gastric series	4.8	80.0	27	1.01	35.0
Extremities	0.1	6.1	1	0.02	16.7

Our results testify the potential for a significant reduction in the collective dose to patients (up to 49%) and a significant benefit to society as a whole by bettering the diagnostic quality and value of radiographs.

MAJOR SCIENTIFIC TOPIC NUMBER: 6.1. ..... (see page 7)

ABSTRACT (See instructions overleaf)

A series of measurements have been performed on the reduction of male gonadal exposure doses in various X-ray examinations of diagnostic radiology using a whole body human phantom. The exposure doses in the gonadal area have been measured by employing Thermoluminescent Dosimeters (LiF-100). The attenuation of exposure doses to gonad have been studied as a function of different thicknesses of lead plates, viz., 0.60 mm, 1.00 mm, 1.50 mm, 1.85 mm and 3.00 mm of sizes 20 cm X 20 cm for various X-ray examinations, namely, Oral Cholecystography (OCG)X-ray, Pelvis X-ray, Hip-joint X-ray, Intravenous Pyelography (IVP) X-ray and Barium-meal X-ray. It has been observed that the basic nature of all the exposure dose attenuation curves of lead (shielding material) are similar and there are no significant variations of exposure doses beyond the lead plate of 1.00 mm thickness. From this experimental study, a lead plate of thickness 1.00 mm has been selected to reduce the exposure-to-gonad doses adequately for different diagnostic X-ray examinations. In each case of the X-ray examination, the exposure reduction factor and the exposure attenuation efficiency for 1.00 mm thick lead shield have been determined. It is recommended that a 1.00 mm thick lead plate should be used as a shield to minimize the exposure doses to the gonads of the patients so as to improve the benefit-to-risk ratio from the uses of ionizing radiation.

PRACTICAL POSSIBILITIES FOR PATIENT DOSE REDUCTION IN DIAGNOSTIC RADIOLOGY

Constantin Milu

Institute of Hygiene, Public Health, Health Services and Management
Bucharest 35, Romania

INTRODUCTION

According to the United Nations Scientific Committee on the Effects of Atomic Radiation (1), the radiation doses from diagnostic radiology are the largest contribution to the collective dose from all man-made sources of radiation. In Romania, for a population of 23 million inhabitants, about 660 X-ray examinations were reported in 1990 per 1,000 persons (1), a value which represents a decrease in comparison with 1970 , when more than 1,000 exams per 1,000 were performed. Unfortunately, still about 26% of the total X-ray examinations are classical fluoroscopies (without image intensifier TV set), which give high doses to both patients and radiologists.

The general standard of the old equipment in diagnostic radiology is very far from the minimum requirements, so that great financial efforts must be done in the near future, in order to improve the present situation.

METHOD

From 1991 to 1993, the Institute of Hygiene, Public Health, Health Services and Management - Bucharest participated to the co-ordinated research programme on "Radiation doses in diagnostic radiology and methods for dose reduction", jointly organized by the International Atomic Energy Agency and the Commission of the European Communities (2).

The patient entrance surface doses (ESD) including backscatter for several X-ray projections were determined, using thermoluminescent dosemeters, before and after application of corrective actions for dose reduction (QC).

RESULTS

The main results are presented in Table 1.

CONCLUSIONS

By increasing kV and reduction of mA.s values several entrance dose reductions can be obtained, particularly for chest PA radiography, but the use of high kilovoltage technique is dependent on radiological equipment available.

An important reduction of the integral dose of the patient was determined by collimation of the beam (reduction of the field size to the investigated area).

The use of appropiate screen-film combination is another practical possibility for patient dose reduction in diagnostic radiology.

Table 1. Measurements of patients entrance surface dose.

HOSPITAL	RAY ROOM	EXAMINATION	DOSE PRIOR TO QC (mGy)	DOSE AFTER QC (mGy)	DOSE REDUCTION IF ANY (%)	CORRECTIVE ACTIONS
1	1	Chest PA	0.95	0.76	20	Increase of kV and reduction of both mA.s and field size
2	2	Chest PA	0.77	0.69	10	Increase of kV and reduction of both mA.s and field size
1	4	Urinary Tract AP	17.98	9.29	48	Increase screen-film sensitivity
1	4	Urinary Tract PA	12.87	10.48	19

IMPLEMENTATION OF SOME DOSE REDUCTION METHODS IN QUALITY ASSURANCE OF DIAGNOSTIC RADIOLOGY IN SOME HOSPITALS IN IRAN

M. Sohrabi, S. Borhan Azad and B. Aghahadi

National Radiation Protection Department
Atomic Energy Organization of Iran
P.O. Box 14155-4494, Tehran, Iran

INTRODUCTION

Although quality assurance (QA) programmes have been implemented in medicine and in particular in diagnostic radiology in Iran since a long time ago through periodic inspections, education and training, determination of genetically significant dose (1), patient and personnel monitoring, etc., a systematic national programme has been recently implemented by sending a detailed questionnaire to about 1000 diagnostic radiology departments. In 1991, the participation in an IAEA co-ordinated research programme on radiation dose in diagnostic radiology and methods for dose reduction showed up to 79% reduction in entrance skin dose (ESD) by keeping or improving the image quality (2,3). As an extension of this work, the programme was implemented on 520 patients in 13 X-ray rooms of 11 hospitals in Tehran using the image quality criteria defined in a CEC Working Document (4). The relationship of ESD to radiographic technique and to image quality was analyzed. In this paper, the results are presented and discussed.

MATERIALS AND METHODS

Based on the returned 350 questionnaires, the per caput average number of examinations, number of films per examination, the frequency of certain examinations and the technical factors applied (mA, kV and exposure time, focus to film distance or FFD, field size, etc.) as well as the departments volunteer to implement the QA programme were deduced. From the voluntary departments, ten hospitals and one mammography clinic in Tehran were selected.

The projections of chest PA and abdomen AP in 12 X-ray rooms and four mammography projections including medio-lateral left and right and cranio-caudal left and right in one X-ray room were considered. A multi-function meter (RMI, Model 240-A), a Rad-Chech PLUS (Victoreen Model 06-526), a dual color sensitometer (X-rite, Incorporated, model 334), a B/W transmission densitometer (X-rite, Incorporated, model 331), a HVL attenuator set (RMI Model 115A), TLD-100 dosimeters (LiF, Harshaw) were used. The conditions of one darkroom in each department including light tightness, fog level, safe light, processor (developer, temperature and rinsing) and cassettes (speed, cleaning, light leakage and air trapping) were tested. The ESD of 520 patients were directly measured by TLDs on the patient's skin at the center of the X-ray field. The following procedures were completely implemented in selected departments:

1- Determination of ESD, kV, mA.s, FFD and image quality scores of 260 patients weighing 60 to 70 kg prior to QA including 10 patients for each selected examination (chest PA, abdomen AP, mammography CCR, CCL, MLR and MLL). The image quality scores was given by field radiologists based on the CEC image quality criteria (4); scores of 1, 2 and 3 respectively for poor, satisfactory and good image qualities.
2- Determination of means values of ESD, kV, mA.s, FFD and image quality score of each group of 10 patients stated in part 1.
3- Based on the information obtained in parts 1 and 2, necessary corrective measures were made reduction such as reduction of mA.s by improving the film developing conditions, reducing the optical density of the film and/or increasing the speed class of film screen combination as well

as optimizing the kV, filtration and FFD by using an anthropologic phantom (Randoman phantom from Alderson Research Lab. Inc.).

4- Repeating parts 1 and 2 after QA in part 3 for another 260 patients applying the same procedure.

RESULTS AND DISCUSSION

Although many QA parameters, both related to the equipment and techniques, seemed necessary to be corrected, due to some existing problems only some parameters were considered for corrective measures including radiological techniques such as increasing kV and FFD as well as decreasing mA.s. Also in a few cases, some other possible corrective measures such as improving the darkroom conditions, selection of best film screen combinations and improving total filtration were also applied. The implementation of the above led to a significant decrease in the mean ESD values while increasing the image quality due to changes in the technical parameters, as shown in table 1. It should be mentioned that in the case of mammography, only type of film and the anti-scattered grid were changed. Under the conditions applied, the mean ESDs have been decreased up to 72%.

Table 1. Effects of applying dose reduction methods on ESD and image quality.

QA parameters			Variations of the means (%) ± SD					
			Chest PA	Abdomen AP	Mammography*			
					CC-R	CC-L	ML-R	ML-L
Dose Reduction Methods	kV	increased	61±21	37±14	0±5	0±5	0±5	0±6

* CC-R=Crano Caudal Right, CC-L=Crano Caudal Left, ML-R=Medo Lateral Right, ML-L=Medo Lateral Left.

Figures 1 and 2 show mean ESD values of patients undergoing respectively chest and abdomen examinations in different X-ray rooms. It is observed the ESD has been significantly decreased after implementation of the QA in all departments. Figures 3 and 4 show the mean scores of image quality, respectively for chest and abdomen examinations. From these figures, it can be concluded that while Figs. 1 and 2 show significant ESD reductions, Figs. 3 and 4 show significant improvement in the image quality of the radiographs. Also table 2 shows the maximum, minimum and their ratios as well as the mean values of the ESD before and after the QA. From table 2, it can be also concluded that the range of the ESDs and in turn the maximum to minimum ESD ratios have been significantly reduced after the QA. It can be concluded that by adjusting the exposure techniques for different X-ray units and using a written protocol for these techniques, the requirement for repeating the radiographs due to over or under exposures will be reduced.

Regarding the rejected films, during the first set of measurements, about 500 films were analyzed by field radiologists from which 18.8% were rejected for repetition. The main reasons for repeating of rejected films included patient movement (5.4%), over exposure (4.2%), exposed by light (3%), under exposure (2.9%), positioning (1.2%), repeated radiographs by mistakes (0.8%) and developing conditions (0.4%). It can be concluded that by using a technical protocol, about 7.1% of the overall rejected films (due to over or under exposure) may be reduced.

As shown in table 1, the limited QA programme applied has been very effective in dose reduction in the X-ray units used in this study. Based on the data collected from the questionnaires, the frequency of chest and abdomen examinations were respectively 4.3 million and 1.6 million in 1994.

So reduction of 72% ESD for chest and 54% for abdomen can lead to a significant reduction of collective effective dose in Iran.

ASSESSMENT OF PARAMETERS REQUIRED FOR OPTIMIZATION OF X-RAY DIAGNOSTIC PROCEDURES

Ivica Prlić, Željko Radalj, Hrvoje Cerovac, Vlatka Brumen

Institute for Medical Research and Occupational Health
Ksaver Street 2. 10000 Zagreb, Republic of Croatia

ABSTRACT:
The quality of diagnostic information provided by an x-ray examination depends on the quality of an x-ray image obtained on the film, intensifying systems or in through computer image reconstruction methods. The quality of the image is defined by two main parameters: degree of resolution and difference in optical densities, the latter being related to the type and thickness of a target tissue.
This study is an attempt to asses those parameters as simple and as reproducible possible. Within the framework of the study, the influence of conditions under which the image was obtained as well as the reproducibility of x-ray diagnostic procedures will be discussed. The results of this study were meant to serve as the basis for optimization of x-ray diagnostic examinations, respecting also the specifications of an available x-ray unit.

INTRODUCTION:
According to the latest survey in which we have completed our data base about the ionizing sources in the Republic Croatia, we have collected all available technical data about the medical x-ray facilities and x-ray units which are still operating.As the result was not encourageble, over 60 % of x-ray units older than 10 years, and as the financial potential of the country is not able to cover immediate replacement of units we were forced to reconsider our radiation protection situation in medical diagnostic and try to implement the CEC image quality criteria (1) and European standards in diagnostic radiology through three steps. First, we have carefully distinguished the x-ray units which are matching the minimum of requirements for good image quality from those which need permanent maintenance to be able to perform the good image quality. In the last five years we have checked every x-ray unit in the country, performing the quality control tests for radiation quality, image quality, patient dose and radiation protection (1-5). Second, we had to make a difference in methodology for the common x-ray units producing the film as the end product and the x-ray units producing the digitized image. The main group were common x-ray units. Dental units and mammography units are considered separately. Third step was to gather the data about the type of examinations performed on the units of interest.. We have decided to cover the five main types proposed by CEC (1). The pediatric situation is considered separately.
At the end we had a situation:

-over a 100 common x-ray unit which need a permanent maintenance because they are older than 7 years and/or the producer is not supplying the spare parts.
-three main manufacturers of these units sometimes not able to calibrate the generator and the whole system
-a big difference in patient dose between the units even of the same type.

There are no Health physicists in our hospitals. That's why we have tried to find the most reliable, quick and reproducible method of checking the parameters which represent the radiation quality of x- ray units, introducing the quality control programme into the daily work in the diagnostic radiology departments .
For the radiologist is the end product important, namely the image.

METHODS AND MATERIALS
The main parameters included in quality control procedures have definitely significant influence on the image quality. In order to find the method which can proper describe the status of x-ray unit we have decided to cut the influence of the film processing and intensifier screen systems. So we have made all our measurements with the film cassette with no intensifier screen at all and with the Al filtering phantom, water phantom 15 cm thick for every x-ray unit the same. Dose was measured with the Victoreen RAD CHECK +, film and TLD dosemeter badges. kVp was measured with Vicoreen kV meter, calibrated by Victoreen. For all possible quality tests we have used a set of phantoms, various step wedges, resolution patterns, etc..mostly produced by Victoreen.
The first step was always to check the actual size of the focal spot end at the same time the resolution which was always documented on the x-ray film This was done for every unit in the same geometry arrangement. After that, we have started to measure kV step by step within the interval from 60 to 120 kVp in steps of 10 kV. The measurements results where fitted with Statgraphics ver.4.2 package using simple regression method (table 1.)

122	130.5	0.25240	0.17687
124	132.8	0.26136	0.18599

Second step was to measure the dose output through the whole kVp range achievable with the generator at the fixed geometry and fixed mAs values. Two sets of dose output were measured: one without any additional filtration and second with 3 mm Al additional filter.

DISCUSSION

The measurements were made to find the kVp where the 3mm Al represents HVL. At that kVp it is recommendable to make the image in such a way that half of the image was shoot once without any additional filter and the other half should be shoot twice using 3mm additional Al filter. The mAs value should be chosen so that the optical density of the film would be about 2.0 and identical on both halfs of the film. Any change in the generator operation parameters (kVp, mAs, etc) has direct influence to optical density mentioned above,by changing it. The whole series of measurements where done for small and broad focus size separately.

We used our own Kodak films always comparing it with the films which were used by users.:

This enables us to have a good overwiev over the once optimized radiation quality of the x-ray unit. The working staff has a simple method to verify the leak of quality theirs x-ray units.

The doses shown in table 1 are presented in mGy/mAs. So, it is always possible to evaluate the skin entrance dose multiplying the applied mAs with the dose value at given kVp in order to get the real dose applied to the patient during the diagnostic procedure. That's why those tables are attached to each x-ray unit.

ABSTRACT (See instructions overleaf)

Doses to patients in X-ray examinations extremely depend on a choice of technical exposure parameters. Approximately the same visualization of anatomical details is possible to achieve using different combination of kilovoltage, charge (anode current and time product) and total filtration, but with quite different doses to patient. (Source -skin distance is designed by type of procedure.) In the newest X-ray units kilovoltage - charge combination is fixed automatically, but the older equipment needs to choice of these parameters "handly" - by technicians.

This paper presents results of evaluation how particular parameters can affect on dose to patients, taking into consideration the mode of X-ray generators. (Kilovoltage seems to be the most important from mathematical point of view.) As in Poland X-ray units with different rectifying system are in use, this analyse takes into account the following systems: half-wave, 6- and 12-rectifiers and constant potential generators. The influence of total filtration is significant as too low filtration was very frequently found error in Polish X-ray units.

As conclusion - a possibility of patient dose reduction is discussed versus an appropriate choice of X-ray equipment and their exposure parameters.

ASSESSMENT OF ORGAN AND TISSUE DOSES FROM COMPUTED TOMOGRAPHY EXAMINATION

Jacek Janeczek
Institute of Atomic Energy, 05-400 Otwock,Swierk, Poland

INTRODUCTION

Computed tomography examinations greatly contribute to the collective dose from diagnostic radiology. This is caused by increase in CT examination frequency and relatively high level of patient irradiation. Advances in design of CT scanners give better quality images but at the cost of increased patient exposure. Organ and tissue doses from CT examinations are usually assessed by Monte Carlo method and mathematical phantom (1). In this work anthropomorphic Alderson phantom and thermoluminescent detectors were used. Particular attention was paid to brain examination. In many CT installations the gantry is tilted during brain examination in order to limit eye lens exposure. M C method can not simulate this and as the result the eye lens and thyroid doses obtained by both methods differ considerably.

METHOD

The study was carried out using five different CT installations: CT/T 8800, CT 9800 and CT MAX made by General Electric; SOMATOM 2 made by Siemens and CT 1200 SX made by Picker. Five most frequent CT examinations were selected: brain, axial orbits, lung, liver and abdomen-pelvis (2). Lithium Fluoride (TLD-100) thermoluminescent dosemeters (3.2x3.2x0.9 mm) were used. They were read on Toledo 954 reader. Quality of the X-ray beam characterized by half value layer (HVL) and kVp value was measured for each scanner. The data were later used for TLD calibration procedure. Obtained values were:a.) HVL=8.5 mm Al, kV_p=125 kV for SOMATOM 2 and b.) HVL=5.5 mm Al, kV_p=120/130 kV for other scanners. Calibration was carried out in a water phantom with 0.6 cm^3 Farmer ion chamber type 2571 as a reference dosemeter. Correction factors from water to ICRU muscle and compact bone were calculated from conversion factors (3) for both X-ray qualities: a.) $f_m/f_w = 1.02$, $f_b/f_w = 3.06$; b.) $f_m/f_w = 1.26$, $f_b/f_w = 3.65$. Settings of nominal slice thickness and exposure (mAs) recommended by each manufacturer for each examination were used. Dose distribution resulting from CT exposure was measured in the phantom at the central part of irradiated area and these data were used for mean dose estimation to organs extending through many phantom slices (4). Since Alderson phantom is made close to Average Man specifications the results are expected to represent mean organ doses for patient of similar specifications.

RESULTS

Operating parameters of CT scanners for two groups of examinations are given in two tables. Organ doses are given in tables for each examination. Dose to skin is measured as local dose in the irradiated area. Red bone marrow is marked as RBM. Organs with doses less than 0.05 mGy were excluded. Radiation field limits for each examination are shown on figures adjacent to tables with organ dose results.

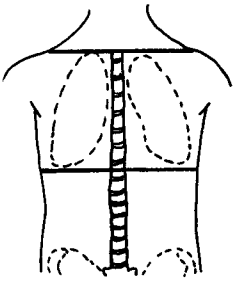
OPERATING PARAMETERS FOR LUNG AND ABDOMEN-PELVIS EXAMINATIONS

Scanner	Slice width (mm)	Lung examination		Abdomen - pelvis examination	
		Exposure settings (mAs)	Number of slices	Exposure settings (mAs)	Number of slices
CT 8800	10	288	23	368	22
CT 9800	10	420	23	510	21
CT 1200	10	240	20	330	20
CT MAX	10	365	24	365	20
SOMAT 2	8	230	31	330	24

For lung examination somatic risk is due to the dose to lungs, breast, bone surface, RBM and oesophagus lying in direct X-ray beam. Considerable scattered radiation dose is to the thyroid , liver and stomach. Genetic risk is minimal due to large distance from gonads to the radiation field.

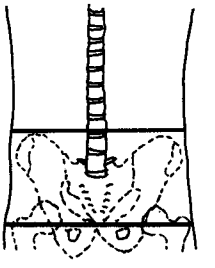
MEAN ORGAN DOSES (mGy) FROM LUNG EXAMINATION

Organ	CT 8800	CT 9800	CT 1200	CT MAX	SOMAT 2
Lung	14.4	33.5	26.6	28.6	26.0
Breast	10.4	26.0	38.7	35.1	37.4
Thyroid	1.4	10.1	4.7	7.2	4.3
Bone surface	1.8	6.3	4.9	5.3	5.3
RBM	2.9	9.9	7.8	8.4	8.4
Oesophagus	11.8	25.7	28.5	28.7	22.6
Liver	3.8	9.8	10.1	10.5	8.5
Stomach	2.7	6.9	7.1	7.4	6.0
Skin	10.9	33.4	32.6	27.0	32.5



MEAN ORGAN DOSES (mGy) ABDOMEN-PELVIS EXAMINATION

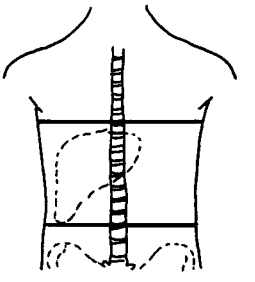
Organ	CT 8800	CT 9800	CT 1200	CT MAX	SOMAT 2
Colon	7.1	36.9	27.5	37.4	19.4
Liver	< 0.05	3.1	3.4	2.8	1.7
Stomach	< 0.05	5.4	5.8	4.9	2.8
Bladder	10.3	24.7	38.6	25.2	25.7
Uterus	10.0	24.0	36.7	25.0	25.3
Ovaries	10.3	24.7	38.6	25.2	25.7
Testes	1.6	2.7	6.5	5.9	3.5
Bone surface	2.2	7.6	9.2	6.5	5.6
RBM	3.7	13.2	16.0	11.7	9.7
Skin	12.8	41.0	56.4	30.0	44.3



Considerable genetic risk from this examination is due to high dose to ovaries which are subjected to direct X-ray beam. Testes with male patients are subjected to scattered radiation. Uterus dose was measured to assess conceptus dose in case when a pregnant patient was subjected to abdomen-pelvis examination. Dose distribution data from abdomen-pelvis exam. were used to calculate organ doses from liver examination.

MEAN ORGAN DOSES (mGy) FROM LIVER EXAMINATION

Organ	CT 8800	CT 9800	CT 1200	CT MAX	SOMAT 2
Oesophagus	1.7	5.5	5.9	4.7	4.8
Liver	12.4	39.9	43.3	34.5	35.5
Stomach	12.2	39.0	42.1	33.4	34.1
Bone surface	0.7	2.4	2.6	2.1	3.4
RBM	1.2	3.8	4.1	3.3	3.4
Skin	12.8	41.0	56.4	30.0	44.3



OPERATING PARAMETERS FOR BRAIN AND AXIAL ORBITS EXAMINATIONS

Scanner	Brain examination			Axial orbits examination		
	Slice width (mm)	Exposure settings (mAs)	Number of slices	Slice width (mm)	Exposure settings (mAs)	Number of slices

COMPARISON OF DOSE TO THE EYE LENS (mGy) FOR THIS WORK AND (5)

	NRPB R-249		This work	
Scanner	Head	Axial orbits	Brain	Axial orbits
CT 8800	31.0	37.0	9.4	26.2
CT 9800	56.0	51.0	13.0	43.5
CT 1200	76.0	78.0	19.0	36.1
CT MAX	42.0	40.0	9.9	41.0
SOMAT 2	45.0	37.0	9.2	52.6

Comparison of dose to the eye lens for CT examinations of the head region done in this study and those obtained in (5) shows that results for axial orbits examination are reasonably close with the exception of CT 1200. The results for brain and head examinations differ considerably because of different irradiation geometry. In many CT installations the gantry is tilted during brain examination by about 20° and the eye lenses are outside the direct radiation beam. For other examinations the mean dose to organs completely covered by the primary X-ray beam measured in this work is between mean and maximum organ dose values obtained in (5) and corrected for mAs values. Dose to organs partly covered by primary X-ray beam is difficult to compare because it critically depends on radiation field limits setting by the radiographer.

CONCLUSIONS

Irradiation geometry should be specified when organ doses from CT head examination are reported to enable their comparison. Visualization of brain region in CT head examination does not have to involve eye irradiation. The eye lens dose can be kept resonably low by properly setting radiation field limits.

ABSTRACT (See instructions overleaf)

Computed tomography (CT) has become a major source of the population exposure to diagnostic X-rays, and the knowledge of the doses delivered by the CT equipment has become very important. Considerable efforts should be made to keep these doses to a reasonable minimum, without sacrificing the image quality. The conditions of exposure in CT are quite different from those in conventional X-ray imaging. This has required the development of specific techniques for assessing patient dose from CT. The aims of this work were to determine the doses delivered to various organs of patients undergoing CT of abdomen, thorax and head as measured on the surface of the body and to estimate the risk to the patients. Dosimetric measurements were performed at two different CT scanners (Siemens SOMATOM DR-H and Shimadzu SCT-4500TE). The doses absorbed by different organs (gonads, thyroid, chest and eye lens) and by the examined partsof the body of 90 patients of various sex and ages were measured with TLD-700.

The doses absorbed by different organs during the diagnostic CT examination of the body depended on the technical parameters, such as the number of scans, mAs, the thickness of scans, scanning times, tube voltage and other characteristics, some of which depended on the type and severity of illness. Clinical parameters, such as patient size and composition and patient cooperation with regard to control and motion, also influence the dose and the image quality.

ABSTRACT

Medical radiological examinations make the greatest over background irradiation to the population. This fact results in to control and to restrict the exposure. The conception of "effective equivalent dose" (effective dose) -H is introduced into practice in order to control dose caused by irradiation of an organism during medical radiological examinations.

X-ray dose indicator(INDOR-S) is the complex of measuring and calculating equipment. X-ray dose indicator is used to define the effective dose equivalent(effective dose) during 61 types of radiological examinations.The apparatus connects to the electronic circuit of anode current definition of every radiological equipment.

Dose indicator fully automatizes the process of patient dose during any type radiological examinations. Dose indicator is conducive to essential reduction of patient irradiation facilitates the work of radiologist and his laboratory assistant. The apparatus gives an opportunity to choose the most sparing methods of patient radiological examinations.

RADIATION FIELD SIZES AND SKIN EXPOSURES IN ORAL RADIOGRAPHY

Clovis A. Hazin; H.J. Khoury; S.V. Silveira; F.J. Lopes Filho

Federal University of Pernambuco
50740-540 Recife PE, Brazil

INTRODUCTION

The increasing use of x-rays in preventive and diagnostic dentistry in Brazil has been cause of concern because dentists, in general, are not acquainted with the basic principles of radiation protection. Recently, the Brazilian Ministry of Health has urged the Departments of Health at the state level to develop actions to register dental x-ray units in their area of jurisdiction and to issue operating permits to those facilities which satisfy some basic technical requirements. On the basis of these recommendations the Instituto de Radioproteção e Dosimetria of the Brazilian Commission of Nuclear Energy has initiated a postal program to assess the performance of dental x-ray sets in the State of Rio de Janeiro (1). The postal kit used in that survey was similar to the one developed by the Bureau of Radiological Health of the U.S. Department of Health, Education, and Welfare (2). In continuation to that study, the Nuclear Energy Department of the Federal University of Pernambuco initiated a survey of dental x-ray apparatus to evaluate the operating conditions of that kind of equipment in Recife, the capital of the State of Pernambuco. The objectives of the survey were: a) to assess the degree of compliance of the equipment and procedures adopted by the dental practitioners in Recife with the accepted radiation protection standards, and b) to estimate the magnitude of the exposure to the patient resulting from a typical dental radiographic procedure.

METHODOLOGY

Data collection was made through both office visits and irradiation of dosimetric packs similar to the postal packs used at the survey carried out in the State of Rio de Janeiro (1). Each pack contains four LiF thermoluminescent chips (TLD-100), a 3-mm aluminum filter and two periapical films which are used to determine beam filtration, radiation field size, and skin dose to the patient. In each facility to be inspected the dosimetric pack was placed over a cubic water phantom and the end of the cone of the x-ray equipment was positioned over the center of the pack. The irradiation was performed by the dentist according to the procedure he (she) would use to get a standard maxillary molar radiograph. Therefore, it would be possible to compare the results of different technical procedures aiming to get the same radiographic picture. Besides, the dentists were asked to fill a form answering questions concerning the number and type of film used, the exposure time, the use of radiation protection devices, etc. The data gathered were used to determine patient skin exposure, radiation field size, and total beam filtration. This preliminary study comprised 76 x-ray sets, the majority of them made in Brazil. Most of the units operate at 50kV or 60 kV, since 70 kV x-ray sets are not common in dental offices in Recife.

RESULTS AND DISCUSSION

Figure 1 shows the range of beam diameters determined in this study. The data show that 34% of the units surveyed have beam diameters below the limit set by the Brazilian Association for Technical Standards - ABNT (4) and that 76% of the sets have beam diameters within the limit recommended by the NCRP-35 (3). It can be noticed that, despite the fact that most of the units are made in Brazil , the manufacturers adopted the NCRP limit of 7.5 cm as the standard for the beam diameter. On the other hand, 24% of the inspected units present field diameters exceeding the 7.5 cm limit. It means that a larger than necessary area of the skin face of the patient is being exposed, and that both patients and staff members receive higher radiation doses due to scattered radiation than they would receive if proper field sizes were used.

Figure 2 illustrates the distribution of skin exposures resulting from simulated maxillary molar radiographs taken in the offices surveyed. The results show that 67% of the x-ray units produce radiation exposures above the recommended value of 500mR (3). Moreover, 13.5% of the skin exposures were six times greater than the acceptable exposure for that type of radiography.

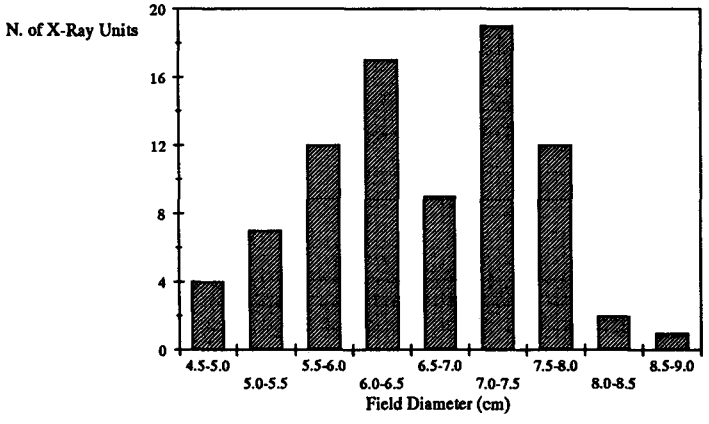

Fig. 1- Beam diameter distribution for the units surveyed.

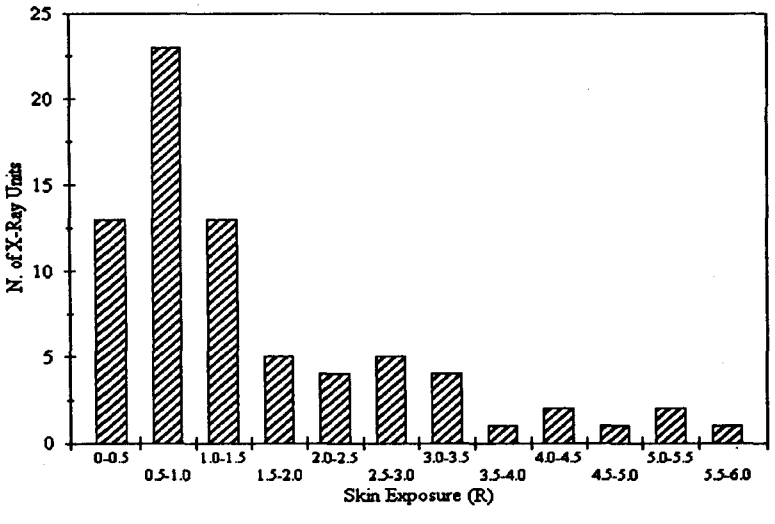

Fig. 2 - Distribution of skin exposures resulting from a standard maxillary molar radiography.

The causes for these excessive exposures are not different from those described elsewhere, specifically, insufficient filtration of the beam, too long exposures, and inadequate film processing. In fact, it was observed that dentists usually use old processing solutions and insufficient film developing times, compensating the inadequate procedure by increasing the exposure time. This is reflected in Fig. 3 that shows the distribution of exposure times used by the dentists surveyed. It can be noticed that 58.7% of the dentists adopt a exposure time around 1.0 s for the maxillary molar radiography, in spite of the fact that the majority of them use Ektaspeed film. Only 8.3% of the dentists utilize exposures of less than 0.5 s, which is considered to be adequate to get images with the Ektaspeed film without loosing radiographic quality. These results support the necessity of educating the dentist with respect to both film processing and radiation protection procedures.

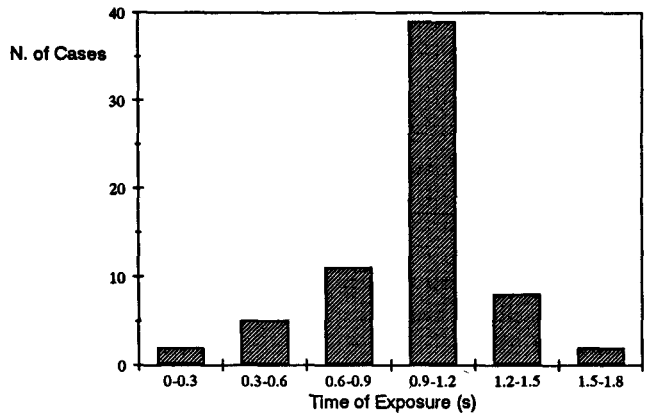

Fig. 3- Distribution of the exposure time used by the dentists surveyed.

The use of adequate beam filtration was also analyzed. The standard adopted recommends that the total filtration of the useful beam should not be less than 1.5mm Al for x-ray units operating at potentials between 50 and 70 kV [3]. However, the results show that 43.6% of the x-ray units surveyed do not meet this standard. The inadequate filtration results in an increase in the dose to the patient and to the dental staff, without contributing to the quality of the radiograph. Both the skin exposure and beam filtration distributions found in this survey are similar to those found by Peixoto and Ferreira (1) in the postal program developed by the IRD, in Rio de Janeiro. These findings reinforce the need of implementing a nationwide program to control the operating conditions of the x-ray dental units in Brazil. This program must be complemented by the training of dentists in the radiation protection procedures.

Resumen: El uso efectivo de los rayos x pretende lograr una buena calidad de imagen con la menor dosis de radiación posible, y con unas técnicas radiológicas óptimas.

El objeto del presente documento es determinar la dosis real a la entrada del paciente en diferentes tipos de exploraciones simples llevadas a cabo en varios hospitales españoles entre los años 1993 a 1995 comparándolas con las técnicas usadas en radiodiagnóstico. En estos hospitales, que constan de un total de 4600 camas, con 258 unidades de rayos x atendiendo a una población de alrededor de 2 millones de personas, han desarrollado un programa de optimización para reducir la dosis a paciente.

Se analizan un total de 2542 examenes de pacientes reales. El único criterio de exclusión, fue la edad, no considerándose pacientes menores de 14 años. Las datos valorados en este estudio, corresponden a aquellos en los cuales hay un mínimo de 10 pacientes por tipo de examen y sala.

1.- Introduction

The Commission of the European Communities in the document " Quality Criteria for Diagnostic Radiographic Images" (1), has proposed reference values for patient entrance doses that are representative of the radiation dose for an average-size patient.

A first analysis of the obteined data, allowed us to compare our results with the reference ones (3), establishing some initial criterion for the radiodiagnostic labour optimization.

But among all criteria we are paying special attention to the methodology used by the operators. In (4) we could see the influence of the collimation affair in the obtained doses, and the proposal of one index (area index), that completes the information.

The aim of this paper, is to value the influence of two other technical parameters, which selection is only controled by operating staff.

2.- Material and Method

The radiographic examinations chosen for this study were those of the lumbar spine (A.P. and LAT.), pelvis (A.P.), skull, and abdomen.

For the estimation of the entrance surface doses presented in this document, we have only considered the data of dose x area product measured, in each exploration, with the transmission camera. The method followed in the calculations is well decribed in (2), (3) and (4)

The data were taken from 962 real adult patient examinations (excluding the ones below 14)

We have only used those measurements for wich we have had at least 10 patients per examination and room.

We calculate for all the explorations in this study, the average value of surface entrance dose considering all the patients in each one.

Unless the thorax explorations, we define the optimum values for the KV and FFD (focus-film distance) for the rest ones, admitting in all cases a margin of tolerance. In the table 1 we can see the number of the total patients considered per esploration, the optimum values and margins for the studied parameters, and also the number of patients who are within each margin or both

EXPLORATION	Total	kV opt.	Number vs. kVopt	FFD opt	Number vs. FFD opt	Number vs. kV & FFD
Skull	**126**	> 70	**102 (81%)**	[95-105]	**33 (26%)**	**23 (18%)**
Pelvis	**174**	> 70	**103 (59%)**	[90-110]	**100 (57%)**	**92 (53%)**
Abdomen	**244**	> 70	**149 (61%)**	[90-110]	**118 (48%)**	**66 (27%)**
L. Spine A.P.	**214**	> 75	**94 (44%)**	[90-110]	**214 (100%)**	**94 (44%)**
L. Spine LAT	**204**	> 85	**67 (33%)**	[90-110]	**204 (100%)**	**67 (33%)**

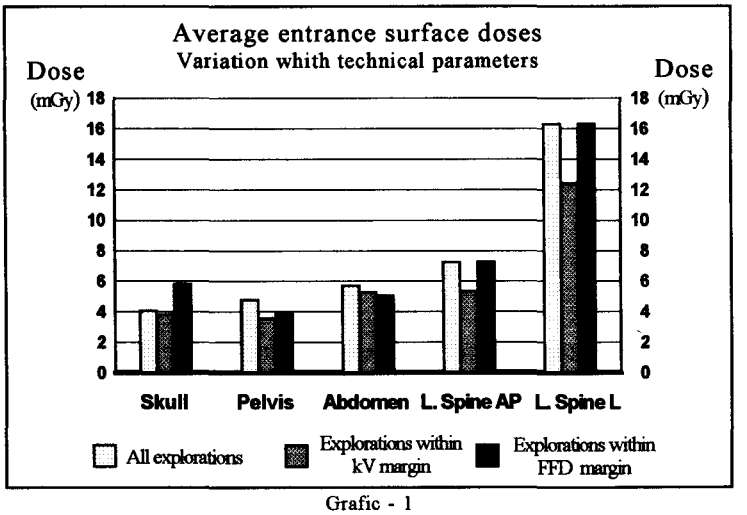
Table - 1

We can calculate the average dose value considering:
1° Those explorations within the kV margin
2° The same ones within the FFD margin
3° The same ones within both margins

The large number of the thorax explorations, and the diferent conditions of them in the diferent rooms, involves the exigency of other analysis.

For one room, we can consider diferent examinations, in some cases made by the same operator, with the same conditions except kV and FFD ones, studying their influence in the obtained doses.

3.- Results and conclusions



Grafic - 1

In the graphic we can see the large influence of the KV selection in all explorations.

This is more important in the lumbar spine and pelvis ones, reaching around 25% of dose in all the cases.

In the skull and abdomen ones, the dose reduction is 7% and 11.5% respectively

About FFD selection, only pelvis and abdomen explorations are significative. In both cases , the obtained value decreses adjusting the distance to the established range.

In the other explorations nothing can be said. In the case of the skull, because of the small number of data, and in the lumbar spine ones because all explorations are within the tolerance.

ABSTRACT (See instructions overleaf)

Interventional and therapeutic procedures are becoming an important part of today's radiological practice. Although these procedures do not contribute significantly to the total number of X-ray examinations performed annually in Poland (below 1% of 21.4 million)they should receive particular attention as they can result in high doses as well to patient as to staff. One of the most frequently carried out interventional radiology procedure in Poland are angiographies (with possibility of additional vessel therapy). This paper presents results of patient dose evaluation for angiography of heart (coronarography), brain angiography and renal arteries catheterization. The importance of technical features of X-ray equipment is underlined. The study was performed in three hospitals, using devices made by Siemens: two of these were Polydoros (with pulsed generators), and the third -the oldest one- was Angiotron CMP (with constant potential, conventional generator). Entrance surface doses to patients were measured using thermoluminescence dosemeters, which were placed directly on the patient skin. Absorbed doses to patients were computed using Monte Carlo simulation programme (own author's code). The results allow to see an influence of generator type and fluoroscopy dose-rate on the value of effective dose to patients.

Introduction

In the United Kingdom, radiation doses from medical sources make up 97% of the total collective effective dose to the population from man-made sources [1], due mainly to the large number of x-rays performed. The contribution of interventional radiology procedures to the collective effective dose in the U.K. is unknown as these procedures are not regularly monitored. The contribution of interventional to the population dose from medical exposures could be as high as 40% in some countries. Thus there is some uncertainty in the collective effective dose from medical sources in the U.K. Furthermore, there is no mention of interventional radiology by the National Protocol. Radiation dose and risks from these procedures are therefore of interest.

It is surprising, therefore that the effective dose to patients from many interventional radiology procedures has not been assessed in large scale regional studies. Though the frequency of the procedures is low, the dose for each examination can be high. Patient exposures are high because the screening times are often long and a large number of radiographic exposures are taken. It is therefore necessary to monitor the dose patients receive during these procedures.

Interventional studies performed on twenty-two different fluoroscopy sets were monitored as part of a Regional patient dosimetry programme. The data have been collected using a computer to read and reset the dose-area product meter and also to collect patient and examination details. Data is loaded onto the regional database at quarterly intervals. All the examinations performed in the room are monitored including many interventional procedures.

Method

Diamentors, (PTW, Freiberg), were used to measure the dose-area product. A Diamentor consists of a large area ionisation chamber and control box. Data was collected for a range of examinations including angioplasty, biliary drainage, embolisation and nephrostomy. The examinations included in this study were performed on twenty-two different sets.

The dosimetry method was based on recommendations made in the National Patient Dosimetry Protocol [2]. The dose-area product is particularly useful for assessing and comparing the radiation dose from screening procedures, where the dose-area product provides a more useful indication of overall patient exposure than measurements of surface dose to particular location. Calibration of the instruments was carried out insitu, using a method traceable to a National Standard [3]. The collection of data in this dose survey was automated by use of an IBM compatible laptop computer to read and reset the Diamentor remotely and also to record the patients and the examination details as follows;

Patients: Name, Age, Sex, Height, Weight

Examination:kV, Screening Time, Number of Radiographs, Number of Spot Exposures, Radiologist

This represents a convenient and practical method of collecting data for a large scale survey of this kind.

The results from each department were copied onto floppy disc and sent to the regional centre at quarterly intervals. At the data collection centre the results were loaded onto the database. In order to make meaningful comparisons, the dose area product values were size corrected, as described elsewhere [7] , to the value the patient would have received had they been reference man size. This method uses the concept of equivalent diameter [8]. The patient is approximated by a cylinder of water having the same height and weight as the body. This reduces the variability due to patient size but does not limit the patient size sample. This correction was applied only to examinations involving the main trunk of the body.

Uncertainties

The uncertainty in the dose-area product reading as quoted by the manufactures is ±3% [8]. The calibration factor, which converts the dose-area product meter reading to mGycm^2 is slightly dependent on the tube potential but a single calibration factor is applied to all the data resulting in an overall uncertainty of ±10% in the result.

Results

The results of the dose survey are summarised in table I, giving the mean and median dose-area product values and size corrected dose-area product for each examination. The number of patients, mean screening time, mean energy imparted number of radiographs and number of spot exposures are also given for each examination. The results presented include over seven hundred interventional procedures. Figure 1 illustrates the variation in dose during these procedures, with the dose received during barium studies also shown.

Table I Summary of Results for Interventional Procedures

Examination	Number of Patients	Dose-Area Product Gycm^2		Size Corrected Dose-Area Product Gycm^2		Mean Screening Time (secs)	Mean Number Radiographs	Mean Number Spot Exposures	Mean Energy Imparted mJ
		Mean	Median	Mean	Median				
Angioplasty	337	12.9	7.8	14.3	7.4	446.8	0.6	30.1	126.0

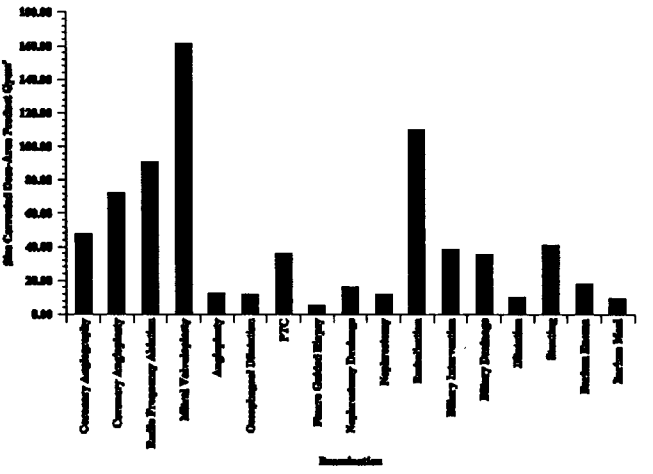

Figure 1 Mean Dose-Area Products for Interventional Procedures

Conclusion

Results are presented here from 2789 patients undergoing a range of interventional procedures. Comparing the results here with the results in [9], 47.7, 72.2,37 161.9 are the results obtained in this study compared with 66.5, 87.5, 68.9, 96.4 from [9] for coronary angiography, coronary angioplasty, biliary drainage and mitral valvuloplasty respectively. Though these examinations are infrequent, contribute significantly to the total dose from medical exposures. These results may be used to compare departments and hence optimise the dose during these procedures.

INTRODUCTION

Mammography is one of the most effective examinations for detecting breast carcinoma. Although the dose is usually much higher than that in other types of X-ray examination, that is accepted by the patient because for fears of suffering cancer. Benefit of relatively high doses derived from mammographic examinations is considered to well exceed the risk of cancer induction by radiation exposure.

The purpose of this study is to investigate patient dose of mammography in Japan by questionnaire sent to 531 institutions selected from whole Japan and direct measurements carried out in 28 hospitals in Aichi Prefecture. The user's guide in mammography published by NCRP(1) and Quality Assurance Program of American College of Radiology(2) were used to assess the exposure and image quality of mammogram.

METHODS

1. Dose Evaluation

At 28 hospitals in Aichi Prefecture selected randomly among those where mammographies were conducted, exposure conditions were surveyed and exposure in air of entrance surface at each mammographic equipment was measured using Victoreen Radocon 500 and ionization chamber Radocon type 30-330, 0.2cc (calibrated by using a national standard dosimeter). The pressed breast thickness of 4 cm was assumed. Average glandular dose to the whole breast per craniocaudal projection, Dg, (Dg=DgN x Xa, where DgN is f-factor (exposure-to-dose conversion factor), the average glandular dose per unit incident exposure and Xa is exposure in air) for 4cm thick compressed breast organ, 50% adipose + 50% glandular tissue breast, is estimated for each mammography unit. Beam quality was evaluated from measurements of first half-value layer (HVL) at each kV employed for mammography. Average glandular dose was computed from the radiographic techniques required to produce 1.3 Optical Density (OD) images.

2. Image Quality Evaluation

Image quality was evaluated using ACR Phantom (RMI 156) at the 28 hospitals where the exposure dose was measured. The film, intensifying screen and automatic developing machine used were the same as those used regularly at these institutions. The photographic density of the films was measured with a fuji 301RS densitometer. The film density was adjusted to 1.30 OD at the center of the image receptor. The developed films were measured, excluding artifacts (stains and flaws), for discrimination capability (complete discrimination was set as 1) and exceeded the standard by more than 10 points.

3. Estimation of Exposure Dose Based on Japan Survey

A questionnaire was sent to 1000 institutions throughout Japan where mammographic screening

examinations are produced. Based on the response, 531 institutions were selected as possible sites to estimate the average glandular dose per unit incident exposure dose. The dose estimation was made based on actual measurement data.

RESULTS

1. Fourteen of the 28 hospitals were using grids. The average glandular dose was 1.298 mGy and cases without grids were about one-half of this dose.

At nine hospitals (32.1%) image quality exceeded the standard (by more than 10 points) by using the ACR Phantom. Among these, eight hospitals used grids. Hospitals where the tube voltage exceeded 30 kV did not meet the standard. The average glandular dose for equipment exceeding the standard was 1.409 mGy; the mean for equipment not meeting the standard was one-half this figure (Table 1.).

Table 1. Average glandular dose(mGy) for QA test of ACR phantom.

QA Score	With Grid	Without Grid	Mean
≧10	1.388	1.582	1.409
<10	1.177	0.587	0.784

2. Estimation of Average Glandular Dose Based on Japan Survey

Based on the response to a questionnaire sent throughout Japan, the average glandular dose per one mammography was estimated at 1.795 ± 2.613 mGy. The average was less than 1 mGy at 240 institutions (45.2%) was less than 2 mGy at 305 institutions (76.3%). There were 365 institutions (87%) where the average was less than 3 mGy. There were 12 institutions where the average was more than 10 mGy (Fig. 1.).

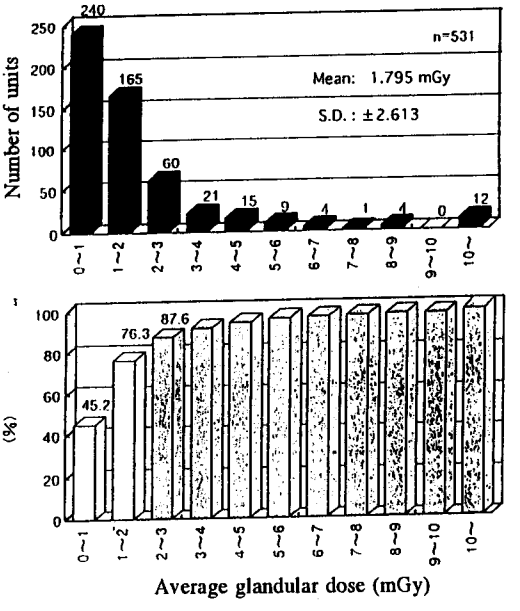

Fig. 1. Distribution of average glandular dose based on the questionnaire.

The institutions using grid for 43% of all institutions; 57% without grid. The average glandular dose was 1.667 ± 1.509 mGy for institutions using grids and 1.907 ± 3.229 mGy for institutions not using grids. For institutions where the average glandular dose was less than 2 mGy, 75% institutions were used with grids and 77% institutions were used without gird.

Among all the various equipment used, 66% combined molybdenum focusing, a molybdenum filter (0.03 mm) and a beryllium window for x-ray radiation opening for exclusive use for mammary x-ray photography. The dose of these institutions was 1.72 mGy. The dose at 54 institutions where x-ray equipment is used for general diagnosis using a tungsten tube was 1.17 mGy (Fig. 2.).

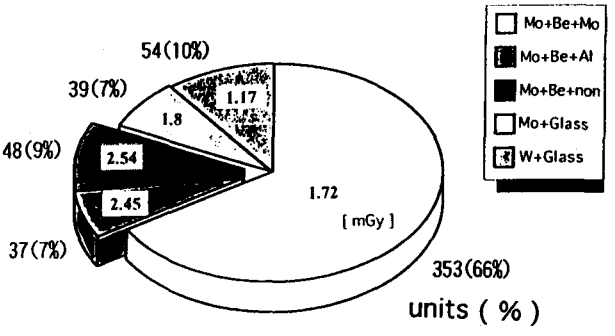

Fig. 2. Comaprison of average glandular dose based on X-ray equipment with focus,window and filter

CONCLUSION

The estimated dose for one mammography based on a nationwide survey in Japan was 1.795 mGy. The actual measurement at 28 hospitals was an average 0.992 mGy. Thus, the estimated dose was higher than that actually measured. Considering mammography accreditation program of ACR, it was suggested that the guidance level of average glandular dose delivered during mammographic screening examinations can be set 2 mGy.

INTRODUCTION

Breast dose from mammography has been estimated by various investigators, because of the established effectiveness of mammography in early screening for breast cancer and the relatively high sensitivity of the breast to radiation carcinogenesis (1,2). Nevertheless, to our knowledge, there is no available information in the literature about absorbed doses from mammography to organs other than the breast. The absorbed doses to the red bone marrow in the sternum and to the thyroid, due to scattered radiation from mammographic examinations, have been measured using a plexiglas upper-body phantom and thermoluminescent dosemeters. Their dependence on several parameters has also been examined.

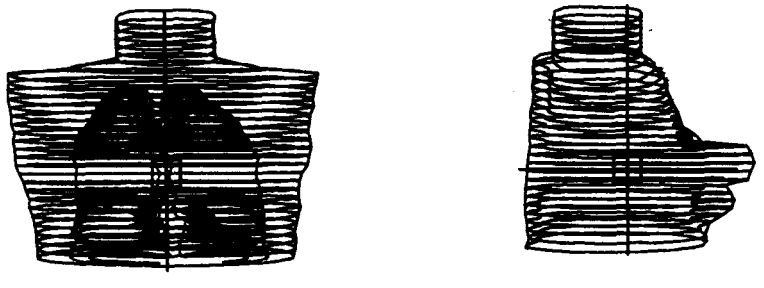
It is necessary to emphasise that this work is still in progress.

MATERIALS AND METHODS

A plexiglas upper-body phantom (figure 1) was used to simulate the female body. The phantom consisted of 30 slices, 1 cm thick, and it simulated the contour of a standard size female upper body. A spongy material inside the phantom simulated the lungs. The compressed breast was simulated by breast-shaped plexiglas slices of various sizes and thicknesses, its midline always aligned with a specific slice. Small holes capable to accommodate thermoluminescent (TL) dosemeters were drilled on each slice of the phantom. The locations of the holes were properly selected to correspond to the following organs inside the body: bone marrow in sternum, thyroid, oesophagus, left and right lung, stomach, colon and liver. In this paper measurements of the doses to the bone marrow and the thyroid are presented.

The dose measurements were performed using two LiF based TLD systems, namely TLD-100 (LiF : Mg, Ti) and GR-200 (LiF : Mg, Cu, P), on 10 sites into the phantom selected to cover the bone marrow in sternum and on 5 sites covering the thyroid.

The TL measurements were performed with a TL analyser Type 711 of the Littlemore Co. The glow-oven was first evacuated at 10^{-2} Torr and N_2 of high purity was left to flow during the readout. The heating rate was 2°C/sec. The light emission was detected by an EMI 9635 QA photomultiplier tube and the glow curves were stored in a computer via a 1024-channel ADC card operating in the MCS mode for further data analysis.



a. b.

Figure 1. The plexiglas upper body female phantom used in the present work.
a. Frontal view
b. Lateral view

Prior to any use the dosemeters were annealed; the TLD-100 at 400°C for 1 hour and at 100°C for 2 hours, whereas the GR-200 at 240°C for 10 min. Before the measurements all the dosemeters were post-irradiation annealed at 80°C for 1 hour. The crystals of both TLD-100 and GR-200 were grouped in terms of sensitivity within 2.5%.

The TL dosemeters were calibrated in beam, against a 10X5-6M ion chamber suitable for measurements in mammography, connected to a Radcal 9015 Monitor.

Most measurements were performed with GR-200 since they are much more sensitive than TLD-100 (at the energies involved by a factor of about 20).

The irradiations were performed on a IMS Giotto Mammography H.F. x-ray unit with a Mo/Mo anode-filter combination and source to image distance 60cm. A thorough quality control of the mammographic unit and the automatic film processor was done prior to the measurements with the phantom. The accuracy and reproducibility of all the exposure parameters (such as kVp, mAs, radiation output) and the automatic exposure control (AEC) system were tested and verified. The performance of the film processor was evaluated by sensitometry.

Measurements were repeated at several irradiation conditions as well as with different plexiglas thicknesses. The high voltage ranged from 26 to 32 kVp and the breast shaped plexiglas thicknesses were 2, 4.5 and 6 cm. These thicknesses correspond to 2.3, 4.9 and 6.4 cm of breast tissue, having a composition of equal parts by weight adipose and glandular tissue (3).

RESULTS AND DISCUSSION

Doses to the bone marrow in sternum and the thyroid at 10 and 5 different sites respectively inside the phantom were measured for three combinations of kVp and plexiglas thickness routinely used in mammography, namely 26 kVp - 2 cm, 28 kVp - 4.5 cm and 30 kVp - 6 cm. Table 1 presents the mean doses to the bone marrow and the thyroid in μGy/mAs and as a percentage of the corresponding entrance dose. These mean values were calculated by merely averaging the corresponding measurements at the different sites.

A general increase of the dose can be observed across the table as kVp, mAs and thickness increase.

Table 1. Mean doses to the bone marrow and the thyroid

	26 kVp, 12 mAs 2 cm plexiglas craniocaudal view		28 kVp, 32 mAs 4.5 cm plexiglas craniocaudal view		30 kVp, 64 mAs 6 cm plexiglas craniocaudal view	
Entrance dose	1197 ± 21 μGy		4550 ± 32 μGy		11934 ± 41 μGy	
	μGy/mAs	% entrance dose	μGy/mAs	% entrance dose	μGy/mAs	% entrance dose
bone marrow	0.40	0.40	0.79	0.56	1.27	0.68
thyroid	0.22	0.22	0.35	0.25	0.51	0.27

The doses measured were generally low, therefore it was decided to restrict further measurements at selected sites only, in order to avoid a prohibitive bulk of measurements. Three sites, namely BMmin, BMmax and BMmid, were chosen for the bone marrow, representing respectively the minimum dose, the maximum dose and the dose to the slice at which the breast shaped plexiglas was centred. One site, TH, was selected to represent the maximum dose to the thyroid.

The dependence of the doses on the mAs and the kVp was then examined separately. The first series of irradiations were performed at 28 kVp with 4.5 cm plexiglas at 24, 28 and 32 mAs (Table 2). These parameters resulted in mammograms with optical densities between 1.2 and 1.55. It was found that the dose rises linearly with the mAs, as it was expected. Therefore, these measurements provide some good evidence on the accuracy of our results, since the ratio dose/mAs remained constant.

Table 2. Dependence of the dose to the bone marrow and to the thyroid on the mAs

	24 mAs		28 mAs		32 mAs	
Optical density	1.21		1.40		1.55	
	μGy	μGy/mAs	μGy	μGy/mAs	μGy	μGy/mAs
BMmin	15.4 ± 1.6	0.64	18.5 ± 2.0	0.66	20.2 ± 1.8	0.63
BMmax	32.2 ± 2.7	1.34	38.9 ± 3.5	1.39	43.6 ± 3.9	1.36
TH	12.4 ± 0.9	0.52	14.6 ± 1.1	0.52	15.9 ± 1.1	0.50

The dependence of the dose to the bone marrow on the kVp was examined by a second series of irradiations which were performed at 32 mAs, with 4.5 cm plexiglas, at 26, 28, 30 and 32 kVp (Table 3). The dose again rises with kVp, being 2.5 to 3 times higher at 32 kVp compared to 26 kVp.

Table 3. Dependence of the dose to the bone marrow on the kVp

	Absorbed dose (μGy)			
Site	26 kVp	28 kVp	30 kVp	32 kVp
BMmid	23.5 ± 3.1	30.4 ± 5.2	46.6 ± 9.9	54.0 ± 12.3
BMmax	27.5 ± 3.8	38.2 ± 6.8	48.5 ± 10.1	78.5 ± 15.2

The maximum dose to the bone marrow and the thyroid after a complete breast screening examination was finally evaluated. A typical screening examination consists of two craniocaudal and two mediolateral views, one for each breast. In order for our results to be meaningful, the irradiation parameters were properly selected to closely match those of a typical examination for the x-ray system used, i.e. 26 kVp, 12 mAs for a plexiglas thickness of 2 cm, 28 kVp, 32 mAs for a plexiglas thickness of 4.5 cm and 30 kVp, 64 mAs for a plexiglas thickness of 6 cm. These conditions result in mammogram with optical densities of 1.2 to 1.6, which is the range normally required in a typical examination (Table 4).

Table 4. Total examination dose (two craniocaudal and two mediolateral views)

	Absorbed dose (μGy)		
Site	26 kVp, 12 mAs/view 2 cm plexiglas	28 kVp, 32 mAs/view 4.5 cm plexiglas	30 kVp, 64 mAs/view 6 cm plexiglas
BMmin	14.5 ± 2.5	55.2 ± 5.2	129 ± 25
BMmid	20.3 ± 3.2	93.9 ± 7.5	199 ± 54
BMmax	26.4 ± 3.5	155 ± 20	337 ± 95
TH	10.6 ± 2.1	40.3 ± 6.2	100 ± 28

Table 4 shows that the maximum measured doses to the bone marrow and the thyroid ranged from 25 to 340 μGy and from 10 to 100 μGy respectively, for a complete examination (four views), depending on breast thickness.

CONCLUSIONS

The absorbed doses to the red bone marrow in the sternum and to the thyroid due to mammographic examinations were measured and their dependence on several irradiation parameters was examined. It was found that the doses depend strongly on the kVp and rise linearly with the mAs. The measured doses for a complete screening examination were found to be generally low. However the dose to the bone marrow can become significant for large breast thicknesses.

RADIATION DOSES AND RISKS TO NEONATES UNDERGOING COMMON RADIOGRAPHIC EXAMINATIONS IN THE NEONATAL INTENSIVE CARE UNIT

Brian J. McParland, PhD, FCCPM and Richard Lee, DCR, RT

Department of Medical Imaging
King Fahad National Guard Hospital, Riyadh, Saudi Arabia

INTRODUCTION

Neonates in the Neonatal Intensive Care Unit (NICU) can receive large numbers of radiographs owing to the clinical conditions they may present [1]. More neonatal radiation dosimetry data are required for three fundamental reasons: (1) to aid in the establishment of reference dose levels for interinstitutional comparisons; (2) to improve childhood cancer risk estimates following neonatal exposure; and (3) to indicate appropriate directions for dose reduction.

This paper describes an investigation of two different NICU radiological techniques with significantly different neonate doses. While patient-matched images taken with both techniques were assessed in a blind review, this component of the study is beyond the scope of this paper and is not discussed here.

The development of neonatal reference dose levels also requires establishing a mechanism of relating neonate size and dose. We have further investigated the variation of neonate ESD and EI with the equivalent patient diameter, d, given by [2,3],

$$d = 2\sqrt{\frac{W}{\pi L}} \qquad [1]$$

where d is in cm, W is the neonate weight in g and L is the neonate length in cm. The ESD and EI data for both techniques were fit by exponential functions in d,

$$ESD = ESD_o \exp(m_{ESD}\, d) \qquad [2a]$$
$$EI = EI_o \exp(m_{EI}\, d) \qquad [2b]$$

METHODS AND MATERIALS

The two techniques reviewed in this study were a "conventional" technique, used at this institution for a number of years, with the kVp variable between 50 and 60 kVp for a fixed 0.8 mAs, and a "low-dose" technique with the kVp increased to between 62 and 70 kVp and the mAs reduced to either 0.4 or 0.5 mAs. This latter technique is similar to that recommended by the CEC [4]. Patient dosimetry was evaluated from the technique used and previously measured dosimetric quantities. Patient dose data evaluated were the entrance skin dose (ESD), the dose-area product (DAP), the energy imparted (EI) and the mean dose (D), estimated by the ratio of the EI to the neonate weight.

All images were acquired with a General Electric AMX-4 mobile unit and a 400-speed Kodak T-Mat G/Lanex Regular film-screen combination. While others have judged such a speed class to yield less suitable images than slower speeds [5], we have found it to be clinically adequate.

The normalized in-air collision kerma ($K_{C,AIR}$/mAs) was measured for all kVp values used in the study using a 15cc thin window ionization chamber and electrometer (Keithley 96035 and 35050A), both with NIST-traceable calibrations. The ESD was determined using these measured $K_{C,AIR}$/mAs values and the technique recorded by the technologist. Backscatter and attenuation through the

incubator Perspex were accounted for and the mass energy absorption coefficient ratio averaged over the energy spectrum was evaluated for ICRU muscle and used to convert to dose. The DAP was approximated by the product of the ESD and the cross-sectional area of the imaged anatomy determined retrospectively from the film. The EI was calculated from the DAP and conversion factors evaluated by Chapple et al [6].

RESULTS

A total of 363 radiographs were acquired for 77 neonates. Of these, 262 films were acquired for the "conventional" technique (160 chest, 63 abdomen and 39 chest/abdomen combined); 101 films were obtained for the "low-dose" technique (72 chest, 13 abdomen and 16 chest/abdomen). The mean number of radiographs per neonate was 4.7, with a range of 1 to 41. Table I presents a summary of the dose quantities measured, the percentage reductions achieved by switching techniques and the levels of statistical significance in these reductions. Table II presents the log dose gradients, m_{ESD} and m_{EI}, determined by taking natural logarithms of both sides of Equations (2a) and (2b) and performing linear regression.

The major risk of concern for the irradiated neonate is childhood cancer. By using fetal risk factors to estimate the neonatal risk, the excess risk of cancer mortality during the first 15 years of life determined from the Oxford Survey of Childhood Cancers [7] is 0.0288 mGy^{-1} (95% confidence limits, 0.0171 mGy^{-1}: 0.0436 mGy^{-1}). A "worst case" estimate using the upper 95% confidence limit would put the risk per radiograph in the conventional technique to be about 1 in 5210, 1 in 4250 and 1 in 3370 for chest, abdomen and combined chest/abdominal films, respectively. The corresponding risks for the low dose technique are 1 in 6550, 1 in 5460 and 1 in 3530. Most neonates receive multiple films: switching techniques for our "worst case" baby who received 41 chest films would reduce the excess relative risk of childhood cancer death from 1 in 127 to 1 in 164.

CONCLUSIONS

A switch to a neonate radiological technique using a 400-speed film/screen combination and kVp's in the range of 62 to 70 kVp and 0.4 mAs results in considerably reduced doses. Although not discussed here, an independent and blind comparison of clinical images taken with both techniques by three radiologists showed no statistically significant difference in image quality.

ABSTRACT (See instructions overleaf)

The ever increasing exposure of population to irradiation because of X ray diagnostics of respiratory tract is not always followed by an adequate radiation protection measures. According to the well known radiobiological law, young organisms are more sensitive to radiation than adults. Therefore, in agreement with the recommendations of WHO, and UNSCEAR, special care has to be taken in radiation protection of children.

The basis for radiation protection is the exact knowledge of doses. The patient dose determination in X ray diagnostics is not a simple task. The dose depends from the kind of examination, the technical condition of the equipment, the way and method of exposure, the patient itself and from the accuracy and precision of dosimetric system. Even with a well calibrated dosimetric system, good statistics of measurements is needed for patient dose estimation. We measured the dose on 45 patients divided in 5 age groups. The dose was determined on the back, the breast, the thyroid, the armpit, the left eye and the gonade region. Similar measurements were also carried out in sinus examination of a group of children.

On the basis of the dose measurement results the risk of some cancerous and genetic hazards was estimated.

AUTOMATION OF TLD DOSIMETRY FOR SIMPLE RADIOGRAPHIC PROCEDURES USING THE HARSHAW 6600 MONITORING SYSTEM

D.A.Broadhead, C-L Chapple and K.Faulkner
Regional Medical Physics Department Newcastle General Hospital
Westgate Road, Newcastle-Upon-Tyne NE4 6BE England

Introduction

Simple radiographic procedures are the most frequently performed x-ray examinations and as a result patient doses should be monitored. In view of the number of examinations performed, it is vital that automated methods of performing direct patient dose measurements are developed. The Harshaw 6600 extremity monitoring system has the potential for use in performing a large scale patient dose survey during radiographic procedures but has not been previously used for this purpose. The potential advantages of this system are, fast readout rate, reproducible time temperature profile, no mechanical contact with the dosemeter and barcode identification allowing individual elemental correction coefficients to be applied to each chip which improves the precision of the result.
Before this system could be used for this purpose, it was rigorously tested. The reproducibility, batch uniformity, detection limit, energy response, fading were all assessed. The overall uncertainty of the results was assessed and compared with the value recommended by the U.K. National Patient Dosimetry Protocol (1). This system has been used to measure fifteen hundred patient dose measurements to date.

Method

The examinations chosen to monitor were chest PA, abdomen AP, pelvis AP, lumbar spine AP and lumbar spine LAT as these are the most frequently performed radiographic exposures. Each department were sent a set of one hundred TLD chips (extremity monitors, x-rads) to use on the patients and ten x-rads to use as background dosemeters, a set of forms to record both patient and examination details. The radiographer placed an extremity monitor in the centre of the field of view, the exposure was taken and the extremity monitor was removed and attached to the patients form. The aim was to collect twenty patients for each category. Once the extremity monitors had been used they were returned to the regional centre where the results were processed and the patient and examination details along with the dose results were entered onto the regional database. A report was generated giving a summary of the dose information.

Results

Table I Performance Testing Results

Test	Results
Reproducibility	2.9%
Batch Uniformity	3.1%
Detection Limit	0.1mGy
Fading (pre-irradiation)	25% over 3 months
Fading (post irradiation)	12% over 3 months
Energy Response	1.6 - 1.3 rel Cs^{137} energy range 45-104keV
Overall Uncertainty at 0.1mGy	20.7%

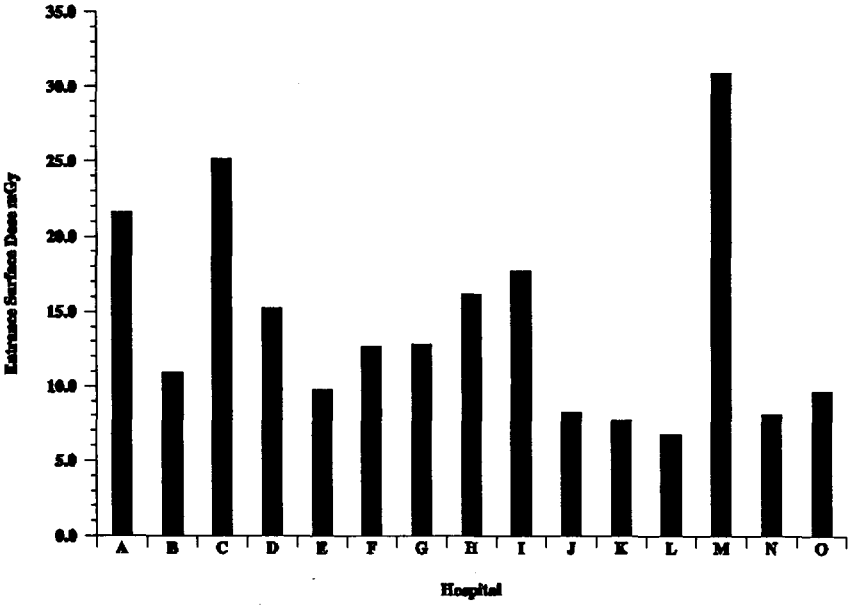

Figure 1 Entrance Surface Dose Results for Lumbar Spine Lateral Examination Throughout the North of England

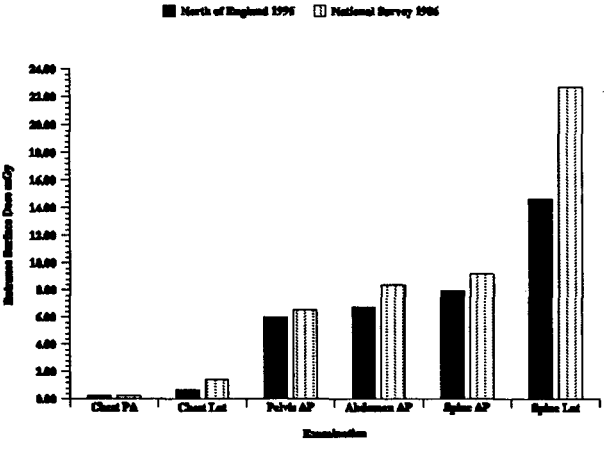

Figure II Mean Doses From the North of England Compared with the National Survey

Table II - Summary of Mean Dose Results and Parameters

Examination	Number of Patients	Entrance Surface Dose mGy			kV	mAs
		Mean	Maximum	Minimum	Mean	Mean
Chest PA	299	0.25	3.63	0.00	71	5.8
Chest Lat	32	0.74	3.59	0.20	80	11.9
Abdomen AP	178	6.77	70.58	0.38	71	35.1
Pelvis AP	291	6.08	65.65	0.23	70	31.6
Lumbar Spine AP	298	8.01	77.43	1.03	74	37.2
Lumbar Spine Lat	291	14.67	92.13	0.48	85	47.5

Figure I illustrates the range in dose values for lumbar spine lateral examination throughout the North of England. Figure II shows the variation in dose between the different examinations and compares results from the North of England with the National Survey [2]. Table I gives a summary of the performance results of the Harshaw extremity monitoring system. Table II lists the mean, maximum and minimum dose results for each examination along with the mean kV and mAs used.
The lumbar spine Lat and abdomen AP results are comparable to the results in [3] of 14 and 5.1 mGy respectively. The chest PA result presented here is higher than the result in [4] of 0.15mGy. There was a broad spread of doses between hospitals for example there was a factor of 4.5 between the minimum mean dose and the maximum mean dose for the lumbar spine lateral examinations. The mean weight of the patients included in this survey was 70.0kg with a standard deviation of 14.8kg.

Conclusion

The Harshaw 6600 personnel monitoring system can be used to monitor patient doses during simple radiographic procedures. The overall uncertainty is within the limits recommended by the National Patient Dosimetry Protocol. One thousand five hundred patient dose results have been presented from seventeen different tubes throughout the North of England. Mean entrance surface dose values are presented for the examinations of chest PA, chest LAT, abdomen AP, pelvis AP, lumbar spine AP and lumbar spine Lat. The results are lower than the results obtained in the last National Survey but are comparable to results from recent surveys.

DIAGNOSTIC RADIOLOGY DOSIMETRY USING IONIZATION CHAMBERS

Maria da Penha Albuquerque and Linda V.E. Caldas

Instituto de Pesquisas Energéticas e Nucleares
Comissão Nacional de Energia Nuclear/SP
C.P. 11049 - CEP 05422-970 - São Paulo - Brazil

INTRODUCTION

Due to the number of diagnostic X-rays equipments in operation in Brazil and to the fact that medical exposure to radiation is by far the major source of exposure to ionizing radiation of the population, the development of a control method to these equipments is being very important, including dose reduction techniques. It is clear that a lot of studies is being carried out in this field (1,2), but until now, in Brazil and Latin America, there is no operational system or method to calibrate dosemeters used in diagnostic radiology measurements. Since 1980 instruments are being calibrated at the Calibration Laboratory of IPEN at radiotherapy and radiation protection levels. Considering the indicated necessities, studies have been undertaken in order to improve the calibration service with tests at the diagnostic radiology level. The objectives of this work are the determination of diagnostic radiology qualities for instruments calibration using a therapy system and to test some instruments used in diagnostic radiology measurements.

MATERIALS AND METHODS

The X-rays generating system consists of a Rigaku Denki generator, model Geigerflex, coupled to a Philips tube model PW/2184/00 (tungsten target and beryllium window). This system was used to establish the diagnostic radiology qualities according to the German norm DIN 6872, part 1 (3), in the range from 30 to 50 kV. The main characteristics of this radiation system are shown in Table I.

Table I. Characteristics of the Rigaku Denki X-rays generating system.
Focus-chamber distance : 100 cm.

Qualities	Tube Voltage kV	Additional Filtration mm Al	Half Value Layer mm Al	Effective Energy keV	Exposure Rate x 10^{-4} C/(kg.min)
DN1	30	2	0.947	19.0	4.29
DN2	40	4	1.84	28.2	3.71
DN3	50	10	3.61	38.9	1.21

The exposure rates were measured with the secondary standard parallel plate ionization chamber (0.03 cm^3) that was calibrated at the National Physical Laboratory (NPL), England. This chamber was used considering its low energy dependence in this range. The maximum tube voltages (kVp) were determined by spectrometry using an Intertechnique spectrometer, with a HPGe Σurisys Mesures detector. Three ionization chambers made at IPEN(4) and four portable monitors usually used in Brazil for diagnostic radiology measurements were used to compare the results obtained with the secondary standard ionization chamber. Their main characteristics are shown in Table II.

Table II. Main characteristics of the ionization chambers tested at diagnostic radiology level.

Instrument	Type	Window Material	Volume cm^3
(A) IPEN-01-Graphite	Clinical dosemeter	Aluminized Mylar	0.6
(B) IPEN-02-Aluminium	Clinical dosemeter	Aluminized Mylar	0.6
(C) IPEN-04- Graphite	Clinical dosemeter	Aluminized Mylar	3.4
(D) VICTOREEN 660-3	Portable Monitor	Equivalent tissue plastic	4
(E) BABYLINE 81-INT	Portable Monitor	Equivalent tissue plastic	515
(F) BABYLINE 81-RATE	Portable Monitor	Equivalent tissue plastic	515
(G) RADCAL 10X5-180	Portable Monitor	Policarbonate	180
(H) RADCAL 10X5-1800	Portable Monitor	Policarbonate	1800

RESULTS

The maximum tube voltages (kVp) obtained using the HPGe spectrometer are shown in the Fig. 1. The obtained values were approximately 31.5, 41.4 and 51.8 kV respectively for the qualities called DN1, DN2 and DN3 by the German norm DIN 6872. The Fig. 2 shows the spectra measured at the same qualities.

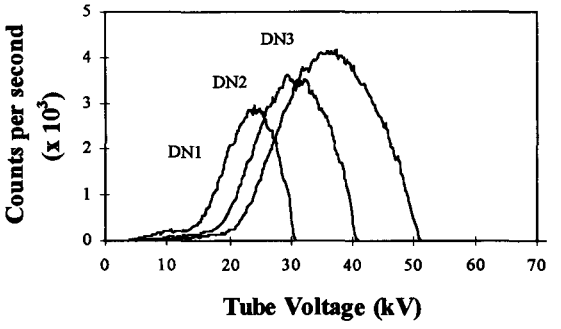

Figura 1. The maximum tube voltage (kVp) determination to DN1, DN2 and DN3 qualities.

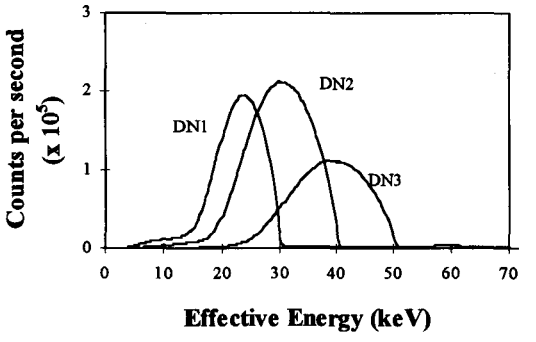

Figura 2. Spectra of the qualities DN1, DN2 and DN3.

The Fig. 3 and 4 show the energy dependence of the tested instruments.

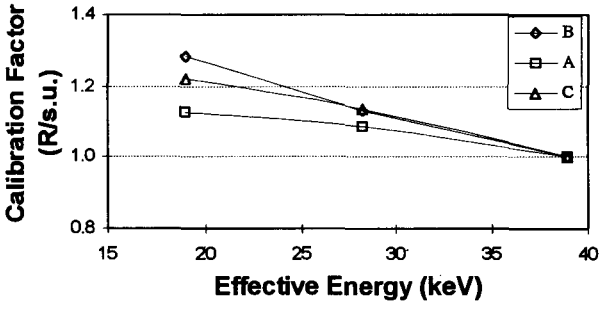

Figura 3. Energy Dependence of the IPEN parallel plate ionization chambers. All values were normalized to 50 kV to make easy the comparison.

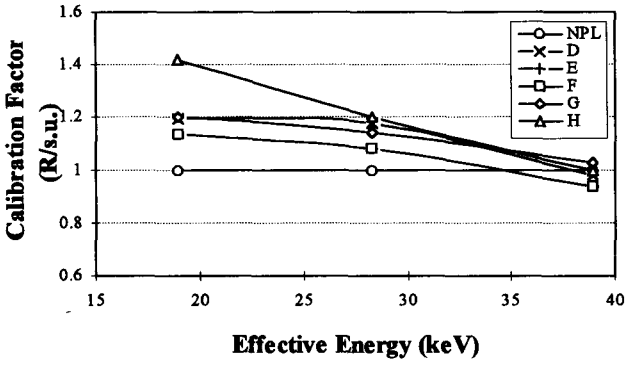

Figura 4. Energy dependence of the portable monitors. All values were normalized to measurements made with the NPL secondary standard ionization chamber measurements.

The Fig. 3 shows that among the homemade chambers the graphite electrode chamber, with a volume of 0.6 cm^3, presents the best energy dependence (13%), which could be compared with that of the secondary standard ionization chamber (8%). In the case of the portable monitors (Fig. 4) the monitors D, E, F and G show less than 20% of energy dependence related to the NPL secondary standard ionization chamber and can be recommended to be used in this range.

CONCLUSIONS

The preliminary results show the importance of the instruments tests at diagnostic radiology qualities, in the case of ionization chambers and specially for some portable monitors. This work is being extended extended for other types of instruments normally used in this kind of measurements; the establishment of the radiation qualities from 60 to 120 kV must be performed to complete the range used in diagnostic radiology, with another adequate X-rays system.

ACKNOWLEDGEMENTS

The authors acknowledge the International Atomic Energy Agency (IAEA) for the donation of the spectrometer, Dr. G. Drexler and Dr. W. Panzer for the related visits and collaboration.

ABSTRACT (See instructions overleaf)

The possibilities of determination of X-ray effective energy using the energy dependence of the response ratio of two thermoluminescent dosimeters are presented. CaF_2:Mn dosimeters with a large and LiF:Mg,Ti with much lower energy dependence, were used. The calibration factors were obtained for the energy of ^{137}Cs gamma rays and dosimeters energy dependences measured with X-ray beams with the known effective energies were normalized to ^{137}Cs gamma radiation. The results obtained from the energy calibration curves were compared with the calculations using the ratios of the mass-energy absorption coefficients and pertain uncertainties were discussed. The method was applied for effective energy determinations of diagnostic X-ray machines.

NIOBIUM FILTER EFFECT ON PATIENT EXPOSURE AND IMAGE QUALITY

INTRODUCTION

The estimated annual dose to the population due to radiological examinations has reached by now the same level of the natural background. In order to reduce the probability of stochastic effects, it's necessary to minimise the medical exposure doses (1). In addition to the traditional techniques employed for dose reduction (intensifying screens, post-elaboration programs, beam filtration...), a niobium filter has been recently introduced with the property of having an X ray absorption peak between 19 and 30 keV (2), thus eliminating the portion of the spectrum that doesn't contribute to the radiological image but increases the patient dose. In this report, some of the image quality characteristics are analysed in order to compare the images obtained with and without filter in usual traditional radiology.

MATERIALS AND METHODS

A NIOBI - X filter, consisting of a 50 μm thick layer of niobium, was used to perform the measurements and obtain the film characteristic curves. The film employed was the Fuji HR-A coupled with a Fuji EC-A screen. The exposures were performed at 60, 80 and 100 kV using a 15 step aluminium wedge to achieve the curves. These curves report the optical densities (O.D.) corresponding to steps of increasing thickness. For each considered voltage, the following curves were obtained:

- the 1st in standard conditions of kV and mAs;
- the 2nd in the same conditions of the 1st adding the Nb filter;
- the 3rd was obtained with the Nb filter in order to achieve almost the same optical densities of the 1st varying the mAs;
- the 4th was obtained with the Nb filter in order to achieve almost the same optical densities of the 1st but increasing the kV and reducing the mAs.

For the dose measurements, the Victoreen NERO was used; this equipment also allowed to check the output parameters of the X ray tube. A further aspect analysed was the differences in spatial resolution with and without filter using the Victoreen Focal Spot Test Tool testing seven different exposure conditions (3).

RESULTS

In Fig. 1, 2 and 3, the experimental data of the characteristic curves are represented. The contrast, expressed as the gradient of the linear part of the fitted experimental data in the curve between the optical densities of 0.25 and 2 over the fog, was calculated. In table 1, the results of each exposure are displayed, including dose measurements (for practical reasons these measurements were performed at different focus - film distances). Being the dose proportional to the mAs, the doses normalised to the mAs are also reported with the respective percentage of reduction. In general, the simple addition of the Nb filter doesn't affect the film contrast but reduces its speed, expressed as the reciprocal of the exposure needed to obtain an O.D. of 1. Varying the mAs and/or the kV suitably, it's possible to obtain characteristic curves that are similar to those obtained without adding the filter. As to the 60 kV curves, the filter effect results in diminuishing the film speed more effectively with respect to the other energies. This can be explained with the absorption peak of niobium that is closer to the average energy of the X ray beam. The reported data shows that the addition of the filter with a suitable choice of exposure parameters results in a remarkable dose reduction. From the data in table 2, we can argue that the filter, used with increased kV and reduced mAs, usually doesn't affect and even improves spatial resolution.

CONCLUSIONS

Finally, we retain to argue that the employ of Nb filter reduces the patient doses without affecting the image quality, allowing a correct medical diagnosis. In the Radiology Department of the Istituti Clinici di Perfezionamento, Milan, the Nb filter is currently used on several radiological devices.

PERFORMANCE OF MAMMOGRAPHIC UNITS

Parviainen T, Servomaa A
Finnish Centre for Radiation and Nuclear Safety
P.O.Box 14, FIN-00881 HELSINKI, Finland

ABSTRACT

The performance of about 50 mammographic units used for mammographic screening in Finland was measured according to the Nordic QA recommendations. The measurements focused on radiation output and quality, focal spot size and spatial resolution, performance of the automatic exposure control (AEC) system, the sensitivity of the image receptor, and film processing. The results show substantial deviations from the recommended values in older units, especially in the focal spot size and in the performance of AEC, but most of the modern mammographic units meet the Nordic performance recommendations to a great extent.

INTRODUCTION

The frequency of mammographic examinations increased manyfold in Finland when the nationwide breast cancer screening programme started in 1987. About 150 000 women are screened annually in Finland[1]. In 1994, about 190 mammographic units were used for mammographic examinations, of which 81 units were used for screening.

High requirements are placed on low-contrast and spatial resolution in order to detect small density differences and small microcalcifications in the breast. The whole imaging chain should be included in the performance measurements, because many parameters in the imaging chain affect the breast dose and image quality. Many studies show deficiencies in the performance of mammographic units. In a Swedish study[2], the tube current deviated from the recommended values in 25%, the focal spot size and spatial resolution in about 60% and the base plus fog in film processing in about 40% of the units measured. A study of the Dutch mammographic quality control[3] revealed deviations of over 30% in darkroom light tightness,in AEC exposure settings and phantom density, in AEC object thickness compensation, in viewing box illumination and in breast compression force. The Nordic countries and the European Union have issued recommendations for the performance and quality assurance of mammographic units[4,5]. We have measured the performance of about 50 mammographic units used for mammographic screening in Finland according to the Nordic QA recommendations.

MATERIAL AND METHODS

The measurements focused on radiation output and quality, image quality, the performance of the automatic exposure control (AEC) system, the sensitivity of image receptor, and film processing. The measurements were made according to the Nordic QA recommendations[4]. The x-ray tube voltage was measured with a kV_pmeter calibrated against an x-ray spectrometer. Focal spot size was measured with a star-test plate. Performance of AEC was tested with respect to object thickness compensation. Film processing was tested sensitometrically by measuring base & fog, gradient and relative speed. Film-screen sensitivity was tested by measuring the dose to image receptor for net optical density 1.0. Spatial resolution was measured with a spatial resolution test plate in a CGR test phantom perpendicular and parallel to the tube axis. Breast compression was measured with a bathroom scale. Radiation output, and linearity was measured by using an MDH 1515 radiation monitor provided with a mammographic ionization chamber (Model 10x5-6M) calibrated in the

secondary standard laboratory. The measuring parameters and methods are described in more detail in the Nordic recommendations for quality assurance in mammography[4].

RESULTS

Table 1 shows the mean values and ranges of the various measured parameters and the recommended values. The greatest deviations from the Nordic recommendations were found in the focal spot size and spatial resolution and in the performance of automatic exposure control. AEC performance fails in the sense that the film optical density depends on the object thickness. Figure 1 shows the distrubution of the focal spot length. Figure 2 shows the gradient distribution (OD 0.25..2.0) of sensitometric curves in film processing.

DISCUSSION

The results show major deviations from the Nordic recommendations. The greatest deviations were detected for older mammographic units. The performance of the new units meets to a great extend the Nordic recommendations. With regard to various parameters about 80% of the units meet the linearity recommendation of the radiation output, film processing meets about 80–90%, automatic exposure control about 45%, spatial resolution about 25–75% (two directions) and sensitivity of image receptors about 70% of the corresponding recommendations. Some of these deviations are similar to the findings reported earlier[2,3]. The performance of all units cannot be expected to meet the recommended values completely within a short time. When old units are replaced by new types, the recommended performance will be achieved gradually.

LOW-CONTRAST PERFORMANCE OF CT UNITS

Servomaa A, Karppinen J, Heikkilä M
Finnish Centre for Radiation and Nuclear Safety (STUK)
P.O.Box 14 FIN-00881 Helsinki, Finland

ABSTRACT

Measurements of patient doses in head CT examinations and measurements of image quality at various surface doses were made for 20 CT units of various types and ages. The mean Multiple Scan Average Dose (MSAD) in head CT examinations was 73 mGy (range 44...121 mGy). Only about 35% of the examinations met the guideline of 50 mGy recommended by IAEA. Wide variations in noise and in low-contrast performance were found in new CT units. The doses needed to detect Ø 2 mm details of 0.6% contrast varied in the new CT units by a factor of about six. The threshold diameter of the low-contrast details varied between 2 and 4 mm and the noise by a factor of about two at a dose of 50 mGy. Spatial resolution varied between 0.8 and 1.0 mm.

INTRODUCTION

The technical performance of CT units has improved in recent years and new innovations have been taken into use, for example the spiral CT. In spite of the technical improvement, patient doses have not decreased as expected. In contrast, patient doses in CT examinations have increased[1]. Patient doses are high in CT examinations[2,3], often considerably higher than in conventional x-ray examinations. Although CT examinations account for only about 2% of all x-ray examinations in Finland[4], they account for about 15% of the collective dose. High doses are often used in order to obtain good image quality, even though lower quality would sometimes be sufficient for reliable diagnosis.

The X-ray spectrum affects both image quality and patient dose. The spectrum depends primarily on the anode material, tube voltage and total filtration. Wide variations appear in the total filtration between various CT units, but only small differences in tube voltages. The basic measures for image quality are spatial and contrast resolutions and image noise. High spatial resolutions are needed to detect small details and high contrast resolutions to detect low-density differences in soft tissue.

MATERIAL AND METHODS

The low-contrast performance of 20 CT units of various types and ages used in Finnish hospitals were measured at various patient doses. Multiple scan average doses (MSAD)[5] were measured on the surface (depth 1 cm) of a Ø 16 cm perspex phantom and on the rotation axes free in air by using an MDH 1015 radiation monitor provided with a CT ionization chamber (Model 10X5 - 10.3 CT) calibrated against the secondary standard. Spatial resolution and low-contrast performance were measured by using an RMI image quality phantom provided with test objects for spatial resolution and low-contrast (0.6%) resolution. Image noise was measured as the standard deviation (SD) of pixel values in a Ø 16 cm water phantom.

RESULTS

Table 1 shows the MSAD doses on the surface of the Ø 16 cm perspex phantom and the radiation output measured on the rotation axes free in air. Only about 35% of the MSAD doses corresponding to the mean mAs value of 440 used in head CT examinations in Finland meet the IAEA recommendations for CT examinations[6] of the head (MSAD of 50 mGy in the middle of Ø 16 cm perspex phantom).

Figure 1 shows the image noise of new CT units with various surface doses on a Ø 16 cm water phantom. Measurements were made by using slice widths of 8 – 10 mm, FOV 180 – 250 mm, matrix size 512 x 512 and standard algorithm. The noise level varies in various new CT units between 2.2 and 4.2 HU with a surface dose of 50 mGy.

Figure 2 shows the low-contrast resolution of new CT units at various surface doses. The doses needed to detect Ø 2 mm details of 0.6% contrast varied in the new CT units by a factor of about six. With a dose of 50 mGy, the low-contrast resolution of new CT units varied by a factor of about two. The differences in low-contrast performance are mainly caused by differences in image noise (See Figures 1 and 2).

Spatial resolution varied between 0.8 and 1.0 mm and no essential differences were detected between various CT units. If and edge algorithm was used, the spatial resolution improved slightly, to 0.5 – 0.6 mm.

DISCUSSION

The results described above show that even new CT units have high doses and wide variations in patient doses and in low-contrast performance. The following conclusions can be drawn from the results:

1 A high percentage of the head CT doses exceeds the IAEA dose recommendation. Many studies reported in literature show that patient doses in CT examinations can be decreased, often sharply.
2 Image noise does not fully describe the low-contrast performance of the CT units although some correlations are discovered between noise and low-contrast performance, as shown in Figures 1 and 2.
3 Optimization of image quality is needed to reduce patient doses in CT examinations. Reasonable image quality with the minimum patient dose can only be obtained with an exact medical indication and with an examination technique suitable for this indication. The optimization procedure is a challenge for the radiologist.

Abstract - In this paper the doses for different CT scans are determined. It's found that x-field profiles are wider than declared scan widths, meaning that x field overlap occurs with neighbouring tomograms and that those regions get x-rayed twice. To lessen that unwanted side-efect, it's necessary to enlarge scan width, or to decrease the number of neighbouring scans. We suggest that table shift should equalise actual field width. In addition, the programme for using CT with minimal radiation risk for patients is given.

INTRODUCTION

Computorized tomograph (CT) has become the principal diagnostic machine of x-ray departments and their number represents the measure of the health standard of a country. Whereas in classic x-ray technique relevant details are imersed in scatered radiation background and masked by inadequate developing , on CT doctor gets a tomogramme with details and clarity of an anatomical preparation. The diagnosis is obtained quickly and very reliably, therefore scanners operate full time. However, due to high patient's doses CT is not an ideal diagnostic mean. That fact is not enough known to both patients and doctors. The needed resolution of forms and densities with CT is acchieved , among other programme requirements, by hard x-irradiation. This obviously is not a non-invasive technique and with such a hard spectrum patient's doses are high opposing any lax and inadvertent sending of patients to CT before other "softer" diagnostic techniques are used. In this paper the possibility of reducing the patient's dose is examined.

METHODS

Scanner's x-field is wholly atipical since it has the shape of triangular thin plate rotating in the circle in which there's the pacient, who successively translates orthogonaly to the beam. Dosimetric measurements in such a field demand more atteention in choosing instruments as well as in interpreting results. Because of field rotation one uses cylindrical chambers only, however in the field up to 10mm wide, it's difficult to obtain the usual situation with entire chamber in the field since the majority of chambers are longer than 10mm. Due to partial irradiation of chambers the calibration factor of the chamber changes , which is compensated for by measuring the dose distribution and beam width. In this way the dose in a scan's field is determined. If the entire chamber is caried through scanner's beam by progression of succesive exposition, the mean dose per scan is obtained with the overlapping efect of neighbouring scans included.

RESULTS

From x-ray film it's clearly visible that the field profile in the phantome,(patient), is considerably wider then the declared scan width. The divergence of nominal values of scan width is given in Table1. Because of tube rotation the traces of incoming beam were superimposed in field profile from all directions, as well as the traces of scattered irradiation. Although the mildest conditions on the scanner were used, all field components caused total film blackening, so that scattered-radiation traces could not have been differentiated from central- beam ones. Therefore the dose distribution in the beam profile could not have been densitometrically established. However it's clear that scan field is wider than successive table

translations for next tomogram and for that reason there is a partial field overlap with two neighbouring scans. That means that those patient's regions get x-rayed twice.

Table 1. x-field divergence

Nominal scan width	10 mm	5 mm	2 mm
Scan width at 1cm depth of cylindrical phantom (C_2H_3Cl)	12 mm	7 mm	4 mm
Scan width on the surface of cylindrical water phantom	12.5 mm	7.5 mm	4.5 mm

The dose efect of neighbouring fields overlap established by progressoin of successive tomograms, is given in Table 2.

Table 2. Doses per scan at 1cm depth of the phantom

Nominal scan width and conditions	10 mm 133 kV,350 mAs, 2s	5 mm 133 kV, 350 mAs, 2 s	2 mm 133 kV, 475 mAs, 2.7 s
Dose per scan without field overlap	2.8 cGy	4.4 cGy	5.5 cGy
Dose per scan with field overlap	3.2 cGy	5.9 cGy	10.6 cGy

CONCLUSION

Results show that field overlap considerably increases dose on CT. The only way of reducing x-field overlap efect would be the use of wider scans or decreasing the number of neighbouring tomograms. The question is how much of CT's capacities can be sacrificed for patient's protection?

In praxis several principles and recommendations should be followed in order to solve the diagnosis vs. protection dilemma:

- always use classical methods before CT examination.
- use layers as thick as possible.
- examine aimed layers with of contrast.
- use 10mm layers, which proved optimal for examination.
- work without native examination whenever possible.
- for cranium examination use 10mm layers, with initiating scan line passing through tragus and orbit's roof.

Abstract

Present investigations deal with diagnostic x-ray qualities as applied in medical diagnostics. The track structure computer program PARTRAC [1] simulating the coupled photon - electron transport and interactions in complex geometries has been used. Differential cross sections for electrons in gold with primary energies in the range of 100 eV to 100 keV have been derived on the basis of Seltzer model in case of ionizations and excitations with new Hartree-Fock input data. The elastic cross section data were taken from Fink et al. and Riley et al.. These cross sections have been inserted into the existing track structure computer program to provide detailed simulations of electron interactions and to describe above mentioned interface effects. The tracks were simulated in a target volume of gold surrounded by water vapour to represent cell tissue and irradiated by 30 keV and 100 keV photons. The simulated geometry was chosen as in experiments using exoelectron emission. The tracks were calculated for comparison in pure water vapour under the same irradiation conditions.

Introduction

Implants and contrast media in the human body may constitute interfaces between tissue and high-Z materials. Such interfaces lead to dose discontinuities during radiation exposures as known from megavoltage therapy. Significant dose enhancement has meanwhile been found in tissue close to a gold layer by using exoelectron technology with a spatial resolution in the micrometer range as it is shown on the fig. 1 [2].

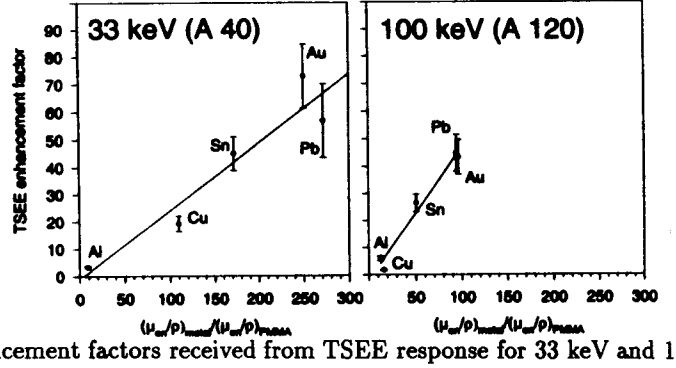

Fig.1 Enhancement factors received from TSEE response for 33 keV and 100 keV x-rays in tissue equivalent material at different metal surfaces under backscatter conditions [2]

Method

The photon-electron transport code **PARTRAC** [1] is used to calculate deposited energy distribution in the vicinity of the tissue - gold interface. The electron track simulation

covers energies from 10 eV to 100 keV. The electron cross sections for water vapour with appropriate density scaling are taken to simulate tissue [1].
New ionization and excitation cross section data for electrons in gold were calculated. Cross section differential in energy were derived for subshells using Seltzer method [3]. New values for the mean kinetic energies of orbital electrons U_j, the expectation values of the electron orbital radius $\langle r_j \rangle$ and the binding energies B_j were obtained from Hartree - Fock calculatins made by P. Indelicato [4]. Results are shown on Fig. 2, 3. Elastic cross section data were taken from Fink et al. [5] and Riley et al. [6].

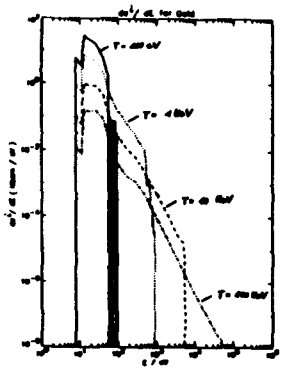

Fig. 2 Differential ionisation cross sections $(d\sigma/dE)^i$ in dependence on the energy transfer E are shown for electron primary energies T=100 eV, 1 keV, 10 keV, 100 keV. Energy edges of the outer shells could be seen (from the left side:6s, 5s,5p, 5d, 4s, 4p, 4d, 4f).

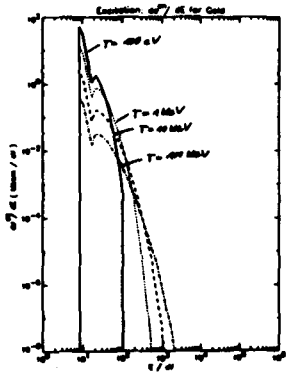

Fig. 3 Excitation differential cross sections $(d\sigma/dE)^{ex}$ in dependence on the energy transfer E are shown for electron primary energies T = 100 eV, 1 keV, 10 keV, 100 keV.

These cross section data have been implemented into the existing track structure computer program.
The experiment to be simulated consists of a PMMA slab ($100x100x5mm^3$), a 100 μm layer of tissue (the region for tracing the secondary electrons) in front of a 100 μm gold layer . The experiment was simulated for 30 keV resp. 100 keV monoenergetic photons.

Results

The results of our calculations are shown in Figures 4 - 5. The energy deposition is found to be considerably higher for the same irradiation conditions in tissue in front of the gold foil than in pure tissue. This can be explained by the large differences in photon interaction cross sections for gold and for tissue and by the different character of interaction. The photoeffect dominates in gold and the Compton effect dominates in tissue causing different structures of secondary electron spectra.
The maximum of the energy deposition occurs at a distance of several micrometers from the gold - tissue interface caused by a larger number high energy electrons emitted from the gold into the tissue. Different to experiments build up maximum of energy deposition is observed for 100 keV photons at a distance of 20 μm from the gold surface, for 30 keV at about 2 μm (Fig. 4 and 5).

Conclusion

The track structure modelling was performed at tissue - gold interfaces for X-ray energies of 30 keV and 100 keV using the **PARTRAC** code under backscatter conditions. This code allows a persecution of electron histories down to 10 eV also for non-equilibrium exchange of secondary electrons across the transition zone of the media interface. Sig-

nificant enhacement of energy deposition was found in tissue layers adjacent to the gold surface as compared with a homogeneous tissue phantom. The enhacement depends on the primary photon energy. Also the range of enhanced energy deposition was found to depend on the primary photon energy that reaches about 17 μm for 30 keV and about 130 μm for 100 keV. A build up maximum of energy deposition was found for 100 keV primary photons at a distance of about 20 μm from the interface, for 30 keV photons at about 2 μm. There is a wide distribution of electron energies up to the primary photon energies originating from gold which is not present for pure tissue conditions. These preliminary results indicate that the PARTRAC code offers a large potential to analyze enhanced energy deposition in tissue close to materials of higher atomic number what is useful for X - ray diagnostics.

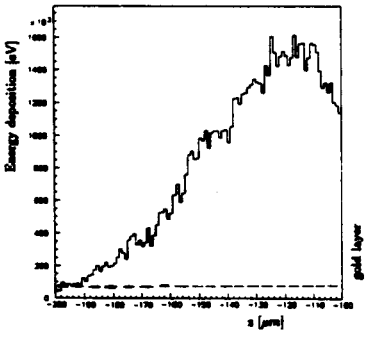

Figure 4 Depth distribution of electron energy deposition in front of the gold foil. The gold - tissue interface is at z = -100 μm. The y-axis are energy depositions in eV normalized to number of photon histories. The broken line shows the level of energy deposition if there is tissue instead of gold. Primary energy of photons: 100 keV.

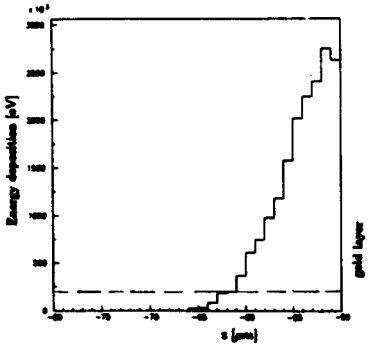

Figure 5 Depth distribution of electron energy deposition in front of the gold foil. The gold - tissue interface is at z = -50 μm. The y-axis are energy depositions in eV normalized to number of photon histories. The broken line shows the level of energy depositions if there is tissue instead of gold. Primary energy of photons: 30 keV.

EFFECTIVE DOSE AND EFFECTIVE DOSE EQUIVALENT IN NUCLEAR MEDICINE

R. E. Toohey and M. G. Stabin
Oak Ridge Institute for Science and Education, Oak Ridge, TN 37831

INTRODUCTION

For years many physicians and physicists have employed the concept of "total body dose" or "whole body dose," i.e., the total energy deposited in the body divided by the total mass of the body, in evaluating the risks of different nuclear medicine procedures. Although this concept may be considered useful for comparing doses received from different procedures, it does not take into account the typical non-uniformity in dose distribution among the several body organs. The effective dose equivalent (H_E), first described in ICRP Publication 26 (1), has been accepted by some as a better quantity to use in evaluating the total risk of a procedure, but its use has been criticized by others primarily because the tissue weighting factors were intended for use with the population of radiation workers, rather than of nuclear medicine patients (2). Nevertheless, the ICRP has suggested in Publication 52 (3) that the H_E may be used in nuclear medicine, and provided in Publication 53 (4) a compendium of dose estimates, including H_E values, for various nuclear medicine procedures undergone at various ages. The effective dose (E) of ICRP Publication 60 (5) is perhaps more suitable for use in nuclear medicine, with tissue weighting factors based on the entire population.

METHODS

Comparisons of H_E and E have previously been published (6). We have used the program MIRDOSE 3.1 to compute total body dose, H_E and E in the adult male and adult (nonpregnant) female for 62 radiopharmaceutical procedures, involving 19 different radionuclides, based on the best current biokinetic data available. The improvements in this latest version of MIRDOSE include mathematical phantoms for the pregnant female at 3-, 6-, and 9-months gestation, and a new model for bone and marrow dosimetry based on the work of Eckerman (7).

RESULTS

The computed values of total body dose, H_E and E are listed in Table 1, for both the adult male and adult female phantoms in MIRDOSE 3.1. As found by Johansson et al. (6), the average ratio of E to H_E is about 0.8, with a relatively narrow spread from 0.48 to 1.77. The ratio of E to total body dose, however, ranges from 1.1 to almost 100. All ratios greater than 10 occur for the iodines; the values for Tc-99m agents fall between 1.4 and 6.9. In view of the non-uniform distributions of most radiopharmaceuticals, we believe that the total body dose is not a useful quantity for evaluating risks, and should be replaced by the quantity effective dose, or the effective dose equivalent, as an interim method in those countries that have not as yet adopted the ICRP 60 (5) methodology.

^{131}I-RETENTION MEASUREMENTS AND LOCALIZATION BY A HIGH-SENSITIVITY WHOLE-BODY COUNTER

G.GREIFENEDER,[1] H. AIGINGER,[1] F. STEGER,[2] J. FLORES [3]

[1] Atominstitute of the Austrian Universities, Vienna, Austria
[2] Austrian Research Center Seibersdorf, Seibersdorf, Austria
[3] Institute of Nuclear Medicine, University of Vienna, Austria

INTRODUCTION

A widely used method to investigate thyroid gland carcinomas but also disorders of the thyroid gland is the measurement of the ^{131}I-retention behaviour using a high-sensitivity whole-body counter (HWBC). Normally just the retention of oral administered Radioiodine is controlled. However, it is possible to visualize the distribution of ^{131}I (using a modified profilescantechnique) beside the retention in the human body and this provides much better information on human metabolism as will be demonstrated in the following.

MATERIALS AND METHODS

Experimental equipment

The profile scanning system used consists of four 8"×4" NaI(Tl)-crystals with multi-slit focused lead collimators inside a massive shielding chamber (total weight of the order of 74 t). Two of these linear scanning detectors are placed above and two below the bed and can be arranged independently in three dimensions. The scanning motion and the data aquisitation was controlled separatly for each detector by a central computer.

Clinical studies

To demonstrate the power of the high sensitive profilescantechnique we investigated 28 patients with total thyroid gland ectomy before and after ^{131}I-therapy. To ensure the absence of new metastasis and to localize remains of thyroid gland oral dosis with 20 µCi of radioactive Iodine has been provided. One hour and 72 hours after administration linear profile scan measurements relative to a comparative standard have been done by the HWBC. Thereby each patient was placed at a fixed position on the bed. The profile of count rates was measured by the profile scanning system (scanning time 600 s, scanning length 190 cm) using a special detector configuration shown in Fig.1.

To study the rate of accumulation of ^{131}I in the human body after its oral administration the retention value has been calculated from the measured count rates and a correction of background radiation and patient activity has been done.

$$R = \frac{P_{72h} - LW_R}{P_{1h} - LW_P} \cdot 100 \cdot \frac{S_{1h}}{S_{72h}} \quad [\%]$$

P_{1h}	count rates 1 h after administration (patient)
S_{1h}	count rates 1 h after administration (standard)
P_{72h}	count rates 72 h after administration (patient)
S_{72h}	count rates 72 h after administration (standard)
LW_P	patient activity
LW_R	background radiation

The profiles thus obtained for each scanning detector represents the longitudinal localization of the ^{131}I-distribution. To achieve the three-dimensional portrayal of the ^{131}I-distribution by the linear profile scan measurements a computational model[1] has been used. The model based on the special detector configuration allows to determine the distribution of radioactivity in the human body from the measured counts (beside the ^{131}I-retention behaviour). So count rates can be directly attributed to organs of the human body.

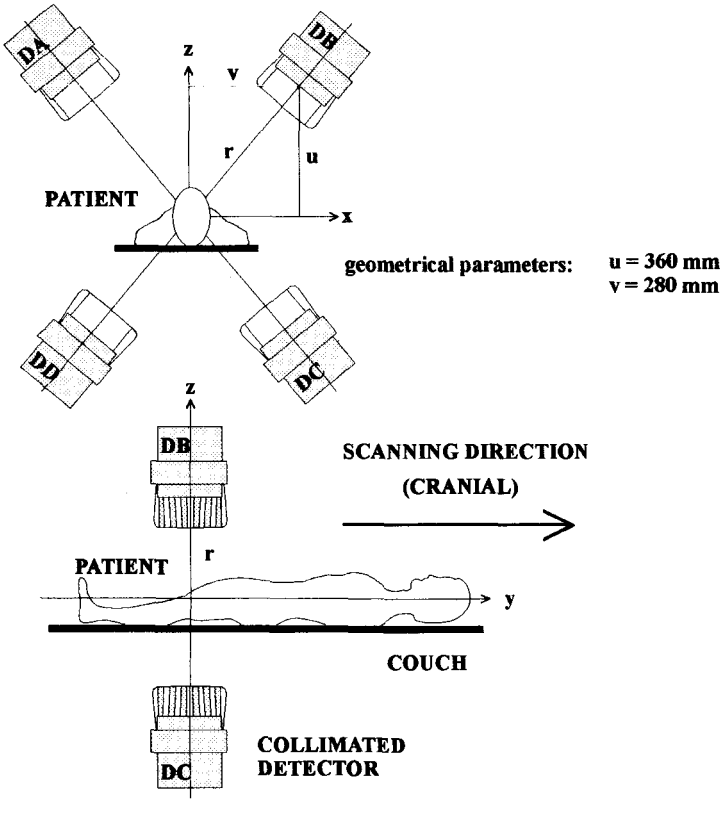

Fig.1. Detector configuration.

RESULTS

After oral administration of ^{131}I, the inorganic iodide is absorbed from the gastrointestinal tract within one hour and is completely transformed to plasma and extraiodide pool. Major portion of the total iodine content is taken up by metastases, most of which is in the form of iodinated aminoacids and the rest of the portion is excreted by the kidney. Normally a retention value of more than 3 % 72 hours after administration is interpreted as a possible of metastasis. Regarding the spatial I^{131}-distribution in addition a decision between localization and dislocalization is possible. Thereby it turned out that one of 10 patients with total thyroid gland ectomy before ^{131}I-therapy showed a retention value of 2.32 % although a localization could be detected shown in Fig.2. On the other side none of the patients after ^{131}I-therapy showed up a localization indicating a metastases even 25 % had a retention value of more than 3 %. Looking just at the retention values the possibiltiy of disorders cannot be excluded of certainty but regarding the three-dimensional distribution in addition a decision between localization and dislocalization is possible (Fig.3). So the physiological or pathalogical meaning of the retention value can be easily interpreted without further investigations by a gammacamera where much higher dosis (20 mCi) is applicated.

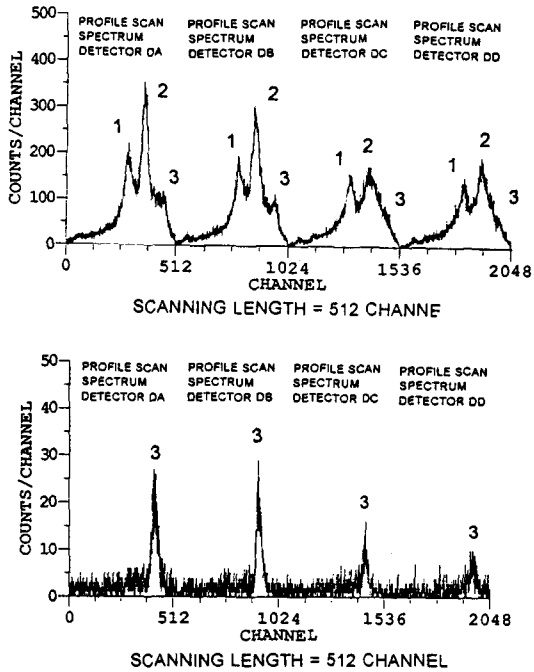

Fig.2. Patient with total thyreoid ectomy before ^{131}I-therapy, retention value: 2.32 %.

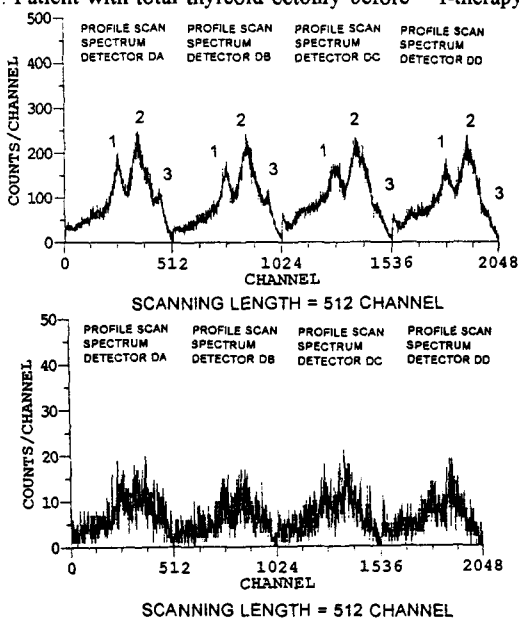

Fig.3. Patient with total thyreoid ectomy after ^{131}I-therapy, retention value: 7.58 %.

ABSTRACT

We made a new mathematical phantom using the patients' digital pictures of bone scintillation in nuclear medicine. The data of ^{99m}Tc bone scintillation pictures include the information on the body sizes and shapes. In the bone scintillation pictures, no three-dimensional data are available, so that the shapes and sizes of whole body and bones were modelled based on standard anatomical geometry. The organs except bone were also modelled after construction of the bone mathematical model. The mathematical phantoms were developed for each patient. The specific effective energy for each phantom can be calculated by the Monte Carlo code to compare it among the patients. Our mathematical phantoms would provide new calculation of internal doses from radiopharmaceuticals in place of the MIRD phantom.

INTRODUCTION

For the estimation of internal doses, many phantoms have been made(1). The calculation model based on the MIRD method have been used for the internal doses of the patients from radiopharmaceuticals on nuclear medicine(2-5). However, the mathematical phantom is based on the reference man(6), and have the uncertainty on its application to each patient because of the variety of body sizes among the patients. It is difficult to correct the uncertainty for each patient. On the other hand, the data of ^{99m}Tc bone scintillation pictures include the information of body sizes and shapes. We made a new mathematical phantom using the ^{99m}Tc bone scintillation pictures which include the information on the body sizes and shapes.

METHOD

The shapes and sizes of whole body and bones were modelled based on standard anatomical and physiological geometry(7). The organs except bone were also modelled after construction of the bone mathematical model. Every shape is geometrically defined as a function of x,y and z-coordinates. In our model, the determination of the x and y-coordinates is based on the picture data and the z-coordinate depends on the body size and weight of standard anatomical geometry. The calculation of the values of specific absorbed energy of a patient needs the exact organ shape and disposition of radiopharmaceuticals. However, it is very difficult and not so useful to define the body in detail for the propose of internal dose estimation. In our study, sensitivity analysis for adjustment was done for examining how the size and shape have an influence on the internal dose.

The ^{99m}Tc bone scintillation pictures are scanned and digitized in order to be read easily. For the bones and whole body, the x and y-coordinates of some points characterizing the shapes of the body and organs are directly read on the digital picture. On the pictures of the bone scintillation, the kidneys are often shown clearly, and the shapes can also be determined.

Those data are the basis for the definition of mathematical phantom as not only the geometry but also the source organs in the patient's body.

After reading pairs of coordinates, the solid geometry of phantom is defined by fixing the scale and the z-coordinate using the values of body height and weight as parameters. The variation of the patients' organ sizes is large compared with the mean value from reference data. This shows that the exact determination of one patient organs is impossible. The relations among organs, body height and weight are dealt with as parameters in the new model taking variations into account.

The new phantoms based on patients' data are able to be classified into some groups by body shapes and ages. In this study, the number of patients is limited, so we classified the patients into four groups, i.e. adult males, adult females, children and babies as the classification in which we take only body geometry into account. Using the classified phantoms, the internal doses of the patients who have no whole body data can be calculated.

MATHEMATICAL PHANTOM

As an example of mathematical phantoms, the shapes of main skeletons of a patient are shown in Figure 1 with the scintillation picture that is basis of the construction. The shapes of the bones are simplified into geometrical solids, and the disposition is based on the shapes on the picture. Considering the density and anatomy of body composition, the volume of the body and bones are determined respectively.

DISCUSSIONS AND CONCLUSIONS

On making mathematical phantoms, the information of shapes, sizes and components of both whole bodies and each organ are needed for each patient. In the bone scintillation pictures, no three-dimensional data are available. However, it is useful to make the phantom using two dimensional scintillation pictures compared with three dimensional data such as MRI or CT, because any subjects examined in nuclear medicine can be estimated without additional exposure to CT using our method.

The organ sizes are closely related with body volume and weight, and the relationship among them, e.g. brain etc.(8), have been reported. For the calculation, however, it is very difficult to apply the

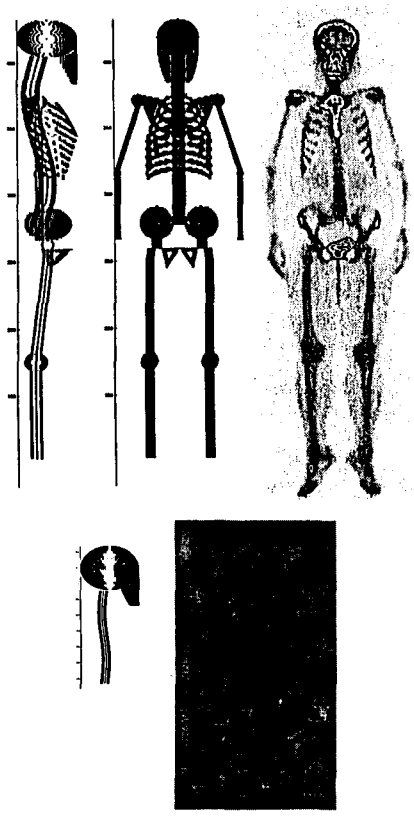

Figure 1. Adult and newborn patients' pictures and skeleton of mathematical phantoms

relation, because the organs reported are not all but several, and the individual variation of values is large.

The human organs are not stable in their lives including patients in hospitals. Arms and legs are typical parts, and the disposition of internal organs like stomach also does not rest in response to their move. The disposition among source and target organs those radiation sensitivities are high is more important than the exact definition of the patient shapes.

Although there are not exactly equal to the patients' bodies anatomically by the uncertainty, the merit of this phantom-construction method using picture data in nuclear medicine is to consider the body size and age of an individual patient for dose calculation. The phantom can also be applied for the patients who have not enough whole body picture data using the classified phantoms according to sizes and shapes. Especially, the age dependence of phantoms is available. The specific effective energy for each phantom can be calculated by the Monte Carlo code to compare it among the patients.

The study of differences of internal dose for the phantom of each body size based on anatomical and physiological data is more important than applying the mean phantom for each patient. Our method for constructing mathematical phantoms would provide new calculation of internal doses from radiopharmaceuticals in place of the MIRD phantom.

INTRODUCTION

Internal dosimetry resulting from nuclear medicine is important in comparing the benefit of a procedure with its potential risk. The estimation of internal dose due to intake of radioisotopes has been established by the Medical Internal Radiation Dose(MIRD) committee of the Society of Nuclear Medicine (1). In the MIRD method, the doses absorbed in target organs are estimated from the activities accumulated in source organs. The information on cumulated activities has been estimated from a few direct measurements with the positron emission tomography(PET) (2) and with a whole-body counter (3), but most data from the direct measurements with PET and SPECT(single photon emission computed tomography) relate to specific organs necessary for nuclear medicine treatment and are very scarce for other source organs in humans. Organ biodistribution of cumulated activities has usually been measured in animals and then extended to humans, despite the metabolic difference.

We have developed a new method to obtain the biodistribution of radioactivities, which are injected into the patient in nuclear medicine procedures, from external exposure measurement with thermoluminescent dosimeters(TLDs). In our new method, a number of TLDs are attached to the patient's body surface close to source organs to obtain information on body-surface doses. As the surface dose is connected to the cumulated activities in source organs through radiation transmission in the human body which can be estimated with the aid of a mathematical phantom, the organ biodistribution of radioactivities can be obtained by the inverse transform method. Here in this study, we estimated by this external measrement the organ biodistributions and absorbed doses of subjects to whom the radiopharmaceuticals of ^{18}F-labelled FDG(Fluoro-Deoxy-Glucose), ^{11}C-labelled Doxepin, ^{11}C-labelled YM 09151-2, ^{11}C-labelled Benzotropin, ^{67}Ga Citrate, ^{99m}Tc MDP(Methylene Di-Phosphonate) were administered in clinical nuclear medicine procedure.

This new method has great advantages, in that cumulated activities in several organs can be obtained easily with a single procedure, and that the measurements of body surface doses are done simultaneously with nuclear medicine procedure, as TLDs are too small to interrupt other medical measurements. We further compared our estimated results for human with the organ biodistribution and absorbed dose for animals directly obtained by the activity measurement and investigated the metabolic difference between human and animal.

MATERIALS AND METHODS

In the MIRD method, the absorbed dose in a target organ is expressed by the sum of contributions from several source organs, as follows:

$$D_i=S_{i,1}.A_1+S_{i,2}.A_2+..... \quad (1)$$

where D_i is the absorbed dose in the i-th target organ, A_j is the cumulated activity in the j-th source organ, and S_{ij} is the absorbed dose in the i-th target organ per unit cumulated activity in the j-th source organ, which means the transmission fraction of radiation.

In our new TLD method, the term of "target organ" is replaced by the term of "TLD position", as follows:

$$C_i=R_{i,1}.x_1+R_{i,2}.x_2+.... \quad (2)$$

where C_i is the absorbed dose in the i-th TLD position, x_j is the integrated activity in the j-th source organ during the TLD attachment on the body surface, and R_{ij} is the absorbed dose at the i-th TLD position per unit cumulated activity in the j-th source organ. The C-vector can be obtained by the TLD measurements, and the R-matrix can be calculated with the VADMAP code(4) by using the MIRD mathematical phantom, so that one can obtain the x-vector by performing the inverse transform of the above matrix equation with the SAND-II

unfolding technique.(5)

CLINICAL EXPERIMENTS

The measurements of body-surface doses with TLDs of BeO were done in clinical PET studies with ^{18}F-FDG, ^{11}C-Doxepin, ^{11}C-Benzotropin and ^{11}C-YM-09151-2 performed at the Cyclotron and Radioisotope Center (CYRIC) of Tohoku University, and in clinical scintigraphy with ^{67}Ga Citrate and ^{99m}Tc MDP performed at the Research Institute for Aging and Cancer of Tohoku University.

The subjects were five normal volunteers for ^{67}Ga Citrate and four normal volunteers for other radiopharmaceuticals. The positron emitters of ^{18}F (half life of 110min) and ^{11}C (half life of 20.4min) also emit 511 keV annihilation gamma rays, ^{67}Ga (half life of 3.26days) emits only gamma rays of 93.3keV (branching ratio of 37%), 185keV (20%) and 300keV (17%), ^{99m}Tc also (half life of 6.01hr) emits 140.5keV(89%) gamma rays.

Three sets of TLDs were attached at each position that was regularly selected without any interruption to clinical studies. The calibration of TLDs was done with 662keV gamma rays of ^{137}Cs whose activity was well characterized. The dose equivalent values in mSv units were directly obtained from the TLD reader after converted with the calibration factor. The average values measured with three TLDs were determined to be the C values in Eq.(2).

It is revealed in our previous study(6) that the TLDs must be attached on a body surface as close to source organs as possible in order to get the results with good accuracy. The following source organs were selected considering the metabolism of these radiopharmaceuticals;

1) For FDG, Doxepin, YM-09151-2, and Benzotropin: Brain, Heart, Lungs, Lever, Kidney, Spleen, Pancreas, Bladder, and Rest of the body; 2) For ^{67}Ga Citrate: Brain, Heart, Lungs, Lever, Kidney, Spleen, Pancreas, Bladder, Stomach, Small Intestine, Upper Large Intestine, Lower Large Intestine, and Rest of the body; 3) For ^{99m}Tc MDP: Brain, Heart, Lungs, Lever, Kidney, Spleen, Pancreas, Bladder, and Rest of the body. The TLD attachment positions were dertermined at 9 to 11 positions on a body surface close to source organs..

RESULTS AND DISCUSSIONS

As in this study only physical decay is considered neglecting the excretion from a subject, total cumulated activities in all source organs are kept constant to the injected activity and the cumulated activity in each organ was normalized to it.

Figures 1 and 2 show the cumulated activities in source organs measured with TLDs for ^{18}FDG and ^{11}C-Doxepin, respectively, as examples. The values are averaged for all of four subjects with errors.

In order to investigate the accuracy of the TLD method, we compared them with the cumulated activities in several source organs, brain, heart, lung, liver, kidney, pancreas, spleen, bladder and the rest of the body, directly measured with the PET image, for ^{18}FDG by Mejia et al.(2), and only in brain for ^{11}C-Doxepin.

This comparison reveals that the cumulated activities estimated with our TLD method give rather good agreement with those estimated with PET within a factor of 2. A big discrepancy only for the lever may be explained as follows; the lever is a large organ which situates near a body surface and its shape is complicated, which means the large deviation of individual from the reference man, and that the response matrix calculated from the MIRD model may include large errors.

From these figures and other results, the following facts are found out,

1) For ^{18}FDG, the brain, bladder and the remainder of the body are the source organs which mostly accumulate the radioactivities,

2) For ^{11}C-Doxepin, YM09151-2 and Benzotropin, the lungs and the remainder of the body highly accumulate the radioactivities,

3) For ^{67}Ga-Citrate, the small intestine and the remainder of the body highly accumulate the radioactivities,

4) For ^{99m}Tc-MDP, the bladder, bone and the remainder of the body highly accumulate the radioactivities.

The cumulated activities in human organs are also compared with those in animal organs, in order to investigate the influence of the metabolic difference between human and animals. The cumulated activities of organs in mouse for Doxepin and Benzotropin and in rat for YM-09151-2 were obtained from the time course of the activity data of each organ after the radioactivity injection through the direct activity measurements of the dissected organs. In Fig. 2, the animal's data of cumulated activities in source organs are compared with the human's data for Doxepin, as an example. These comparison revealed the following facts,

1) For Doxepin and YM09151-2, the cumulated activities of all source organs in human are larger than those in mouse and rat, except that lever activities are close together for human and mouse. The cumulated activity of lung in human is especially much higher than that in mouse and rat.
2) For Benzotropin, the cumulated activities of heart, liver, kidney and spleen in mouse are, on the contrary, higher than those in human, although brain activity in human is higher than that in mouse.

This result clearly indicates that the organ biodistributions in human and in small animals like mouse and rat are quite different each other for different radiopharmaceuticals because of their metabolic and blood flow differences and that it gives quite poor accuracy or wrong result in some cases to estimate the organ biodistribution and absorbed dose to human by measuring the organ biodistribution of animals.

CONCLUSION

It can be concluded from these clinical results that the new method to estimate organ biodistribution in humans from the surface dose measured with TLDs gives sufficiently good results considering experimental errors. This TLD method has great advantages, in that cumulated activities in several human organs can very easily be estimated, in contrast with the PET study that requires many procedures to estimate the biodistribution, and that the TLD measurements can be done simultaneously with medical study without interrupting it. Thus, this method would be useful in estimating the personal dose from medical procedures because of the easy handling of TLDs.

ABSTRACT

Effective dose estimation due to the administration of I-131-IOH and Tc-99m-DTPA, is carried out by modified procedure using constant volume standard MIRD model and dynamic urinary bladder model. These dose estimates are transformed to patients of India physique using data of Jain et al on specific organ masses and does transformation technique of Yamaguchi. For the same activity administered, the effective dose in Indian population is found to be 10-15% higher in comparison to their ICRP counterpart. The new bladder model gives higher effective does estimates due to I-131-IOH than the other model. In case of Tc-99m-DTPA, the dose estimates are found to be invarient of model employed. Further, the additional total stochastic risk caused due to these investigations are found to be marginally different in Indian patient population from ICRP population.

INTRODUCTION

Radiosotopic renal dynamic studies provides unequivocal information on renal failure, urinary tract infaction and obstruction, and renal transplant evaluation. The radiation dosimetry in such investigations is involved with calculation of radiation dose to inner mucosal surface and to the urinary bladder wall from the administered radiopharmaceuticals. Although Tc-99m MAG_3 has many desirable characteristics, however due to its prohibitive cost, it is seldomly used and still I-131-IOH and Tc-99m-DTPA are the radiopharmaceuticals of choice in the Indian Context. ICRP 62(1) has given effective dose coefficients for these radiopharmaceuticals in adults using constant volume standard MIRD phantom with ellipsoidal configuration (2). Besides the limitation of fixed volume (202.6 ml) in the model, no attempt was made to represent the physical dynamics of bladder filling and emptying. A new urinary bladder model of expanding sphere and with many other innovations to take into consideration some of the complexicities of the dynamic situation, has been proposed (3). A limited study carried out recently (4) showed that employment of the new model did alter the bladder wall dosimetry. A study is undertaken at the Institute to estimate effective dose due to the administration of I-131-IOH and Tc-99m-DTPA employing the modified procedure(s) and to investigate the effect of the two urinary bladder models on

the radiation risk estimates in Indian patients due to these radiopharmaceuticals.

MATERIALS AND METHOD

The effect of urinary bladder models on effective dose and radiation risk estimates is confined to adult patient population. These radiopharmaceuticals are excreted rapidly and deliver significant doses to urinary bladder wall which contribute more than 50% to the effective dose. As a first step, absorbed dose coefficients to the urinary bladder wall for similar initial volume and voiding schedule due to these radiopharmaceuticals for both the urinary bladder models, are taken from Thomas et al (3). As an average Indian differs from Reference man as regards anatomical and physiological characteristics, Dose TransformatioN Factor (DTF) are computed using data of Jain et al (6) for specific organ masses and the technique of yamaguchi (7) for Indian physique. Thus the DTF weighted organ absorbed dose coefficients gives absorbed dose coefficients for Indian subjects. Effective doses are calculated by employing the revised values of tissue weighting factor and modified procedure (5). The effective doses are multiplied by nominal probability coefficients for stochastic effects and the total activity used in the investigation for getting an idea of the risk associated with the procedure.

RESULTS

Comparison of the absorbed dose and effective dose coefficients for the two radiopharmaceuticals using the two different urinary bladder models, in Indian adults is shown in the table. Both the models give comparable values; however, the new model estimates higher effective dose due to I-131-IOH while there is practically no change in the case of Tc-99m-DTPA.

In general, the effective doses are 10-13% higher in Indian patients in comparison to the estimates made in Reference man for the same activity. In radiation risk estimates there is no effect of urinary models if Tc-99m-DTPA is employed while the use of I-131-IOH give marginally higher values.

Table Absorved and effective dose coefficients in Indian Patients due to administration of I-131-IOH and Tc-99m-DTPA

Radio Pharmaceutical	Absorbed dose coefficients in Indian patients in mGy/MBq		Effective dose coefficients in Indian patients mSv/MBq	
	MIRD	NEW MODEL	MIRD	NEW MODEL
I-131-IOH	0.31	0.37	5.30	6.10
Tc-99m-DTPA	0.036	0.036	0.52	0.52

Radiation Dose to the Pediatric Population of Slovak Republic from Diagnostic Nuclear Medicine Procedures.

S.Ftáčniková[1], A.Füriová[2]

[1]Institute of Preventive & Clinical Medicine, Bratislava, Slovak Republic
[2]National Oncological Institute - Hospital St.Elis., Clinic of Nuclear Medicine, Bratislava, Slovak Republic

Abstract

The increased number of *in vivo* diagnostic nuclear medicine examinations has created the need for more precise determination of radiation dose to the population, specially to the children.

A questionnaire survey has been performed on all nuclear medicine facilities in Slovak Republic through 1982 to 1994 with a special attention to pediatric patients in 1994. The information obtained was about the age distribution, number of different types of examinations, radiopharmaceuticals used and the value of mean administered radioactivity per exam. These data were used to evaluate the mean effective dose per exam and per capita, the collective effective dose for special type of examinations, for different radiopharmaceuticals and for radionuclides used in diagnostic procedures. In calculations we used the best available biokinetic models of the distribution of radiopharmaceuticals in organs as a function of age (2).

The results show that the Slovak Republic appeared favorable in comparison to other countries in the judicious use of diagnostic nuclear medicine procedures performed on pediatric population.

Materials and Methods

The effective dose provides a possibility of expressing the radiation risk to patients undergoing different radiodiagnostic procedures by means of single figure. To evaluate the radiation dose to population from radiodiagnostic procedures we used a mathematical formalism which is described in our previous paper (1).

In Slovak Republic 12 nuclear medicine departments are located. For years 1992 through 1994 we send our questionnaires to all nuclear medicine facilities in Slovakia and received 100 % response. The requested information was about the type of radiopharmaceuticals used and the mean administered radioactivity per examination, about the frequency of examinations and in 1994 also the information about the age distribution of the pediatric patients was received (there were 4 groups defined - up to 1 year, 5 years, 10 years and 15 years old children).

The mean effective dose for the procedure was determined by multiplying the administered radioactivity by the value of effective dose per unit of applied radiopharmaceutical's activity. These latter quantities were taken from the work of Stabin at al.(2), where the values of effective dose per unit of administered activity were published for 6 different age groups (newborn, 1 year, 5 years, 10 years, 15 years old children and for adults) and for different radiopharmaceuticals used in nuclear medicine procedures.

Results and Discussion

In 1994 in all 12 nuclear medicine departments in Slovakia 1742 diagnostic procedures on children have been performed what represents about 6.2 % of all exams performed that year. For comparison in 1992 it was about 7 % and in 1993 about 4.3 % (1). The frequency of pediatric examinations is approximately 1.3 nuclear medicine procedures per thousand children.

In Table 1 summary of all diagnostic nuclear medicine procedures performed in Slovak Republic on children in 1994 is listed, their number, the used radiopharmaceuticals, the values of mean effective dose per exam, collective effective dose and the quantity of mean administered radioactivity per different exams. The data are divided according to child's age. The collective effective dose from these procedures is about 3581 man mSv and the value of mean effective dose per exam was evaluated to be about 2.06 mSv. The most common procedures performed were: kidney dynamic scintigraphy (30.3 %), radiorenography (22 %) and bone static scintigraphy (13.1 %). The kidney dynamic scintigraphy was also

the main source of overall collective effective dose (22.8 %), the second biggest contributor was the bone static scintigraphy (20.5 %).

The data in Table 2 indicate relative frequency of radionuclides and their contribution to the annual collective dose equivalent in 1994 in Slovak Republic for pediatric patients. Approximately 75.3 % of radionuclide pediatric studies in Slovak Republic in 1994 were performed with ^{99m}Tc labeled radiopharmaceuticals, contributing about 88.3 % to the collective effective dose (Table 2).^{131}I was second most common used isotope (23 %) with the contribution to the S_E about 5.2 % ^{67}Ga and ^{51}Cr-based radiopharmaceuticals contributed to the S_E about 6.1 % and 0.4 % respectively.

Conclusion.

The radiation dose in nuclear medicine examinations might be used as the criteria for the quality of health care of patients. This is done by evaluating the mean effective dose per examination. In Slovak Republic this value for pediatric patients is approximately half of value for adult population - in 1992 the mean value of effective dose per exam was about 3.9 mSv (1). This is in agreement with the requirement that radiation dose to the child could not be higher than for adult. In other site the number of nuclear medicine examinations per 1000 inhabitants (1.3 exams/1000 children and 5.5 exams/1000 adults) is several times lower than in Czech Republic and other countries (1). The Slovak Republic appeared favorable in comparison to other countries in the judicious use of diagnostic nuclear medicine procedures.

INTRODUCTION

Treatment of chronic rheumatoid synovitis is directed to control the inflammatory process causing pain and disability. Radiation synovectomy is suggested to be an alternative to surgical treatment /1/,/2/. Safety is one of the most important aspects when this method is applied. The physical properties suggest minimal exposure to non- target organs by the reduction of leakage of the radionuclide Dy-165 /3/,/4/,/5/. The aim of this study was to evaluate the applikation of the whole-body counter in the General Hospital Vienna for the study of the biodistribution and biokinetics of 165-dysprosium-ferric-hydroxide.

MATERIALS AND METHODS

From March 1995 to October 1995 it was possible to measure 6 out-patients and 3 in-patients, who were treated with 165-dysprosium-ferric-hydroxide (Dy-165). The use of Dy-165 has some considerable advantages: The half-life of Dy-165 (only 2.3 houres) is important to reduce the whole-body dose due to the relative high activity of approximately 11000 MBq (≈ 300 mCi) applied. The maximum soft tissue penetration of its β-particles is 5.7 mm, which is the range necessary to penetrate the inflammed synovia. The emission of γ-radiation acounts to two thirds of the 6 % of the whole disintegration is with an energy of 95 keV. This radiation is used to monitor the kinetic distribution of Dy-165 after injection with the whole-body counter.

The clinical whole-body counter

The clinical whole-body counter is placed in a room of the Department of Nuclear Medicine, which is specially built for the use of this instrument. The walls to the adjacent rooms are shielded with 6 mm lead to reduce the environmental background radiation. All coulers, lacquers and floor coverings used have very low radioactive concentration to reduce the background in the room (Figure 1).The tunnel construction consists of the transport construction and the shielding. The transport construction carries the guide rails of the movable patient-bed, the shielding of the measurement area and the holding device of the detectors and collimators. The lead shielding is divided in a measurement tunnel with 10 cm lead shielding and a shadow shield with 5 cm lead shielding. The patient-bed is made of acrylglass which guarantees a negligible absorption of the gamma radiation in the bed. Two slit collimators of 10 cm thickness can be brought in front of the detectors. The slit width can be varied continuously from 0 mm to 300 mm with an accuracy of ± 0.3 mm.

The localisation of Dy-165 is measured with four NaI-detectors of 6" diameter and 4" thickness. The detectors are arranged in pairs above and below the shadow shield. The scanning motion of the bed, the data acquisition separately for each detector, the storage of the data and the output of the results are controled by a computer.

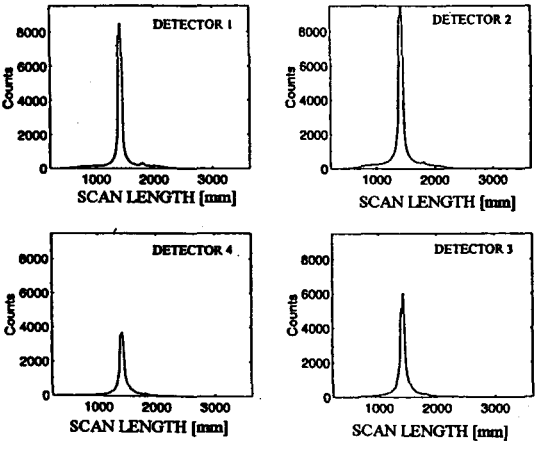

Figure 4.

RESULTS

Measurements with the whole-body counter result in activity profiles displayed as a plot of counts (impulses/channel≈1cm) against position along the scan-length (= longitudinal axis of the body), showing a peak as a activity deposit is traversed. Figures 2-4 show such activity profiles.

The results of the measurements of 9 patients can be summerized as followes:

With the aid of the whole-body counter it was possible to monitor the distribution of activity. The applied activity ranged from 500 MBq to 9000 MBq (15 mCi to 250 mCi) (Tab.2.). The activity profiles of 3 patients showed a uniform distribution of the nuclide in the whole knee joint. The measurement of 1 patient showed a concentration in the area of the hollow of the knee and in the case of 5 patients with small or no effusion the Dy-165 became concentrated in the knee. The activity profiles of 7 patients showed a considerable increase of the counts on both sides of the peak, as can be seen in figure 4. This increase is not the result of a leakage of the injected activity outside the knee joint, but can be explained as an effect of scattered rays of the highly energetic peaks in the γ-energyspectrum of Dysprosium-165. This effect arised only at activities above 6000 MBq. In 5 patients no leakage could be monitored. In 4 patients it was possible to determine some leakage outside the knee joint. In 3 cases occured a concentration of this activity in the urinary bladder. Using the software

MIRDOSE II (Oak Ridge Iac.) we determined the dose to the bladder, which amounted to about 15 mGy, 64 mGy and 50 mGy respectively. A more detailed interpretation of the activity profiles of the fourth patient revealed a small leakage of the injected activity out of the joint whereby a concentration was seen in the inguinal lymphatic nodes of the same leg.
Monitoring of activity profiles of more complex anatomical or pathological structures was also possible using the clinical whole-body counter. One patient suffered for an approximately 12 cm long effusion in the recessus suprapatellaris. The Dy-165 was homogenously distributed into both the joint and the recessus. The analyses of the activity profiles clearly showed an increase in the counts in the direction of the thigh, corresponding with the fact that Dy-165 was distributed in the joint and in the recessus.

DISCUSSION

The measurements with the whole-body counter represent a reliable method for the lokalisation of Dy-165 in the course of some hours after application. By the aid of the activity profiles of the four detectors it is possible to localize an incorporated or injected radionuclide with an accuracy of ± 1 cm in the three coordinates. The main peak marks the position of the knee joint, the small peak on its right side (Figures 3 and 4) represents the position where a small amount of activity had escaped. The count-rates of the four detectors make it possible to determine the position of this small peak and relate the peak to an anatomical structure. The rather high background activity results from scattered rays (Figure 4). With data received from phantom-measurements it was possible to determine the amount of activity applied and the exposure to non-target organs i.e. the urinary bladder and the lymphatic nodes. Using the MIRDOSE II software we determined the energy dose in these organs. The radiation exposure of the patient in the case of a concentration of escaped activity in the urinary bladder can be reduced by advising the patient to use the toilet immediately after detection of the leakage.
This method guarantees a very detailed information about the activity distribution. Our results show, that the leakage of 165-dysprosium-ferric-hydroxide out of the joint is neglectable. The radiation exposure due to this treatment is relative low.
The clinical whole-body counter of the Department of Nuclear Medicine in the General Hospital Vienna with its scanning device can be properly used for the localization of small areas of activities within the whole body of a patient.

INTRODUCTION

To estimate total radiation risk of diagnostic medical procedures, epidemiological studies are necessary. Concerning nuclear medicine investigations, only a few studies have been published in the literature (1,2). Furthermore in Greece, the number of nuclear medicine examinations has been increased during the last five years while new radiopharmaceuticals (^{131}I MIBG, ^{201}Tl chloride, ^{67}Ga citrate, etc) and new techniques are available.

A term that permits the comparison of exposure of patients undergone different medical examinations using ionising radiation is the effective dose, E. According to the recommendations of I.C.R.P. (3), the probability of stochastic effects depends not only on the absorbed dose but on the type and energy of radiation and the tissue irradiated, as well. This is taken into account by weighting the absorbed dose for radiation quality and for the relative contribution of that organ to the total detriment. The doubly weighted absorbed dose is called effective dose, E, and has replaced the previously used effective dose equivalent, E.D.E.

Minor changes have been applied to tissue weighting factors, w_T which resulted in reduction of effective dose from radiopharmaceuticals labelled with ^{99m}Tc and in increase of effective dose from iodide radioisotopes.

MATERIALS AND METHODS

Effective dose per MBq was calculated for a number of radiopharmaceuticals commonly used in nuclear medicine procedures. The calculations referred to adults of equal numbers of both sexes. For that reason for gonads we used the mean value of absorbed dose of testes and ovaries.

Effective dose is expressed by the formula

$$E=\sum_T w_T.H_T = \sum_T w_T \sum_R w_R.D_{T,R}$$

where w_T is the tissue weighting factor, H_T is the equivalent dose in a tissue or organ, w_R is the radiation weighting factor and $D_{T,R}$ is the mean absorbed dose over tissue T caused by radiation R.

The radiation weighting factor, w_R was taken equal to unity for all the γ, X and beta emitting radionuclides (3). To estimate the effective dose for a radiopharmaceutical, the absorbed dose $D_{T,R}$ was multiplied by the relative tissue weighting factor, w_T and the products were summed. Data regarding the mean absorbed doses per organ, $D_{T,R}$ for each one of the radiopharmaceuticals was taken from ICRP 53 (4), except for ^{99m}Tc sestamibi. Data for this radiopharmaceutical was taken from a description of a commercial kit.

We considered that the remainder consisted of the following tissues and organs: adrenals, muscle, pancreas, spleen, kidney, brain, upper large intestine, small intestine and uterus. To each of them, except uterus, we attributed a weighted factor of 0.0059. In the case of uterus (half population) the weighing factor was 0.0029. In exceptional cases, in which one of the remainder receives an equivalent dose in excess of the highest dose in any of the twelve organs, a weighting factor of 0.025 was applied to that tissue and a weighting factor of 0.025 to the average dose in the rest of the remainder.

The data concerning the number and the type of nuclear medicine examination used in this study, has been collected from the nuclear medicine departments of the hospitals AHEPA, Ippokratio and Theagenio, which cover all the nuclear medicine procedures done in public hospitals in Thessaloniki, second largest city in Greece. The number of examinations was 50102 during the period 1990-1994.

RESULTS

Effective dose per MBq of administrered radiopharmaceutical was calculated based on data from ICRP 53 and ICRP 60. The values of effective dose, E, are given in table 1. Effective dose equivalent (E.D.E.) values published in ICRP 53 are also given for comparison. The effective dose (E) values are compatible with those calculated by other investigators (5).

Table 1 also contains the type of examination/organ, the radiopharmaceutical used, the range of activities administered, the number of examinations, the value of E.D.E. and effective dose, E, and the collective E.D.E. and collective effective dose, S, in man-Sv.

* Red Blood Cell Volume ** Red Cell Survival Time

The mean value of E.D.E. is 3.18 mSv per examination and the mean value of effective dose, is 2.67 mSv per examination. The frequency of examinations in effective dose range is shown in figure 1.

DISCUSSION

The collective effective dose compared to collective E.D.E. appears to be decreased, due to the different weighting factors. We must notice that effective dose from ^{131}I, which is used for thyroid uptake tests, is remarkably increased. Thyroid uptake with ^{131}I represents only 0.8% of the total number of examinations, but due to the relatively large radiation dose per investigation, contributes to the 8% of the collective effective dose. We should also mention that thyroid scans with ^{99m}Tc are 27.3% of the number of examinations, but its relative contribution is limited to 13.5% of collective effective dose.

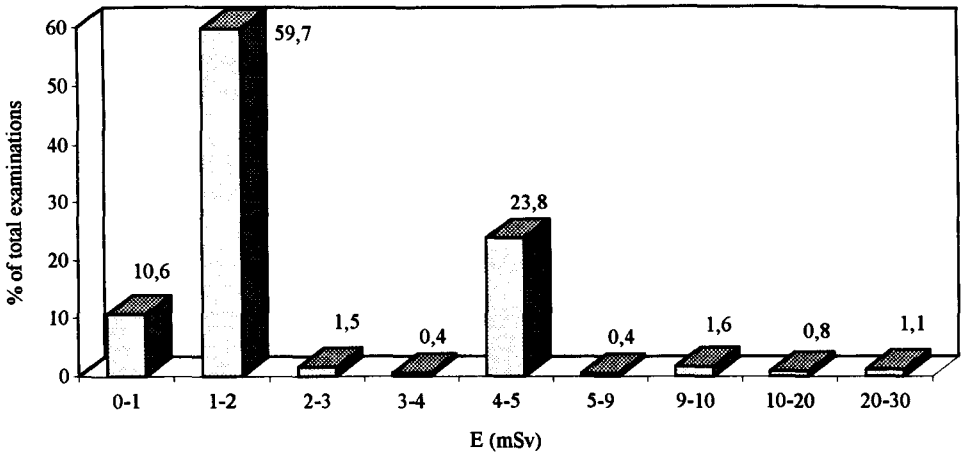

Figure 1. Percentage of examinations in effective dose range.

Although the nuclear medicine diagnostic procedures performed at the three hospitals are twenty eight in total, 80% of the collective effective dose, S, is due only to five types of investigations (thyroid, bone, liver/spleen, kidney-DTPA and thyroid uptake), which correspond to the 87% of the total nunber of examinations. Furthermore, bone scans contribute to 39% of the collective effective dose.

Various nuclear medicine examinations result to different effective dose values, but as it can be seen from figure 1, the 70% of the examinations corresponds to 0-2 mSv and the 24 % of them, due mainly to bone scans, corresponds to 4-5 mSv.

NATIONAL COMPARISON OF ^{131}I SOLUTION MEASUREMENTS IN ROMANIAN NUCLEAR MEDICINE UNITS

Maria Sahagia, Anamaria C.Razdolescu, E.L.Grigorescu, C.Ivan, A.Luca

Institute for Physics and Nuclear Engineering, Bucharest, POB MG6, Romania

INTRODUCTION

The national comparison regarding ^{131}I solution activity measurement, organized by the Radionuclide Metrology Laboratory (RML) aimed at the quality assurance of the measurements of activity along the process of production, quality control, distribution and use of radiopharmaceuticals, Na^{131}I being one of the most used.

Such trial comparisons are often organized in various countries as a step for the assurance of the measurement traceability up to national and international standards. Their necessity was imposed by the fact that many errors are made in hospitals during the administration of radiopharmaceuticals, generally resulting in a supplementary irradiation of the patients [1-4]. RML , recognized as an authorized metrology laboratory, organized previously national comparisons regarding environmental radioactivity measurements[5-6].

The comparison involved the following steps: preparation, standardization, check and distribution of the solution, measurement and processing of the obtained results.

1. PREPARATION AND DISTRIBUTION OF THE SOLUTION

1.1. Preparation and standardization of the solution

The standard ^{131} I solutions had a radionuclidic purity superior to 99%. Three successive gravimetric dilutions were made, with a maximum uncertainty of the dilution factor of ± 0.1%. The third dilution solution was standardized absolutely, by using the $4\pi\beta$-γ coincidence method, in the variant of efficiency extrapolation. The activity concentration, a_{III} , was determined as the mean of nine sources prepared gravimetrically from the solution. The expanded uncertainty of the activity concentration was 0.52% (for a 99% confidence level). The concentration of the first and second dilution solutions, a_I and a_{II} , were calculated from a_{III} value, by using the dilution factor value. The activity concentrations and their expanded uncertainties , U, are presented in Table 1.

Table 1

Dilution	Activity concentration a, MBq/g	Expanded uncertainty, U,%
I	19.14	± 0.72
II	1.931	± 0.62
III	0.4837	± 0.52

1.2. Preparation of vials and check of activity

10 ml vials, normally used in the distribution of radiopharmaceuticals were selected to have as uniformly thick walls as possible; the selection was made by weighing empty vials; a difference of ± 0.5% from the mean weight was accepted. The solution was dispensed gravimetrically in vials, with a maximum uncertainty of ± 0.05%. The mass of solution in a vial m_i , was situated in the interval 4.8...5.2 g. The activities of the vials, A (MBq), were calculated according to the relationship

$$A_i = am_i \qquad (1)$$

where a is one of the values presented in the table 1 A total number of 36 vials were prepared. All were measured in the calibrated high-pressure ionization chamber CENTRONIC type IG12/A2. The measurements aimed at the assay of the weighing precision and uniformity of vial walls and of the dilution factors values used for the calculation of the values in Table 1.

The difference between the measured and calculated from weighing values was <±0.1%.

1.3. Distribution

The participants were selected as to cover the most important institutions involved in ^{131}I use and measurement, as our Radioisotope Department, as sole producer of radiopharmaceuticals in Romania, the National Institute of Metrology; the Control Laboratories of the Ministry of Health, 18 hospitals using mainly ^{131}I and ^{99m}Tc, analysis laboratories and the producer of Romanian calibrators. A form requiring detailed information regarding the type of the measurement equipment, calibration data, method of measurement, applied corrections, was issued. The participants were asked to asses the value of ^{131}I vial activity, in MBq, on the reference data, with the uncertainty value for a 68.3% confidence level and the possible presence of other contaminant radionuclides.

2. MEASUREMENT AND RESULTS

2.1. Assay of Radioisotope Department Calibrators

The first calibration, in the production department, is very important as in many cases this value is taken as reference when ^{131}I is administrated to the patients. Three calibrators (ionization chamber type), used currently in measurements, were verified. The check of calibration was made on a wide interval of activities A, situated between 2.4MBq and 95MBq, by using vials prepared from the three dilutions. The calibrations of the calibrators were made by their manufacturers and were verified regularly by using a reference source. Table 2 represents the obtained results, expressed as mean ratios between the measured activities, A_m , and A values on the whole interval

$$R = (A_m / A) \quad (2)$$

The standard deviation values, S_R , are presented, too.

Table 2

Calibrator	ROBOTRON,1989	ROBOTRON,1990	PITMAN,1978
R	0.969	0.986	0.948
S_R	±0.42%	±0.67%	± 0.58%

The conclusion is that all three calibrators assure calibration uncertainties less than 5.0%, generally declared by the manufacturers; however, a small underestimate of activity values can be noticed.

2.2. Measurements of the other participants

In contradiction with the literature reported intercomparisons, involving only hospitals and ionization chamber calibrators, in our case the area of participants was different, at the same time, the measurements were performed by using ionization chamber radionuclide calibrators, 12 results reported, and spectrometric Ge(Li) or NaI(Tl) systems, 6 results reported. The distributed vials had generally activities of about 10MBq with an expanded uncertainty of ±0.67%. In the case of calibrators, the measurements were made directly; no correction regarding background counting rate was applied. In the case of spectrometric measurements some elaborated procedures were applied. They included the following steps: preparation of measurement samples from the distributed solution; calibration of the spectrometric equipment using appropriate standards delivered by our laboratory [7] or other well-known laboratories as: IAEA, LMRI, Amersham plc, UVVVR. The measurements of samples were made generally by using the 364.5 keV quantum photopeak; all required corrections were applied. Table 3 represents the obtained R values, defined according to the relationship (2), by different participants, their reported uncertainties, S_R, measurement method and type of participant laboratory.

Table 3

No.of particip.	R value	S_R,%	Method of measurement	Type of lab.
1	1.276	10	Picker calibrator,10MBq vial	hospital
	0.768	10	Picker calibrator, 100MBq vial	

2	1.062	2.2	Picker calibrator	hospital

4	1.007	1.6	Capintec CRC 12 calibrator	hospital
5	0.976	3.6	gamma spectrometry	control lab
6	1.007	1.4	standardized ionization chamber*	Metrology Institute
	0.997	0.94	gamma spectrometry	
7	0.998	-	Capintec CRC 15 calibrator	Control lab
	1.025	-	Pitman Calibrator	
8	0.906	-	calibrator	hospital
9	0.991	1.6	Robotron calibrator	hospital
	0.862	1.7	gamma spectrometry	
10	1.383	1.6	gamma spectrometry	analyses lab
11	1.669	-	Mediac calibrator	hospital
12	0.999	1.3	Romanian RI14G calibrator	manufacturer
13	0.978	2.5	gamma spectrom, point source	analyses lab.
14	1.006	3.2	gamma spectrom.point source	analyses lab.

*The same manufacturer as 12.

3. ANALYSIS OF RESULTS

The mean value, R , calculated from the tables 2 and 3 is R=1.040; S_R =±4.0%, and if we exclude the highly erroneous value R=1.669, the new result is R=1.008, S_R =±2.9%. The results are normally distributed near R=1.008 what denotes the fact that no systematic error is made during the measurements at the national level. The best results were obtained with Capintec and Romanian Calibrators and some spectrometric measurements, carefully made. By comparing the obtained results with the requirements of European and Romanian Pharmacopoeia [8,9] which impose an upper limit of measurement uncertainties of ±10% for radiopharmaceuticals, one may conclude that the ratio of laboratories measuring ^{131}I activity in a satisfactory manner is 76%. This figure is inferior to Germany 84% and the United Kingdom 96%. The situation of Romanian hospitals is worse, as we delivered samples to 18 hospitals and only 7 of them submitted results; the percentage of satisfactory results is only 66%. These situations were notified to these units and the correction was made.

CONCLUSIONS

1. The large scale ^{131} I solution national comparison demonstrated the traceability of methods and equipment of measurements to national standards; special attention must be paid in the future to the hospitals measurements.

2. The very good results obtained by some participants, using radionuclide calibrators and standard solutions delivered by well-known foreign producers proved once more, indirectly the traceability of our standards and measurement methods to the international standards.

MEASUREMENT OF INCORPORATED HIGH ACTIVITIES WITH NUCLEAR MEDICINE EQUIPMENT

P. Friedel[1], F. König[2], H. Aiginger[1], E. Ogris[2]

[1]Atominstitut der Österreichischen Universitäten, Vienna, Austria,
[2]Abteilung für Nuklearmedizin-Donauspital, Vienna, Austria

INTRODUCTION

The purpose of this work is the comparison between two instruments frequently used in nuclear medicine: the Whole Body Counter and the SPECT-camera.
Since decades the WBC is a well-established method for quantitative measurement of activity. Apart from some methods of localisation the WBC serves exclusively for the proof of incorporated low activities.
The SPECT-camera is a relatively new imaging system with increasing popularity in nuclear medicine diagnostics. Because of its excellent tomographic abilities it is used almost always in a qualitative way. In the last years one tried to involve the SPECT-camera more and more also in quantitative tasks.
This work tests the capabilities of two of such instruments concerning the quantitative determination of such high activities like they are used for SPECT-acquisitions.

MATERIALS AND METHODS

In order to execute the quantitative measurement of activity under conditions near to such when measuring patients, a torso-kidney-phantom was developed according to MIRD (1) specifications. The phantom made of Plexiglas represents a 20cm high section of the human torso. Two kidney-cavities located at half height of the phantom can be filled with activity (see Figure 1).

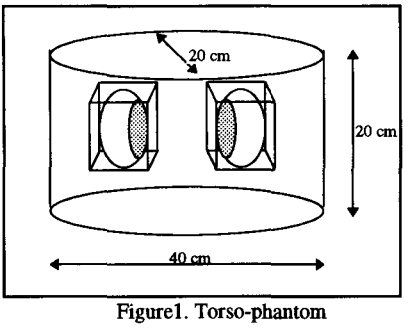

Figure1. Torso-phantom

The WBC (Canberra ACCUSCAN II) is build in *shadow shield*-geometry with 10cm strong steel slabs. Two detector-systems are available for the detection of radiation: A NaJ-scintillation-detector with a crystal size of 5x3x20 inches. It is mostly used for the quantitative evaluation because of its higher efficiency. And a co-axial Germanium-detector with 30% relative efficiency mainly used for the element-identification because of its higher energy-resolution.
The evaluation of the WBC-spectra was done using ABACOS-plus software installed on a DEC MicroVAX 3400.
At activities of 400 MBq of Tc^{99m} the detector-system of the WBC delivers deadtimes of 97%. With the help of a simple collimator built of 1cm strong lead-slabs, which leave a 5mm gap in front of the detector, the deadtime is reduced to 25%.
The source can be measured in *scan-* or in *fixed*-geometry. While deadtime-losses can not be corrected when the source is scanning under the detector, they can be partly corrected in *fixed*-geometry by adding the lost time to the predetermined acquisition time.

For the SPECT-measurements an ELSCINT Apex Helix HR doublehead-camera with an Apex SP-1 processing-station and CLIP-software was used. The acquisitions of the Tc^{99m}-filled kidney-torso-phantom were performed with those acquisition-parameters, which are standard in clinical kidney-studies: Isotope Tc^{99m}, 3° step-and-shoot acquisition, acquisition time 20min, matrix 128x128.

The following correction- and segmentation-algorithms were performed on the acquisition-data before and after the reconstruction: decay-correction, attenuation-correction according to the *first-order Chang* method (2), Compton-scatter-correction according to the *multi energy window* method (3) and finally for the determination of the active volume a segmentation according to a 30% *fixed threshold* method (4,5) or the method of the second deviation (6).

RESULTS

When measuring Tc^{99m}-sources from 1 to 500 MBq with the WBC in scan-geometry, the NaJ-detector shows an activity-dependent efficiency caused by short-term deadtime-effects (see Figure 2). This leads to negligible quantitative errors at activities under 50 MBq, but to errors up to 30% at higher activities. By using an efficiency-curve calculated by means of *least-squares-fit* instead of one single efficiency-value the accuracy for the entire area of activity can be increased to only 2.5% deviation.

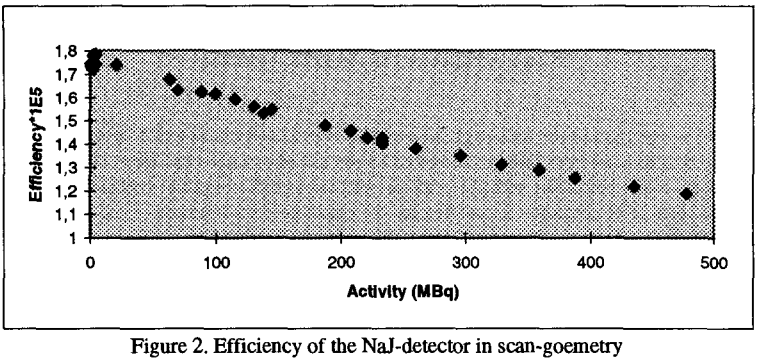

Figure 2. Efficiency of the NaJ-detector in scan-goemetry

Measurements with the Germanium-detector in scan-geometry deliver qualitatively analogous results, but with a more flat curve because of the detector's lower efficiency and the better time resolution (see Fig. 3).

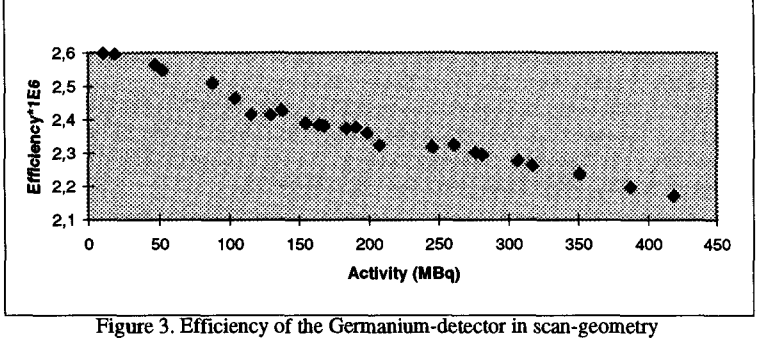

Figure 3. Efficiency of the Germanium-detector in scan-geometry

In a geometry with the source placed motionless under the detector, pile-up effects lead to a similar efficiency course despite electronic deadtime-correction. The above mentioned correction reduces in this geometry too the quantitatve deviations from 15% to 2.5% for NaJ- and Ge-detector.

The evaluation of the SPECT-acquisitions showed different accuracy for quantitative measurement of activity depending on the methods of correction used. The Compton-correction method implemented on this system was useless in this case, since the algorithm itself causes 20% quantitative error.

At the determination of the active volume no essential difference between the two segmentation methods was recognisable. With attenuation-corrected acquisition-data only a negligibly higher accuracy was to reach, than with uncorrected data. Under the ideal conditions of measurement present when working with a motionless phantom placed always identically a quantitative accuracy of 9% is possible with a SPECT-system. No activity dependence could be seen (see Figure 4).

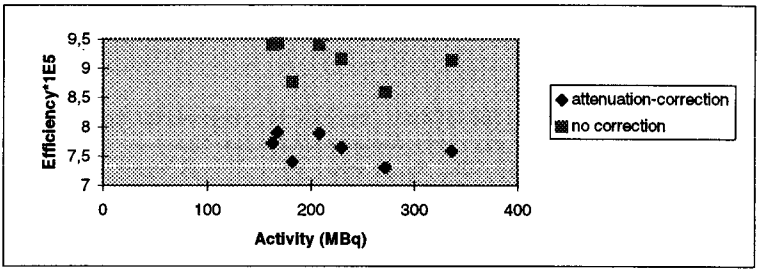

Figure 4. Efficiency of the SPECT-camera

DISCUSSION

Although the WBC is not thought for such high activities, it could easily be adapted by a simple slit-collimator. The still remaining deadtime effects could be corrected by the use of activity-dependent efficiency-values.
At activities between 1 and 500 MBq with the NaJ- as well as with Germanium-detector using this procedure an accuracy of less than 2.5% deviation is possible for the quantitative determination of activity. Even at slight changes in the position or size of the measured object this accuracy can be kept.

The most essential role in quantitative measurement of activity with a SPECT-system has the selection of the mechanisms of correction. Only certain combinations of correction- and segmentation-algorithms have a positive impact on the accuracy.
Only under the ideal conditions of acquisition when working with a phantom errors of 9% for the quantitative determination of activity and 25% for the determination of volume are possible with a SPECT-system. Deviations from this ideal conditions like the above mentioned cause uncertainties of more than 50%.

ABSTRACT (See instructions overleaf)

Quantification of I-131 uptake in metastases from thyroid carcinomas is essential for appropriate patient selection and therapy dose calculation. Measurement of activity in opposing projections and tissue attenuation from a transmission scan has been considered the method of choice (M.J.Myers et al.,Br.J.Radiol., 1981 ,54,p.1062). The technique is both cumbersome and high activity of I-131 filled flood phantom pose a radiation hazard. Transmission measurements with a collimated point source and a uptake probe address safety concerns but make positioning difficult. Measurement of the reference standard under tissue equivalent absorbers selected to simulate soft tissue thickness calculated from anatomical imaging studies is both convenient and safe. Phantom studies have shown accuracy equivalent to the transmission technique.

MAJOR SCIENTIFIC TOPIC NUMBER 6.3 (see page 7)

ABSTRACT (See instructions overleaf)

Both a blessing and a curse in the use of high dose rate (HDR) remote afterloading brachytherapy devices is the complete computer control of the clinical treatment. In our hospital's commercial system (Nucletron MicroSelectron), the treatment planning computer system downloads all information on source movement, both in time and in distance, onto a EPROM card that is used at the treatment console to control the Ir-192 source during treatments. Our QA procedure for the last 1.5 years involves testing this card prior to the patients first treatment to verify its correctness in controlling the source.

As a test we place clear GafChromic dosimetry medium (Model 37-041) in intimate contact with the applicator. The specific patients card then controls the irradiation (1-6 mins.). Examination of the now blue-colored film with a ruler allows quantitative determination of the distance between dwell positions seen as small dots and the offset of the first dwell position from the end of the applicator. Qualitative determination of relative dwell times is by inspection. It takes ~ 33 Gy to achieve an O.D. = 1 and to date no clinical case has given us a film too light or too dark to use. Advantages of this film include no need for external development so the image may be viewed immediately, insensitivity to normal room light, and archivability. The cost is ~ 2 $U.S./case. Examples will be given to demonstrate practical techniques of this radiochromic film.

ACCIDENT IN A LINEAR ELECTRON ACCELERATOR FOR MEDICAL USE

R. H. Rojkind, J. J. Kunst, P. Gisone and E. Palacios

Ente Nacional Regulador Nuclear
Av. del Libertador 8250 (1429), Buenos Aires, Argentina

ABSTRACT

Early in 1993, at a medical centre located in a north-eastern city in Argentina, the first 32 patients treated with a 6 MV photon beam electron linear accelerator, were accidentally irradiated for a total five weeks period at about twice the expected daily dose rates.

The accident occurred as a result of an erroneous calibration of the ionization chamber dosimeter of the medical centre causing an incorrect calibration of the accelerator's photon beam. Due to abnormal clinical effects shown by some patients, the radiotherapist took some actions that avoided an extension of the accident.

Fifty percent of the patients showed local injuries, while the severity observed in a patient's evolution could be associated with the received doses.

INTRODUCTION

During the commissioning in late 1992, the dosimetric acceptance tests of the linear accelerator were performed with a dosimeter owned by the supplier, because the ionization chamber dosimeter of the medical centre was only available in early 1993.

The radiotherapist had 8 year's experience in telecobaltherapy and had just finished his training in electron beam therapy, while the physicist who had been part of the operating team as required by the Argentine regulations, had completed his training in 1990. Since then the physicist had had further experience in telecobaltherapy without any additional performance in photon beam calibration.

INITIAL ACCIDENT CONDITIONS

1 - Situation before the photon beam calibration

The accelerator's physicist did with the following data before calibrating the photon beam: 1) The calibration certificate of the ionization chamber dosimeter, on whose accuracy the physicist did not doubt at all; 2) The results of the dosimetric acceptance tests performed by the supplier, indicating a value of approximately 1.4 m.u./cGy for the ratio between the readings -in monitor units (m.u.)- provided by the dose monitor installed in the radiation head of the accelerator and the doses to water delivered by the accelerator.

2 - Situation after the photon beam calibration

A beam calibration factor of Dw=2.3 m.u./cGy was obtained (absorbed dose in water phantom under standard irradiation conditions). This value could not be adjusted to the usual value of about 1 m.u./cGy and, consequently, an unsuccessful attempt was made to obtain advice from another physicists in Buenos Aires. The Dw value was not compared with the results of the accelerator acceptance tests, no double independent beam calibration was requested (1) and no inter-comparison of the medical centre's dosimeter and other dosimeter was made.

DEVELOPMENT OF THE ACCIDENT

1. The calibration factor for exposure in air of the medical centre's ionization chamber dosimeter, used to calibrate the photon beam when therapy started, was:

$$N_X = 47.41 \text{ Roentgen /digit}$$

2. Between the mid-second and late-third weeks in operation, some of the patients showed radiation induced early effects (diarrheic defecations, radiodermitis). Considering this situation, therapy was discontinued for the most compromised patients.
3. At such time, another physicist was called in and he verified that the doses planning was correct. An inter-comparison of dosimeters was planned but was not performed.
4. During the fourth week, treatments were restarted for some patients and treatments was started for some new ones. By the end of the fifth week, this second group of patients showed early clinical effects. Consequently, an inter-comparison of dosimeters was performed and the conclusion was reached that the doses received by the patients in the accelerator were 2.3 times higher than planned. At that time, all the treatments involving the use of the linear accelerator was discontinued.
5. A third physicist was called in and he assessed that the correct value of the calibration factor for exposure in air of the ionization chamber dosimeter was:

$$N_X = 109 \text{ Roentgen/digit.}$$

6. A total number of 32 patients were treated with dose rates higher than planned, before the dosimeter's calibration error was corrected.
7. Two weeks later, the accelerator's operation was restarted after reprogramming the treatments and since then no other patients have shown any unusual effects.
8. With decreasing frequency, an external physicist supervised planning work and doses administration with the accelerator.

RADIOPATHOLOGIC FEATURES AMONG THE AFFECTED PATIENTS

On the basis of the received doses, most of the patients showed early effects, particularly in their skin and mucosa, that is compartimental and high mitotic indexes tissues. Both the skin and the intestine are tissues with high α/β ratio values (10 Gy), in which the variation of the isoeffect dose with fractionating is weak (2); this fact explains the acceleration of the appearance of early effects and the increase of their severity with the administration of higher doses per fraction.

Table I shows the time T before appearance of early effects as of the initiation of the treatment and the doses received by the organs under treatment; Fig. 1 shows the excess of doses received by the patients with respect to that planned for the organs under treatment. The doses are indicated in terms of the instantaneous equivalent dose **De** given by Walinder's expression (3):

$$\mathbf{De(T)} = \int_0^T \mathbf{0.568}\ \dot{\mathbf{D}}\mathbf{(t)}\ \mathbf{(T-t)}^{-0.29}\,\mathbf{dt}$$

	Radiodermitis	Enterocolitis	Esophagitis
De (Gy)	13 to 26	14 to 24	17 to 21
T (days)	8 to 28	10 to 16	7 to 21

Table I: Instantaneous equivalent dose **De** received in organs under treatment and time T before appearance of early effects

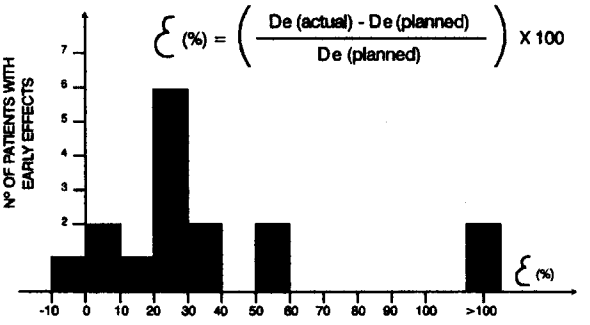

Fig. 1: Excess (%) of instantaneous equivalent dose **De** received, with respect to that planned for the organs under treatment

Concerning late effects, one of the patients showed radio-induced fibrosis and another one died after an intestinal resection a few months after receiving an instantaneous equivalent dose **De**=25 Gy. In the second case, there were early proctorrhage and symptoms compatible with those of a gastrointestinal syndrome. This involves the possibility of causality between this late effect and the cause of death.

The geographical isolation of the site, as well as the previous vital commitment of these patients and the scarce completeness of the clinical records of the patients, hinder in this accident the assessment of an unequivocal causality between late effects and the morbimortality associated with the treatments.

CONCLUSIONS AND LESSONS LEARNED

The accident was caused by an error in the calibration of the medical centre's ionization chamber dosimeter. The professionals involved did not perceive the hazard, in spite of the strong indications found (paradigm (4) of the accuracy of the calibration of the dosimeter).

The initial doubts were focused to the physicist's work; however, later on, considering the chronology of early signs and symptoms, suspicion arose that the doses being used might not be that foreseen and the decision was taken to inter-compare dosimeters. This confirms the relevance that the clinical follow-up of the patients has in order to early detect accidental situations, as it was pointed out in previous cases (5).

In order to prevent the occurrence of these type of accidents, a double and independent initial dosimetric calibration must be implemented (1) for electron linear accelerators, while technical training for the personnel must be intensified and made compatible with the complexity of the system they must use.

Abstract for IRPA 9 (1996)

LESSONS LEARNED FROM ACCIDENTS IN RADIOTHERAPY

Authors: P. Ortiz, J. Novotny, J. Haywood.

There are situations that are unique to radiotherapy: persons (patients) are intentionally delivered very high radiation doses by exposing them to direct radiation beams and radiation sources are incorporated to their bodies as part their treatment. A departure of the prescribed doses may have severe or even fatal consequences. Not only overexposure but also doses below the intended ones are accidental exposures in radiotherapy. According to the Basic Safety Standards for Radiation Protection and for the Safety of Radiation sources, accidental exposures include any treatment delivered to the wrong patient, the wrong tissue, using the wrong source or wrong radiation beam, with a dose or dose fractionation differing significantly from the values prescribed or which may lead to undue secondary effects.

Lessons learned from previous accidents can avoid reoccurrence, at not only at the same facility but at any other facility in the world. For this reason, information on accidents has been collected and a review of more than 50 events has been made. The result is being published in an IAEA document.

The lessons learned, summarized in the document, can be used as checklist for testing the vulnerability of any given facility to the initiating events which triggered the accidents reviewed and factors which made it possible that an initiating event culminated in an accident are present. Initiating events and contributing factors are then classified and measures are derived from them to reduce the vulnerability of any facility. The lessons can also be used as a checklist for self control as well as for external audits to radiotherapy facilities.

NEUTRON SPECTRA OBTAINED FROM PROTONS ON A LITHIUM TARGET FOR BORON NEUTRON CAPTURE THERAPY

INTRODUCTION

The Boron Neutron Capture Therapy (BNCT) will give a powerfull treatment of surface and deeper seated tumors. The basic principle of it is relatively straightforward. The stabile nuclide boron-10, with a large cross section for absorption by thermal neutrons, is concentrated in a tumor by means of a transfer substance like p-boronphenylalanine. The tumor is exposed to neutrons and the radiation emitted after neutron capture, $^{10}B(n,\alpha)^{7}Li$, has a short range in the tissue, in such a way that only tumor cells are destroyed. Thermal neutron beams can be applied for near surface tumors, while the epithermal neutron beams have their application in treatment of deeper-seated tumors. The epithermal neutron beams can be produced by reactors and accelerators. With accelerators different targets and reactions are used to obtain an appropriate neutron beam. This paper presents the neutron distribution and neutron doses obtained from lithum target where neutrons are produced in $^{7}Li(p,n)^{7}Be$ reaction. The proton energies considered are in the 2.0-2.4MeV range.

BNCT

BNCT is a binary radiotherapy modality (1). In BNCT, boron-10, which has a particulary large cross section for capture of thermal neutrons (neutrons having energies less than 0.5eV) is preferentially introduced into the malignant tissue by administration of a suitable boronated pharmaceutical. A thermal neutron field is then generated within the irradiation volume by application of an external beam produced by a nuclear reactor, accelerator or, possibly some other neutron source. The objective of this procedure is to cause selective destruction of the malignant tissue by energetic secondary charged particles, specifficaly helium-4 and lithium-7 ions that results from neutron capture interactions in boron-10. The total energy of this charged particle pair is 2.35MeV. This energy is deposited along charged particle tracks that are comparable in length to cellular dimensions, thereby offering the possibility of cancer cell inactivation with only limited damage to nearby healthy tissue. In recent years, the direction of BNCT research worldwide has been strongly influenced by the recognition that an epithermal neutron beam (neutrons predominantly in the energy range of 1-10keV) will ultimately prove to be optimal for human clinical application. Such a beam is expected to have an advantage compared to the thermal neutron beam currently used in Japan because epithermal neutrons will penetrate a few centimeter into tissue before forming a thermal peak. The properly designed neutron beam is, itself, not expected to cause unacceptable normal tissue damage. Therefore, with an epithermal neutron beam it may be possible to treat some deeper seated tumors without surgery during irradiation and also spare healthy surface tissue.
It is the purpose of our work to develop therapeutical neutron sources based either on a reactor or an accelerator properly designed for operation and irradiation under the condition,

i.e. infrastructure of an hospital. With this paper neutronic calculations and considerations of the layout are discussed.

REACTORS AND ACCELERATORS

Epithermal neutron beams for BNCT can be generated by nuclear reactors and by accelerator based neutron sources. So far, however only reactors have actualy been used to produce therapeutically useful epithermal neutron beams for BNCT. Some low intensity prototypes of accelerator based sources, generally featuring the use of proton beams and beryllium or lithium targets have already been constructed.

Our group suggested a reactor based on MTR type fuel plates as a therapeutical neutron source (2). Water is used as coolant and in-core moderator. Jackets of various materials surrounding the core for ex-core slowing down have been optimized for epithermal neutron extraction. The reactor core design is based on the core envisaged for the FRM-II research reactor at Munich. The neutronic calculations show, that the necessary flux intensity at the irradiation position can be achieved with a power of about 200kW, which is much lower than the power of the reactors (some 10MW) used hitherto.,

One of the promising concepts for use of accelerator based neutron sources for BNCT is the use of 2MeV protons on lithium target, using the $^{7}Li(p,n)^{7}Be$ reaction. There are four important properties of this reaction which makes it a promising candidate for a neutron source for BNCT. First, the energies of emitted neutrons are below 800keV which is not too far from the required neutron energy needed for BNCT. The neutron energy required for BNCT is between 1keV and 10keV with reference of the treatment of surface or deeper seated tumors. Second, the total cross section of the $^{7}Li(p,n)^{7}Be$ reaction is relatively high and it is in the order of a few hundreds of mb for proton energy of 2-2.5MeV. Third, the target is a solid one and not radioactive. Fourth, the power released on the target is 25kW for 2.5MeV protons and 10mA of current. This current reaches the upper limit achievable with accelerators at present. It is, therefore, necessary to optimize the yield of neutrons with energies suitable for BNCT, i.e. 1-10keV.

NEUTRON SPECTRA FOR LITHIUM TARGET

The neutron spectra ($Y_n(E_n,\Theta)$) for maximum proton energy (E_{pmax}) of 2400keV is calculted by equation [1].

$$Y_n(E_n,\theta)\left[\frac{neutrons}{ssrkeVmA}\right] = 6.242\times10^{15}\,\frac{1}{(E_{pmax}-E_{th})}\,\frac{N(Li)}{\left|\partial E_n/\partial E_p\right|}\,\frac{d\sigma(E_p,\theta)}{d\Omega}\,\frac{1}{\left[dE_p/dx\right]} \qquad [1]$$

A solid lithium thick target (some 100μm) is considered. The neutron spectra is calculated for different neutron angles (θ). The calculations are done for three proton regions. For $E_p \geq 1950$keV the energy dependent cross section is used (3). For proton energies between threshold E_{th}=1881keV and 1950keV the cross section of equation [2] is used for neutrons that have positive cosφ in the c.m. system. In addition, a third region of proton energy considered was between 1881keV and 1920.6keV, within which the neutrons may have also negative cosφ in the c.m. system.

$$\frac{d\sigma(E_p,\theta)}{d\Omega} = \frac{\sigma_t(E_p)}{4\pi}\left|\frac{\sin\varphi d\varphi}{\sin\theta d\theta}\right| \qquad [2]$$

θ is the direction of the neutron with respect to proton in the laboratory system and φ is the neutron emmision angle in the centre of mass system.

The total neutron yield obtained from 2.4MeV protons is higher than from 2MeV protons, but the neutrons obtained from these protons have lower energies. For BNCT the neutrons between energies from 1keV and 10keV are needed. The neutrons obtained from 2MeV protons are not far in their energies from the BNCT required energies. With the proton beam of 2MeV the neutrons emitted at $\theta=45°$ have about a constant neutron distribution between 40keV and 160keV. The neutron yield is about 1.2×10^{6} neutrons per (keV s sr mA). For neutrons emitted at $\theta=60°$ the neutron spectrum between 30keV and 120keV is constant with a yield of 10^{6} neutrons/(s sr mA). This energy is so close to the therapeuticaly required that a minimum of slowing down is necessary. Protons with higher energies will yield more neutrons, but those neutrons have also higher energies demanding for more slowing down afflicted with losses. Therefore we have concentrated our calculations on the 2MeV proton beam for creating neutrons.

MODERATOR CONSIDERATIONS FOR LITHIUM TARGET

The lithium target is situated in the centre of Ni sphere with radius of 100cm. The Ni acts as a reflector. In the Ni sphere the channel for proton beam (200mm diameter), a cooling gap (1cm) and a neutron channel (300mm diameter) are simulated. The axis of the latter is rotated for 60° toward axis of proton channel. Zu addition a D_2O moderator (20cm radius) is located at the begining of the neutron channel. The forward, direct neutron beam with too high energies is slowed down by moderator and appropriate axis angle of neutron channel.
The results of first calculations made with MCNP code (4) are given in Table 1. Different collant materials are tested. A modified reflector/moderator combination ($Ni+Ni/D_2O$) is also considered.

Moderator	$Ni+D_2O$	$Ni+Ni/D_2O$	$Ni+D_2O$	$Ni+D_2O$	$Ni+D_2O$
Coolant	H_2O	H_2O	D_2O	N_2	Ar
Φ_{et}(n/cm^{2}s)	1.80×10^{-3}	1.79×10^{-3}	1.82×10^{-3}	1.81×10^{-3}	1.81×10^{-3}
D_{et}(Sv/s)	3.65×10^{-14}	3.64×10^{-14}	3.67×10^{-14}	3.68×10^{-14}	3.68×10^{-14}
Φ_{es}(n/cm^{2}s)	5.30×10^{-5}	5.27×10^{-5}	5.05×10^{-5}	5.19×10^{-5}	5.19×10^{-5}
D_{es}(Sv/s)	8.35×10^{-16}	8.3×10^{-16}	8.12×10^{-16}	8.35×10^{-16}	8.35×10^{-16}

Table 1. Relative values of epithermal fluxes and doses on target and Ni sphere surface

CONCLUSION

According to the calculations, the assumed neutron source intensity based on a proton beam with 25kW will provide a sufficient neutron flux at the irradiation position. (The flux ratio between the target and the Ni sphere surface (1m distance) is 100).
The comparison of different material combinations shows low difference in flux and dose values, so that there is enough flexibility for shielding materials and cooling.

INVESTIGATION OF DEUTERATED MODERATORS FOR D(d,n)^{3}He NEUTRON CAPTURE THERAPY

G.Shani, L.Tsvang and S.Rozin
Ben-Gurion University, Beer-Sheva, Israel

INTRODUCTION

Neutron capture therapy (NCT) is becoming an important technique for brain and skin cancer therapy. An atom of high cross-section for neutron interaction (mostly ^{10}B) is incorporated into tumor cells, then, following a neutron interaction, charged particles are emitted causing cell lethality. So far, in Japan and the US, nuclear reactor were used as neutron sources. We propose the use of neutron generators as the source of neutrons for this purpose, because it has some advantages as compared with the nuclear reactor (1). The neutron generators use charged particles (electrons, protons and light nuclei) or photons interaction with a target atoms (D, Be, W) for the neutron production. One of the basic parts in the proposed neutron generator is a moderator-reflector assembly, which will transform the primary neutron energy spectrum to that required for NCT. The requirements for NCT (a low γ-rays dose and neutron energy in the range 1eV-50keV) impose the use of moderator-reflector assembly of complex geometrical shape and the use of most effective materials. The best material for that purpose is a heavy water (D_2O) (1-3), however it has several disadvantages such as: high price, the necessity of making of complex shape container, because D_2O can be used only in liquid phase, and difficulty in free trade. The purpose of our work is to find the materials that can serve the purpose as heavy water, free of these disadvantages.

MATERIALS AND METHODS

We have investigated neutron moderation properties of the deuterated polyethylene $(C_2D_4)_n$, deuterated polystyrene $(C_8D_8)_n$, heavy water, polyethylene and paraffin. Calculations were made with the code MCNP, version 3.A . We have used the cross-section library ENDFB.4, corrected with the code NJOY for 300^{o}K. We have investigated a simple geometrical model where the neutron source was located on the symmetry axis between the moderator and the reflector, both having a cylindrical shape. Beryllium (Be) was chosen as the reflector material. The thickness of the reflector was 10.5 cm (1). Two types of the neutron sources were assumed in the calculations: monodirectional and isotropic. The neutron energy was 2.8 MeV, corresponding the D(d,n)^{3}He reaction (1). In these calculations the following parameters were considered: the number of neutrons with energy below and above 100 keV, crossing an external surface of the moderator, in cylindrical sectors corresponding to angle intervals of 10^o in the 0^o-70^o range as a function of the moderator thickness; the number of photons, produced by neutron interactions with the moderator and reflector; the photons energy spectrum; neutrons energy spectrum, with 50 keV energy steps in the mentioned sectors and the average neutrons energy in the mentioned sectors.

RESULTS

An optimal thickness was found for each of investigated material so that a maximum number of neutrons with energy below 100 keV was obtained at the external surface of the moderator, in the angle interval 0^o-70^o. In Table 1 are shown the optimal thicknesses of the moderators, in cm and the normalized numbers of neutrons of energy below 100 keV, for each material, for the two sources. It is seen in Table 1 that the neutrons number for

deuterated polyethylene is smaller then that for heavy water, and that deuterated polystyrene provides

Table 1: Relative Epithermal Neutron Intensities

Source type \ Material		Heavy water	Heavy polyethylene	Heavy polystyrene	Polyethylene	Paraffin
Mon	Relative No. of neutrons	1	0.992	0.889	0.43	0.43
	Opt.tickness	18	14	18	7	8
Isot.	Relative No. of neutrons	1	0.969	0.904	0.482	0.497
	Opt.tickness	14	12	14	6	6

12% less neutrons. The neutron energy spectra for D_2O and $(C_2D_4)_n$ in the angle intervals 0^o-10^o and 40^o-50^o (the monodirectional source case) are given in Fig.1. It is seen that deuterated polyethylene decreases the number of neutrons in the higher energy interval better than heavy water, in the 0^o-10^o interval and there is practically no difference in the 40^o-50^o interval.

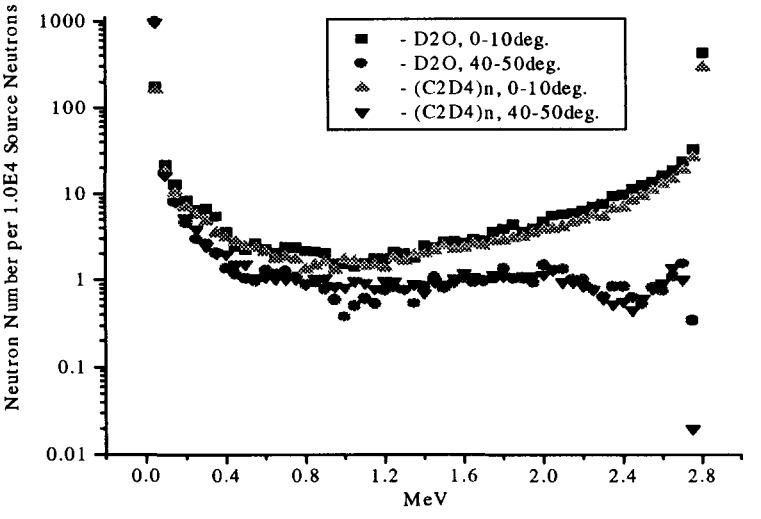

Figure 1. Neutron Energy Spectra

In case of an isotropic source the same variation in high energy neutrons intensity is obtained, for D_2O and $(C_2D_4)_n$, for both directions. A comparison between deuterated polystyrene and heavy water gives inferior results, but significantly better than that for polyethylene and the paraffin. The values of the average neutrons energies at the external surface of the moderator in the angle intervals 0^o-10^o and 40^o-50^o are shown in Table 2. It is seen that the average neutron energy after moderation with $(C_2D_4)_n$ is less than that with D_2O for both neutron sources, it is about the same for $(C_8D_8)_n$. In Figs. 2 and 3 are shown the photons intensities produced by neutron interactions in the moderator and reflector, and their energy spectrum

respectively, for the isotropic source. It is seen in Fig.2 that $(C_2D_4)_n$ and $(C_8D_8)_n$ moderators produce more photons than D_2O, but together with the reflector, the difference in photons number is smaller.

Table 2: Average Neutron Energy

Source type \ Material		Heavy water	Heavy polyethylene	Heavy polystyrene	Polyethylene	Paraffin
Mon	0 - 10 deg.	1.943	1.802	1.872	2.343	2.315
	40 - 50 deg.	0.118	0.117	0.158	0.362	0.346
Isot.	0 - 10 deg.	0.518	0.408	0.55	1.063	1.13
	40 - 50 deg.	0.278	0.208	0.304	0.763	0.817

Fig.3 shows that there are no photons of energy 4 MeV from D_2O, but estimating the contribution of these photons for other moderators to the total ionization of all photons, gives about 13-15%.

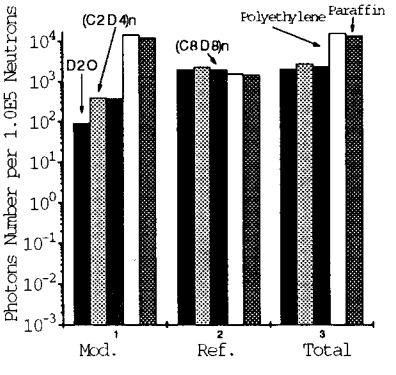

Figure 2. Number of photons produced by neutrons

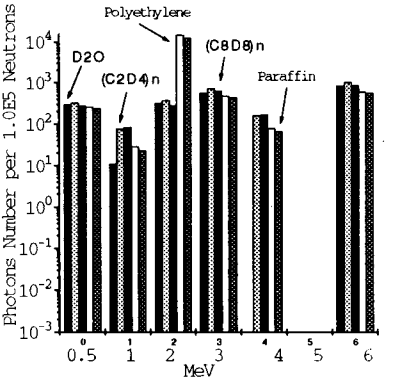

Figure 3. Photon energy spectra

CONCLUSIONS

The results show clearly that deuterated polyethylene can replace heavy water as a neutron moderator for NCT. Deuterated polyethylene was produced in the past (4) and was used as a thin target in accelerator experiments. Its production might be cheaper and easier than that of heavy water.

INTRODUCTION

In the treatment planning of proton beam irradiation, owing to its excellency in dose distribution, radiologists can administrate doses larger than those in the conventional therapy with high energy X-rays. The remarkable performance of the proton therapy with deep-seated tumors is now widely recognized[1]. In the irradiation port of proton beam, collimators and other devices inserted upstream of the beam to the patient interrupt a considerable part of the protons bearing kinetic energy up to 200 MeV. As is well known, high energy protons can generate high energy neutrons when they interact with matter[2]. These strongly penetrating neutrons cause subsidiary exposure to the patient treated with proton beam. One of the authors (Takada) had estimated that transporting efficiency of the irradiation facility employing so-called (single) scattering method is ten percent or so at best[2]. Hence, for the purpose of providing information in making a clinical decision to select the treatment modality and for radiation protection, it is of interest to evaluate these neutron doses and know their importance. Investigations were made at the Proton Medical Research Center (PMRC), the University of Tsukuba.

A CRUDE ESTIMATION OF SUBSIDIARY NEUTRON DOSE

Firstly, we show a crude estimation of the patient neutron dose based on a simplified model. The configuration of collimators in the vertical irradiation port of PMRC is depicted in Fig.1. Assuming that the protons propagate as a corn shaped beam from the scatterer with the two-dimensional Gaussian distribution in the plane perpendicular to the beam axis, it is estimated that ten per cent of protons incident on the beam port are interrupted by the Upper Collimator (UC), fifty per cent by the Lower Collimator (LC), and at least thirty per cent by the Block Collimator (BC). According to the typical settings of irradiation control devices for liver tumor (a common cancer in Japan) treatment, kinetic energy of protons are approximately 180 MeV at UC and 135 MeV (in average) at LC and BC. The data of IAEA[3] (Fig.2) shows that protons of 180 MeV and of 135 MeV stopped in a copper target generate about 0.6 and 0.3 neutrons per proton, respectively.

The fluence of proton beam at this treatment is evaluated as follows. The spectrum of proton beam at the frontal edge of the spread-out Bragg peak (SOBP), $\Phi(E_i)/\Phi$, can be derived form the design shape of the ridge filter. With thus-calculated spectrum, the absorbed dose to water in the region of SOBP by unit fluence of protons, D/Φ, is estimated as a weighted average of mass collision stopping power of water (Fig.3). The value of D/Φ being evaluated as 5.9 MeV/(g/cm^2), the proton fluence corresponding to the absorbed dose of 1 Gy at the target volume in this typical situation is estimated as 1.1×10^9 cm^{-2}.

The calculated value of conversion coefficient from neutron fluence to dose equivalent at 10 mm depth in the tissue equivalent slab[4] varies only 10 % in the energy region between 2 MeV and 100 MeV. So, the value at 10 MeV, 7.2×10^{-10} Sv$\cdot$cm^2 (factor 2 is multiplied following the 1985 Statement of ICRP), is used in this estimation.

The subsidiary neutron dose of 0.01 Sv per 1 Gy of proton dose at the tumor region is obtained in this estimation. The results are summarized in Table 1.

MONITORING OF SUBSIDIARY NEUTRON DOSE BY SODIUM ACTIVATION

The time structure of the proton beam at PMRC being strongly bunched (FWHM = 50 ns), conventional methods of neutron dosimetry are not applicable. Therefore, measurement of activated urinary sodium of the patient is utilized to estimate thermal neutron fluence through the body. There are many materials, *e.g.*, ^{109}Ag and ^{195}Au, being used for activation analysis, but of these materials only sodium is suitable for our purpose. Because, the quantity that is important in

clinical decision making is not a neutron fluence at some specified point on the patient, but the averaged fluence throughout the body. Sodium, the ninth most abundant element in the human body (0.08 %), and having large capture cross section (474 mb) is the most adequate material for this purpose. Urinary sodium is always in equilibrium with blood serum sodium. The ratio of sodium concentration in urine and in blood serum is almost constant with a value of 0.5[5]. Thus, we can obtain average thermal neutron fluence by measuring the activation of urinary sodium.

To confirm the feasibility of this idea, sodium activation measurement was conducted with a patient who was administrated 3 Gy of proton dose to an abdominal tumor. The urine was sampled about 20 minutes after the irradiation. The radioactivity of 9.5×10^{-1} (±13 %) Bq of ^{24}Na at the time of irradiation was measured with the urine sample of 50 cm^3. Using the normal concentration of urinary sodium (7×10^{-5} mol/cm^3), average thermal neutron fluence is estimated as 3.7×10^7 cm^{-2}. Thus, the thermal neutron dose to this patient is evaluated as 0.6 mSv using the conversion coefficient for thermal neutrons given by ICRP[4].

Neutrons are thermalized in the matter surrounding the patient as well as in the body of the patient itself. A series of phantom experiments were conducted to verify which is dominant. The amount of activation of NaCl solution set inside the phantom (polyethylene, cubic) decreased when bottom part of the phantom was removed. The result shows that the thermalization in the body of the patient is dominant.

In order to estimate from the thermal neutron fluence, knowledge of the neutron spectrum is needed. The spectrum of neutrons to which the patient is exposed, however, is influenced by the configuration of irradiation control devices such as collimators, filters and degraders. As a result, the spectra are each different. However, detailed structure of each spectrum is not so important for our purpose, because it is sufficient to know the ratio of subsidiary neutron dose to the administrated proton dose, and moreover the value of dose equivalent is not so sensitively affected by the detailed structure of neutron spectrum. So, a computer simulation was conducted to obtain a neutron spectrum in the phantom with a "typical" configuration of irradiation control devices. The HERMES[6] code was used to simulate generation and propagation of high energy neutrons. To simulate transportation of fast and slow neutrons, the DOT[7] and ANISN[8] codes were employed.

A sample of geometries and spectra in the numerical analysis are shown in Figs. 4 and 5. In this case, the neutron spectrum is considered to be the "hardest", since neutrons are generated just upstream the phantom. The dose due to whole neutrons is estimated about 25 times of thermal neutron dose from this investigation.

Consequently, the subsidiary neutron dose per unit dose of administrated protons is estimated about 5 mSv/Gy.

Radiation therapy with a proton beam has a number of important advantages over conventional radiation therapy. The proton beam allows the maximum dose to be confined to the treatment volume while the dose to surrounding normal tissues is minimized. Realization of these advantages requires higher precision of the proton beam dosimetry.

For absorbed dose rate measurements of therapeutic proton beams we use the KD-27012 clinical dosimeters with thimble air–filled ionization chambers VAK-251 (volume 50 mm^3) and VAK-253 (volume 1.5 cm^3) with air–equivalent walls. The dosimeter calibration was made with the ^{60}Co source of the therapeutic γ-unit, placed in one of the cabins of the clinico–physical facility in accordance with the recommendations of the "Code of practice for clinical proton dosimetry"[1]. The ^{60}Co source was calibrated against the primary standard of the Prague Institute of Radiation Dosimetry with the accuracy of 1.3% [10]. Using the γ–unit as a calibrated stand for ionization chambers of our clinical dosimeters was described in [3,4].

The absorbed dose calibration factor for the proton beams A_{cal} may be obtained from the calibration of the ionization chamber in the ^{60}Co source using the relations:

$$A_{cal} = N_k * C_p = N_x * (W_{air}/e)_\gamma/(1-g) * C_p \ ,$$

where N_k (Gy/reading) is the air kerma calibration factor and N_x (R/reading) is the exposure calibration factor in the ^{60}Co beam.

The proton conversion factor C_p may be obtained using the formulae from [1]:

$$C_p = A_{wall} * [(\bar{S}/\rho)^{tissue}_{air}]_p * k \ ,$$

where

$$k = (1-g) * \frac{(W_{air}/e)_p}{(W_{air}/e)_\gamma} * \frac{[(\bar{\mu}_{en}/\rho)^{wall}_{air}]_\gamma}{[(\bar{L}/\rho)^{wall}_{air}]_\gamma}.$$

The following coefficients were used for our dosimeter calibration:

- A_{wall} is the wall perturbation factor that takes into account absorption and scattering of γ-rays produced in the ionization chamber walls. The value $A_{wall} = 0.99 \pm 0.01$ is in accordance with these values for all chambers with similar geometrical dimensions.

- $[(\bar{S}/\rho)^{tissue}_{air}]_p$ is the ratio of the mass stopping powers of tissue to air for the proton beam - may be obtained from [5,6]. The "Supplement to the Code of Practice for Clinical Proton Dosimetry" [2] incorporates the new stopping power data from [6]. Differences in the ratios calculated from these two compilations are less than 2%. For proton energies 50 - 1000 MeV this ratio varies very slowly and

in [3] it was used as a constant value 1.136 ± 0.016 (1.4%). Table 1 also presents A_{cal} calculated for proton energies 10 MeV and 200 MeV. As we can see A_{cal} very slightly depends on the energy of protons;

- (1 - g) - correction to bremsstrahlung in the air in the ^{60}Co beam (g = 0.003) [1];
- $(W_{air}/e)_p = 35.2eV \quad (4.0\%) \qquad (W_{air}/e)_\gamma = 33.97eV \quad (0.2\%)$ - the average energy required to produce an ion pair in dry air for γ-rays and protons [1]. These values are recommended in [1,2] for all proton energies. But this value of $(W_{air}/e)_p$ is based on measurements at a proton energy of 1.8 MeV [7]. Recently many investigations of the energy required to produce an ion pair for heavy charged particles and in particular a correlation between $(W_{air}/e)_p$ and the LET of particles were performed. For example, in the paper [9] values of $(W_{air}/e)_p/(W_{air}/e)_\gamma$ for different heavy charged particles with different energies from the published data were plotted versus the unrestricted LET. This plot shows that for protons with energy higher than 10 MeV $(W_{air}/e)_p/(W_{air}/e)_\gamma$ is equal to 1.0 and increases with increasing LET (or decreasing proton energy). This value is in agreement with the $(W_{air}/e)_p$ obtained in [8]. This plot also confirms the value $(W_{air}/e)_p/(W_{air}/e)_\gamma$ measured at a 1.8 Mev in [7] and recommended in [1,2]; The $(W_{air}/e)_p$ value of 34.2 ± 0.5 for the dry air found in latest measurements [11] by using a water calorimeter to calibrate an ionization chamber in proton and ^{60}Co beams also confirmed this plot. This value undoubtedly has to be recommended for determination of the dose in therapeutic proton beams.
- $[(\bar{\mu}_{en}/\rho)^{wall}_{air}]_\gamma = 1.0227$ (1%) - the ratio between the mean mass energy absorption coefficients of the chamber wall material and the air for γ-rays for our ionization chambers [4];
- $[(\bar{L}/\rho)^{wall}_{air}]_\gamma = 1.0076$ (1%) - the ratio between the mean restricted collision mass stopping powers of the chamber wall material and the air for γ-rays [4].

The results of the ionization chamber calibration with different parameters are presented in Table 1.

The full estimated uncertainty of the A_{cal} value with $(W_{air}/e)_p = 1.007$ from [11] is about 3% (one standard deviation).

CONCLUSIONS

- The method for determination of the dose rate absorbed by tissues for the JINR medical proton beam on the basis of clinical dosimeter calibration with the ^{60}Co γ–source is described. The results of the ionization chamber calibration using different parameters are presented. The basic parameters used for calculations were taken from various papers.
- The energy dependence of the calibrated factor is very slight and influence of the proton beam energy distribution is negligible.

ABSTRACT

The main reason of overirradiation in brachytherapy is an incorrect dose definition in support point on the distance of 20 mm from the source centre. Small geometry change source situation, inexactitude its activity definition can lead to considerable errors because of great dose change near by the source.

Removal these mistakes can be reached by the perfect means of certification. For this purpose the special device is suggested. It allows to define support point dose with the mistake no more than +5% and answers dosimetry and radiobiology requirements.

ABSTRACT (See instructions overleaf)

The influence of bone inhomogeneity in brachytherapy dose distribution is commonly ignored in dose calculation for treatment of carcinoma of the nasopharynx (NPC). This results in an uncertainty in dose determination for the tumor and critical organs near bony structures such as the nasopharynx. The influence of bone inhomogeneity in dose distribution from an ^{125}I source model 6702 was measured. For comparison, a similar study was conducted using ^{192}Ir. another commonly used isotope in NPC. The measurements were performed using LiF thermoluminescent dosimetry (TLD) chips and ion chamber dosimetry. Special phantoms were designed to hold the sources and TLD chips. These phantoms consisted of solid water for homogenous phantoms or a combination of solid water and solid water and solid bone in different configurations to create inhomogeneous phantoms. A human skull was also used to determine the dose to the critical tissues around the nasopharynx from both ^{125}I and ^{192}Ir sources. For ^{125}I a decrease in the dose delivered to the proximal side of the bone of as much as 25%. On the digital side of 1.5 cm of bone, the decrease was as much as 70% as compared to the homogeneous phantom. No significant dose reduction due to the presence of the bone was noted for ^{192}Ir.

ABSTRACT (See instructions overleaf)

Brain injury in leukemia patients.

Todua F. Beraia M.

Purpose:Leukemia, a malignancy of the bone marrow, is the most common form of childhood cancer. Leukemia is always disseminated at the diagnosis and can often involve nervous sistem. Cases of neuroleikemia in infants without specific treatment is 65%.

Methods and Materials: We studied CT findings of brain in 85 cases of infant neuroleukemia. 60- limphoid form and 25- mieloid. Patients were treated by scheme BFM-90 in 12 cases treatment was associated with brain radiotheraphy - 25 Gray.

Results: All patients with mieloid form lneuroleukemia demonstrated typical findings of hydrocephalia with normal intracranial pressure, ventricular and sulcar dilatation, brain atrophy. The changes were more significant in radiotheraphy group. In not treated patients brain atrophy was regionally-mostly in frontal region and were diffuse after chemotheraphy.

Conclusion: In leukemia patients with clinically normal nervous sistem was revealed brain injury in 10% of cases and mostly after radiotherafhy. CT imaging findings are not always specific for patologic conditions and must be interpreted in conjuction with chemical and laboratory date.

NEW RESULTS ON SHORT-TERM ANNEALING FOR CLINICAL TL DOSIMETRY

U. Fill, D. Regulla

GSF - Forschungszentrum fuer Umwelt und Gesundheit
Institut fuer Strahlenschutz, Neuherberg
85758 Oberschleissheim, Germany

ABSTRACT

Traditional annealing procedures for lithium fluoride are time-consuming and last between 6 to 24 hours; they allow one read-out cycle a day only. This represents problems especially in clinical routine if the number of detectors is limited. A short-term annealing procedure was developed in 1971 for the use in radiation protection with doses below 0.1 Gy [3]. This method enables the user to perform a large number of read-out cycles a day. The present study shows a modified short-term annealing cycle that can also be used in radiation therapy for dose levels between 0.5 and 6 Gy. The procedure requires about 1 h annealing time in total, including heating-up, 15 min at 400°C and an oven specific cooling-down profile. It can be applied without any drawback in precision. No further temperature treatment like e.g. thermal stabilization, was used in the present investigations. The low temperature peaks have been eliminated by using a self-developed computerized glow curve analysis software. A reproducibility test with 10 measuring cycles yielded precision of 0.2-0.4 % (1 s.d.) for individual LiF:Mg,Ti (TLD-100) chips. Further advantages of the described annealing procedure are an increase of response and a reduction of supralinearity.

INTRODUCTION

Precision in dose assessment with LiF:Mg,Ti (TLD-100) detectors suffers from the change of sensitivity caused by the required temperature treatments. Detector annealing subsequent to the readout cycle (e.g. pre-irradiation annealing) should minimize the change. Traditional annealing procedures with a duration of 6 to 24 hours [1, 2] allow only one read-out cycle a day. In 1971 the procedure of short-term annealing was developed for the use of thermoluminescence detectors in radiation protection for doses below 0.1 Gy [3]. The proposed procedure of pre-irradiation annealing lasts 5 min at 400°C, while pre-readout annealing consists of 5 min at 100°C to thermally stabilize the glow-curve. This method was modified here for doses up to 6 Gy as used in radiotherapy, with the pre-irradiation annealing time at 400°C increased to 15 min. The pre-readout annealing is substituted by a numerical stabilization procedure using a GSF developed computerized glow curve deconvolution (CGCD) software, called TLD_GLOW [4]. The procedure enables the user to perform a number of readings a day. The present study proves that short-term annealing after only slight modifications can also be used in radiation therapy up to at least 6 Gy.

MATERIAL AND METHOD

The investigations have been carried out with LiF (TLD-100) chips of the dimensions 1/8" x 1/8"x 0.035". Similar investigations were performed earlier with LiF (TLD-100) rods of 1 mm in diameter and 6 mm length [5].

Three series of tests with (a) long-term conventional annealing, (b) short-term annealing with low heating-up and cooling-down rates and (c) short-term annealing with fast heating-up and cooling-down rates were carried out at GSF. Each test sequence contains the evaluation of calibration factors, the determination of a supralinearity correction function and a blind test. All necessary calculations were performed using the GSF-developed software TLD_CALC for precise TL dosimetry [6].

The thermal treatments, i.e. pre-irradiation annealing for series (a) and (b) were performed in a

volume-type oven TLDO manufactured by PTW, Freiburg, Germany. The pre-irradiation annealing for serie (c) was carried out with a disc-type oven, developed at GSF [3, 7].

The time-temperature profile for TLD-100 detectors, as used in most hospitals, consists of 1 h at 400°C followed by 2 h at 100°C. The whole process lasts about 4 h and was used for serie (a) experiments. The short-term annealing procedures as used in the present investigations lasts about 1 h for serie (b) and about 30 min for serie (c) including 15 min at 400°C as well as heating-up and cooling-down periods. For the serie (c) experiment the detectors were placed manually on an aluminum plate and further on a disc pre-heated to 400°C. After 15 min the detectors were removed, also manually and placed on a cooling element of room temperature. The cooling-down period to about 50°C takes about 15 min (figure 1).

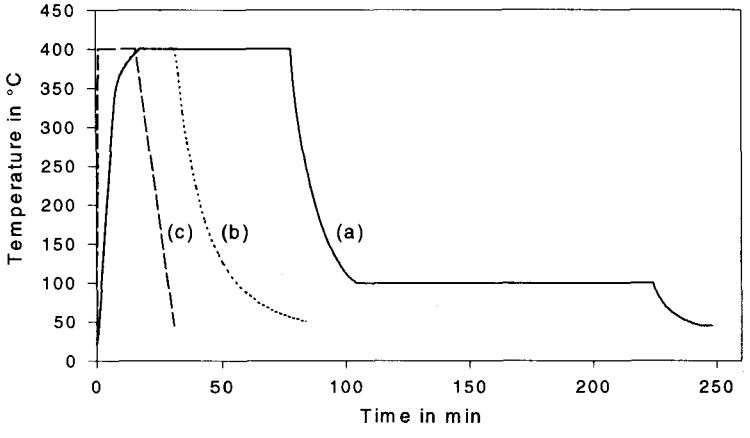

Figure 1. Comparison of duration of the three annealing cycles used for the present investigations: (a) Conventional annealing as used at most hospitals, (b) short-term annealing with low heating-up and cooling-down rates and (c) schematic view of the short-term annealing with fast heating-up and cooling-down rates.

For detectors with doses higher than 3 Gy the short-term annealing does not provide to a complete regeneration. In this case four annealing cycles have to be performed to get back the original calibration factors.

The TL read-out equipment was an automatic turn-table nitrogen hot-gas-reader, type H5500, manufactured by Harshaw/Bicron, Cleveland, USA, with a PC controlled linear heating profile. It starts at 120°C and reaches 320°C at a heating rate of 10°C/s. Before detector change the H5500 cools down to 50°C. Linearity of the heating profile is essential, because the obtained glow curves were supposed to be processed with the CGCD software TLD_GLOW, to eliminate the low temperature glow peaks without using a thermal stabilization [4]. For dosimetry the current integrals of the peaks 4 and 5 were used.

All irradiations were carried out at a ^{137}Cs radiation source in the Secondary Standard Dosimetry Laboratory (SSDL) of GSF using a Buchler Calibrator, type OB20, manufactured by Amersham/Buchler [8]. The TL detectors were exposed in 1 m source distance under a 3 mm thick build-up layer of acrylic glass to provide charged particle equilibrium. The measuring quantity was absorbed dose to water.

RESULTS AND DISCUSSION

With the above described methods and procedures the following results were achieved:

(1) Coefficients of variation of about 0.3% for individual calibration factors were obtained at all three test series for 10 calibration cycles each.

(2) Detector responses increased by 17% for serie (b) and 31% for serie (c) experiments if compared with conventional annealing in test serie (a).

(3) Supralinearity turned out to be exactly the same for all three test series - in opposite to the earlier reported investigations [5]. There might be two reasons for that: (a) In the present investigations 'chips' have been used instead of 'rods'. Due to differences in batch production both may show different supralinear behaviour. (b) The changes in the supralinear behaviour between conventional and short-term annealing are due to peaks above peak 5. These peaks have been disregarded in this study by using the CGCD software. By contrast, the investigations in [5] used thermal stabilization, a Harshaw ATLAS reader with continuous 350°C gas flow and a region of interest exceeding peak 5. We assume that argument (b) is more probable, but further investigations are necessary to clarify this discrepancy.

(4) Three blind tests for the test series (a), (b) and (c) showed a total statistical uncertainty in dose assessment better than 0.8%. The complete blind test results are given in table 1.

Table 1. Results of three blind tests with 10 detectors for each dose as obtained with (a) conventional, (b) short-term annealing with a low heating-up and cooling-down rate and (c) short-term annealing with a fast heating up and cooling-down rate. Unknown doses by ^{137}Cs gamma radiation (CPE) applied at the SSDL of GSF.

Series	Unknown dose	Evaluated dose ± 1 s.d.	D(evaluated)/D(unknown)
(a)	0.700 Gy	0.698 Gy ± 0.003	0.997
(a)	2.600 Gy	2.622 Gy ± 0.016	1.008
(b)	0.800 Gy	0.797 Gy ± 0.005	0.996
(b)	2.400 Gy	2.401 Gy ± 0.010	1.000
(b)	3.600 Gy	3.627 Gy ± 0.020	1.007
(c)	0.600 Gy	0.603 Gy ± 0.005	1.005
(c)	2.300 Gy	2.316 Gy ± 0.015	1.007
(c)	3.100 Gy	3.123 Gy ± 0.023	1.007

CONCLUSION

The modified short-term annealing procedure for therapy-level doses has been applied at GSF for research purposes since 1992 without any problems. Dosimetric advantages combined with considerable time saving in all calibration and measurement cycles as well as successful tests in clinical routine [5] revealed, that short-term annealing is superior to conventional annealing procedures.

CANCER INCIDENCE AFTER RADIOTHERAPY FOR SKIN HAEMANGIOMADURING INFANCY

Bertil Arvidsson[1], Sture Lindberg[2], Per Karlsson[2], Erik Holmberg[3], Lena Marie Lundberg[1] and Arne Wallgren[2]

[1]Dept of Radiation Physics
[2]Dept of Oncology
[3]Oncological Centre
Sahlgrenska University Hospital
Göteborg, Sweden

INTRODUCTION

Infants who were irradiated because of cutaneous haemangiomas have been followed up through registers for up to 55 years after the treatment and incident cancers have been recorded. The aim of the study was to describe the cohort, the treatment techniques and dosimetry and present the incidence of new cancers in comparison with an age and sex matched Swedish population.

MATERIAL AND METHODS

Between 1930 and 1995, 12 055 infants (8 028 girls, 4027 boys) were treated with Radionuclides for haemangioma of the skin at the Radiotherapy Department, SahlgrenskaUniversity Hospital, Göteborg, Sweden according to the treatment registers.

Altogether 14 954 haemangiomas were treated in 12 055 infants. The most common location was in the head and neck region, together representing 37 % of all treated haemangiomas. The median age of the children at the first treatment was 5 months. Eighty–eight per cent were treated before 12 month of age and only 4.5% had their first treatment after 18 month of age.

In all 11 867 patients were traced and only 100 could not be identified. Sixty individuals were either dead (n = 35) or know to have emigrated (n = 25) before 1958. The remaining 11 807 persons contributed 370 517 persons years at risk (123 977) males, 246 540 females) during the years from 1958 to 1989, at which period the cohort was followed up in the Swedish Cancer Register for incident cancer cases.

STATISTICAL METHODS

The expected numbers of cancers for all sites of this population were calculated on the basis of age, sex and year specific cancer incidence rates for the West of Sweden Health Care Region.

The standardized incidence ratio (SIR) was calculated as the ratio between observed and expected numbers of cancer. Confidence intervals (CIs) were estimated assuming a Poisson distribution of the cases. The excess relative risk (ERR) was calculated as the ratio between the excess and the expected numbers of cancer. The excess number was defined as the difference between observed and expected numbers. The ERR per Gy was derived from the ERR divided by the mean absorbed dose in Gy, and the excess absolute risk (EAR) was estimated as the excess number of cancer patients per person–year (PY) and per Gy (3).

DOSIMETRY

The methods and procedures for the estimation of the cumulative absorbed dose in the different risk organs for the whole cohort have been described previously (1).
The location of the haemangiomas was coded in different regions over the surface of the body. A phantom of the size of a 5–6 monthold child was constructed and 11 risk organs were specified. The absorbed dose to these organs per 100 mg of ^{226}Ra in the source of application (mgh ^{226}Ra) was calculated for all the regions separately using a computed dose–planning
system.

We only included the gamma irradiation in the dose response evaluation since it contributes to the main part of the risk organ doses. The contribution to the doses from the β–irradiation was not included.

RESULTS

In the cohort o1 11 807 children, 248 cancers were found in 225 individuals against 204 expected. The standardized incidence ratio (SIR) was 1.21 (95% CI 1.06–1.37). The exclusion of the first 5 years after exposure did not change the SIR (1.22, CI 1.07–1.38). No overall difference was observed between the sexes. In males, 62 cancers were found (SIR 1.25, 95% CI 1.03–1.38).

Table 1 shows the number of cancers of the different organ systems and the relative rates in comparison with an age–, sex– and time–matched population. The data are further divided according to the type of radium therapy, γ–ray treatment(329 771 person years) or β–ray treatment (40 746 person years). There was a significantly increased number of cancers only among those who had been treated with γ–rays (SIR 1.26, 95% CI 1.09–1.42) but not among those treated with β–rays only (SIR 0.90, 95% CI 0.57–1.37).

Table 1

Numbers of cancers according to site and the standardized incidence ratio (SIR) is presented. Numbers are given for the total material and according to treatment technique. Assuming a Poisson distribution, 95% confidence intervals (CI) are given for the total material

Site (ICD-7)	^{226}Ra γ		^{226}Ra β		Total		
	Number of cancers	SIR	Number of cancers	SIR	Number of cancers	SIR	95% CI
Oral, digestive organs (140–158)	20	1.12	0	–	20	0.98	(0.60–1.51)
Respiratory organs (160–164)	5	0.96	0	–	5	0.83	(0.27–1.94)

A significant difference from 1.0 ($p < 0.05$) is indicated (*).

Significantly increased numbers of tumours were found in the central nervous system (ICD–7 193), 34 cases, SIR 1.85 (95% CI 1.28–2.59), the thyroid (ICD–7 194), 15 cases, SIR 1.88 (95% CI 1.05–3.09) and other endocrine glands (ICD–7 195), 23 cases, SIR 2.58 (95% CI 1.64 – 3.87). Of the 15 thyroid cancers 14 were reported as papillary cancers and one as a medullary cancer. There were 23 tumours in other endocrine glands (ICD–7 195): one inthe adrenals, 13 in parathyroid glands (SIR 3.03, 95% CI 1.61–5.17), 5 in the pituitary (SIR 1.96. 95% CI 0.63–4.59), 3 in the thymus and one was an insulinoma.Two of the parathyroid tumours were detected at the time of treatment for thyroid cancer. The excess relative risk (ERR) was 7.5 per Gy (95% CI 0.4–18.1) for thyroid cancer, and the excess absolute risk (EAR) 1.6 per 10^4 PY and Gy (95% CI 0.092–3.9). For cerebral tumours EAR was 10.9 per Gy (95% CI 3.6–20.5) and the EAR was 5.4 per 10^4 PY and Gy (95% CI 1.8–10.1).

DISCUSSION

We have used a cohort of nearly 12 000 children treated with ^{226}Ra for haemangioma to investigate carcinogenic effects of ionizing radiation in infancy. In this cohort, there was a slight but significant excess of neoplasms (SIR = 1.21, 95% CI 1.06–1.37).

We only found a significant excess of tumours in those who were treated before 1950. This was probably due to their longer follow-up and higher age compared to those who were treated in 1950 or later.

For individual sites, only the rates of cancers of the CNS, the thyroid and other endocrine glands were significantly higher than expected. Neoplasms of other endocrine glands were dominated by parathyroid and pituitary tumours, adding to the excess of intracranial and neck tumours.

A similar overall excess of neoplasm was found in patients treated in much the same way in Stockholm (4). As in our study, thyroid neoplasm's were also in excess in their study. The ERR per Gy for thyroid cancer in the Stockholm study (4) was 4.9 compared with 7.5 (95% CI0.4-18.1) in our cohort. The estimates from the two Swedish cohorts should be compared with the Rochester study (5) where the ERR was 9 per Gy infants irradiated for thymic enlargement. For brain tumours our cohort showed a significant excess but the Stockholm cohort had no excess at all. The mean absorbed dose in the CSN was almost the same for the Stockholm (6) and Gothenburg cohorts, 0.07 Gy and 0.08 Gy repectively. The EAR for brain tumours in our study, 5.4 per PY and Gy (95% CI 1.8-10.1) should be compared with the Israeli tinea capitis study (7) with an EAR of 0.6 per 10^4 PY and Gy. Except for chance, there is no obvious explanation for the difference in relative rates of CNS neoplasm's between the Gotenburg and the Stockholm study and why our cohort has a much higher EAR for brain tumours than the Israeli study.

PRESENTING AUTHOR (IF DIFFERENT)

MAJOR SCIENTIFIC TOPIC NUMBER ..... (see page 7)

ABSTRACT (See instructions overleaf)

IR-8 reactor of the Russian Research Center (RRC) Kurchatov Institute was used for neutron capture therapy (NCT) investigations with experimental animals. Besides that, new methods and devices for operative neutron fluxes control, on line prompt γ -ray neutron dosimetry for operative control NCT and tailoring neutron beam for NCT were worked out. The following major methodic results are obtained:

1. Methods and devices for neutron beam control.

The devices are suggested for operative control of neutron fluxes, their spectral and dose characteristics with the energy range from 10 neV to 10 MeV, in which spectrometry of prompt γ - rays produced in the interaction of neutrons with the multilayered targets, is used.

2. Method on line neutron dosimetry.

Also a method for in situ neutron dosimetry on line by means of prompt γ -ray spectrometry is offered. This method is based on the determination of nuclear reactions quantity in the irradiated objects by the registered intensity of γ -rays. The energy of each reaction product, absorbed in the object is computed with the help of nuclear and atomic data tables.

3. Thermal and epithermal neutron beam tailoring method.

The hydrogenous scatterer of small thickness is suggested for tailoring of intensive therapeutic neutron beams with small contribution of fast neutrons (1%) and γ -rays. The scatterer is disposed in tangential experimental channel of reactor. Decreasing of fast neutron contribution and consequently fast neutrons KERMA reducing of the neutron beam are achieved due to peculiar energy dependence of neutron scattering cross section on hydrogen nuclei.

ASSESSMENT OF EFFECTIVE DOSE AND UTERUS DOSE FOR WORKERS IN MEDICAL RADIOLOGY

Chr. J. Huyskens and Y. Franken

Centre for Radiation Protection, Eindhoven University of Technology
P.O. Box 513, 5600 MB Eindhoven, The Netherlands

INTRODUCTION

Using model calculations for x-ray shielding and dosimetry, we analysed the protective effect of lead aprons on the effective dose and organ doses to workers in medical radiology. We investigated the relationship between effective dose and personal dose measurements. Our study enables the choice of appropriate correction factors for converting depth dose measurements into effective dose, for typical exposure situations in medical radiology. In consideration of protection of the conceptus, we give guidance on the control of the equivalent dose to the uterus.

Estimation of organ doses and the effective dose from scattered x-rays is complex because the depth dose distribution in the body is highly energy dependent. In practical radiology it is further complicated by partial body shielding with protective aprons and from variations in exposure orientation.

We developed a computer model to calculate equivalent organ doses as a function of x-ray energy spectrum, shielding parameters and exposure geometry. Our model refers to whole body exposure by broad parallel beams, in simulated exposure geometries that represent typical working conditions in medical radiology. All equivalent organ doses are calculated per unit kerma-in-air at the surface of the trunk. We adopted the appropriate organ dose conversion factors derived from Monte Carlo calculations in mathematical phantoms (4). The effective dose is calculated as the weighted sum over relevant organs with their assigned weighting factors, according to the definition by ICRP (5).

We analysed the reduction of the effective dose from use of lead aprons of different model, fit and lead thickness, all in function of tube potential and variations in exposure geometry as they occur in actual practice. The protection efficiency is strongly dependent on model and fit in combination with exposure geometry. After all, unshielded and partially unshielded organs have a dominating influence on the effective dose.

We give conversion factors for assessment of the effective dose from personal depth dose measurements. The calculations of the badge depth dose in personal monitoring refer to the depth dose equivalent at 10 mm tissue in AP-orientation (6). Our study enables the choice of an appropriate division factor (shortly called: divider) for correction of unshielded badge depth dose measurements, that always significantly overestimate the effective dose. Our divider may be applied to unshielded badge measurements "mid front" at collar or chest, outside the apron, provided that the apron suits the exposure geometry and the fit is reasonably good. We strongly advise against placing a single badge under the apron. Our calculations have clearly shown that considerable levels of effective dose cannot be assessed due to the substantial enhancement of the lower detection limit for dosimetry under the apron. For tube voltages above 100 kV, the lower detection limit is increased by a factor of 10 to 20. At lower energies, the increase of the lower detection limit is much higher. Furthermore, the degree of underestimation of the effective dose by shielded badge depth dose is highly sensitive to variations of tube voltage and lead thickness.

We analysed the protective influence of lead aprons on the uterus dose and the relationship between the uterus dose and badge depth dose measurements. We conclude that lead aprons reduce the uterus dose equivalent by over a factor of 5. Our findings show that the uterus dose can be adequately controlled by depth dose measurements with a dosemeter under the apron at the surface of the abdomen, that is especially assigned to dose control of the conceptus.

A compilation of all calculated results as reported above, is available from the authors in a database structure on a 3.5" diskette.

PROTECTION EFFICIENCY

The protective effect of aprons can be described by the protection efficiency, defined as the percentage by which the effective dose is reduced. Fig.1 summarizes the calculated protection efficiency in function of lead thickness and tube voltage. The protection efficiency for wrap-around aprons in a mixed 60% AP 30% lateral and 10% PA exposed geometry is the same as for frontal ones in predominant AP geometry with less than 20% lateral exposure. From our calculations we derived a rule of thumb that provides a reasonable estimate for the protection efficiency as a function of tube voltage [kV] in kilovolts and lead thickness [Pb] in millimetres.

$$\text{PROTECTION EFFICIENCY} \approx 85 - \frac{kV - 50}{20 \times Pb}$$

This approximation refers to lead aprons of reasonably good fit, without neck shielding. The formula is not valid for the specified lead equivalence of composite aprons. Our calculations show that well fitting frontal aprons of 0.25 mm guarantee a protection efficiency above 70%, which is adequate for working in general radiology. For tube voltages below 70 kV, a lead thickness of 0.15 mm is sufficient. For interventional radiology, which involves lateral and dorsal exposure, it is a must to use a good fit wrap-around apron. Such an apron of 0.25 mm Pb provides a dose reduction of at least 70%. For high workloads and high tube voltage, a 0.35 mm Pb apron should be considered. Further increasing lead thickness above 0.35 mm does not deliver substantial extra dose reduction to justify the extra weight of the apron. Additional neck shielding of 0.35 mm Pb however, results in a further 5% to 10% reduction of the effective dose, because of almost complete shielding of the thyroid and oesophagus. Using an apron thickness of 0.35 mm Pb in combination with neck protection of 0.25 mm brings about the maximally achievable protection efficiency of 85% to 90%.

CORRECTION FACTORS FOR PERSONAL DOSIMETRY

We have calculated the ratio between unshielded depth dose equivalent and the corresponding effective dose when using protective aprons under various conditions. Results are given in Fig.2 for wrap-around aprons in a mixed 60% AP, 30% lateral and 10% PA exposure geometry. To avoid underestimation of effective dose, we have adopted that only exposure in frontal direction contributes to the depth dose. For the same reason Fig.2 only shows lower values for the divider, which apply to poor fit. For single badge dosimetry with the badge placed outside the apron "mid front" at collar or chest, a divider of 5 gives a conservative approximation of the effective dose:

$$\text{EFFECTIVE DOSE} \leq \frac{1}{5} \times HP_{UNSHIELDED}$$

Dual badge monitoring is recommended, where the annual effective dose may amount to a substantial fraction of the occupational dose limit (7). An accurate estimate of the effective dose can be derived from the combination of the reading for the unshielded depth dose from the badge worn outside the lead apron, and the shielded depth dose recorded by the dosemeter that is worn mid-front at waist level under the apron. For dual badge monitoring we conclude a widely applicable formula to calculate the effective dose:

$$\text{EFFECTIVE DOSE} \approx \frac{1}{10} \times HP_{UNSHIELDED} + HP_{SHIELDED}$$

This empirical formula applies to aprons without neck shielding, irrespective of tube voltage and for lead thickness above 0.15 mm, if the type of apron suits the exposure geometry. For exposure conditions that occur in interventional radiology, the degree of overestimation is always less than 50%. For situations where neck shielding is used, the empirical formula for the effective dose is:

$$\text{EFFECTIVE DOSE} \approx \frac{1}{30} \times HP_{UNSHIELDED} + HP_{SHIELDED}$$

For interventional radiology, this simple approximation gives less than 30% overestimation and, again, no underestimation.

CONTROL OF UTERUS DOSE

For female workers, the dose control of the abdominal region is of special interest in radiation protection, with an eye to protection of the conceptus. We use the uterus dose equivalent as a first approximation of the dose to the foetus. The protection factor for the uterus is defined as the ratio between uterus dose without and with shielding respectively. Values for the protection factor for the uterus are given Fig.3, in function of lead thickness and tube voltage. This shows that both frontal aprons in a predominant AP orientation and wrap-around aprons in a mixed geometry guarantee a protection factor above 5, even for very high tube voltages, if lead thickness is 0.25 mm.

A special dosemeter may be worn at the surface of the abdomen under the apron, for dose control for the unborn child. We analysed the relationship between such depth dose measurements and the uterus dose. Our data demonstrate that the uterus dose is always slightly overestimated (Fig.4). In view of the uncertainties that are associated with operational dosimetry, a prudent first approach is to use the uncorrected shielded depth dose to estimate the equivalent dose to the uterus. If, for special reasons, a more precise estimate is wanted, one may divide the reading by the appropriate correction factor from Fig.4.

MAJOR SCIENTIFIC TOPIC NUMBER 5.A... (see page 7)

ABSTRACT (See instructions overleaf)

The paper presents the dosimetric system and detail results of measurements for 1995 and overview of variation of selected doses through years 1966-95.

Actually population of people under control enumerate 26.000 employed in about 2600 X-ray departmens. Health care workers constitute about 80 % of the total monitored population. Annual dose for 98 % of people under control is below 1 mSv. A similar percentage applies to all categories of workers except those undertaking operational radiology.

The historical variation of annual dose received by the X-ray workers since 1966 is discused.

SPECTROSCOPY OF PATIENT SCATTERED X-RAYS USING GE DETECTORS

INTRODUCTION

One of the main tasks in radiation protection is the reliable determination of risk relevant dose quantities-like organ doses, effective dose or partial body doses-for exposed persons. In cases, when a more detailed description of an exposure situation is demanded, the radiation field has to be analysed with regard to the type of radiation, the spectral energy distribution and the direction of incidence, to convert personnel dose (or any other measured dose) into a risk relevant dose descriptor. Especially in context with the increasing number of long lasting interventional examinations or treatments in diagnostic radiology this became a pressing problem in the recent past.

A catalogue of spectra was prepared (1) which contains spectra of radiation scattered by a water phantom in dependence of scatter angle and tube voltage. In addition, for rougher estimates or when measured dose values are not available, approximate air kerma values in a distance of 50 cm to the centre of the phantom are presented.

METHOD

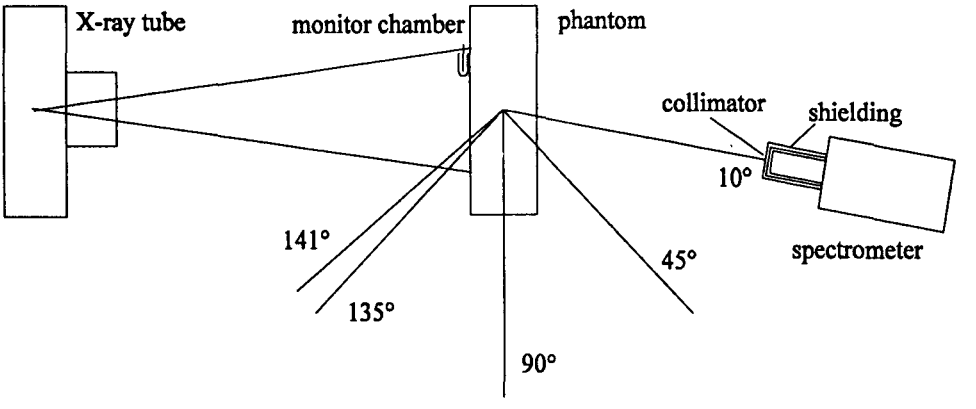

Figure 1. Experimental arrangement

A water filled perspex phantom (30 cm x 30 cm x 15 cm) was irradiated in 70 cm focus to phantom distance. Size of the central rectangular field: 16 cm x 16 cm. The measurements were performed at a diagnostic X-ray unit (Polymat 50 with a Pantex 125 X-ray tube, total filtration 3 mm Aluminium) operated in fluoroscopic mode. The spectrometer was equipped with a cylindrical (height: 50 mm; diameter: 56 mm) high purity Germanium detector (EG&G Ortec, GMX-25190 with Beryllium entrance window). To avoid distortion of the measured pulse height distributions by pile-up effect, the beam impinging onto the detector was highly collimated (beam diameter: 1.4 mm). In all other directions the detector was shielded by 3 mm copper and 12 mm lead.

Spectra were measured for the indicated directions (fig. 1) at tube voltages of 52 kV and at 60 kV to 110 kV in steps of 10 kV. Because of the small aperture of the narrow collimator it became necessary to position the spectrometer in a comparatively large distance of 212 cm to the centre of the phantom to register all the radiation scattered by the phantom into the considered direction. To achieve the desired spectra measured pulse height distributions were corrected in a stripping procedure using detector response functions calculated by Monte Carlo methods for the detector and collimator arrangement in the spectrometer (2,3). Air kerma in the phantom to collimator distance was calculated on the basis of spectral photon fluence and diameter of the collimating diaphragm.

To provide approximate values for the integral photon fluence and for air kerma in a realistic distance (50 cm) to the phantom centre dependence of air kerma from distance along the indicated directions (fig. 1) was measured by means of a 1000 cm^3 ionisation chamber (20341, PTW). Thereby a 0.2 cm^3 soft X-ray chamber (R 17927, PTW) served as monitor in the entrance plane of the phantom to compensate for fluctuations of the X-ray tube output.

RESULTS and DISCUSSION

Figure 2 shows as an example one of 35 spectra of the catalogue. The spectrum is presented in arbitrary units for energy intervals of 1 keV, normalised to unity in the peak interval. As to be expected the characteristic K-lines are shifted towards lower energies and the spectrum with a mean photon energy of 51.1 keV is in total significantly harder than the primary spectrum meeting the phantom with a mean photon energy of 43.5 keV (4).

To validate the applied methods (measurement and stripping procedure) selected primary spectra were measured in a modified experimental arrangement and compared with data from other publications (4,5). Part of the scattered spectra could also be compared with spectra calculated by Monte Carlo Methods (6). In both cases the agreement was good.

The absolute values for air kerma and integral photon fluence per unit of the product of tube current x exposure time (mAs), as presented in figure 2, depend strongly on the geometrical arrangement of X-ray tube and phantom (distance, field size), the condition of the X-ray tube and the not strict proportionality between mAs value and X-ray tube output. Consequently they can only be considered as rough approximate values.

ABSTRACT (See instructions overleaf)

The results obtained in individual dosimetry indicate that the level of exposure to X-rays in interventional radiology workers is higher than observed among other radiologists. In order to assess the actual exposure level in the personnel involved in various operations with the use of X-rays, the exposure rate on the body surface of the subjects under study was measured. These measurements were carried out in 20 hospitals during the following operations: cardiac pacemaker insertion, haemodynamics of the heart, extracorporeal lithotrypsy, transcutaneous, removal of kidney stone, radiological control of biliary routes, orthopedic surgery.

It has been found that the estimated dose equivalent depends to a large extent, on the function performed by individuals. In all hospitals the oprating physician was the most exposed person. The level of exposure depends also on the kind of the operational technique adopted, the quality and characteristics of X-ray equipment and physical parameters applied.

ABSTRACT (See instructions overleaf)

The Endoscopic Retrograde Cholangiopancreatography (ERCP) and Angiocardiography are standard medical diagnosis methods in these days. The commercial X-ray tube and accessories for those operations comes with typical radiation shielding for the operators i.e. doctors and nurses. This paper will present results of the survey of the operators radiation dose during the whole operation. The results shown that the hands of the doctor was completely exposure to the X-ray without any shielding while he was adjusting the table which the patient was laid upon. According to the results, we suggested some extra shielding could be added. The corresponding results after the shielding was added will be presented and discussed. We also suggested some operation procedure which could reduce some radiation dose. It will be discussed in this paper too.

SCATTERED FRACTIONS OF DOSE FROM 18 AND 25 MV X-RAY RADIOTHERAPY LINEAR ACCELERATORS

INTRODUCTION

Over the years, measurements have been made at a few energies[1,2] to estimate the scattered fraction of dose from the patient in medical radiotherapy operations. This information has been a useful aid in the determination of shielding requirements for these facilities. With these measurements, known characteristics of photons, and various other known parameters, Monte Carlo codes are being used to calculate the scattered fractions and hence the shielding requirements for the photons of other energies commonly used in radiotherapeutic applications.

The National Institute of Standards and Technology (NIST) acquired a Sagittaire medical linear accelerator (linac) which was previously located at the Yale-New Haven Hospital. This linac provides an x-ray beam of 25 MV photons and electron beams with energies up to 32 MeV. The housing on the gantry was permanently removed from the accelerator during installation. A Varian Clinac® 1800 linear accelerator was used to produce the 18 MV photons at the Frederick Memorial Hospital Regional Cancer Therapy Center in Frederick, MD.

This paper represents a study of the photon dose scattered from a patient in typical radiation treatment situations as it relates to the dose delivered at the isocenter in water. The results of these measurements will be compared to Monte Carlo calculations. Photon spectral measurements were not made at this time. Neutron spectral measurements were made on this Sagittaire machine in its previous location[3] and that work was not repeated here, although a brief study of the neutron component of the 18 and 25 MV linacs was performed utilizing thermoluminescent dosimetry (TLD) to determine the isotropy of the neutron dose.

MATERIALS AND METHODS

A commercial drinking fountain water-bottle with a radius of 12.8 cm was used as the patient phantom for this work. A Capintec 0.076 cc chamber complete with its ^{60}Co buildup cap was inserted in a sleeve and placed at the isocenter within the phantom. The phantom was filled with water to the edge of the neck and placed at the isocenter of the accelerators (100 cm from the targets) to provide the scattered radiation. The beam for each accelerator was set to a 20 cm x 20 cm field at the isocenter.

A Victoreen model 550-3 (330cc) chamber with its ^{60}Co buildup cap was placed in front of a 26 mm sheet (25 cm x 25 cm) of polystyrene at two meters from the isocenter. An appropriate amount of buildup material was then placed in front of the chamber. The chamber was connected to a Victoreen model 500 electrometer. Approximately 30 cm in front but out of the direct path of the Victoreen chamber, a 12.7 cm diameter polyethylene moderating sphere containing TLD-600 (neutron and gamma sensitive) and TLD-700

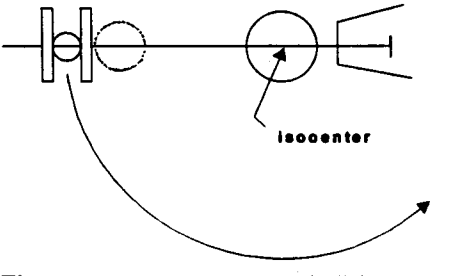

Figure 1 Experimental setup. The lighter circle indicates the location of the TLDs though they actually sat below the level of the chamber.

(gamma sensitive) chips was placed to measure the neutron component of dose equivalent throughout the angles of interest. The sphere remained in the same place for all measurements on a given accelerator, but was not necessarily in the same place from accelerator to accelerator. A top view of this setup can be seen in Figure 1.

Because there was a shift in the predominant energy of scattered photons as the chamber was moved through the angles, various thicknesses of polystyrene were placed in front of the Victoreen chamber to determine the appropriate thickness of buildup material to obtain a good photon signal reading yet exclude noise from secondary electrons. This was performed at each measurement angle. A preliminary investigation in the forward direction had shown that the effect of buildup material both in front and behind the chamber had nearly the same effect as standard build-up caps. The difference did appear to be somewhat energy dependent; however, it was consistent throughout the work on each accelerator, so was ignored.

Numerous measurements were made at angles from 0° to 140° for the 18 MeV photon beam. Because of the nature of the setup for the Sagittaire linac however, measurements were made only at a few select angles from 0° to 140° and the variation with angle was assumed to be smooth as found for the other accelerator. Repeated measurements were made on each accelerator with no phantom in the beam to check for air and wall scatter, and with the jaws in the closed position to get an assessment of head leakage contributions at each measurement location.

TLD measurements were made every 20° from 0° to 140° about the isocenter on the linear accelerators. Five chips of ^{7}LiF enriched LiF (TLD-700) and five chips of ^{6}LiF enriched LiF (TLD-600) were placed at each measurement location. Control TLDs were maintained throughout to account for any transit or extraneous exposures that may have occured. The TLDs were calibrated to ^{252}Cf for the neutron dose-equivalent calibration factor.

RESULTS AND DISCUSSION

Note that only the results from the 18 MV accelerator are presented below.

Neutron Dose Equivalent

We were interested in the neutron isotropy about the target, not the isocenter. The distance from the target along a 170 cm arc about the isocenter is:

$$R = a\sqrt{(5 + 4 \cos \varphi)}$$

where R is the distance from the target, a = 1 meter, and ϕ is the angle about the isocenter from the central beam axis. The measured dose equivalent (DE) was then corrected by $1/r^2$ to get the DE at 270 cm from the target.

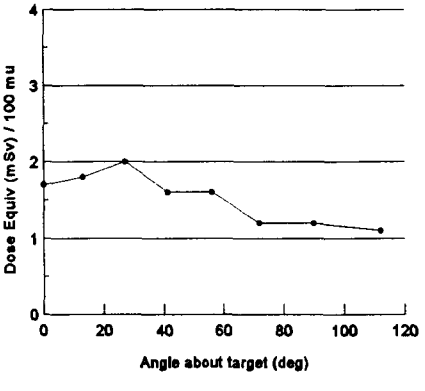

Figure 2 Neutron doses corrected to 270 cm from the target vs. angle about the target from the central beam axis

The TLDs gave expected results, namely, that the dose from neutons is relatively isotropic about the target with somewhat higher readings in the forward direction, see Figure 2. The energies of neutrons from this type of accelerator have been shown to fall predominately fall between 0.01 and 1 MeV[4], much lower than the calibration energy, so an exact determination of dose equivalent was not possible.

Photon Scattered Fractions

Figure 3 shows the scattered fractions of dose about the isocenter at 2 meters for 18 MV x-rays. The ordinate represents the ratio of the dose measured 2 m from the isocenter per unit dose at the center of the phantom. Measurements were made in the horizontal plane at angles of 10, 15, 20, 25, 30, 40, 50, 60, 75, 90, 105 and 120° from the central beam axis. The ratio is seen to drop off sharply with increasing angle which is as expected. Table 1 compares our values with those from an earlier report. Our values are smaller than those from Abrath, et al[2] by about 50% at the smaller angles to 150% at the larger angles.

Further work showed that a $1/r^2$ approximation does not hold for scattered radiation. Our measurements indicate that the ratios of dose at 1 m to that at 2 m varies from 2.5 to 3.8 and appears to be somewhat machine dependent. These measurements were made at both 30 an 90° for 6, 10 and 18 MV beams, but neither energy nor angle seemed to play a predominant role. Another finding of interest concerns the field size dependence of the scatter fraction. It is a common practice to take results from a 10 cm x 10 cm field and multiply by 4 to obtain an estimate for the result of a 20 cm x 20 cm field. Our investigation has shown that this is not the case: the result is acutally less than 4, and that the multiplicative factor is more a function of angle than of energy. Further work is being done to address this issue.

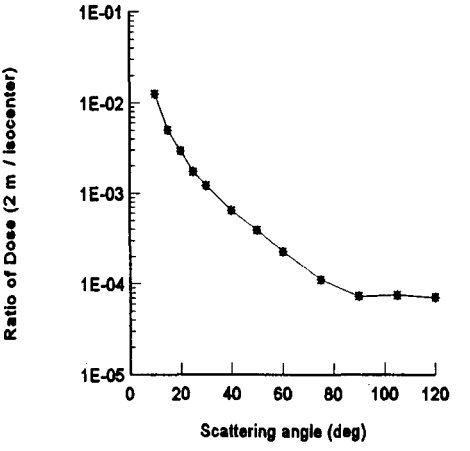

Figure 3 Ratio of radiation scattered at 2 m to that at isocenter vs. angle of scatter from central beam axis.

Differences in measurement technique lead to the inconsistencies in reported scattered fraction values found in the literature. The numerator can be affected by such variables as primary beam quality vs. scattered beam quality, distance of measurement from the isocenter, build-up thickness used, etc. The denominator can be affected by whether the value at the isocenter is recorded as measured at depth in the phantom or as computed to d_{max} for the energy of interest. Monte Carlo codes in progress should help resolve some of these issues.

Table 1 Comparison of our work with previous work. The values for Abrath *et al.* were read from their graph.

Angle	20°	30°	40°	60°	90°	120°
Our work	2.9 E-03	1.2 E-03	6.4 E-04	2.3 E-04	7.3 E-05	7.1 E-05
Abrath *et al*	5.2 E-03	2.2 E-03	9.2 E-04	3.5 E-04	1.8 E-04	1.6 E-04

ABSTRACT (See instructions overleaf)

To study the complex backgrounds of leakage-scattering-radiation of CO-60 units an area near the source loading-slot was examined, where the radiation passes through deep narrow slits producing "Hot Spots" in the thick lead-tungsten composed shielding-case of the instrument. Using a new approach, developed at the clinic in Vienna, these needle-like radiation was investigated in 3 phases: 1) photon-energy-determination of the leakage-radiation, 2) TLD-expositions to proof average absolute-doserate and 3) high- resolution-filmdensitometric determination of spikes in the 2D-dose distribution of the "Hot Spot-areas" combined with a calibration-procedure to get the correct maximum absolute doserate. Due to the results some constructive supplements had to be done to satisfy the German and Austrian regulations for radiation protection. This will be discussed in detail.

HVL and energy of the leakage radiation was determined using a calibrated ionisation-chamber. Films, exposed for a longer period, showed several well defined narrow "Hot Spots" embedded in a circular string-shaped radiation field. They were used as a positioning-aid for the arrangement of LiF-TLD-crystals. The TLDs were Co-60-calibrated with known doserate and good exposition-homogeneity. Even these results show a medium doserate caused by an integration-effect over the Hot Spot- exposed TLD-volume. A good approach to the maximum pointdoserate inside a Hot Spot was obtained by exposition of KODAK-OG-films using CAWO-U cassettes with OG8 intensifier foils. After the microdensitometric analysis of different time-exposed films the TLD-values and the optical density values were connected. The result was a calibration in relation to absolute energy-doserate.

ABSTRACT (See instructions overleaf)

The Harshaw 6600 personnel monitoring system can be used to measure extremity doses using ext-rads and whole body monitoring using three or four element cards. Limited performance data on these two systems is available specifically of relevance to usage in hospitals. The ext-rad comprises of a single dosemeter element, the chipstrate consists of a 3 by 3mm chip of LiF thermoluminescent material hermetically bonded to a kapton substrate to which a barcode strip has been attached. The whole body dosemeter consists of a TLD card and holder. The card consists of 3 solid LiF TL elements. The holder which is made of ABS plastic contains various filters for radiation type and energy discrimination.

Both these types of dosemeter have been type tested for their response to different photon energies ranging from 45-104keV and o°, 20°, 40° and 60° angles of incident of the photon beam. Both angular and energy response were assessed on a 30 x 30 x 15cm PMMA phantom and on a 30 x 30 x 30 cm water phantom. All irradiations were done using the ISO wide spectrum series reference radiations.

The radiation dose quantity Hp(0.07) was calculated for the extremity monitor and both Hp(0.07) and Hp(10) were calculated for the whole body card. All the results were normalised to the dosemeters response to Cs137. All measurements were compared with the true dose in the phantom using previously published conversion coefficients, with a view to assessing the performance of the dosemeters according to the recommendations of the ICRP.

ABSTRACT (See instructions overleaf)

The results of the individual survey of workers in medical field show that more than 99 % of the workers are exposed to levels lower than 5 mSv per year. These data, which are obtained with the legal dosemeter, a film badge, concern only the whole body exposure and more precisely the chest exposure, but they do not inform on the exposure of particular parts of the body. Moreover, with a measurement threshold equal to 0.2 mSv, low exposures are not detected with this dosemeter.

Recent improvements in detection and electronics are at the origin of new personal dosemeters well suited for operational dosimetry, especially for the most exposed workers in nuclear medicine, brachytherapy and interventional radiology.

Two dosemeters were evaluated for these medical applications : one measures whole body exposure and the other one records extremity, shoulder or forehead exposure with a remote detector. These two devices have a silicon semi-conductor detector and offer a range of capabilities : dose and dose rate measurement and readout, audible and visual programmable alarms.

Measurements were performed in various working situations thus confirming the interest of these dosemeters for a detailed analysis of working conditions, the detection of low exposures or high, localized irradiations and the training of staff. They also underline the possibility and necessity for an efficient operational dosimetry, indispensable complement to the legal survey.

ABSTRACT (See instructions overleaf)

The concern regarding associated safety considerations had been the issue of debate to re-examine the justification for imposing wide range of restrictions on the patients administered with large doses of radioiodine for the treatment of thyroid cancer. The present communication is therefore intended to present analysis of the radiation levels monitored in 50 thyroid cancer patients treated with high doses of radioiodine (50 - 200 mci) at our centre. The radiation levels on the surface of the thyroid, 20 cm away from thyroid surface, at lead screen, at one meter from patient and also at the entrance of the isolation room were measured. It has been observed that a patient admitted with a maximum activity of 200mCi with involvement of extra thyroidal lymph nodes take as long as 5-7 days when the criteria for discharge of patient being used as 2mR/hr at a distance of 1 meter from the patient. On the contrary the patient administered with 100mCi I-131 was found to attain the desired level within a period 3-4 days. The patients administered with smaller doses (50mCi) required the isolation of only 2-3 days. In view of the patients undergoing high degree of mental agony during isolation particularly those requiring prolonged isolation of 7-8 days, the standards of radiation levels laid down for discharge of the patient need to be reviewed and if possible appropriately changed to minimize the patient discomfort. Further analysis has revealed that this would be possible only if a method of patient counselling is evolved both prior to and after discharge of the patient.

RADIATION DOSE RATES FROM PATIENTS UNDERGOING GALLIUM-67 CITRATE STUDY

INTRODUCTION

In 1990, ICRP widened the definition of the medical exposure[1]. When a patient is administered radiopharmaceuticals for his or her diagnosis or treatment, radiation exposure to the family attending the radioactive patients is regarded as medical exposure. Although definite dose limit to the medical exposure was not recommended by ICRP, the exposure should be kept as low as reasonably achievable. Therefore it might be necessary to set a dose constraint in nuclear medicine.

So, it is important to assess the magnitude of radiation exposure of the person who attend the patient. We have started some experimental and clinical studies on this subject. In the first stage of this studies, we chose Ga-67 citrate of a radiopharmaceutical for tumor imaging. We have performed to document the radiation exposures around the Ga-67 citrate patients and to estimate the radiation doses of the other persons who may come into close contact to them.

MATERIALS AND METHODS

In twenty three adult patients, administered Ga-67 citrate to diagnose for their examination, radiation dose rates ($\dot{X}$(mR/h)) around the patients were measured with three ionization survey meters (Aloka Model ICS-301). Records of the measurements were performed at times of 0.1 and 48.0 h after

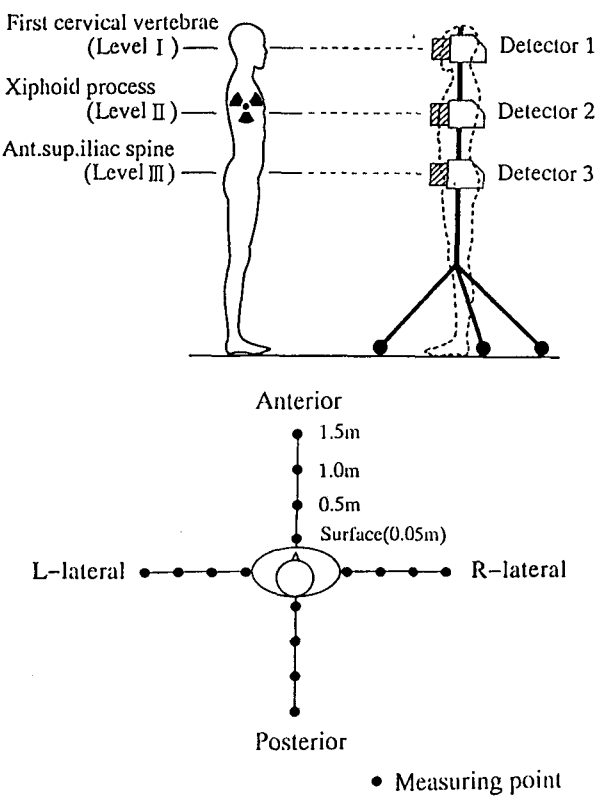

Figure 1. Detector arrangements for the dose estimation around the Ga-67 citrate patients.

injections of Ga-67 citrate.

The arrangements of these equipments were shown in Figure 1. X was normalized by the injection activity of 111 MBq and was converted into equivalent dose rate ($\dot{H}_{1cm}$ (μ Sv/h)) of 1cm in depth with a factor of 15.2 (μ Sv/mR). Biological half lives of 30 h (17%) and 613 h (83%) investigated by Evelyn E. Watson et al. [2] and physical half life (78.3 h) were used for the calculation of potential equivalent dose (H_{1cm}(μ Sv)) around the patient. The H_{1cm}s for a first week after the administrations of Ga-67 citrate were calculated from the effective decay constant (λ) of Ga-67 citrate and the initial $\dot{H}_{1cm}$s (A_0) of the measurements, using a equation:

$$H_{1cm} = A_0 (1-\exp(-\lambda \cdot t)) \lambda^{-1} \quad \cdots\cdots (1)$$

Where, the "t" is an integrating time to estimate the H_{1cm}. In figure 1, the broken line person was assumed to be a person exposed to the radiation from the Ga-67 citrate patient. To estimate the effective dose (E) of the other person who comes into close contact to the Ga-67 citrate patient, E of this broken line person at each distance from the patient was calculated by a equation:

$$E = 0.06H_a + 0.28H_b + 0.61H_c + 0.05H_{MAX} \quad \cdots\cdots (2)$$

H_a, H_b and H_c were corresponding to the H_{1cm}s calculated from the Xs of the detector 1, 2 and 3, respectively. H_{MAX} was defined as a maximum dose of H_a, H_b and H_c. Coefficients of 0.06, 0.28, 0.61 and 0.05 were obtained as partial sums of tissue weiting factors,as shown in Table 1.

Table1. Distributions of tissue weighting factors in recomendations-1990 of ICRP in areas with each detector.

	Detector1 (Head and Neck)	Detector2 (Thorax and Brachium)	Detector3 (Abdomen and Femur)	Max. of the three (Other tissue)
	0.05(thyroid)	0.12(lung)	0.20(gonads)	0.05(remainder)
		0.05(breast)	0.12(stomach)	
		0.05(oesophagus)	0.05(liver)	
			0.05(bladder)	
			0.12(colon)	
	0.012(bone marrow)	0.048(bone marrow)	0.06(bone marrow)	
	0.002(bone surface)	0.004(bone surface)	0.004(bone surface)	
	0.002(skin)	0.004(skin)	0.004(skin)	0.001(skin)
Total	0.066(~0.06)	0.276(~0.28)	0.608(~0.61)	0.051(~0.05)

RESULTS

The maximum $\dot{X}$ of 2.71 mR/h per 111 MBq was recorded at the Level II and the posterior projection. In all records, the $\dot{X}$s in posterior projection were similar to those in anterior, however, right and left lateral $\dot{X}$s were obviously lower than those. $\dot{X}$s at 0.5, 1.0, and 1.5 m from the patients were about one-fifth, one-tenth and one-twentieth of the surface one, respectively. The $\dot{X}$s in this investigation were obviously higher than the theoretical attenuation according to the inverse square law, when it was assumed that a Ga-67 citrate patient was a point source put in a free air. The retention rate calculated from $\dot{X}$s at 0.1 and 48.0 h after administration of Ga-67 citrate indicated a good agreement with that by Evelyn E. Watson et al.. H_{1cm} and E for a first week (168 h) were determined by the equation (1) and (2), as shown in Table 2. The maximum H_{1cm}

for a first week were 2216, 410, 172 and 89 μSv at distances of 0.05, 0.5, 1.0 and 1.5 m, respectively. These H_{1cm}s for a first week were equal to 82.4 percent of total radiation doses for unlimited time (∞ h).

Table2. Potential equivalent dose (H_{1cm}) and effective dose (E) around the Ga-67 citrate patient.

Area of dose evaluation	μ Sv/168h/111MBq (n=23)			
	Distances from Ga-67 citrate patient			
	0.05m	0.5m	1.0m	1.5m
Head and neck (H_{1cm})	1047	288	136	72
Thorax and brachium (H_{1cm})	2216	410	172	89
Abdomen and femur (H_{1cm})	1945	393	158	80
Effective dose (E)	1980	392	161	83

$$E=0.06H_a+0.28H_b+0.61H_c+0.05H_{MAX}$$

CONCLUSION

As far from 0.05 to 1.5 m, radiation exposure rates projected from Ga-67 citrate patients effectively reduce, however these rates are maintained for a long time. Accordingly an area around the patient is considered as a small hazard of radiations, particularly for the persons who may come into close contact to him. The patient provides only a small risk to otheres, but it should be recommend to aviod a long contact to the patient.

RADIATION EXPOSURE AROUND PATIENTS AFTER ADMINISTRATION OF Tc-99m-DPD OR Tl-201-CHLORIDE

Ernst Havlik,[1] A. Kurtaran,[2] and J. Preitfellner [2]

[1] Dept. of Biomedical Engineering and Physics, Univ. of Vienna
and L.Boltzmann-Institute of Nuclear Medicine, Vienna,
[2] Dept. of Nuclear Medicine, Univ.Clinic Vienna

INTRODUCTION

In connection with the diagnostic use of radiopharmaceuticals in nuclear medicine it often is asked if the radiation exposure by patients after administration of the radioactive substances might endanger their sorroundings and to what extent countermeasures are necessary for protection (e.g. establishment of special waiting rooms, hospitalization of the patients in special bedrooms as it is normal in nuclear medicine therapy). We examined quantitatively the radiation exposure caused by two of the most frequent nuclear medicine investigations: bone scintigraphy with Tc-99m-Dicarboxypropan-Diphosphonat (-DPD) and cardiac studies with Tl-201-chloride, respectively.

MATERIAL AND METHODS

Dose rate measurements were performed in 0.5m, 1m and 2 m distance from the surface of the bodies of two groups of patients, within the first 4 h after they had received 600±30 MBq of Tc-99m-DPD or 100±10 MBq Tl-201-chloride, in time periods of 30 minutes. In the case of Tl-201-chloride the measurements were repeated 24 hours (in some cases in addition up to 370 hours) after administration. Both groups consisted of 16 patients.

We used three calibrated dose rate detectors of the same type (Berthold LB 133®) in a stationary geometry. The patients were sitting on an chair, and the sensitive counting volumes of the detectors were positioned in about the height of the sternum (ventral).

RESULTS

In Table 1 the initial values of the dose rates are listed. Figure 1 shows the time course of the measured dose rates. Monoexponential functions were fitted. In the

Table1. Initial values of the dose rates in μGy/h (mean ± SD; n=16)

Distance	Tc-99m-DPD	Tl-201-chloride
0.5 m	19,7 ± 3,9	3,82 ± 1,04
1 m	5,66 ± 0,75	1,18 ± 0,29
2 m	1,85 ± 0,13	0,30 ± 0,08

case of Tc-99m-DPD the dose rates decreased with an effective half-life of 2.3 hours; in the case of Tl-201-chloride the effective half-life was estimated to be 60 hours. The corresponding biological half-lives thus were 3.7 hours and 330 hours, respectively. The total error in all cases was about 10%.

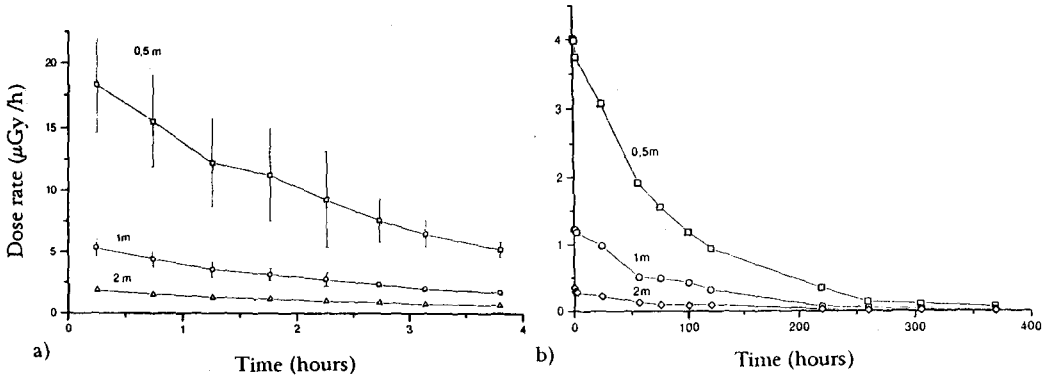

Figure1. Time courses of the dose rate (in μGy/h) in 0.5, 1 and 2m distance from patients after administration of 600 MBq Tc-99m-DPD (Figure 1a) and 100 MBq Tl-201-chloride (Figure 1b), (mean ± SD; n=16).

DISCUSSION

Integrating the dose rate functions the dose around the patients can be calculated for any time period after the administration of the radiopharmaceuticals (Figure 2). Thus the possible radiation exposure of other patients, attendents, and nurses in the surrounding of the "radiating" patients were estimated. Let us discuss five cases of possible exposure to other persons.

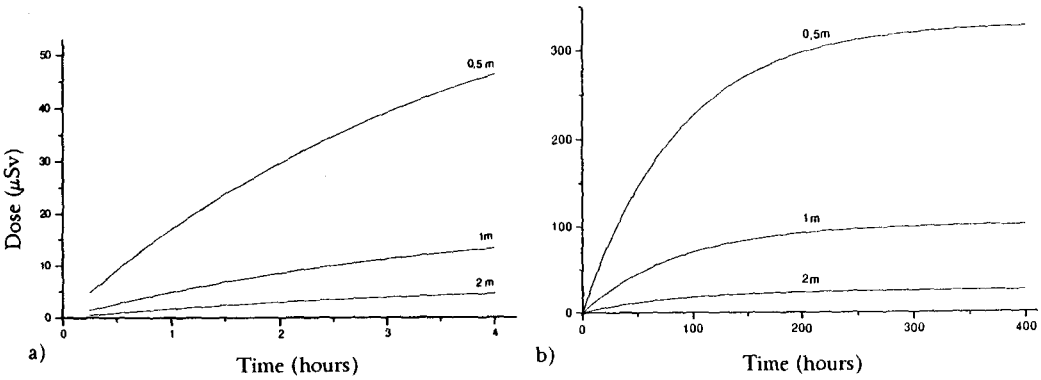

Figure 2. Courses of the radiation doses (in μSv) in 0.5, 1 and 2m distance from patients after administration of Tc-99m-DPD (Fig.2a) and Tl-201-chloride (Fig.2b), calculated from the mean values of the dose rates.

Tc-99m-DPD

The maximum dose around a patient after application of 600 MBq Tc-99m-DPD was calculated to be 67 μGy in 0.5m (19 μGy in 1m, 6.7 μGy in 2m) distance (1).

Case A: After application the "radiating" patient is sitting for 4 hours in a distance of 0.5m beside another patient. This is the longest time period a patient has to wait for bone scintigraphy. The exposure of the neighbour patient then may amount to 46 μSv, corresponding to 3% of the maximum permissible additional annual exposure to non-radiation workers.

Case B: After bone scintingraphy a patient is realeased from the hospital or is situated as in-patient in a ward. During a permanent stay in a mean distance of 1m an accompanying person or a nurse may be exposed by a dose of 7 μSv, corresponding to <0.5% of the permissible annual dose.

Tl-201-chloride

In the case of Tl-201-chloride the maximum doses in 0.5m, 1m and 2m distance from the patient are 330 μSv, 102 μSv and 26 μSv, respectively.

Case C: Due to a cardiac investigation a patient is sitting permanently from ½ to 4 hours after administration of Tl-201-chloride in a distance of 0.5m beside another patient. Then the exposure to this patient is 13 μSv, corresponding to <0.9% of the permissible annual dose.

Case D: After a cardiac investigation a patient is released from the hospital or is situated in a ward. During a permanent stay in a mean distance of 1m during the whole following day the exposure to a relative or to a nurse is <26 μSv, corresponding to <1.8% of the maximum permissible annual dose.

Case E: The patient (Case D) is hospitalized for two weeks or longer in the same sick-room. In this case from a permanent stay in 1m distance a nurse may receive a dose of 105 μSv. Considering a working time of 40 hours per week, this maximum dose ist reduced to 25 μSv, corresponding to <1,7% of the permissible annual dose.

As a result even under very restrictive assumptions the doses to the environment caused by "radiating" patients are far below the limits set by radiation protection regulations. There is no necessity to separate patients from other patients in a special waiting area after administration of the radioactive agents. This result is confirmed by studies of other researching groups (2), (3).

INTRODUCTION

During operation of a PET-Center, the air is contaminated by radioactivity. Apart from accidents, this contamination may be caused, for example, by neutron-induced air activity during operation of a cyclotron, leaks in the chemical process units and the use of radioactive gases on patients. Therefore, the room air as well as the waste air have to be monitored. Due to lack of experience, there is still uncertainty regarding the scope and the proper layout of such measuring systems.
This paper will discuss the principle of a waste air monitoring system which features adequate sensitivity as well as the required retaining capability in case the activity is exceeded.

RADIATION EXPOSURE THROUGH WASTE AIR

According to (1), the activity concentration of radionuclides, where the submersion is determinative for the limit value, must not exceed 200 $Bq.m^{-3}$ in the air on the annual average.
In the borderline case of an infinitely expanded activity cloud and on the basis of dose factors according to (2) and (3) this will result in an effective dose of 0.31 mSv per year for C-11, N-13 and O-15, and 0.35 mSv for F-18, and 0.43 mSv for Ar-41. For infants (1 year) these values have to be multiplied by a factor of 1.2. The indicated dose values can be attributed to the γ-submersion by nearly 100%. The share of the effective dose due to inhalation of 0.05 $mSv.y^{-1}$ is only perceptible with F-18. The exposure of skin and eye lenses caused by β-submersion is only 3 $\mu Sv.y^{-1}$ effective skin dose or 14 $\mu Sv.y^{-1}$ for the lenses, even for O-15 with its high β-energy of 1.73 MeV.
The actually occurring radiation exposure, however, is always below 0.01 $mSv.y^{4}$ (4), due to the activity cloud which is always limited in scope and the dilution factor. Keeping this in mind, one can, therefore, define a higher limit value - in accord with (1) - on the basis of propagation calculations and the estimation of the expected dose of the population in order not to have to restrict the operation of a PET center.

TASKS AND POSITIONING OF THE MEASURING SYSTEMS

The measuring and monitoring system for PET nuclides is designed to

- prevent the release of high activity concentrations from the respective working area, so-called advance measuring systems
- determine the emitted activity relative to the approved limit values or limit values stipulated by law, the integration measuring system.

Advance Measuring Systems (5)

These measuring systems are used for the rapid measurement of radioactive PET nuclides which, when released from the waste air channel, would exceed the permissible emission values. At the same time, these measuring systems control, for example, blocking flaps or initiate a storing process to allow the short-lived PET nuclides to decay. The time required for measuring these activities is dependent upon the selected detector configuration, and in particular upon the ratio of the partial waste air flow being monitored relative to the total waste air quantity. To prevent that activity can leak out during the measurement, a delay volume that is dimensioned according to the requirements is installed into the partial waste air path before the blocking flap.

These measuring systems are used, e.g., in the partial waste air paths of the cyclotron, in hot cells, the PET room, etc.
Figure 1 shows the schematic layout of an advance measuring system.

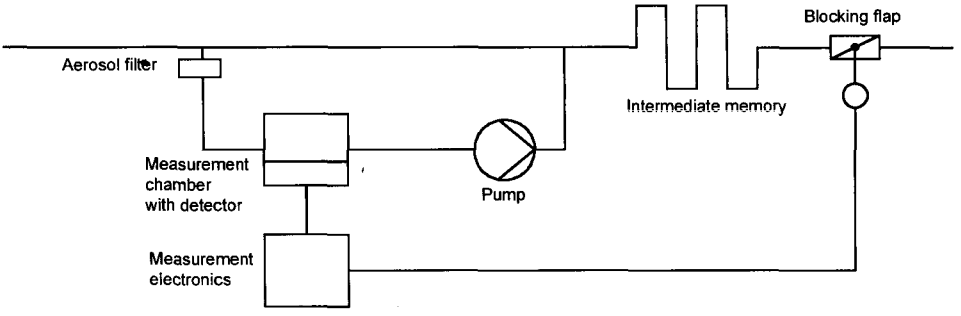

Figure 1: Waste air monitoring by an advance measuring system

Integration Measuring System (5)

This measuring system is designed to monitor and register the activity emission relative to the fixed limit values in Bq/m^3 as well as integral in Bq/time. The detector configuration is installed close to the blocking flap in order to get representative data on a possible activity emission. This measuring system has to be designed so sensitive that any exceeding of the activity concentration of 200 Bq/m^3 will safely be detected at any time.
We recommend using setups featuring bypass sampling in a partial air flow, since due to the defined measurement volume and the chance to shield off gamma interference radiation one will obtain a clear calibration value and thus a representative measurement value.

Figure 2 shows such an integration measuring system.

DETECTOR CONFIGURATIONS

Since PET nuclides are positron sources, all detectors that are used for beta measurement can be used. In addition, one can also perform a measurement via the 511 keV gamma destruction radiation.
The drawback of gamma measurements is, however, that all important PET nuclides are energetically identical, but Ar-41 is taken into account as an air activation product with 1.29 MeV with different calibration factors, and a defined measurement geometry without gamma interference by the 511 keV radiation is hard to achieve. Large-area proportional counter tubes used for beta measurement have the drawback that one gets about the same calibration factors for the radionuclides O-15, C-11, N-13 and Ar-14. For F-18, the calibration factor is only about 30% less sensitive than the reference nuclide C-11. This means: on the basis of the German Radiological Protection Ordinance (1), which defines the same limit value for all radionuclides (except F-18), the radioactivity emission in waste air will not be overrated to the disadvantage of the user.
Large-area proportional counter tubes can be regarded as the optimum detector for positron sources and other gaseous β-activities. They have a lower γ-sensitivity (< 1%) and allow adjustment to large measurement volumes. For the integration measuring system, we recommend using an 8 liter measurement chamber with flanged proportional counter tubes (active area: 900 cm^2). This ensures that one will get a calibration factor of less than 80 $(Bq.m^{-3})/cps$ and one can monitor the limit value of 200 $Bq.m^{-3}$ in a measurement cycle of less than 4 minutes. For the advance measuring systems one can use, for example, 1 liter measurement chambers with flanged proportional counter tubes (active area: 200 cm^2). In this case, one can obtain a calibration factor of less than 600 $(Bq.m^{-3})/cps$.

SUMMARY

We present measurements of the radioactive contamination of the air in the laboratories of the some nuclear medicine centers and the follow-up of the effects of the nuclear activity.

The purpose of the measurements is to decrease to a minimum the occupational exposure and the monitoring of radioactivity in the atmosphere.

INTRODUCTION

The human nuclear activity contributes to the radioactive loading of the atmosphere, beside the initially natural radioactive loading. The radioactive substances in the aerosols or gases, may directly irradiate the human body by inhalation, ingestion or immersion, or indirectly through water and food (1, 5, 8).This paper presents the results of the verifications of air contamination in the laboratory rooms of the Nuclear Medicine Units in comparison with the atmosphere of Cluj-Napoca town (4).

MATERIALS AND METHODS

Radioiodine was selected as an indicator of contamination of the occupationally exposed workers because of its noxious effects (1). The air samples were collected in different workrooms e.g. laboratories for the first dilution, administrative and measuring offices.

The principle of the working methods is the pumping of known air quantity through special filters and measuring the filter radioactivity (2, 8, 9).

The filtering cartridge for ^{131}I is made of active coal impregnated with $AgNO_3$ solutions (2) and was measured with the well type NaI(Tl) crystal connected to an impulse-meter having an efficiency of 20% to 40%.

The beta radioactivity of the SYNPOR membrane situated in the front of he active coal was measured in anticoincidence counter connected to an impulse-meter. The efficiency is about 9,8% and the counting times were of about 2 hours.

In 1991 the filtering cartridge made of active coal impregnated $AgNO_3$ solution was replaced by the SLF 2I-50 special filter for radioiodine and the SYNPOR membrane filter was replaced by the FPP filter.

The results have been determined with the following formula:

$$A = \frac{R - F}{E \cdot e \cdot V}$$

where A=sample activity (Bq/m^3 or mBq/m^3); R=filter counting rate (imp/s); F=fund (imp/s); E=counting system efficiency; e=filtering efficiency; V=volume of filtered air (m^3).

In 1994 the used filters were searched for ^{131}I, ^{137}Cs and ^{60}Co by measuring them with a GeLi detector connected to a ICA-80 multichannel analyzer.

RESULTS AND DISCUSSION

Table 1 resumes the results obtained in 1979 of the average concentration of ^{131}I in the laboratory air where this isotope was used.

Table 1. Average values for ^{131}I in air in 3 medical laboratories in 1979.

Labor. No.	Dates	^{131}I (Bq/m^3)
1	May 21	1,34±0,15
1	May 21	3.78±0.44
1	May 28	3.03±0.33
1	May 28	under MDC
2	October 15	1.67±0.18
2	October 15	2.34±0.24
2	October 16	1.67±0.18
2	October 16	2.18±0.22
3	June 28	1.67±0.18
3	June 28	2.07±0.27
3	July 3	5.37±0.56
3	July 3	5.56±0.56
3	July 6	2.37±0.26
3	July 6	1.93±0.20

MDC=1.1 Bq/m^3

Analyzing the results we see that the values are under the occupationally maximum allowable concentration (1), but in the 3rd laboratory they are increased because of the high number of patients diagnosed and treated there.

The ^{131}I concentration in the atmosphere was determined simultaneously. For these determinations a larger air volume was collected, the sampling was up to 18 hours for diminishing the MDC value. The ^{131}I concentration is under the minimal detectable concentration and the results for beta radioactivity of aerosols varied between 4 mBq/m^3 and 48 mBq/m^3.

On May 1986 the maximum concentration of ^{131}I was of 170 Bq/m^3 and after 20 May all the values were under 3,3 Bq/m^3.

The values registered in 1995 for the studied workrooms of the ^{131}I concentration range between 1,11 Bq/m^3 and 29,63 Bq/m^3 and are situated on an average below the admissible levels of the occupational exposure norms.

CONCLUSION

In the nuclear medicine laboratory the radio protection norms have been respected, the studied workrooms do present safe work conditions.

Although the air quality in Cluj-Napoca town for overall beta radioactivity and ^{131}I, ^{137}Cs and ^{60}Co measurements is not harmful, the air radioactivity must be kept under control.

NUCLID PRODUCTION WITH CYCLOTRONS AND RADIATION PROTECTION PROBLEMS

DIPL.ING.ERICH L. HUBER, VIENNA

With cyclotrons it is possible to produce nuclids used for medical and biological examinations with short halftime in a simple manner. The short halftime is the benefit for the mean irradiation of patients but it has the disadvantage that the production rate of the nuclids has to be very high. The time between production and administration of the nuclid to the patient is responsible of the produced activity of the radioactive agens. The longer this time and the shorter the half time is, results the irradiation risk. It shall be calculated the dependence of these factors and measures will be layed down to optimize the risks of the production and use of the radioactive agens.

DIE AUSWIRKUNG DER PRODUKTION VON NUKLIDEN IM ZYKLOTRON AUF DEN STRAHLENMSCHUTZ

Das Zyklotron bietet die Möglichkeit Radionuklide herzustellen, die für nuklearmedizinische Untersuchungen neue Methoden und dies bei wesentlich geringerer Strahlenbelastung des Patienten ergibt. Die hiebei erzeugten Radionuklide besitzen eine kürzere Halbwertszeit, müssen also in höherer Konzentration bzw. Aktivität angewendet werden, um die erforderlichen Resultate zu liefern. Die Aktivität, die im Zyklotron erzeugt werden muß, hängt davon ab, nach welcher Zeit die Nuklide verabreicht werden und die Messung erfolgt. Je länger diese Zeit ist und je kürzer die Halbwertszeit des Nuklids ist, desto größer ist das Risiko einer Strahlenbelastung. In welchem Ausmaß dieses Risiko durch die Erzeugung erhöht und bei der Anwendung vermindert wird,soll berechnet werden, und wie weit zusätzliche bzw. andere Strahlenschutzmaßnahmen erforderlich sind, soll angegeben werden.

PRINCIPLE

The conventional cyclotron consists of a circular, evacuated chamber situated in a uniform magnetic field. Inside this chamber are two hollow electrodes with an electrostatic difference of potential where a positive ion is accelerated to high energy E = 4.8x10e-11(HRZ)2/A, where E is expressed in MeV,H in gauss,R in cm and A,Z are the mass and the atomic number of the accelerated positive ion. The magnetic field strength of the order of tens of kilogauss limits the design of the cyclotron. Protons and Alfa particle are accelerated with a magnetic field strength of 15 kilogauss and a dee diameter of 76 cm to about 15 MeV. For the installation in medical institutions smaller compact cyclotrons are used, where the magnetic field varies with azimuthal angle, which are called AVF azimuthally varying field cyclotron. There are more than 80 short-lived radionuklides used by medical institutions, most with physical half-lives less than a few days, produced approximately 50% by cyclotrons. Most of interest /2

for medical purposes for instance for the Positron Emitter Tomography (PET) are the „physiological" radioisotopes (11C,13N,15O,18F). The estimated radionuclidic production with a 40 MeV cyclotron is as following:
14N(p,4He)11C, 20.30 m Half-Life, 45.5 TBq Activity, 11 h/w Production
16O(p,4He)13N, 9.96 m Half-Life, 4.8 TBq Activity, 3 h/w Production
14N(d,n)15O, 2.02 m Half-Life, 6.8 TBq Activity, 3 h/w Production
18O(p,n)18F, 109.80 m Half-Life, 34.6 TBq Activity, 13 h/w Production
20N(d,4He)18F, 109.80 m Half-Life, 2.1 TBq Activity, 2 h/w Production
124Xe(p,2n)123I, 13.00 h Half-Life, 2.3 TBq Activity, 4 h/w Production
Other Radioisotopes, 43.0 TBq, 8 h/w Production
The main areas of the cyclotron are the vault of the cyclotron and two target bunkers with automatic pneumatic transportation systems to manipulation and labelling laboratories and the PET area and also with shielding wagon running on a monorail to connect bunkers with hot radiochemical laboratories.
The generation of neutron and photon fluxes into the vault and the bunkers needs ordinary concrete shielding with an addition of 1% of borate materials with a thickness of about 250 cm. Lower shielding levels of about 50 cm of concrete has to be projected for the hot radiochemical laboratories. The calculation of the shielding walls will be made with an overestimation of about tenfold to protect the workers. The nuclei present in the air and in the dust are responsible for radioactive gaseous effluents mainly from the interaction of primary and secondary particles.Therefore an air circulation system of 0.5-1 time/h during the run and 8-10 after the decay time is necessary to protect workers and population. The following main isotopes contribute the airborne radioactivity:
14N(n,2n)13N, Half-Life 9.96 m, Beta+(1.25 MeV)
16O(n,2n)15O, Half-Life 122 s, Beta+(1.7 MeV)
16O(n,p)16N, Half-Life 7.20 s, Beta+,Gamma
40Ar(n,4He)37S, Half-Life 5.06 m, Beta-(4.8 MeV)
40Ar(n,p)40Cl, Half-Life 1.40 m, Beta-(7.5 MeV)
40Ar(n,Gamma)41Ar, Half-Life 1.83 h, Beta-,Gamma
It was found that the proportion of the gamma dose near the accelerators is generally negligible considering the neutron dose equivalent. This means,that the control of the gamma dose alone is insufficient for the accidental dosimetry around cyclotrons.
Possible sources of radioactive liquid waste are from accidental releases from the cooling water circuit, from the radiochemical laboratory, from the PET area and their treated patients.
Possible sources of radioactive liquid waste are from accidental releases from the cooling water circuit, from the radiochemical laboratory, from the PET area and their treated patients.

CALCULATIONS
The production of radioactive sources for medical diagnostic methods with a cyclotron needs a very different way compared with using long-living nuclids. To have the same measurement effects with short-living nuclids you must use /3

much higher activities. Additionally you need yet higher activities produced by the cyclotron. This means that the level of radiation protection must be higher to protect workers on the one side and lower to protect the population on the other hand and vice versa.
To estimate the necessary protection, the activities of cyclotron produced radionuclides will be calculated and compared with the activities using long-living nuclides. Finally the dose ratio will be calculated dependent from the half-lifes for workers and patients.
The activity of the nuclid originated in the cyclotron is Ao. After the time To the intake of the nuclid of the patient is beginning and continues until Td.
After To is the activity Ad=Ao.exp(-To.ln2/T), with the Half-life T. From this results the proportional dose D= Ao.(-T/ln2).(exp(-(To+Td).ln2/T)-exp(-To.ln2/T))
The dose comparison between two nuclids with different half-lifes after the Td leads to the unknown activity Ax=A.(T/Tx).exp(-Td.ln2/T.(1-T/Tx)).
The activity at the time of the production can be calculated as follows:
A=Ao.exp(-To.ln2/T) and Ax=Axo.exp(-To.ln2/Tx). Therefore is
Ao=A.exp(To.ln2/T) and Axo=A.(T/Tx).exp(-Td.ln2(1/T-1/Tx)).exp(to.ln2/Tx)
Important is the ratio Axo/Ao=(T)TX(-ln2.(To+Td).(1/T).(1-T/Tx)).
Also important is the proportional dose ratio DX/D=exp(-Td.ln2.(1(T).(1-T/Tx)).
wherein is
Ao the activity of the known nuclid at the production in the cyclotron
Axo the activity of the nuclid produced in the cyclotron
T the half-life of the nuclid used without cyclotron
Tx the half-life of the cyclotron produced nuclid
Td the time of the measurement and
To the time between the production of the nuclid in the cyclotron and the begin of the measurement.
The exposure factor of the patient result from following equation if you use the effective half-life: EFP=Ax(Txeff)/A(Teff), 1/Teff=1/Tphys.+1/Tbiol.
For Txbiol.>>Txphys. and Tphys.>>Tbiol. is EFP -- Txphys./Tbiol.
Also you can define the exposure factor of the worker EFW which result from the time between the cyclotron production or the delivery of the nuclid intil the measurement.
With the manipulationtime Tm is EFW=T/Tx.exp((Td+Tm)(1-T/Tx)ln2/T)
This gives the result for T>>TX and Td+Tm=Tx of EFW --(T/2)/Tx.

CONCLUSIONS

The activity of the nuclids produced in a 40 MeV cyclotron is about 100 TBq / week.
The medical examinations with 99mTc, 131J use activities from 1.5 til 740 MBq dependent from the radiopharmakon. From the standpoint of the patient the radiation protection is much higher using cyclotron produced nuclids because of the short half-life. On the other hand the shorter the half-life the higher is the required activity production and also the risk of irradiation. It is also more difficult to control the intake of workers. Therefore the radiation production expense will increase very intensively with decrease of risk.

MEASUREMENT OF THE EXPOSURE OF THE SWISS POPULATION TO MAGNETIC FIELDS OF 50 Hz POWER FREQUENCY AND 162/3 Hz IN RAILWAYS

M. Stratmann, Ch. Wernli

Paul Scherrer Institut, Radiation Metrology Section, 5232 Villigen PSI, Switzerland

INTRODUCTION

All installations that generate, transmit, or use electric power cause electric and magnetic fields. Common to all types of sources is a strong dependence of the magnetic flux density on the distance to the source. However, this information is not sufficient to know to what degree various parts of the population are exposed to magnetic fields during the different periods of the day. For this reason a study was carried out to assess the typical exposure of the Swiss population to the magnetic fields of 50 Hz power frequency and to 162/3 Hz magnetic fields in railways. A method of data reduction that allows for the determination of frequency distribution and percentiles for any selection of measurements was applied.

50 Hz MEASUREMENTS

These measurements were made with EMDEX-II instruments which register the resultant of the magnetic flux density up to about 300 μT. In the broadband mode the frequency response is flat from 40 to 800 Hz. Thus, for 50 Hz fields the magnetic flux density is measured correctly, while fields from railways (16 2/3 Hz) are underestimated.

Data from 464 employees were collected on weekdays (24 h, sampling interval (sa) = 10 s). To complete the time range and the demographic spectrum, 45 of the employees collaborated also for weekend measurements (48 h, sa = 30 s). In addition, data from 43 house keepers were included as well (24 h, sa = 10 s). The collected data were transferred to a notebook and the time series were evaluated with the EMCALC V2.12 software. The information of a simple protocol served to split the time series into 5 environmental categories: at work, commuting, at home, at rest and miscellaneous. For each environmental category of every person the frequency distribution was calculated with the EMCALC software. For further analysis the numerical output data were transferred to a large EXCEL table.

162/3 Hz MEASUREMENTS

Measurements in railways were made with HFR-1200 instruments. The instruments register the resultant of the magnetic flux density in the frequency range from 16 to 500 Hz with a sampling interval of 2 seconds, 1 minute or 1 hour.

Magnetic field measurements were made in fast trains from Zurich to Geneva and also from Zurich to Chur. More data were collected in double-decker S-trains around Zurich. In all cases the magnetic flux density was measured at floor-level, at waist-height and in the luggage rack. Most of the time the sampling interval was 1 minute, only short measurements were made with a sampling interval of 2 seconds. The collected data were transferred to a notebook and the time series were evaluated with the HFR-1200 software and the graphic program EXCEL V5.0.

RESULTS

50 Hz fields

The evaluation of the complete data set gives the following results: Median 0.05 μT, geometric mean 0.06 μT, geometric standard deviation 3.8, arithmetic mean 0.21 μT. 69% of the recorded values are below 0.1 μT, 3% are above 1 μT, and only 0.17% are above 10 μT. The results for "commuting" are intermediate, but these values may represent only a lower limit. 162/3 Hz fields from railways, which are likely to be an important source for this category, are not included in these results.

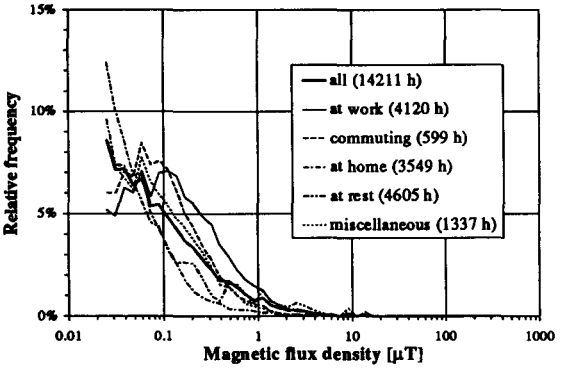

Figure 1:

50 Hz magnetic fields: Relative frequency distribution curves for the complete data set and the main categories. Total measurement times were put in parenthesis.

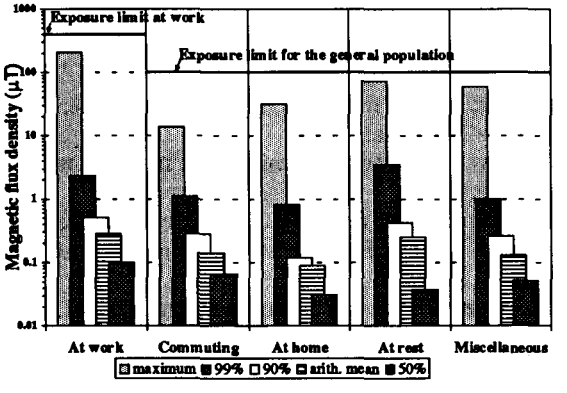

Figure 2:

50 Hz magnetic fields: Maximum, arithmetic mean, 99%, 90%, and 50% percentiles. The exposure limits for the general population (100 μT [3]) and at work (400 μT [4]) which are based on acute biological effects, were never exceeded.

As in similar studies [1, 2], the data of the 50 Hz measurements for all 5 main categories show an approximately log-normal distribution. As expected, the highest exposures were found in the category "at work" and the lowest magnetic flux densities were recorded "at home". Quite surprisingly for the category "at rest" the measured magnetic flux densities are partially higher than those "at home" (see Figure 1) and the arithmetic mean is almost as high as "at work" ($mean_{at\ work}$ = 0.28 μT; $mean_{at\ rest}$ = 0.25 μT; see Figure 2). This is mainly due to a small number of cases with fields in the range from 1 to 15 μT. The main reason for these high readings was, that some people put the EMDEX meter during the night very close to a clock radio or a similar electric appliance. For this reason the measured magnetic flux densities during the night may not be representative for the exposure of the person. Therefore, detailed measurements were made in bedrooms. With the exception of two cases the arithmetic mean within the area of the bed had been close to the arithmetic mean in the category „at home" of earlier

measurements (< 0.1 μT). In one of the exceptional cases an electrical mattress caused arithmetic means between 0.08 μT and 0.45 μT. In the other case higher values (arithmetic means between 0.18 μT and 1.95 μT) had been measured around the pillow only because of a nearby clock radio.

162/3 Hz fields

In trains the arithmetic means of the magnetic flux density varied in most cases between 3 μT and 6 μT with a maximum of 20 μT. A maximum single value of 75 μT was measured in a double-decker train on the lower floor at ground-level. In contrast to the 50 Hz magnetic fields the readings for 162/3 Hz in trains show almost symmetric distributions. The exposure limit for the general population for 162/3 Hz magnetic fields of 300 μT [3] has never been exceeded.

CONCLUSIONS

In residences a range from 0.02 to 0.04 μT can be considered as background level for 50 Hz power frequency magnetic fields. A significant enhancement of magnetic field exposure may be generated by electrical appliances. This is the case in particular if the distance to appliances containing transformers or motors is less than 1 m for an extended period of time. In trains (162/3 Hz) mean magnetic flux densities of 3 μT to 6 μT can be considered as typical. The recommended exposure limits of 100 μT for 50 Hz and 300 μT for 162/3 Hz have never been exceeded.

INTRODUCTION

Man is constantly exposed to electromagnetic radiation which is a constituent part of the biosphere. Due to the technological progress and numerous man-made sources such as those used in industry, traffic, medicine, defence, communication network as well as some home appliances, the character of the natural electromagnetic field has altered significantly. These sources of nonionizing radiation cause atmospheric pollution similar to the pollution from various industrial sources. Unambiguous detection of the mutagenic potential of these radiations is necessary for genetic well being of future generations.

DIRECT DNA ANALYSIS

DNA was isolated from brain and testis tissues of male Swiss albino mice exposed to low power microwave ($1 mW/cm^2$, 2.45 GHz continuous wave) for 2 hrs daily for a period of about 200 days. A variant of the restriction fragment length polymorphism (RFLP) approach was developed to study the effect of at the DNA sequence level using a single restriction enzyme digest and hybridization with a short synthetic oligodeoxynucleotide probe specific for a simple repetitive sequence $(GACA)_9$.

RATIONALE: Eukaryotic genome harbors two principally different classes of DNA: a) single copy DNA present once per haploid chromosome set; b) repetitive DNA existing from a few to a few hundred thousand (or million) copies. The whole array of repetitive sequences may comprise from less than 10% to more than 90% of the genome in different animal and plant species (in man it is about 30%). Short sequence motifs (less than 10 bases long) are ubiquitous repetitive components of eukaryotic genome (1). The number of repeat units of such simple sequences vary considerably causing allelic variation. When sequences complimentary to these repeat units are used as hybridization probes, polymorphism at several loci is simultaneously detected and individual specific hybridization patterns are generated (2). Of the various types of hybridization patterns obtained, multilocus monomorphic band profile is particularly useful because any loss or gain of band due to sequence rearrangement or sporadic mutations can be easily detected by the technique.

CYTOGENETIC ANALYSIS

The sensitive analysis of sister chromatid exchange (SCE) induction , which represents a sensitive and qualitative index of mutagen-carcinogen-induced DNA damage in eukaryotic chromosomes, was used as a cytogenetic end point to assess the mutagenic potential of microwaves. Bromodeoxuridine (BrdU) tablets (25 mg) were implanted subcutaneously. 19 hrs posttablet implantation, mitotic arrests were established by administration of colchicine (25 µg/animal). Metaphase plates prepared from bone marrow, were stained by modified fluorescent plus Giemsa (FPG) technique (3).

RESULTS

A multilocus monomorphic band profile was demonstrated with Southern blots in both the tissues of brain and testis studied. Hybridization profile of the brain DNA showed a sharp band (mol. wt 8.2 kb) in both the control and the exposed group of animals (Fig.1, arrow). In the exposed animals, an additional band at 7.7.kb appeared below this particular band. Gel track analysis showed a sharp peak marked 1 (Fig. 3 a,b) in both the control and the exposed animals and the appearance of a second peak marked 2 (Fig. 3 d-g) in all the exposed animals.

The hybridization profile in the testis DNA is not a reflection of sharp band difference in this region between exposed and control animals but rather a broadening of the band width. Both control and exposed animals revealed a sharp band in the testis DNA in the region of 8.1. kb (Fig. 2, arrow). The track histogram of both control and exposed animals showed a sharp peak marked 1, corresponding to 8.1 kb (Fig. 4, a-c). In the exposed animals, there was a change in the peak profile with the appearance of a second peak marked 2 corresponding to 7.7 kb (Fig. 4, d-g).

It is interesting to note that amidst a large number of bands at identical positions in DNA of both controls and exposed group of animals, rearrangement of DNA is consistently observed in all the exposed animals in the same region between 7-8 kb, irrespective of the duration of the exposure.

No statistically significant differences in the SCE frequency were recorded between the control and the irradiated animals exposed for various intervals of time. The mean value of SCEs in both control and exposed group of animals fell between 2.47+1.80 to 3.53+1.76; range 0-7 . The distributions were reasonably continuous and unimodal so that the difference in mean value could be evaluated in terms of standard statistical parameters of normal distribution. One level of ANOVA test was applied for the evaluation of the SCE frequencies using epistat software programme.

DISCUSSION

In the present study, the DNA analysis from exposed animals with nine repeat 5'-GACA-3' probe show similar profiles as those produced from the control animals with the notable exception of a prominent 7.7 kb Hinf I fragment specific to all exposed animals. Since this particular fragment is not present in the control animals but appears after microwave exposure, it is suggested that probably in the unexposed animals, the copy number of these repeat sequences is not sufficient to form a distinct band. Microwave exposure may have led to the amplification of these tandem sequences generating more copies of GACA sequences in this particular region. Although it is not known at present whether exposure to a mutagenic agent or a specific class of mutagens increases the mutation rate in the region of these tandem repeat units, it is known that stress induces amplification by extra replication of DNA segments in the non coding repeat sequences (4). The observed change of DNA rearrangement could be attributed to some sort of non-specific stress created by low intensity microwave field.

However low power microwave did not induce increased incidences of SCE formation in the exposed animals compared to the controls. This may be explained on the basis that though both SCEs and amplification phenomenon form a part of recombinational events, mechanisms of their formations are different. Interestingly, a parallel can be drawn at this juncture.

between microwaves and ionizing radiation (IR), which although a powerful mutagen (and a carcinogen), is a poor inducer of SCEs [5,6].

The technique of direct DNA analysis, which seems to monitor even minute sequence variation in the genome, therefore, appears to be a powerful technique for the assessment of the nonionizing radiation effects. Furthermore, based on the present study and other recent documents (7), what seems imperative is the (re)evaluation of the recommended safe limits of microwave exposure from the personnel and people who are exposed.

A REVIEW OF THE POSSIBLE EFFECTS OF 50/60 HZ ELECTRIC AND MAGNETIC FIELDS ON MELATONIN SECRETION

Jacques LAMBROZO[1]

1. EDF-GDF Service des Etudes Médicales. Paris

INTRODUCTION

The possible relationship between exposure to extremely low electric and magnetic fields (EMF) and biological effects has become a public concern and a very active research topic. Many in vitro and in vivo studies have been carried out to explore the possible mechanism by which those fields can influence the fonctionning of living cells and whole animals. One of the ways in which electric or magnetic fields may effect animals and men is via melatonin.

ANIMAL DATA

In Rodents:

Electric fields: three kinds of reactions to 60 - Hz electric field have been described: reduction of pineal melatonin synthesis [(1)], reduction of serum melatonin due to an increase of degradation or of tissue uptake of melatonin [(2)], absence of effect of chronic exposure [(3)].

Magnetic fields:

	SPECIES	FIELD	FREQUENCY AND ORIENTATION	DURATION	EFFECT
YELLON (4)	Adult Djungarian hamsters (male and female)	100 µT	60 Hz	15 min 2 hours before darkness 'long days'	. 1st experiment - Nocturnal melatonin rise in pineal and serum: delayed January - Nocturnal peak: shifted and blunted . 1st replicate - Nocturnal melatonin rise in pineal and serum: reduced (6 months later) June - Nocturnal peak: blunted . 2nd replicate - No statistical differences between control and exposed hamsters January
YELLON (5)	Djungarian hamsters (male and female)	100 µT	60 Hz	15 min 2 hours before darkness 'short days'	. Nocturnal melatonin rise in pineal and serum: delayed
WILSON (6)	Djungarian hamsters	100 µT	60 Hz	15 min 2 hours before darkness	. Nocturnal pineal melatonin rise: decreased . Medial basal hypothalamus norepinephrine: increased
KATO (7)	Adult rats Wistar-King albino (male)	1 µT 5 µT 50 µT 250 µT	50 Hz circularly polarized	6 weeks	. Nocturnal pineal and plasma melatonin levels: decreased . No dose-response relationship
KATO (8)	Adult rats Wistar-King albino (male)	0.02 µT 1 µT	50 Hz horizontal or vertical	6 weeks	. No significant differences in pineal or plasma melatonin levels
KATO (9)	Adult rats Long-Evans (male)	0.02 µT 1 µT	50 Hz circularly polarized	6 weeks	. 0.02 µT : pineal and plasma melatonin levels: decreased at 12.00 h pineal melatonin level: not decreased at 24.00 h . 1 µT : pineal and plasma melatonin levels: decreased at 24.00 h and at 12.00 h
LOSCHER (10)	Adult rats Sprague-Dawley (female)	0.3 µT 1 µT	50 Hz vertical	12 weeks	. Nocturnal plasma melatonin level: decreased
SELMAOUI (11)	Adults rats Wistar (male)	1 µT 10 µT 100 µT	50 Hz Vertical	12 hours (short term) 4 weeks (long term)	. Short term exposure : 100 µT : plasma melatonin level and NAT activity : decreased (30 %) 1 µT-10 µT : no difference in serum melatonin NAT activity . Long term exposure : 1 µT : no difference 10 µT-100 µt : plasma melatonin decreased NAT activity decreased no dose-response relationship

60 Hz electric and magnetic fields in non rodent mammals

Lee [12] exposed female lambs aged 8 weeks to a mean electric field of 6 kV/m and a mean magnetic field of 40 mG (4 μT) for a year, by keeping them below electric transmission lines. He was unable to show a change in the nocturnal secretion of melatonin or any change in the age of the onset of puberty or estrus. This study have been replicated providing the same negative results.

Baboons [13] were exposed first to an electric field of 6 kV/m, with a magnetic field of 50 μT, and then to an electric field of 30 kV/m and a magnetic field of 100 μT. There appeared to be no alteration in the profile of the plama melatonin concentration during the experiment. However, when the type of exposure was changed to one with « rapid » field onset/offset, there was a reduction of about 15 % of the levels of melatonin previously observed during pre-exposure. These initial results require confirmation .

HUMAN DATA

The data for human subjects is not more consistent than the animal data. Wilson[14] fitted with conventional electric bankets, studied on volunteers the excretion of the principal urinary metabolite of melatonin, 6-sulfatoxy melatonin. He found no change in the urinary excretion of this metabolite. When continuous polymerwire (CPW) electric bankets, generating a magnetic field 50 % greater than conventional electric bankets, were used, 7 of the 28 volunteers showed a drop in their 6-sulfatoxy melatonin excretion during the exposure period, followed by an increase when exposure stopped.

Graham[15] exposed healthy volunteers to a 60-Hz magnetic field of 20 μT, resulting from an ON/OFF effect every 15 secs for one minute, repeated every other hour. The results indicate that there was no statistically significant difference between the exposed and control groups. The exposed subjects were separated, post hoc, into two sub-groups, one with a high, and the other with a low basal melatonin secretion. The response of the exposed subjects with the lowest basal melatonin secretion (< 60 ng/ml) was a reduction in the level of serum melatonin. A replicate experiment failed to find the results reported in the original one : there was no difference in the response to a magnetic field exposure between subjects with a lower basal level of melatonin and the subjects with a higher level. Touitou [16] exposed healthy volunteers to a continuous and intermittent 50-Hz magnetic field of 10 μT. The levels of serum melatonin and urine 6-sulfatoxy melatonin in exposed men did not differ significantly from those in control subjects.

CONCLUSIONS

A diminution and/or a retardation of the nocturnal peak of melatonin have been reported in rodents exposed to electric and/or magnetic fields. Experimental date from primates and man showed insufficient evidence of such a change.
Modification of melatonin secretion cannot be considered at the moment as a verified biological explanation for the epidemiologic studies that find an association between breast cancer or depressive disorders and occupational or residential EMF exposure.

ABSTRACT (See instructions overleaf)

Fluorescence in situ hybridization (FISH) has been shown to be a feasible technique of detecting chromosome rearrangements, being currently used for analysis of induced chromosomal damage.

The experimental evidence on genetic effects with 50-60Hz electromagnetic fields (EMF) indicate contradictory results; however, the majority of the reports failed to demonstrate adverse effects.

Blood peripheral lymphocytes from normal donors, phytohemaglutinin stimulated, were in vitro exposed to a 50 Hz EMF at a flux density of 300, 115, and 28 μT during the time of cultures for cytogenetic analysis (72h). After harvesting, following "chromosome painting" FISH procedures, microscope slides with chromosome spreads were hybridized with two whole-chromosome DNA-libraries and detected with fluorescein-labeled avidin. Under fluorescence microscope, stable chromosome aberrations such us deletions, and translocations, insertions, rings, and duplications were easily detected.

The FISH aberration scoring, under progress, are compared with the conventional light microscope scoring previously done which include, both, stable and unstable chromosomal mutations. With the current results we could conclude that even the use of more accurate techniques as FISH, continuous 50 Hz EMF are not able to produce chromosomal damage at the detectable level.

EFFECT OF COMBINED IONIZING AND NON-IONIZING RADIATIONS ON THE EXPRESSION OF THE C-JUN ONCOPROTEIN

I. Lagroye, J.L. Poncy

CEA/DSV/DRR/SRCA, Laboratoire de Radiotoxicologie, BP 12, 91680 Bruyères le Châtel, France.

INTRODUCTION

The question of the effects of extremely-low frequency electromagnetic fields (ELF-EMF) on public health remains very controversial. Epidemiological studies (1, 2) indicated a correlation between ELF-EMF exposure and the incidence of childhood leukemia. Nevertheless, laboratory investigations regarding ELF-EMF genotoxic effects in *in vitro* biological systems failed to evidence any genomic damage (3-6). Recently however, attention has focused on the potential role of electromagnetic signals in cellular promotion implied in carcinogenesis process.

For instance, the transcription of oncogenes (7,8) has been reported to be responsive to ELF-EMF and the number of transformed foci in cells treated with a phorbol ester have been demonstrated to be enhanced after magnetic field exposure (9). Furthermore, cells irradiated with ^{60}Co showed increased chromosomal aberrations when they were exposed to ELF-EMF (10). Recently it was demonstrated that the number of ionizing radiation-induced micronuclei raised after ELF-EMF exposure in two of the three rat tracheal cell lines tested (11).

The aim of this study was to determine if ELF-EMF may induce the expression of the oncoprotein c-JUN, involved in cell transformation, either alone or after preexposition to gamma rays.

MATERIAL AND METHODS

Cell culture

Both cell lines used were obtained from gamma rays-irradiated rat tracheal cells in primary culture or from spontaneous immortalized clone.

Cells were maintained in HD medium (3v. Ham F12/ 1v. DMEM) with 1% of decomplemented fetal bovine serum at 37°C in a 5% carbon dioxide atmosphere.

Radiation exposures

Electromagnetic fields were generated with 2 pairs of Helmholtz coils put in a plastic box shielded with mu-metal and placed in a 5% CO_2 incubator. The electromagnetic signal consists of a sinusoidally varying field with a frequency of 50 Hz and a 0.1 mT r.m.s. amplitude, combined with a 0.05 mT static geomagnetic-like field (horizontal and vertical components).

EMF sham-exposures were performed in a similar mu-metal shielded box, without Helmholtz coils and placed in another incubator where measured background sinusoidal field was < 0.001 mT.

Confluent tracheal epithelial cells were gamma-irradiated (^{60}Co, 6 Gy, 0.8 $Gy.min^{-1}$) and control cells were mock-exposed. A uniform time of 1 hour elapsed from the irradiation time to the initiation of continuous incubation in the sham- or ELF-EMF exposure system.

Western blotting

Adapted from (12), cells were lysed 1.5, 4, 6 and 10 hours after ionizing irradiation, extracted and 10 µg protein samples were separated by SDS-PAGE on a 12% polyacrylamide gel and blotted onto a PVDF membrane. c-JUN protein was assayed using a polyclonal c-JUN/AP1 antibody (Santa Cruz Biotechnology) and the enhanced chemiluminescence (ECL) detection procedure (Amersham).

RESULTS

Experiments were done in triplicate and typical results are shown below. Two bands are usually observed and the major one was taking into account for data interpretation.

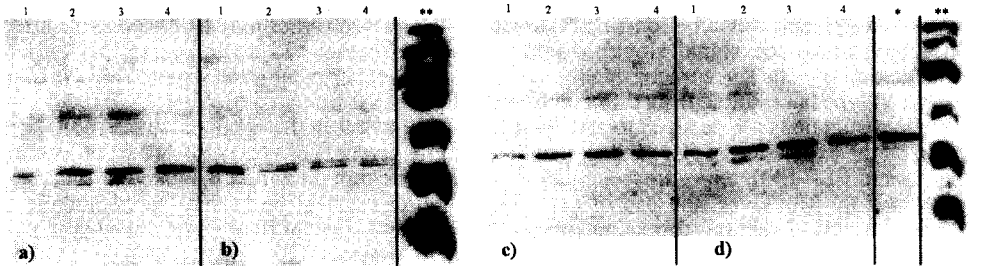

Figure: Expression of c-JUN in an epithelial tracheal cell line, after ionizing and/or non-ionizing irradiation. Cells were harvested 1.30h (**a**), 4 h (**b**), 6h (**c**) and 10h (**d**) after γ rays exposure.
(lane **1**): 0 Gy+Sham EMF; (lane **2**): 0 Gy+EMF;
(lane **3**): 6 Gy+Sham EMF; (lane **4**): 6 Gy+EMF.
*: positive control; cells were treated by Phorbol 12 myristate 13 acetate (PMA, 100 ng/ml, 1 hour).
**: molecular weight markers (97.4 - 68 - 49 - 31 - 20.1 - 14.4 kDa).

The preliminary results, obtained with a spontaneous immortalized cell line, seemed to indicate that the level of JUN protein was significantly increased in cells exposed continuously during 6 and 10 hours to ELF-EMF after a gamma rays irradiation (6 Gy) versus untreated and only gamma-irradiated cells. In this previous experiment, cells were not exposed to ELF-EMF alone, because of material constraints.
Data concerning another cell line failed to reproduce these results. Indeed, no synergistic effect of ionizing and electromagnetic fields was observed regarding the induction of JUN protein. However, under our experimental conditions, ELF-EMF alone enhanced the induction of this oncoprotein in a quite similar way as gamma rays. The figure shows that c-JUN is early induced (30 minutes after ELF-EMF exposure and 1.30 hour after ionizing irradiation) and durably expressed until 10 hours of exposure.

DISCUSSION

ELF-EMF have been recently suggested to act as promotor agents in carcinogenesis processes (9-11,13). As overexpression of protooncogenes and their products is involved in epigenetic mechanisms (14), we examined the ability of two epithelial tracheal cell lines to synthetize the c-JUN protein in response to ELF-EMF exposure, with or without a previous ionizing radiation acting as an initiator.

c-jun belongs to the early response genes family and is known to be induced until several hours after ionizing radiations (15) and enhancement in the transcription of oncogenes including c-jun was previously reported in T CEM-CM3 lymphoblastic cells after 1 hour exposure to a very similar electromagnetic signal, excepted the absence of the static field (7). The same group recently indicated that the same signal could increase the transcription of the ras oncogene (16). EMF were also demonstrated to alter polypeptide synthesis in salivary gland cells, with an increased expression of several non-identified proteins (17). Furthermore, messengers such as Ca^{2+} or inositol triphosphate, involved in signal transduction pathways and leading to the transcription of genes such as c-jun, have been reported to be responsive to ELF-EMF (18,19).

Rat tracheal cell lines are usefull in transformation assays using chemical agents (20) and have been demonstrated to be responsive to ELF-EMF after gamma irradiation. A synergistic effect of the combination of gamma irradiation and ELF-EMF exposure, depending however on the cell line tested (two of the three cell lines used were responsive), has been observed concerning micronuclei induction but no effect of ELF-EMF alone was detectable (11). In this study, data obtained in a spontaneous immortalized tracheal cell line suggested such a synergism on the delayed induction of c-JUN expression. In a second cell line isolated from irradiated primary epithelial cell culture, no synergistic effect was detectable but ELF-EMF exposure alone appeared having an effect on the

early induction and delayed expression of JUN protein. Being assumed that both cell lines used behaved in a different way after ionizing treatment, data reported earlier may be linked to the effect of the electromagnetic signal alone. Moreover, these effects could be linked to the level of transformation of cells since tracheal cell lines used in this experiment were issued from the same primary cell type but resulted from different treatments.
Further investigations are needeed to ascertain ELF-EMF effect in the spontaneous immortalized cell line on the expression of JUN and to elucidate the effectiveness of synergistic effect of ionizing radiation and ELF-EMF exposure in induction of oncogene protein which is related to act in cell transformation. Moreover, the use of primary epithelial tracheal cells may be of interest to determine the role of cell transformation level in the biological effect of ELF-EMF alone which may emphasize the hypothesis of ELF-EMF promotor effect.

ABSTRACT (See instructions overleaf)

The cellular effects of weak electromagnetic fields of extremely low frequency (ELF, 1-300 Hz) have been extensively investigated. Some effects of ELF are questionable due to poor reproducibility. One possible reason for this could be dependence of resonance frequencies on genome structure of cells under investigation. We tested whether the resonance ELF frequencies can be different for mutant and wild-type strains of *E. coli* K12. The effect of weak ElF, 30 μT magnetic flux density, on the genome conformation was studied by the method of anomalous viscosity time dependencies in the 6-68 Hz frequency range. We observed four frequency windows with resonance frequencies of 8.9 Hz, 15.5 Hz, 29.4 Hz, and 62 Hz when exposing the K12 AB1157 cells which had a few genetic markers. In the same frequency range the wild-type K12 EMG2 cells had only three effective windows with resonance frequencies 8.3 Hz, 27 Hz and 56 Hz. The resonance frequencies were different significantly ($p<0.001$-0.000001) in studied strains. It was shown, that at the 8.9 Hz resonance frequency the ELF affected the rate of cell division which was measured by means of dilution plating and protein/DNA synthesis, measured by incorporation of ^{3}H-Lucite/^{3}H-thymidin. Using electrophoresis, we observed the 8.9 Hz-induced changes in the number of proteins tightly bound to DNA. Conclusions: 1) Weak ELF fields which were comparable in magnitude with those of typical electrical devices affected *E. coli* cells at the selected frequencies. 2) These effective frequencies were different for two *E. coli* strains which distinguished genetically.

MAJOR SCIENTIFIC TOPIC NUMBER 7.2.... (see page 7)

ABSTRACT (See instructions overleaf)

The discussion on the existence and relevance of hypersensitive reactions to weak electromagnetic fields suffers from the lack of a generally accepted definition of the phenomenon. Based on the assumption that relevant electromagnetic biological interaction is mainly based on induced intracorporal current densities, perception thresholds of directly applied 50 Hz currents have been measured on a statistical sample of the general population by a mobile measurement setup and double blind experiments. This results have been compared with magnetic field provocation experiments on normal and hypersensitive persons. The results are presented and discussed.

SICKNESS ABSENCE FROM 1978 TO 1992 OF ELECTRICITE DE FRANCE (EDF) WORKERS EXPOSED TO ELF-EMF : The substation group

INTRODUCTION

Electromagnetic fields are suspected of many health effects, including cancers, immunity and fertility disorders, congenital malformations, suicides and depression...(1-2). Although the results of all studies are contradictory and no biological mechanism has been found, populations are concerned about this matter.

This study analyses the absence from work of some EDF employees who are *a priori* the most professionally exposed to ELF EMF. Absence from work is taken as an health indicator. Although it is not specific, it can be predictive of serious health problems (3). The specific context of EDF has made it possible to collect and analyse the medical aspect of absence from work, that is rare in France.

We were interested with employees working with high voltage (over 90 kV). Three job categories have been selected : live line workers, substation maintenance workers and substation exploitation workers (called in the company the ATEX). The first group concerned the live linemen and the results were exposed previously (4,5). It appeared they had more accidents at work, but this was more related to the job of lineman rather than to the EMF exposure. Nevertheless, substation workers have an exposure less intensive but longer than live linemen. We present here the result about the absenteeism of the substation workers, maintenance and exploitation.

OBJECTIVES

The objective of this retrospective longitudinal study is to describe the profile of absence from work for medical reasons for the substation workers, maintenance and exploitation, over a period of 15 years (1978-1992), and then to compare it with a representative sample of EDF GDF employees, of same age and sex, and for the same period (reference group).

Cancer pathology is not the aim of the study, because of its rarity in this young selected population. But we were particularly attentive to the psychiatric disorders.

POPULATION

The EDF generation and transmission department, which deals with all the employees concerned by high voltage, have 34 operational sub-groups. Each of them includes :

- a maintenance substation team, also about 15 persons. That is about 500 persons each year concerned by the study,
- four or five substation grouping, each with 7 or 8 ATEX (substation exploitation workers). That is about 1100 persons each year concerned by the study.

The substation maintenance workers are exposed to EMF, with an average occupational exposure of about 35 µT. The ATEX may be particularly exposed, especially in term of duration, when they live at their place of work. This was the case for two-thirds of them in 1992.

METHODOLOGY

To be included in the study, workers must be men, having worked for at least one year accumulated either in a live line team, a substation team or as ATEX, in the EDF generation and transmission department, between 1978 and 1992. A subject remains in the exposed group even if he leaves the exposed job. The absenteeism is taken into account up to 31 December, 1992 or to his departure of the company, by retirement or by resignation (but this event is rare, 0.05% per year). All employees who have left the exposed job before 1978 have been excluded from the study.

The substation group included the substation workers (maintenance and exploitation) and subjects having worked either simultaneously or consecutively on both lines and substations.

A reference group had been chosen, at random, from all the EDF GDF non-management male employees, one reference subject for each exposed worker, matched on the first year of employment.

For each person included in the study, his job history and his socio-demographical data for 1993 were extraxted from the employees data base. The epidemiological data base of the Service Général de Médecine de Contrôle, who manages the social security of the company, supplied the absence data : number of absences with the date, duration of absences, and diagnoses if they are known. Mortality data (death during occupational life), long term illness and invalidity data were also available.

The socio-professionnal data were analysed using *Epi Info* software in the Service des Etude Médicales, to compare the exposed and the reference groups. The absenteeism data were analysed using *SAS* software in the Service Général de Médecine de Contrôle, with the method of person x years. The tests used are *Chi2* and *Student*.

RESULTS

The substation group is composed of 2327 persons exposed from one year or more, divided into 685 maintenance substation workers, 1121 ATEX and 521 mixed workers (maintenance and/or exploitation). Among these exposed workers, 243 (10.4%) no longer had an exposed job in 1992, and 289 (12.4%) had left the company.

Their average length of work in the company was 17.8 years (from 1 to 44 years) and their average length of exposure was 11.8 years (from 1 to 37 years). These 2327 persons correspond to 22168 persons x years.

In 1993, the socio-demographical data, which could influence the absenteeism, were comparable between the exposed and the reference group : they had the same mean age (41 vs 41.3 years old) and a similar distribution into the different matrimonial situations (unmarried, married or co-habited, separated or divorced, widowed). The exposed workers had more children than the reference workers, but this factor concerns more the female absenteeism than the male absenteeism.

The absenteeism of the exposed group is significantly less important than that of their referees ($p<1‰$) (table 1) : there are less substation workers who stop work (34.5% vs 38.9%), they are absent less often (1.46 vs 1.67 absence in a year) and their absences are shorter in duration (21 days vs 23.3 days). But the absenteeism is different if substation maintenance or substation exploitation workers are considered : substation exploitation workers (ATEX) have a less significant absence rate than their referees (1.45% vs 2.33%); substation maintenance workers have an absence rate over their referees (3.03% vs 2.6%) because there are more exposed people who take sick leave but they take it less often than their referees.

The medical diagnoses (table 2) are also significantly different : sick leaves for psychiatric (2.1% vs 4.1%) and respiratory (13.4% vs 15.3%) diseases are less frequent in the exposed group than in the reference group. On the other hand, sick leaves for accidents at work are more frequent in the exposed population (7% vs 4.5%).

CONCLUSIONS

The substation workers have better health indexes than their referees, and it is not very surprising because they are carefully selected to do this job. But the differences are less important between the substation workers and their referees than those between the live linemen and their referees.

No pathology, which has been described as possibly linked to electromagnetic fields, has appeared through the medical absenteeism surveillance in our study.

Tables 1 : Absences variables

	exposed	referees	p

WEAK MAGNETIC FIELDS INJURIOUS TO HEALTH, STRONG MAGNETIC FIELDS HARMLESS ? RADIATION PROTECTION BY THE PRESENT OF MAGNETIC FIELDS.

DIPL.ING.ERICH L. H U B E R, VIENNA

Usually magnetic fields are part of the environment without making injuries to health. Only when limits in standards were fixed the certainty become conscious that electromagnetic fields in their various forms must be hazardous. The effects of the pure magnetic fields cannot be found out easy because it is difficult to screen the magnetic fields, especially the magnetic field of the earth. This analysis shall also find out how to hold limits by using extremly high magnetic fields in medicine and research. The results show that screening is not the only method when the praxis requires behaviour where screening is not possible.

GESUNDHEITSSCHÄDLICH BEI GERINGEN, UNGEFÄHRLICH BEI STARKEN FELDSTÄRKEN ? STRAHLENSCHUTZ BEIM AUFENTHALT IN MAGNETFELDERN

Immer häufiger treten Magnetfelder in unser Gesichtsfeld, ohne daß eigentlich Schäden in gravierender Weise auftreten, von denen Menschen unmittelbar betroffen sind. Erst durch normative Festlegung von Grenzwerten wurde zwingend bewußt, daß gewisse gesundheitliche Beeinträchtigungen auch durch elektromagnetische Felder hervorgerufen werden können. Inwieweit das magnetische Feld daran beteiligt ist, läßt sich nur für bestimmte Effekte begründen. Wie man den Forderungen nach Einhaltung dieser Grenzwerte in extrem hohen Magnetfeldern gerecht werden kann, soll dieser Beitrag untersuchen, wobei die Anwendung von Untersuchungsmethoden in Medizin und Wissenschaft an erster Stelle stehen soll. Es ergibt sich dabei, daß die Abschirmung nach außen keineswegs ausreicht, um die Forderungen von Normen und Richtlinien zu erfüllen, sondern daß es zu einem großen Teil auch darauf ankommt wie Untersuchungen durchgeführt werden.

To realize the hazards of magnetic fields first you must know the parameters of the magnetic fields which can cause harms. Magnetic fields are not directly observable, but their effects are very evident. The main magnetic term is the magnetic induction B measured in tesla (T) / SI unit and gauss (G) /CGS unit,where 1 nanotesla (10E-9 tesla) = 1 gamma (10E-5 gauss). These dimensions are first used in the measurement of the Earths magnetic field, whose attributes mainly touch peoples health. But because nobody can escape from the Earth magnetic field we must try to know the hazards of artificial fields. In any case the whole electromagnetic spectrum is responsable for the welfare of the human being. The question is whether the ionizing energy is only responsible for stochastic changes which leads to cancer deseases or if the nonionizing part of the electromagnetic spectrum also can be made responsible for such health defects. The primary modes of action of non-ionizing radiation is either photochemical or thermal. Photochemical reactions

primarily occur upon absorption of radiant energy in the ultraviolet and visible portions of the spectrum. Thermal effects are produced primarily upon absorption of visible, infrared, and microwave radiation. In biological systems the energy transfer produces electron excitation, which can result in dissociation of the molecule if the bonding electrons are involved, dissipation of the excitation energy in form of fluorescence or phosphorescence, the formation of free radicals and degradation into heat.
Looking at radio frequency and microwave radiation between 10 MHz and 300 GHz we learn that microwaves interact with matter primarily through the conversion of electromagnetic energy to potential molecular energy in the absorbing medium, where dissipation of the potential energy results in the production of heat. The depth of penetration of microwaves into the body is approximately equal to 0.1 of the wavelengths between 3 cm and 200 cm.
But the avascular organs as the eye, the hollow viscera and the testes are of primary interest, because they do not have a high capacity for removing heat through the circulation of blood. The interaction with the central nervous system and the phenomen of „pearl chain formation" become also aligned in a specific pattern in a microwave field.
The electromagnetic waves in this sphere result from electric fields, measured in Volt/ Meter and magnetic fields, measured in Ampere / Meter. Being in the far field region we can use the power density S measured in Watt/m2 to characterize the quality of the electromagnetic field of antennas. The intake of electromagnetic energy into biological systems is given through the specific absorption rate SAR in W/kg or the specific absorption SA in Joule/kg for pulsed radiation. Limits are given in new standards for instance ÖNORM S1119 and S1120 over the range from electro- and magnetostatic fields until 30 kHz (ELF Extremely low frequencies and VLF Very low frequencies),and from 30 kHz to 3000 GHz.
The classification of electromagnetic waves often overlap and the discription of a wave in terms of energy, wavelength, or frequency differs from region to region. Gamma rays and x rays generally are discribed in terms of photon energy; ultraviolet, visible light and infrared radiations in terms of wavelength; and radio frequencies in terms of frequency. The term „ionizing radiation" emphasizes the minimum photon energies capable of producing ionization, dislodging orbital electrons and produce ion pairs. Therefore is the lower limit for ionization effect from the standpoint of biological systems 12 electron volts. Lower frequencies or higher wavelengths characterize the term of „non-ionizing radiation".
A very important point of view is the perception of radiation risk especially if events with high consequences and low probability occur. Effects from ionizing radiation represent around 1% of the global burden of disease. This small contribution is dominated by natural radiation, medical care of patients, and fallout from nuclear weapons test. Industrial radiation sources contribute less than one-hundredth of 1%. Nevertheless it is not possible to say with cercainty that a particular cancer victim has died for instance from radon exposure. Therefore the public generally believes the risks are lower than scientific estimates would substantiate. The correct scientific method is the a priori

investigation of putative sources of risk and this carried out for example that studies of childhood leukaemia around nuclear installations reveal little,if any, evidence for an increased risk of it. But this does not help much when I want to know if the probability if the cancer is caused by radiation effect is more than 50 % or not. Only on this condition there is a chance of compensation. This would be legal either for ionizing radiation and for non-ionizing radiation.
The first step in the discussion between cancer disease and electromagnetic fields is done. But the chance to use the results of epidemiologic studies as an exhibition is very small, nearly zero. The advocates of this cancer-field theory examinated 50 Hz- magnetic fields with inductions of 0.3 mikrotesla. Known is only the muscle excitation with magnetic fields about 0.8 tesla and timegradient of about 120 tesla/second. However the causal connection between cancer and magnetic field strength of about 0.3 mikrotesla could not be found hitherto.
The development to examine biological effects of very weak magnetic or electric field with extremely and very low frequencies similar to those of natural background as o.o3-0.077 mikrotesla and 2.5 V/m does not lead to useable statements but gives assumptions of further work.
Of more interest is the biological effect of static magnetic fields over a long period, but the exposure in 3-10 millitesla over 10 years could not demonstrate any health effect. For magnetic resonance imaging there are used magnetic field strength of about o.5,1 and 1.5 tesla and the surrounding line inside the examination room has to be lower than 0.5 millitesla. So we see that outside of the examination room will no dangerous static magnetic field occur.Although the praxis of examination shows that physicians will be exposed inside the 0.5 millitesla line close to the patient the propability of health risks will be small. How far 1.5 tesla are injurious to the health of the patient is unknown till now. The same must be said of other magnetostatic facilities used for research with field strength up to 19 tesla for instance. But in this case measurements can be handled in the manner that scientists are not touched by dangerous influences.

SURVEY OF NON-IONIZING RADIATION LEVEL IN THE JRR-3M

Sakae KINASE and Takenori YAMAGUCHI

Japan Atomic Energy Research Institute
Tokai-mura,Naka-gun,Ibaraki-ken,319-11,Japan

ABSTRACT

Measurements of the free space levels of magnetic field in the Japan Research Reactor No.3 Modified (JRR-3M) and computer simulation of generating electromagnetic fields are presented. Extremely low frequency (ELF:50Hz) and very low frequency (VLF) field levels in the JRR-3M were fairly lower than applicable guidelines or standards. Simulation of generating electromagnetic fields would suggest that the generators were electrical devices, such as semiconductor power converter and video display terminal (VDT). These devices could produce not only ELF but also VLF electromagnetic fields.

INTRODUCTION

There has been a considerable development of science such as accelerator, superconducting magnetic energy storage (SMES) and nuclear fusion. Now VDTs are widespread among the general public in Japan. These man-made sources have increased chance of occupational and public exposure to non-ionizing radiation (NIR). The International Radiation Protection Association (IRPA) created the International Non-Ionizing Radiation Committee (INIRC) in 1977, and published some reports as to NIR(1).

In Japan, public concern has been growing about possible adverse effects of low frequency electromagnetic fields on human health. The Ministry of Posts and Telecommunication (MPT) indicated guidelines on protection standards for exposure to NIR in 1990(2). However, there are not many scientific data in Japan for the Japanese guidelines on limits of exposure to NIR. It is very important to measure magnetic field levels in workplace and home. There are also concerns about electromagnetic interference and compatibility (EMI/C) of electromagnetic fields. In the nuclear facilities, electronic personal dosimeter is adopted for personal dose measurement for the workers at radiation controlled areas, but the electronic personal dosimeter is not always independent of electromagnetic fields. For the purpose of personal dose monitoring for workers, it is necessary to measure the normal levels of magnetic field.

In the present work, measurements and simulation were carried out so as to obtain knowledge of NIR risk.

METHODS

Measurements of magnetic flux densities were made in the JRR-3M while it was not in operation. The JRR-3M attained its first criticality in March 1990 as a high-performance multi-purpose research reactor and started operation with maximum output of 20MW in November of the year. There are various utilization facilities installed in the JRR-3M, magnetic fields caused by these facilities influenced not only radiation workers but also instruments.

Two types of instruments were used for measuring ELF magnetic flux densities and VLF magnetic field strengths. One is ELF/power frequency EMF survey meter MODEL HI-3604 (HOLADAY) which has 6.5 inch diameter 400 turn electrically shielded magnetic field sensing coil. Its sensitivity for magnetic fields ranges 0.1mG-20G. The other is VDT/VLF radiation survey meter MODEL HI-3603 (HOLADAY) which has 8 inch diameter magnetic field sensing loop. Its

sensitivity for magnetic fields ranges 1-1999mA/m. Magnetic fields were measured along three orthogonal axes, since both instruments did not have three orthogonal field sensors. The magnetic flux densities and magnetic field strengths were expressed by the root of the sum of these mean squared mutually orthogonal components. All the measurements were taken at a height of 1m above the floor except for some cases. Temperature and relative humidity in the JRR-3M were 18.8℃ and 54.0%, respectively.

Recently there has been widespread VDT in workplaces and homes. A survey was made of VDT. This model is 15 inch cathode ray tube (CRT). The vertical deflection frequency is 56.4Hz, the horizontal deflection frequency 24kHz.

Root mean square (RMS) electromagnetic fields were determined by measurements as variation of the distance from centre of the VDT's surface. In order to reduce the proximity effect, the distance between the electromagnetic field strength meter and operator had to be at least 2.5m. Measured time period for ELF electromagnetic fields was over 1 second, for VLF fields 6 minutes. VLF electromagnetic field strengths were averaged over 6 minutes. The VDT's brightness was adjusted to an average level. The survey meter and the VDT were mounted on each non-conductive tripod.

There has been a tendency for fluorescent light and air conditioner etc. to be equipped with inverter which would produce electromagnetic wave. A computer simulation was performed for a double-way rectifier circuit using PSPICE (P Simulation Program with Integrated Circuit Emphasis, MicroSim Co.) so as to make clear the sources of electromagnetic wave. Simulated circuit consisted of four semiconductor controlled rectifiers, two FETs and SMES, and was controlled by pulse width modulation (PWM). Electromagnetic fields generated by semiconductor were estimated by Fast Fourier transform (FFT) of alternating-current.

RESULTS AND DISCUSSION

As shown in Figure 1, the magnetic field levels measured in the JRR-3M are low. The maximum magnetic flux density at the near surface of the electrical devices is fairly lower than applicable guidelines. These data were found by measurements at the distance 10cm from devices' surface. There are relatively high levels of magnetic field of vacuum device for a adiabatic tub and automatic voltage regulator which contain semiconductor elements. Observation of the magnetic fields using oscilloscope indicated that 50Hz frequency and higher harmonics of the magnetic flux densities were generated from electrical devices. As for high frequency, harmonics of the magnetic flux densities due to frequency-conversion at the electrical devices were observed.

Figure 2 shows ELF electric field strengths generated by VDT. The distances between the survey meter and the VDT are 0.1,0.2,...,1.0m. Table 1 shows the electric and the magnetic fields at 10cm from the VDT's surface and IRPA guidelines. Using these field strengths value, induced current density in human head was found from calculation. Its current density was 0.6mA/m^2 as worst case assuming a 7.5E-2m radius loop and conductivity 1S/m. Normally,, the spontaneous endogenous current density in body is about 10mA/m^2. The health risk caused by electromagnetic fields of VDT is not necessarily considered.

Computer simulation indicated that electronic circuit consisted of nonlinear elements and controlled by PWM emitted not only ELF but also VLF electromagnetic wave.

CONCLUSIONS

[1] The magnetic field levels measured at JRR-3M were fairly lower than IRPA and Japanese guidelines. VDT electromagnetic fields were also lower than these guidelines.

[2] Electrical devices, such as semiconductor power converter and VDT could produce not only ELF but also VLF electromagnetic fields.

NON-IONISING ELECTROMAGNETIC FIELDS ON OFFSHORE INSTALLATIONS

Gillian M. Stark, [1] and Brian Heaton, [1]

[1] Department of Biomedical Physics and Bioengineering, University of Aberdeen, Foresterhill, Aberdeen, UK.

INTRODUCTION

The concern over the effects of occupational exposure to non-ionising electromagnetic fields (EMF) has greatly increased in recent years. A great deal of knowledge is known about the thermal effects of radiofrequency EMF's and at the moment, many epidemiological and laboratory studies are being performed on extremely low frequency (ELF) and very low frequency (VLF) EMF's. Some studies have reported an increased risk of leukaemia and other cancers in children living close to overhead power cables and power industry electrical workers.

Wertheimer and Leeper reported cancer links in children residing near overhead power cables as early as 1979 (1) and many subsequent studies have continued to make similar associations (2,3,4,5 and 6). These studies suggest that prolonged exposure to higher than normal magnetic fields increases the occurrence of certain cancers in both children and adults. The most common associations are between EMF's and leukaemia, other haematopoetic cancers, brain cancers, central nervous system cancers or melanomas.

Studies of adults living near overhead lines by Youngson et al (7)) and working in the electricity industry by Armstrong et al (8) and Savitz & Loomis (9) have also shown associations with certain cancers. The epidemiological studies are incomplete in several areas and many have been openly criticised. As yet, there is no conclusive laboratory evidence but studies are ongoing (10,11,12). The Hendee and Boteler study (12) suggested that " EMF's might be cancer promoters but are unlikely to be cancer initiators".

In addition to ELF studies, there have been many reports investigating exposure to EMF's from visual display units (13) with equivocal results. Laboratory studies have reported conflicting results and as yet the hazard, if any, is still uncertain (14). Reports have also recorded exposure levels of operators in broadcast radio stations showing a variety of levels dependant on the occupation (15).

In December 1992, the Commission of the European Communities proposed a council Directive on the minimum safety and health requirements regarding the exposure of workers to the risks arising from physical agents including electric and magnetic fields at frequencies up to 300 GHz (16). The proposed Directive contains a set of ceiling levels expressed as fundamental dosimetric quantities and action levels expressed in terms of electric field strength, magnetic field strength and power density.

On offshore oil producing installations there are many sources of electromagnetic fields operating at a variety of different frequencies. These include transformers and generators capable of large power generation, numerous switch rooms, radiofrequency communications including microwave and satellite links. Due to the confined work areas, the switch rooms and transformer rooms are frequently used as office areas by engineers and technicians. This paper the results of these fields on several offshore platforms and compares the measured fields with the proposed CEC directive.

METHODS

Three different field strength meters and a VDT adapter were used for the measurements to cover the broad frequency range available on offshore installations. These include the Holaday HI-3600-02 power frequency field strength meter used for measuring both electric and magnetic fields in the frequency range 30-300 Hz. The Holaday HI-3600 VDT Radiation Survey adapter fits onto the aforementioned field strength meter and is sensitive to electric fields between 2 - 300 kHz and to magnetic fields between 8 - 300 kHz. The Holaday HI-3000 broadband isotropic field strength meter uses two probes. The electric field probe is sensitive to frequencies between 0.5 MHz - 5 GHz and the magnetic field probe between 5 - 300 MHz. The higher frequency RAHAM Model 4 Isotropic Wideband Electromagnetic radiation hazard meter measures the electromagnetic field in terms of power density in the 10 MHz - 26 Ghz range.

RESULTS

The results clearly fit into three different categories, including power generation and distribution system measurements, VDU measurements and telecommunication equipment measurements. The maximum electromagnetic fields from the power production were summarised and are tabulated below :

Area	Maximum Magnetic Field (μT)	Maximum Electric Field ($V.m^{-1}$)
Platform A	181.95	120.0
Platform B	227.98	651.0
Platform C	2590.43	31.0
Platform D	816.15	522.0
Platform E	532.67	1400.0

Table 1 Summary of maximum levels of magnetic and electric fields at 60 Hz found on offshore platforms.

The maximum levels measured were typically found close to the transformers and the incoming supplies from those transformers to the distribution boards and were all found in the switch rooms and transformer rooms of the oil processing package. From the table, the maximum level of magnetic field found throughout the platforms measured was 2.6 mT on Platform C. This exceeds the first action level of 333 μT recommended by the CEC for this frequency as do levels on Platform D and Platform E. The levels found on Platform C not only exceeds the first action level but also the hazardous activities level of 1 mT for this frequency. The maximum electric field of 1.4 $kV.m^{-1}$ found on Platform E near a VDU screen, is within the recommendations by the CEC (10 $kV.m^{-1}$).

At the time of measurements, the load on the drilling package was minimal on all but one of the platforms (platform C) and the subsequent levels were lower than those in processing. The maximum magnetic field found in the drilling package was found on platform D and was 129.92 μT. Power is produced at 6.8 or 11 kV for all the processing applications and at 600 V for the drilling applications. Induction welding is used frequently on offshore installations and levels were found to be no greater than 9.24 μT.

The maximum ELF electric and magnetic fields near VDT's found on the platforms are summarised and presented below in table 2.

Position	Electric Field Strength ($V.m^{-1}$)	Magnetic Field Strength ($mA.m^{-1}$)	Magnetic Flux Density (nT)
Platform A	120	439	553
Platform B	138	2014	2530
Platform C	16	444	558
Platform D	102	2411	3030
Platform E	1400	1852	2327

Table 2 Summary of maximum ELF measurements in front of VDU screens on offshore platforms.

Throughout the platforms, the maximum magnetic field measured near a VDU was found to be 3030 nT (3.03 μT) and the maximum electric field was 1.4 $kV.m^{-1}$. The maximum magnetic field measurements are much lower than those found in the switch rooms and are well below the recommendations by the CEC of 333 μT for the magnetic flux density.

Similarly for VLF magnetic and electric fields, the CEC draft proposal recommends that the magnetic flux density does not exceed 20 μT and the electric field does not exceed 614 $V.m^{-1}$ for the frequency range 1-300 kHz. Again the results are summarised and presented below in table 3.

Position	Electric Field Strength ($V.m^{-1}$)	Magnetic Field Strength ($mA.m^{-1}$)	Magnetic Flux Density (nT)
Platform A	94	250	314
Platform B	37	411	516
Platform D	81	358	450
Platform E	8	46	58

Table 3 Summary of maximum VLF measurements in front of VDU screens on offshore platforms.

Clearly the VLF levels found near VDU's are well within the recommendations by the CEC even those measurements taken close to the screen. The maximum levels from the telecommunications equipment on the four platforms are presented below in table 4.

Platform	Electric field strength ($V.m^{-1}$)	Magnetic field strength ($mA.m^{-1}$)	Magnetic flux density (nT)	Power Density ($mW.cm^{-2}$)
Platform A	N	77	97.33	20
Platform B	N	N	N	2
Platform D	141.42	510	640.74	N
Platform E	316.20	390	486.68	N

Table 4 Summary of maximum radiofrequency measurements found on the platforms where N is negligible and approximately equal to the background.

The majority of the maximum levels were found near the outside aerials but on platform E, maximum levels were found near some of the handheld radiofrequency sources. The maximum electric field strength was found to be 316 $V.m^{-1}$ at a frequency of 156 MHz. At this frequency, the CEC recommendation is 61.4 $V.m^{-1}$ and therefore the electric field found at this frequency is much greater than the first action level and is even greater than the hazardous action level (3 times the first action level) of 184.2 $V.m^{-1}$.

The higher frequency measurements of power density produced maximum levels of 20 $mW.cm^{-2}$ near a VHF aerial on Platform A. None of the other sources produced power density levels exceeding the CEC action level of 1 $mW.cm^{-2}$.

CONCLUSION

The majority of the levels measured were found to be below the recommendations by the CEC for all frequencies measured although some did exceed them. On three platforms, levels at ELF were found to exceed the recommendations with a maximum of 2.6 mT found on one platform which is approximately 8 times the CEC recommendation of 333 μT. Levels measured near the telecommunications equipment also exceeded recommendations on isolated incidences. Throughout the measurements, the time dependency of the exposure has not been taken into account and clearly this greatly reduces the overall exposure.

METHODS OF DEVELOPING AN EMISSION CATASTER FOR LOW FREQUENCY ELECTRIC AND MAGNETIC FIELDS

Elmar Stenzel, Olaf Frohn, Karsten Koffke, Jörg Dunker, Olaf Plotzke

Forschungsgesellschaft für Energie und Umwelttechnologie
FGEU mbH, Yorckstraße 60, 10965 Berlin

Introduction

In the common environment each individual is exposed to a large variety of power frequency or extremely low frequency (EFL) electric and magnetic fields. Traditionally these fields have been thought to be harmless but recent scientific studies reveal, however, that at least effects do exists. Therefore further investigations have to be carried out in order to obtain a greater data base. As a major point new ways have to be established that allow an effective collection of all relevant data concerning the exposition in this fields. In our contribution for the first time methods that consider simultaneously all major field emittants in the range of 0-500 Hz spread over the area as great as a town district. These methods have been developed and successfully tested in the district Buch/Karow of Berlin during the research study *"Emissionskataster der elektrischen und magnetischen Feldexposition im Stadtgebiet Berlin - Eine vergleichende Pilotstudie in ausgewählten öffentlichen Bereichen" (Emission cataster of electric and magnetic field exposure in Berlin - a comparative study in selected public areas)* [1][2][3]. In this study the following field sources have been taken to consideration:

- 110-kV, 220-kV, 380-kV transmission lines
- 110-kV power transmission cables
- relay station Karow
- 10-kV medium voltage level
- 1-kV distribution level
- power stations
- railway
- urban railway

General methods

In contrast to conventional environmental factors electric and magnetic fields are characterised by the following special properties:

- strong spatial fluctuation
- fast temporal variations

The latter are concerning mainly magnetic fields witch are able to penetrate almost every material whereas electric fields are strongly distorted near vegetation or buildings what in most cases is leading to near field reduction. In order to enable a collection of field strength data over a large area it is necessary to make further simplifying assumptions:

- mean or maximal (worst case) current values
- undisturbed electric fields

Based on these assumptions it is possible to extrapolate measured data within acceptable errors. Measurements therefore are only necessary to classify objects and to normalize calculated data. In the case of power transmission lines i. e. it is possible to bring calculated and measured data into congruency within 95% [4]. This can be done via measuring traverse profiles on well defined positions and knowledge of all important parameters, particular transmission line currents and exact distance between conductors and ground that depends on operational and environmental conditions.

A suitable way for determining the catenary wire current and the backwards directed current of railway lines or urban railway lines can be achieved by simultaneous measurement of magnetic field strength at different distances (i. e. 5, 10, 15 and 20 m) over longer time periods. Subsequential simulation calculations carried out with the current as input parameter have to be varied as long as their profile fits with the measured values. Also in this case an exact knowledge of the railway line configuration is required.

Computational methods and graphical processing

In the above mentioned project a newly developed software [5] was used that enables simulation of whole units of energy distribution facilities and allows calculation of large areas in a straightforward manner. Based on the construction documents the corresponding objects as super grids etc. have been transferred to the computer. Exact positioning could be achieved easily by taking the coordinates out of digitalized maps which have been obtained by vectoring analogue maps in the *"Landeskoordinatensystem Soldner Berlin"*. After computation calculated isolines of the field strengths together with object geometry's could be transferred back to the digital maps using the CAD program AutoCadLT™.

Example: Power Transmission Lines

The investigated area is divided by three transmission lines of 380-kV, 220-kV and 110-kV respectively. The latter is partially installed as an earth cable. The corresponding magnetic flux (Fig. 1) was calculated assuming medium currents and air temperature of 10°C (according to DIN VDE 0210).

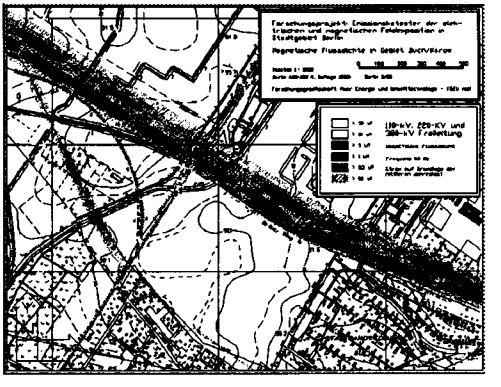

Fig. 1: Calculated magnetic field strength of power transmission lines in Berlin-Buch/Karow 1 m over ground (maximum field strength: 4.2 µT).

Calculations are based on the documents and data provided by the energy supply companies. Errors in height data, especially the minimal rope-ground distance, case distinct variations in calculated ground field strength as demonstrated in Fig. 2.

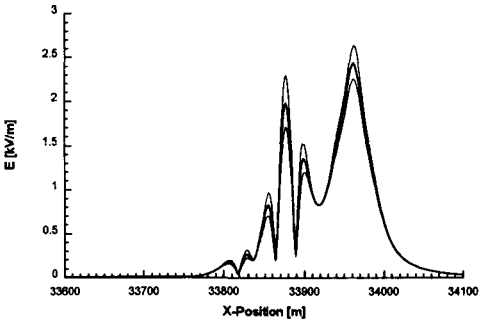

Fig. 2: Example of transverse profiles of the electric field strength under the 3 transmission lines in Berlin-Buch/Karow calculated for a variation of the minimal rope-ground distance of ± 1 m (x-position in the *"Landeskoordinatensystem Soldner Berlin"*).

An example for the good agreement that can be achieved between measurement and calculation is shown in Fig. 3, were the profile along the trace axis of the 380-kV transmission line is displayed. Even the drastic decrease of the electric field strength near the super grids is perfectly matched by the calculation curve.

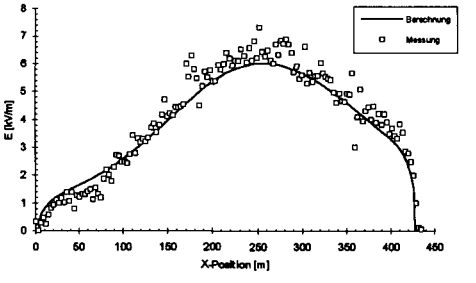

Fig. 3: Measured and calculated electric field strength on the centre line of the 380-kV transmission line.

Example: Railway

In the area under investigation is also running an electrificated railway line with two tracks. Computation was based on a model of three conductors (two rails and the cat wire), which general configuration is given in the literature. currents were assumed to be maximal (2x500 A, 16 2/3 Hz) and the part of the backward current in the rails was set to 95%. These values have to be seen as upper limits and thus the calculation could be seen as a worst case approximation. Although in Berlin-Buch/Karow railway as well as urban railway lines are running on an embankment of a height of 4 m, the reference height for the magnetic field strength was set to 1 m, since this height is relevant for persons in the environment of the railway line.

The results obtained with these approximations are shown in Fig. 4, but one has to keep in mind that the depicted field strengths represent maximum values that only be expected during short time intervals.

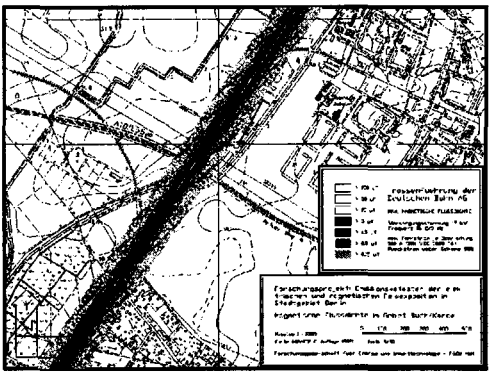

Fig. 4: Magnetic field strength near the railway embankment in Berlin-Buch/Karow calculated for maximal current (2x500A, 16 2/3 Hz), at 1 m over ground (maximum field strength: 20 µT).

In general mean values of the magnetic field strength are about one order of magnitude lower as can be seen in Fig. 5, which shows a measurement over a longer time period.

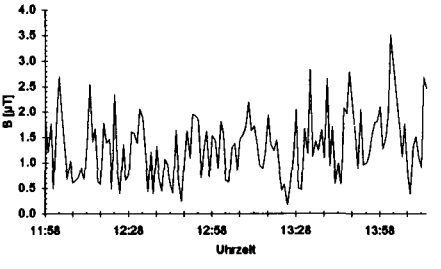

Fig. 5: Typical long-time measurement of magnetic field strength along a railway line in Berlin-Buch/Karow measured 1 m over ground at a distance of 12 m.

General results

Further major results of magnetic field strengths are shown in the following spreadsheet:

	B [µT]	current	f [Hz]
power transmission lines			
110-kV	2.0	med.	50
220-kV	4.2	med.	50
380-kV	2.6	med.	50
110-kV cable	0.24	med.	50
10/1-kV cable	0.67	med.	50
power stations (max.)	3.45	med.	50
power stations (value in 1.7 m)	0.3	med.	50
railway	20	max.	16 2/3
urban railway	29	max.	DC

One should keep in mind that some field strengths represent medium values while others base on maximum currents. A complete discussion of the obtained data is given in [6].

Conclusion

The main conclusions of the reported examples can be summarized as follows:

a) An isolated consideration of a single field source often not is possible since other sources, as other transmission or railway lines, do contribute to the total field strength in a non neglectable amount.

b) Excellent agreement between measurement and calculation is achievable under exact knowledge of all relevant parameters. This even holds for the more complex calculation of electric field strength, although in practice the electric field is often influenced by the environment.

c) Computation of electric and magnetic fields with acceptable errors and reasonable effort is possible also for large areas. High precision, however, requires exact determination of operational parameters and environmental conditions. Simple adoption out of data sheets always leads to great inaccuracies.

d) Magnetic fields of 10-kV and 1-kV cables in the investigation area could not be separated.

e) No relation was found between the number of underground 1-kV cables and the corresponding magnetic field strength in streets. An explanation is the compensation of single fields, as verified by computational simulation.

f) The current asymmetry on the 1-kV distribution level is in the range 1-3 A and contributes the major part to the magnetic field.

g) Magnetic field strength near the inspected power stations exceeded the street level only in the local environment (distance below 1 m).

h) In the case of railway lines the problem of strong time variations of cat wire currents is up to now only be accessible assuming maximum currents.

The research project *"Emissionskataster der elektrischen und magnetischen Feldexposition im Stadtgebiet Berlin - Eine vergleichende Pilotstudie in ausgewählten öffentlichen Bereichen"* therefore contributes to a great part to the clarification of the following points:

- realizability of low freq. electric and magnetic cataster
- creation of a real environmental data base
- estimation of the actual effort
- testing of computational methods
- reasonableness of extended field methods

Since the calculated field strengths in most cases remain below critical values [7][8] or don't case technical troubles even at this early point the conclusion can be drawn that a standardized extensive evaluation of low frequency fields is not top priority. Additional investigations of selected areas, however will yield further important insight.

The project was supported by:

SENSORS FOR LOW FREQUENCY ELECTROMAGNETIC RADIATION

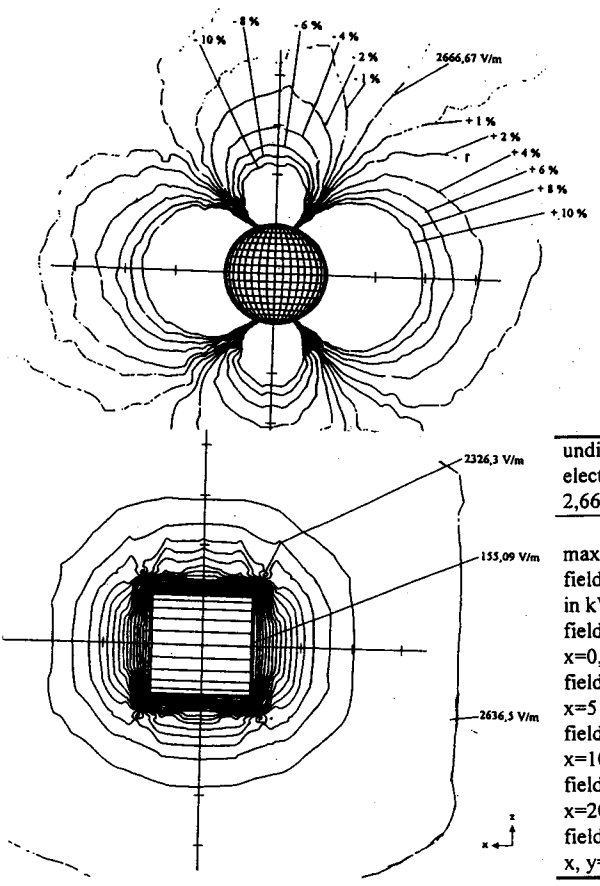
Elmar Huber and Manfred Urban
Forschungszentrum Karlsruhe; Technik und Umwelt; PO Box 3640; D-76021 Karlsruhe, Germany

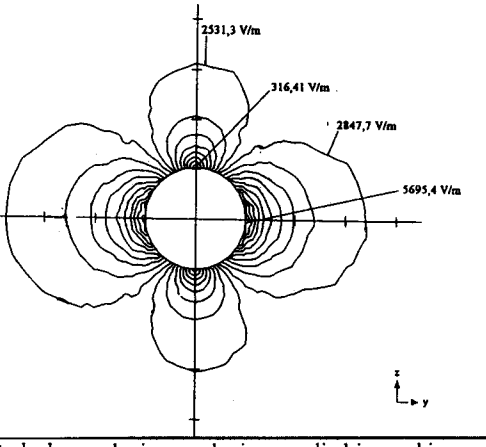
INTRODUCTION

For estimating the personal exposure from low frequency electric and magnetic fields suitable measurement systems are necessary. Investigations of appropriate magnetic and electric field probes and sensors have been done as a basis for a pocket sized personal dosimeter. There exist many different sensors, which can be used for the measurement of static and low frequency magnetic fields, such as inductive transducers, hall generators, tunnel diode oscillators, flux gate sensors and magnetoresistive sensors. In contrast to the magnetic sensors there are less different sensor types based on different physical detection principles available showing a sufficient sensitivity for low frequency electrical fields. Important is the knowledge on the feed back of the sensor itself on the detected field strength. Whether a sensor is suitable for a certain application is depending on its frequency related sensitivity, its signal to noise ratio, linearity and detection range, sensitivity to environmental influences as temperature, humidity etc. This presentation will focus on some important basic aspects of the measurement of low frequency electrical and magnetic fields for radiation protection purposes.

ELECTRICAL FIELD: DETECTOR GEOMETRY INFLUENCES ON THE UNDISTURBED FIELD

By means of analytical and numerical (1) investigations feed back effects on the undisturbed electrical field have been investigated. The results are presented in the following examples of three different sensor geometries, spheres, cylinders and cubes (Fig.1)



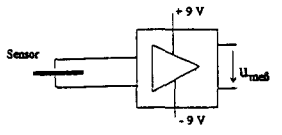


undisturbed electrical field 2,667 kV/m	spheric geometry r = 1 cm	spheric geometry r = 2 cm	cylindric geometry r = 1 cm	cubic geometry a/2 = 1 cm
	analytical	numerical	numerical	numerical
maximum field in kV/m	8,0	9,1	10,9	9,8
field in kV/m x=0, y, z	8,0	9,1	10,9	9,8
field in kV/m x=5 mm, y, z	6,9	5,9	6,0	5,4
field in kV/m x=10 mm, y, z	3,5	3,3	10,9	9,8
field in kV/m x=20 mm, y, z	2,8	2,9	3,0	3,0
field in kV/m x, y=0, z	2,7	3,1	3,1	3,0

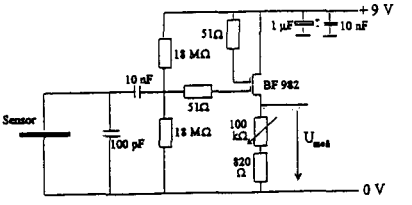
Fig. 1: Feed back of different sensor geometries on the undisturbed electrical field (the origin of the x,y,z - coordinate system is the geometric center of the object)

ELECTRICAL FIELD: EXAMPLE FOR THE MEASUREMENT, INFLUENCED CHARGE METHOD

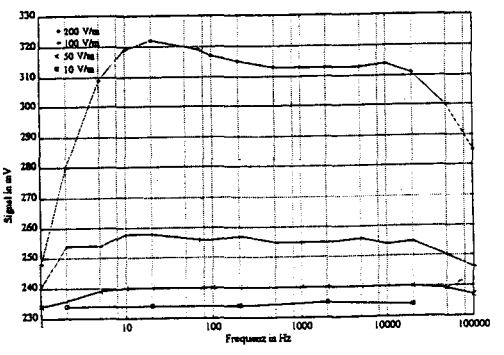
There are different detection principles for electrical fields such as the measurement of induced electrical charge, induced coulomb force on charges, deviation of electron beams, piezo-effect, electro-optical effects (Pockels-, Kerr-Effect), modification of the gate to source voltage of field effect transistors by induced charges etc. There is a big spectrum of different electronical implementations resulting in different sensitivities and frequency responses of a sensor. The following examples show two possibilities for the measurement of induced charges on a capacitive sensor, a differential amplifier circuit and a field effect transistor circuit (2, modified). They show differences in detection efficiency and frequency dependence (Fig. 2).



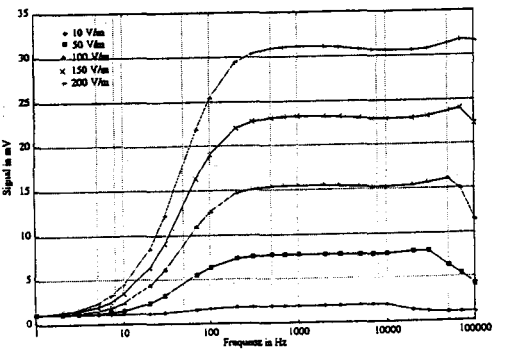
capacitive sensor 72 mm diameter, 125 pF



capacitive sensor 72 mm diameter, 125 pF



without electrical field: 1,1 mV



without electrical field: 233 mV

Fig. 2: Frequency dependent sensitivity of given sensors detecting induced charges on a capacitive sensor using
a) a differential amplifier circuit (left) and
b) a field effect transistor circuit (right)

Electrical field strengths of 0, 10, 50, 100 and 200 V/m and frequencies varying from 1 Hz to 100 kHz have been applied. There is a small lower frequency detection limit for the differential amplifier version, which can be varied by modification the amplifier entrance circuit. The entrance capacity reacts as a frequency dependent short circuit resulting in a frequency depending loss of sensitivity. The linearity of the sensor signal is poor. The absolute sensitivity of course depends on the effective area, where electrical charge is induced.

When field effect transistor circuits are used (Fig. 2 b), there is a higher detection limit at lower frequencies. The limiting factor for the lower frequency limit is the resistance R_E, which was chosen to be 18MΩ. Higher nominal values for R_E often have been found to show lower resistance's as indicated. In addition air humidity and resulting current losses become important and result in instable circuit conditions. To increase the sensitivity the parallel capacitance, which is 100 pF in Fig. 2b, has to be increased. As a consequence the lower frequency limit increases also. It is a question of optimisation on the application conditions, what is best.

MAGNETIC FIELD: DIFFERENT SENSOR PRINCIPLES AND THEIR APPLICATION RANGE

The following sensors for the measurement of static and low frequency magnetic fields have been investigated: inductive transducers, hall generators, tunnel diode oscillators, fluxgate sensors and magnetoresistive sensors. The results in terms of detection range for the magnetic field strength and the detectable frequency range are presented in Fig. 3.

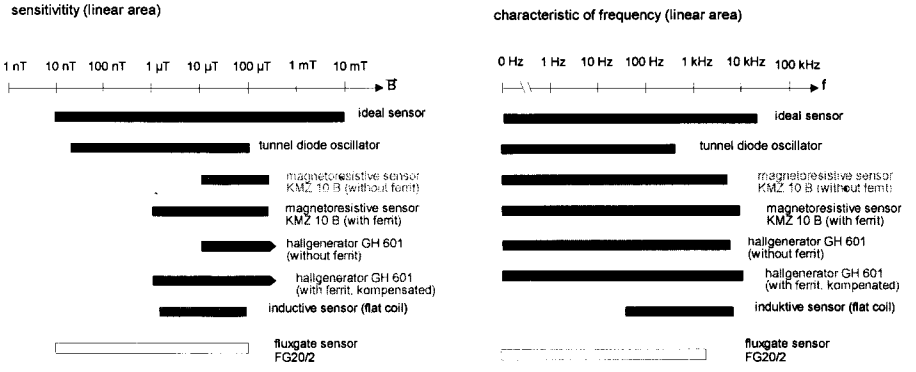


Fig. 3: Comparison of different sensor types, the linear range of their sensitivity and the detectable frequency range

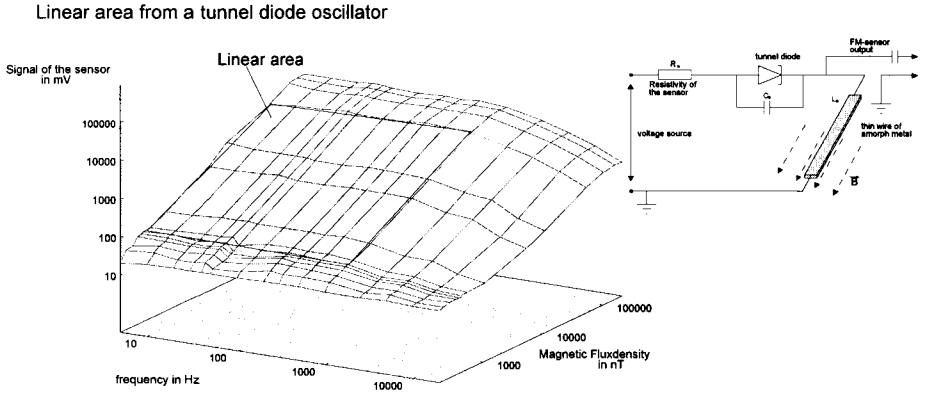

Fig. 4: Linear range from a tunnel diode oscillator

For radiation protection purposes an ideal sensor should cover the sensitivity rage from 10 nT up to at least 10 mT and the frequency rage from DC up to 30 kHz. Compared to that conditions, none of the tested sensors covers all. In consequence a combination of different sensor types will be necessary. Such a combination could be a fluxgate sensor combined with a coil. The mentioned coil has to cover the „upper" frequency range. An example for the linear range of the sensor signal of a tunnel diode oscillator over frequency and the magnetic field is presented in Fig. 4. Also for magnetic field sensors the choice, which is best, depends strongly on the application.

NUMERICAL EVALUATION OF SAR IN PREGNANT WOMEN DURING MRI EXAMINATIONS

Paolo Vecchia[1], D. Aragno[1], S. Canino[1], P.L. Indovina[2], R. La Torre[3], A. Polichetti[1]

[1]Physics Laboratory, National Institute of Health, Rome, Italy,

INTRODUCTION

Magnetic Resonance Imaging (MRI) tomography, although among the safest diagnostic techniques presently exploited, presents some risks for patients. Among the major causes of risk is heating of tissues elicited, through the Joule effect, by the electric currents induced by the radiofrequency (RF) electromagnetic field used in MRI. International guidelines from radiation protection organizations such as the International Non-Ionizing Radiation Committee of IRPA (IRPA/INIRC) have been published in order to protect the patients from RF electromagnetic fields during MRI examinations (1): limits are given in terms of Specific Absorption Rate (SAR), i.e. the power absorbed per unit mass, which is regarded as the most suitable physical quantity to describe the thermal load induced in the body by RF fields.

Special caution in the use of this technique is recommended by IRPA/INIRC in the case of pregnant women: the MRI examinations should be postponed until after the first trimester, and limited to cases in which the diagnostic information cannot be obtained by ecography. This caution results from the scarce available information on the safety of MRI during pregnancy. An important step to obtain more information on this subject is the theoretical determination of SAR in the mother and in the fetus. To evaluate the SAR distribution in the different tissues of models that we have developed on the basis of information from ecographic scanning, we have employed a numerical technique, the impedance method, previously used to determine SAR in a model of the human torso subject to different procedures of MRI tomography (2,3).

Preliminary results on SAR distribution are presented and discussed.

THE IMPEDANCE METHOD

In the frequency region used in MRI diagnostic examinations, the absorption of RF energy in the body is mainly associated with the magnetic field, depending on several physical properties of the field, like frequency, strength, polarization (relative to the body), and on the geometrical and physical properties of the body. In the impedance method the properties of the body are summarized in a numerical model composed of a given number of cells, each one characterized by its mass and its electric impedance, calculated from the mass density and the electric permittivity and conductivity of the tissues composing the cell. The body is replaced by a three-dimensional network of impedances that can be subjected to a mesh analysis: calculating by the Faraday's law of induction the electromotive force due to the time-varying magnetic field in each loop, it is possible to evaluate the electric current circulating in each cell, and then the SAR relative to each single cell, and the SAR averaged on the various tissues.

This technique, which uses a quasi-static approximation, has some limitations in frequency: it was shown in fact, by means of comparisons with analytical calculations of SAR in cylindrical models, that the impedance method provides reliable estimates of SAR up to 30 MHz, while at higher frequencies the estimates are systematically greater than the analytically evaluated SARs (3).

THE NUMERICAL MODEL

On the base of transverse sections of the pregnant woman obtained from ecographic examinations, we have made some cell models of the mother-fetus system at different stages of pregnancy. The anatomical resolution of these sections is 5 mm, while, to increase the precision of results (as suggested by comparisons between analytical and numerical solutions obtained on a multi-layer cylinder), in the numerical models we have used cubic cells of 1 mm edge, obviously at expense of computation time and memory resources. Each transverse section is

contained in a 32 cm x 21 cm rectangle, corresponding to 67200 cells.

Models refer to the 12th week, the 24th-26th week, and the 38th-40th week. In Figure 1 a transverse section of the pregnant woman at the end of the first trimester is shown, corresponding to the horizontal plane 10 cm above the base of the uterus.

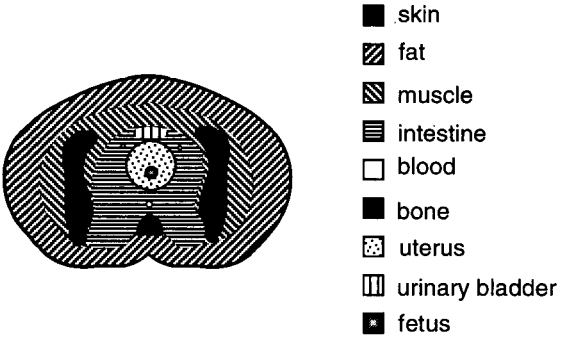

Figure 1. Transverse section at 10 cm above the base of the uterus at 12th week of pregnancy.

RESULTS AND DISCUSSION

Our preliminary results refer to the SAR deposited in the woman at the 12th week of pregnancy by an RF magnetic field directed along the axis of the body, at the frequencies of 13 and 30 MHz. In this paper, we only consider the 30 MHz frequency, which corresponds to the higher values of SAR, as it could be foreseen by simple theoretical considerations, synthesized as follows:

$$SAR \sim \sigma(f)\, E^2 \sim \sigma(f)\, (dB/dt)^2 \sim \sigma(f)\, f^2\, B^2$$

where $\sigma(f)$ is the electric conductivity, increasing with the frequency f, E is the induced electric field and B is the magnetic flux density.

For exposure to continuous waves, and in the case of magnetic flux density B = 1.26 μT at 30 MHz, the calculated distribution of SAR in different tissues and organs is that shown in Figure 2.

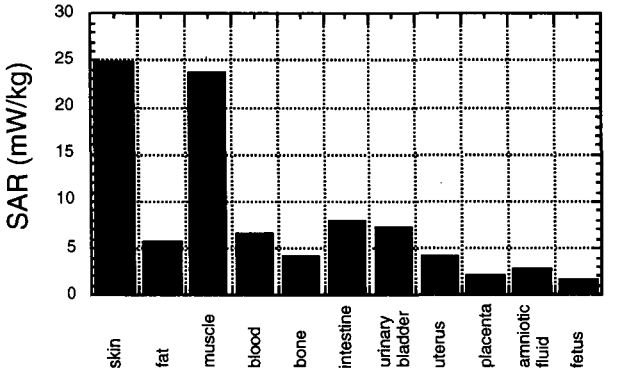

Figure 2. SAR distribution in a pregnant woman at 12th week. (B=1.26 μT, continuous wave, f = 30 MHz)

By means of suitable correction factors, we can obtain SAR values in more realistic situations. These correspond to various MRI procedures which use different values of the magnetic flux density and pulsed fields with duty-cycle $D = N_i N_s \tau / T$, where N_i is the number of pulses in a sequence, N_s is the number of excited slices during a sequence, t is the pulse width and T is the repetition time of sequences: in Table I data are shown relative to SAR deposited in the fetus and in the amniotic fluid for some typical MRI examinations.

Table I. SAR in the fetus and in the amniotic fluid for some typical pulse sequences.

MRI procedure (f = 30 MHz)	**Correction factor**	**SAR (mW/kg) in the fetus**	**SAR (mW/kg) in the amniotic fluid**
Continuous wave: B = 1.26 μT	1	1.6	2.7
Spin Echo: 1 echo, 1 π pulse τ = 1 ms, T = 1 s, B = 23.6 μT	0.35	0.57	0.94
Fast Imaging: 1 echo, 1 π /2 pulse τ = 5 ms, T = 0.1 s, B = 2.36 μT	0.175	0.29	0.47
Inversion Recovery: 4 echoes 5 π pulses, 12 slices τ = 0.5 ms, T = 1 s, B = 47.1 μT	41.9	68.5	112.4

Owing to the specificity of the "target" organ (the fetus in the amniotic fluid), the results are not easily comparable with the recommended SAR limits (1) which refer to individuals with thermoregulatory system. However, it is possible to evaluate the temperature rise in the amniotic fluid and in the fetus supposing the absence of a mechanism to get rid of the heating produced by electromagnetic energy absorption. Considering the specific heat of amniotic fluid and fetus equal to that of water, and imposing an upper limit of 0.5 °C to the temperature rise, we obtain a limit of 2093 J/kg for the product SAR x Δt, where Δt is the exposure duration. In the case of an MRI examination lasting 1 h, the limit for SAR is 0.6 W/kg, much higher than the values shown in Table I.

CONCLUSIONS

Preliminary results from the application of the impedance method to a realistic numerical model of the pregnant woman seem to indicate that SAR deposited in the fetus and in the amniotic fluid, at the end of the first trimester of pregnancy, is not such to cause too high rises in temperature.

Work is in progress relative to different polarizations of the RF magnetic field and to the other stages of pregnancy.

Occupational exposure to radiofrequency radiation from (4 - 7 MHz) RF dielectric heat sealers.

S.Y. Acram and M.J. Smit
Netherlands Institute for Radiation Technology
P.O. Box 1359, 1000 BJ Amsterdam, The Netherlands.

Introduction

We have conducted radiation measurements on 12 welding machines which were operated in a factory in the Netherlands. These machines were welded through electromagnetic fields, used to weld plastic parts through rapid heating. High temperatures are reached through application of frequencies between 5 and 7 MHz. The present investigation includes 3 different machine types: EA20 (5 machines), EA50 (4 machines) and HD500 (3 machines).

The production process

RF heaters are usually operated by women in their fertile ages. They perform their work standing upright in front of the RF sealers. Three machines however were operated by two women, who alternatively performed an operation on one of the machines. This regards the machines numbers 6, 7 and 8.

The purpose of the measurements was to determine the radiation level. It was to be investigated whether the RF radiation doses received from the RF sealing apparatus was acceptable according to the international regulations provided by the International Radiation Protection Association/International Non-Ionizing Radiation Committee (abbreviated as IRPA/INIRC). These regulations are strongly recommended by the Netherlands Institute for Radiation Technology (NIFRT).

A good assessment of the exposure levels is required because the operators of the RF welding apparatus are in close proximity, i.e. within two wavelengths from the radiation source. Both the electric as well as the magnetic field should be measured. For each, the strength is measured on seven locations on the body. During the measurements, the operator was in his normal working position. In cases where the readings went off the scale, a second (control) measurement was carried out at a larger distance. However, these did not affect the outcome of the investigation.

Description of equipment

Field strength measurements were done using a "Holaday Broadband Isotropic Field Strength Meter" type HI-3012. This is an analog instrument which displays Field Strength Units squared ($|FSU|^2$). Both electric as well as magnetic fields can be measured. The instrument has been manufactured in the United States in 1991. It come with two probes:
an MSE E-field probe with a range between 10^2 and 10^9 V^2/m^2;
and the HCH H-field probe with a range from 0.05 to 10.0 A^2/m^2.
The working range of the HI-3012 is between 0.5 MHz and 5 GHz (for electric fields) and between 0.5 and MHz and 300 MHz (for magnetic fields).

For both probes the accuracy is ±0.5 dB.
The apparatus has to be calibrated before use. The calibration is done by a specialised institution which provides a calibration factor (CF). This factor can be used to correct possible deviations. This factor (a number) is determined separately for each probe and is reported in a calibration report. Furthermore measurements were corrected for the time (during an operation) that the machine was not active. For this purpose a so-called Duty Cycle (DC) was determined. This is an effective average.

Results

The results have been combined in the following two tables. The strengths of the electric and magnetic fields provide an indication of the radiation levels to which the operator is exposed during the regular production process. Measurements have been corrected with the Duty Factor and the Calibration Factor. Comparison of the relative strengths of radiation exposure on different areas of the body shows that the eyes and the abdomen are more exposed to both E and H-field than knees and feet. In other words, those body parts that are at the same height or slightly above the welding spool are more exposed.

The table shows that excessively high electric fields are present near machines 2, 4, 6, 9, 11 and 12. The remaining 6 machines do not appear to deviate substantially from the accepted exposure-value as regards the E-field. The norm is derived from the peak-frequency. This results in a more rigorous value. Using an average frequency would result in a less stringent norm. However, this makes hardly any difference as regards the number of machines where the norm is exceeded.

As regards the different types of machines this means the following:

for the HD-500 and the EA-50 the norm is established using a frequency of 7 MHz. This results in a norm of 87.71 V/m (electric) and 0.23 A/m (magnetic).

for the EA-20 the norm is established using a frequency of 5 MHz. This results in a norm of 122.80 V/m (electric) and 0.32 A/m (magnetic).

Table 1 Electric Field Strength [V/m]

#	Eyes	Neck	Chest	Abdomen	Pelvic	Knees	Feet	Norm
1	64.42	91.10	128.83	78.89	40.74	14.40	12.88	122.80

3	4.40	6.22	11.35	8.03	5.08	0.00	0.00	122.80
4	>53.52	107.04	>169.25	>169.25	65.55	16.93	15.14	122.80
5	8.28	5.23	6.92	5.85	4.14	3.70	2.48	122.80
6	>107.60	131.78	263.56	284.67	152.16	48.12	48.12	87.71
7	2.07	1.46	6.54	4.63	4.14	1.46	0.65	87.71
8	25.44	25.44	31.15	17.99	17.99	1.80	0.00	122.80
9	89.89	>201.00	0.64	>201.00	142.13	34.81	49.23	87.71
10	60.56	54.16	66.34	60.56	46.91	13.54	23.45	87.71
11	>156.08	78.54	99.35	86.04	60.84	19.24	14.90	87.71
12	112.84	138.20	9.03	338.52	178.42	30.90	0.00	87.71

Magnetic field measurements are less favourable than those for the electric field.
This follows from the data in the table.
In fact, only machines 5 and 7 are within the established norm.

Table 2 Magnetic Field Strength [A/m]

11	0.56	0.49	>0.59	>0.59	>0.59	0.26	0.02	0.23
12	1.33	1.11	>1.33	>1.33	>1.33	0.73	0.16	0.23

As regards exposure numbers for operators the following remarks are in order:

It can be seen that there is no relation between E-field radiation and H-field radiation
The radiation emitted varies with size, shape and thickness of the material to be processed
There is no proportional increase for exposure levels for either E-fields or H-fields with machine power (in kilowatts)

Conclusion

The present investigation shows clearly that RF-welders 2, 4, 6, 9, 11 and 12 very significantly exceed the standard norm. For some machines the readings were off scale, therefore an extra measurement was done at a larger distance.

It follows that for the machines mentioned certain provisions are necessary. People who are carrying certain medical aids such as pacemakers and other electronically regulated life-supporting equipment should not be allowed to enter the area where the RF welders are located if the welders are in operation. Pregnant women should not participate in this stage of the production process.

Recommendations

Machines where the norm is exceeded should be insulated in order to minimize the radiation exposure of the operator. Metal foil can already reduce the RF radiation.
The area where the machines are situated should be marked with special warning signs.
It is recommended that a medical file is created for each of the operators. This file should be updated twice yearly.

RADAR OCCUPATIONAL EXPOSURE: INTERFERENCES WITH THE FUNCTION OF THE NERVOUS SYSTEM

Răzvan Dănulescu, Violeta Borza, Gheorghe Bălăceanu, Doina Popa, Eugenia Dănulescu,

Public Health and Medical Research Institute, Iaşi, Romania

INTRODUCTION

In the modern life and work environment the electromagnetic pollution is obviously increased and therefore the knowledge of its level and effects constitutes a major priority and challenge for the scientific community (4,11,12). In this international context the estimation of the health status of the microwaves exposed people colligated with the evaluation of the exposure have an important role not only for the scientific knowledge but especially for the improvement of the protection standards (7,13). Therefore the case of pulsed microwaves which seems to have peculiar biological effects (1,3), especially on the nervous system (10), has determined us to try to study in a clinical and epidemiological approach the occurrence of such effects upon chronic exposed humans.

OBJECTIVE

To assess the possible impairment of the nervous system function due to the chronic occupational exposure to low and medium levels of pulsed microwaves.

STUDY DESIGN

Cross-sectional study in 60 occupationally exposed people in radar maintenance activity, compared to matched controls, followed by a long-term survey of the main findings.

METHODS

Assessment of microwaves exposure (frequencies, power densities, SAR estimations, ergonomic investigations, questionnaires).

Assessment of the nervous system function few days after the cessation of the work: questionnaires, careful psychiatric and neurological examinations, psychological tests and electrophysiological investigations (EEG, short-latency evoked potentials, electroneuromyography - EMG, excitability, H-index as a measure of the sensitive conduction velocity, motor conduction velocity). Medical investigations in order to eliminate other causes of central or peripheral neuropathia have also been done. Yearly assessments of microwaves and of the nervous system (NS) function have subsequently been performed.

The exposed lot has included 60 electronic and electrotechnical technicians and engineers with the mean age of 39.7±3.6 years and the length of service in radar maintenance of 15.9±5.3 years. The control lot has comprised 36 people with the same electronic and electrotechnical training and activity, from the same factory, but which were never been exposed to microwaves. The age, the length of service and the other characteristics of the controls are matched with those of the exposed.

RESULTS

The investigation of the occupational exposure to pulsed microwaves has shown frequencies in the range 0.2-10 Ghz, average power densities of 0.01 - 5 - 10 mW/cm^2 and great variations of partial and total exposures to complex field distribution, with extremely various power densities and frequencies, generated in a close and small workspace by multiple unshielded generators. By using the methods and diagrams from the "Radiofrequency Radiation Dosimetry Handbook (Fourth Edition)", CH Durney, 1986, (5,11), we have estimated the Specific Absorption Rates (SARs). Various whole body SARs have been estimated: 0.01 - 2 W/kg. The local SARs, even more difficult to estimate, were greater for the head (neck) and hands (wrists).

The NS investigations has shown neurasthenia at 80% of the exposed versus 8.3% at the controls, the difference being statistically significant ($p<0.0005$); the relative and the attributable risk calculations have shown that pulsed microwave exposure is a risk factor and even a determinant factor for the neurasthenia. Significant changes of psychological tests (increase of the reaction time, decrease of the intellectual efficiency, impairments of the recent memory, attention, mood and behaviour) that support the higher and significant prevalence of neurasthenia have also been found. The mean age of the neurasthenic subjects is equal with the age of the whole lot, but the length of service of these subjects is statistically different (16.3±5.2 years vs. 11.6±5.7 years, $p<0.001$). This also means that the exposure in the above mentioned conditions could be a determinant factor for the neurasthenia. The prevalence of this finding is the same at the engineers and at the technicians, although the first group has a much more intense intellectual work. This also could be an evidence for the microwaves role in neurosis. The frequency and the severity of the neurotic symptoms are more intense when the length of service and/or the exposure are greater. Amplitude and frequency changes of EEG has revealed hypovoltages at 67% of the neurasthenic subjects and also decrease of the alpha waves index and increase of the theta and delta waves percentage. The auditory evoked-potentials have especially shown an increase of the latency of the second wave, which may reflect a possible long term stimulation of the Varolio pons as a structure of the acoustic way.

At the peripheral nervous system level we have found decreases of the peripheral nerves conduction velocity, especially sensitive, in 46.7% of the exposed people vs. 16% at the exposed, the difference being statistically significant ($p<0.001$). Slight neurological signs of polineuropathia have also been found. The relative and the attributable risk calculations have shown that pulsed microwave exposure is also a risk factor and even a determinant factor for the impairment of the conductibility on the studied nerves. The analysis of these changes has shown the followings: 30% of the exposed have a decrease of the sensitive conduction velocity (20% having only an aspect of incipient sensitive polineuropathia and the others - 10% - having also a decrease of motor conduction velocity, so they display an aspect of incipient sensitive-motor polineuropathia). 13.33% presents nervous conduction speeds at the lower limit of the normal and 3.33% have typical changes of motor polineuropathia. We have calculated the correlation index between the length of service and the H-index (sensitive conduction velocity) in all the exposed lot and we have found an inverse correlation: $r = -0.68$, which shows that the sensitive conduction velocity significantly decreases when the length of service increases. The calculation of the regression has found that an increase with

0.88 years of the length of service decrease the H-index with 0.52, relation considered as a signal and a stimulus towards further studies.

It is to be mentioned that the yearly revaluation of these findings showed similar aspects, but the people which worked less showed a slight improvement of some parameters.

CONCLUSIONS

The long time exposure at pulsed microwaves with average power densities rather small in comparison with the IRPA guidelines (7,11,13) on limits of exposure to RF seems to determine various degrees of neurasthenia, behavioural changes and peripheral polineuropathia aspects.

These changes with statistical significance, correlated with the length of service and exposure levels, the persistence at the exposed people of these impairments as well as, the absence of other neurotrop agents, have determined us to state the possible persistent interference of the pulsed microwaves with the electroneurophysiological phenomena.

It is to be mentioned that the findings concerning the long term pulsed microwaves effects on the peripheral nervous system in humans as well as the chronic changes of the auditory evoked potentials may contribute, if confirmed, to a better understanding of the interaction mechanisms of the electromagnetic fields and radiations with the nervous system and, of the significance for the human health and well-being of this interaction (2,6,8,9,14). So, we consider that this kind of studies must be continued as a complement to the experimental ones and that they could be really useful for the scientific knowledge.

EFFECTS OF 415 MHz FREQUENCY ON HUMAN LYMPHOCYTE GENOME

V. Garaj-Vrhovac[1], S. Vojvodić[2], A. Fučić[1] and D. Kubelka[1]

[1]Institute for Medical Research and Occupational Health, Zagreb, Croatia
[2]Croatian Post and Communication, Zagreb, Croatia

INTRODUCTION

The continuously increasing use of artificial sources of electromagnetic radiation in industry and medicine has been accompanied in everyday life with telecommunication systems which is followed with great interest in possible hazardous effects of this type of radiation. The interesting applications of mobile telecommunications and the use of cellular phones are of topic interest.

Numerous cytogenetic investigations are focused on the effects of microwave radiation from mobile communications frequency of 450 and 950 MHz on isolated cells in vitro (1).

The aim of this work was to investigate the effects of microwaves from mobile telephone freqeuncies on human peripheral blood lymphocytes cultured in vitro.

MATERIAL AND METHODS

To investigate the effects of microwaves from mobile telephone frequencies on human cells cultured in vitro, blood samples were taken from two healthy female donors, between 25 and 35 years of age (mean age 30 years). They were not smokers, and in the preceding year, they were not occupationally or for the purpose of diagnostics or therapy exposed to radiation. Whole blood samples were irradiated in semipermeabile membrane 24/32 cm (the Scientific Instrument Centre, Ltd).

The source of microwaves was a mobile telephone apparatus, standard NMT-450*. The samples of blood were irradiated in the real, everyday environmental conditions of a standard telephone user, at room temperature of 24 °C.

Four ml of heparinized blood was injected in 10 cm long semipermeabile membrane and each such prepared sample was located on unconductive surface 10 cm far away from the middle part of the telephone antenna. Orientation of samples was parallel to the antenna (in the direction of electrical field vector). The samples were exposed to microwave frequency of 415 MHz , at time intervals of 10, 20 and 30 minutes, output power 15 W.

Calibration and frequency measurement were performed on STABILOCK 4015 (Schlumberger) and during the experiment output and reflected power were continuously measured using power metre PM 400-1000 (PROCOM).

Following exposure, 72-h cultures were set up and slides were prepared according to standard methods for analysis of micronuclei (2). The method involves cultivation of 0.3 ml of whole blood, 4 ml of F-10 medium (Gibcco) supplemented with bovin serum (20%) and phytohaemagglutinnine (Murex). After 44 hours of cell cultivation, cytochalasin B (Sigma) at a final concentration of 3 μg/ml was added. The method is adapted from Fenech and Morley (2).

Five hundred binuclear lymphocytes were scored per sample. Results were expressed as total number of micronuclei per cell and their distribution.

**NMT (Nordic Mobile Telephone) is a standard of analogous (frequency modulation) mobile telephone network.*

RESULTS AND DISCUSSION

In order to show possible cytogenetic damages caused by exposure to 415 MHz waves, the micronucleus test was used as a very sensitive method which give possibility to detect micronuclei which contain lost chromatid/chromosome fragments in the form of "micronuclei".

The data obtained on the frequency of micronuclei in human lymphocytes after in vitro exposure to microwaves of 415 MHz with varied exposure intervals, is shown in Table 1.

Table 2. gives measured and calculated values of relevant parameters during the experiment.

The output power value of the antenna was a constant, and reflected power value was 0 W.

Exposure (min)	*No. of CB cells*	*No.of micronuclei*	*Micronuclei distribution/cells*					*Cells with MN*	*Micronuclei/cells (±SD)*
			0	*1*	*2*	*3*	*4*		
10	500	22	481	16	3			19	0.044±0.23
20	500	29	479	15	4	3		21	0.062±0.32
30	500	31	476	20	2	1	1	24	0.064±0.33
control	500	9	491	8	1			9	0.020±0.15

Table 1. The frequency and distribution of micronuclei in human lymphocytes exposed to 412,.950 MHz

Output power (W)	*Frequency of continuous electromagnetic wave (MHz)*	*Calculated mean value of power density in the sample** (mW/cm^2)*	*Exposure time (min)*
15	412.950	19.709	10, 20, 30

Table 2. Experimental conditions

The number of micronuclei in non-irradiated control samples was 6 per 500 analysed cells. On the contrary, in the cells exposed for 10 min, the number of micronuceli was 22 per 500 binuclear cells. After 20 min the number of micronuclei increased to 29, and after 30 min to 31 micronuclei per 500 cells. Beside the increased number of cells with micronucleus, various distribution of micronuclei per cell was also noted. The cells with 1, 2, 3 and 4 micronuclei observed in the exposed samples, indicated the effect of 415 MHz waves on mitotic spindle or formation of DNA breaks. The data obtained pointed also to an increase in the number of micronuclei in relation to the length of exposure, whereas other authors reported that effect of 954 MHz waves disappeared with increasing distance from the source (1).

One of the most important priorities in research of electromagnetic field effects is investigation of its synergistic effects with chemicals (3).Significantly higher mitomycin C induced SCE frequencies were observed in lymphocytes previously exposed to 954 MHz waves (4).

***Calculation was based on ideal circumstances, with ceertain approximations. The samples has assumed the free space impendance*

DNA damage caused by electromagnetic fields has been recently determined by identification of Single Gel Electrophoresis (SCGE) or comet tail lengths using comet assay described by Singh et al. (5). According to results reported by Verschaeve et al. in human peripheral blood lymphocytes exposed in vitro to frequency of 954 MHz, increase of single strand DNA breaks were observed compared to control value (1).

Since studies of other authors as well as results obtained in our investigation indicate the presence of damage of human lymphocytes genome caused by exposure to microwaves from mobile communication, further cytogenetic investigations are necessary in order to estimate the effects of exposure and to determine permissible levels of exposure.

DETERMINATION OF THRESHOLD VALUES OF ELECTROMAGNETIC NEAR-FIELDS FOR PATIENTS WITH IMPLANTED PACEMAKERS IN THE FREQUENCY RANGE 30KHZ - 50MHZ

X. Xu and V. Hansen
Bergische Universität Gesamthochschule Wuppertal, D-42097 Wuppertal, Germany

Abstract

In order to protect persons with implanted pacemakers, threshold values of electromagnetic fields should be prescribed. In the German standard DIN VDE 0848 threshold values in the frequency range 30 kHz - 50 MHz are only given for far-fields. However, near-fields have usually higher densities and their behavior is much more complicated than that of far-fields. Therefore, it is significant to determine threshold values of near-fields. In this work, we follow the following procedure: 1. The near-field is characterized by using a Taylor series with a few terms. 2. The induced field in the human body is calculated for each single Taylor term. 3. The coupling mechanism of each single Taylor term is investigated for a number of different pacemaker models at different locations. 4. Threshold values of the near-field are determined regarding the maximum allowed disturbing voltage at the entrance of the implanted pacemaker. This procedure is also applied to far-field problems and exhibits a very good agreement with the known threshold values.

1. Introduction

In the field of electromagnetic compatibility and protection of persons, it is desirable that the danger probability for people in a certain area can be obtained directly from local measurements of electromagnetic fields [1]. It is possible to define threshold values of electromagnetic fields for persons with pacemakers if the relation between the field at absence of the human body and the disturbing voltage induced by this field at the entrance of the pacemaker is known. The maximum allowed disturbing voltage is prescribed in the German Standard DIN VDE 0848. In order to achieve this goal, one has to characterize electromagnetic fields with the help of a few parameters. Attempts have been made with conventional methods e.g. the multipole method and the plane wave expansion. But those methods do not lead to a substantial reduction of the number of parameters with which near-fields can be described.

In Section 2, a Taylor series is introduced to characterize electromagnetic fields in a region, whose size is much smaller than the wavelength and the distance between this region and the sources. It is also shown, how the Taylor coefficients can be determined from the measured field densities in this region considering the constraints due to Maxwell's equations. The total field is then a sum of the products of the dimensionless Taylor coefficients and the fields of single Taylor terms. In Section 3, the induced field in the human body is calculated for each single term. Then, the disturbing voltage at the entrance of the pacemaker is investigated in Section 4 for a number of different pacemaker models. Considering that the total disturbing voltage should not exceed the maximum allowed disturbing voltage, threshold values can be given in concrete cases.

2. A General Taylor Series and Constraints

A general expression of the electric and magnetic field strength in a source-free area can be written in the following way:

$$\vec{E} = \sum_{l+m+n=0}^{\infty} \vec{E}_{lmn} x^l y^m z^n , \quad \vec{H} = \sum_{l+m+n=0}^{\infty} \vec{H}_{lmn} x^l y^m z^n . \tag{1}$$

We concentrate our attention to the magnetic field density because of the similarity of the two fields. By substituting the equation into the wave equation and the equation $\nabla \cdot \vec{H} = 0$, one obtains

$$(l+2)(l+1)\vec{H}_{l+2mn} + (m+2)(m+1)\vec{H}_{lm+2n} + (n+2)(n+1)\vec{H}_{lmn+2} + k^2\vec{H}_{lmn} = 0 , \tag{2}$$

$$\vec{e}_x(l+1)\vec{H}_{l+1mn} + \vec{e}_y(m+1)\vec{H}_{lm+1n} + \vec{e}_z(n+1)\vec{H}_{lmn+1} = 0 , \tag{3}$$

where k is the wave number. In a small area, one needs only a few Taylor terms to describe the magnetic field:

$$\vec{H}_t(x,y,z) = \vec{H}_1 + x\vec{H}_2 + y\vec{H}_3 + z\vec{H}_4 + x^2\vec{H}_5 + y^2\vec{H}_6 + z^2\vec{H}_7 + xy\vec{H}_8 + xz\vec{H}_9 + yz\vec{H}_{10} . \tag{4}$$

Equations (2) und (3) can be represented by 7 constraints,with which the coefficients $\vec{H}_1 \ldots \vec{H}_{10}$ are determined from the measured field data. In order to compensate for the errors in the measurements and to maintain the physical properties of the field, one must consider the 7 conditions determining the coefficients. For this purpose, the least squares method of Gauss and the method of Lagrange's multipliers are employed [2]. Denoting the measured fields and the fields described by the Taylor series with the index m and t, respectively, one has only to find the coefficients which minimize the expression

$$S = \sum \left[(H_{xm} - H_{xt})^2 + (H_{ym} - H_{yt})^2 + (H_{zm} - H_{zt})^2 \right] \tag{5}$$

under the constraints, where the sum is over all points at which the field is measured. It follows a linear algebraic equation system from which the coefficients can be determined with a sufficient number of measured data.

As an example we show a log-periodic antenna with 10 elements located in the xz-plane (Fig 1). Between two adjacent elements there are relations $h_{n+1}/h_n = d_{n+1}/d_n = 0.83$. The first element has a length of 5 m and a radius of 5 mm. The elements are crossways connected by a double transmitting line of a wave impedance 50 Ω and fed at the middle of the shortest element with $1V$ at 30 MHz. The near field is computed by using the method of moments. In a cube of $(2.4\ m)^3$ with its center at the point (0.2 m, 6.2 m, 0.2 m), the Taylor coefficients are calculated by the method described above. The field distribution reconstructed with the Taylor coefficients by using Equation (4) only differs a little from that calculated using the method of moments. The error is less than 1%.

3. Calculation of the electromagnetic field in the human body

The electromagnetic field in the human body induced by the single terms should be calculated in this section. As the single terms do not satisfy all Maxwell equations, we replace the single terms by single Huygens' sources [3], whose fields satisfy Maxwell's equations. With the help of the Huygens' sources, we can construct fields in the volume V_A which are very similar to the original Taylor terms. For example, if one places an electric current sheet $\vec{J}_A^{2y} = \vec{n} \times \vec{e}_y\, x\, [A/m^2]$ immediately inside a cuboid, whose outer space is filled with ideal magnetic material, one obtains a magnetic field in the cuboid which differs hardly from $\vec{e}_y\, x\, [A/m^2]$.

The numerical calculation of the field in the human body is performed by using the Finite Integration Technique [4]. Fig. 2 shows the body model and the pattern of the magnetic field in the volume with the human body at 30 MHz in the plane $y = 0$ m for the electric current sheet $\vec{J}_A^{2y}$. One can see that the magnetic field in the volume is almost linear in x like that in the volume without the human body. Similarly, the electromagnetic fields in the human body for other terms are calculated [5].

4. Coupling in the pacemaker and threshold values of electromagnetic near-fields

With the knowledge of the field in the human body, the disturbing voltage for all single terms can be calculated by using the method of moments. The case and the electrode of the pacemaker are modeled by a grid, in which the influence of the entrance impedance and isolation of the electrode can be investigated. For a set of Taylor coefficients, it is then easy to obtain the total disturbing voltages by summing the voltage for all single terms. In order to determine threshold values of electromagnetic fields, it is necessary to consider different positions of the pacemaker and electrode because of different implanting techniques employed. Therefore, the disturbing voltage was calculated for 36 different positions and configurations of the pacemaker and the electrode. The maximum value of the total disturbing voltage for the magnetic field $U_{St\max}^H$ and the electric field $U_{St\max}^E$ can be written as

$$U_{St\max}^H = \sum_{n=1}^{10} \sum_{\alpha}^{x,y,z} \left[\left| \frac{H_{n\alpha}}{[H_{n\alpha}]} \right| \left| U_{n\alpha}^H(k_{\max}) \right| \right],\ U_{St\max}^E = \sum_{n=1}^{10} \sum_{\alpha}^{x,y,z} \left[\left| \frac{E_{n\alpha}}{[E_{n\alpha}]} \right| \left| U_{n\alpha}^E(k_{\max}) \right| \right], \tag{6}$$

where $H_{n\alpha}/[H_{n\alpha}]$ and $E_{n\alpha}/[E_{n\alpha}]$ are the dimensionless coefficients and $U_{n\alpha}^H(k_{\max})$ and $U_{n\alpha}^E(k_{\max})$ the disturbing voltages for the single terms in the worst case. We obtain an estimate of the disturbing voltage independent of the position of the pacemaker system. The safety of persons with pacemakers in antenna fields is guaranteed if

$$U_{St\max}^H \le U_{SS}/2,\ U_{St\max}^E \le U_{SS}/2, \tag{7}$$

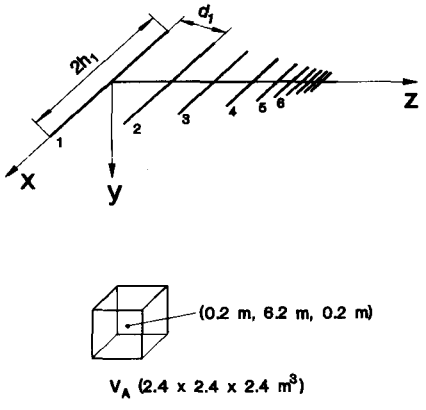

Fig. 1: Geometry of the logarithmic-periodic antenna

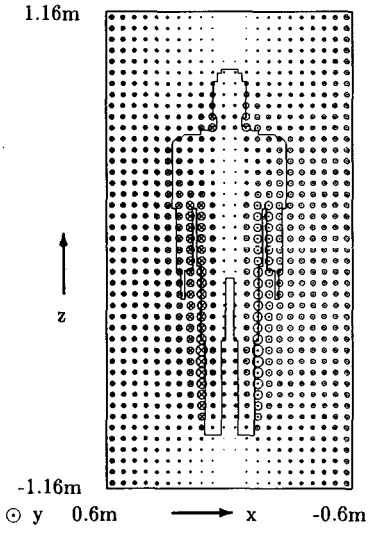

Fig. 2: Real part of the magnetic field $\vec{H}_{J_m}^{(x,y)}$ in the volume with the human body, generated by Huygens' current sheet $\vec{J}_A^{2y}$ (max. 1,46 A/m)

where $U_{SS}/2$ is the maximum magnitude of the disturbing voltage defined in Section 4.2.2.1.1 of Part 2 of the German standard DIN/VDE 0848.

At 30 MHz the maximum top magnitude is 0.145 V. With the coefficients for the field in the volume V_A near the logarithmic-periodic antenna calculated in Section 2, we conclude that the feeding voltage of the logarithmic-periodic antenna should not exceed 244 V.

The concept was also applied to far-field problems. The comparison of our results with those in DIN VDE 0848 shows a very good agreement in the frequency range up to 10 MHz (see the following Table). At 3 MHz, for instance, we have a threshold value of 14.6 V/m, whereas that in DIN VDE 0848 is 16.1 V/m.

Threshold values	$\hat{E}$/0.3MHz	$\hat{E}$/3MHz	$\hat{E}$/30MHz	$\hat{H}$/0.3MHz	$\hat{H}$/3MHz	$\hat{H}$/30MHz
DIN VDE 0848	48.4 V/m	16.1 V/m	4.1 V/m	0.128 A/m	0.043 A/m	0.011 A/m
Taylor Series	38.4 V/m	14.6 V/m	7.7 V/m	0.114 A/m	0.036 A/m	0.018 A/m

Aknowledgement

This work was financially supported by the Federal Institute for Occupational Safety and Health (Bundesanstalt für Arbeitsschutz), Germany.

RADIO AND TV BROADCASTING IN ITALY: A NATIONAL PROJECT FOR HEALTH AND ENVIRONMENT IMPACT ANALYSIS

Paolo Vecchia[1], V.Lepori[2], A.Polichetti[1]

[1]Physics Laboratory, National Institute of Health, Rome, Italy
[2]Prevention and Protection Service, Local Health Unit No. 5, Como, Italy

INTRODUCTION

The development of radio- and TV-broadcasting in Italy has been characterised in the last decades by an almost complete deregulation on the siting and power of emitters, the only licensing procedure being related to the assignment of transmission frequencies. That has led to a number of antennas which is probably among the highest in the world.

At the same time, the adoption of a European provisional standard issued by CENELEC (1), as well as the development of a national law on the safe exposure of the general public to radiofrequency electromagnetic fields (which is expected to be enforced within a short time), give special importance to the assessment of the health and environmental impact of each plant. A national project for such analysis has recently been launched in Italy, based on a census of all broadcasters operating in the Country.

THE NATIONAL PROJECT FOR HEALTH AND ENVIRONMENT IMPACT ANALYSIS

The project, involving both national and regional health and environment authorities, was launched by the National Institute of Health in 1993 and was expected to develop in the following stages:

1) implementation of a national archive of broadcasters;
2) organisation of regional archives, to be managed by local authorities;
3) check and update of the data;
4) local and global analyses.

Phase 1 was completed in 1994. The data, provided by the Ministry of Telecommunications, were loaded on a data base designed for this project. The archive was officially recognised by the Italian National Institute for Statistics (ISTAT) and included within the National Statistical Program.

Phase 2 is in progress. Subsets of the general data base have been extracted for each Italian region and are being distributed to individual health authorities, which have full responsibility for their management.

Phase 3 has been started only in a few regions, or even in smaller areas (e.g. provinces). The reliability of data is checked by cross-links with registers of local technical services of the Ministry of Telecommunications and by direct inspections. Technical data which may be missing (e.g. characteristics of the antenna, radiation pattern etc.) are also collected and inserted.

Phase 4 will be extensively exploited upon completion of the previous ones. However, preliminary evaluations have been performed, both at national and local level, whose results are summarised later in this paper.

CHARACTERISTICS OF THE ARCHIVE

The national database is installed on a computer Apple Macintosh and is managed by a special software, user-oriented, based on the application program FileMaker Pro. Regional archives are managed by the same software, either in Macintosh or in DOS-Windows environment.

Broadcasters are classified by region, subdivided by province and further on by municipality. Each data set is divided in turn into two parts, for radio and TV emitters, respectively. The database is linked with an archive of demographic data, allowing analysis of the distribution of emitters relative to the population.

Due to the features of the application program, which allows any field of the database to be used as a key, selection or sorting of broadcasters is possible in a great number of ways, e.g. by site, by frequency, by radiated power, etc.

At present, a limited number of fields are available in each record of the data set to describe the space distribution of electromagnetic radiation around the emitter. The possibility of linking an archive of different types of antennas and related characteristics is being explored, to allow a more refined and complete picture of the radiation pattern.

For this purpose, computational programs are also being developed to calculate the space distribution of the electric and magnetic fields around the plant, based on the technical characteristics of the antenna. The calculations could be run from inside the application program, to directly provide the diagrams of exposure levels.

PRELIMINARY ANALYSES

A global evaluation of available data indicates that 56,101 broadcasting plants have been licensed, almost equally divided into TV (21,769) and radio (27,332) stations. The distribution of broadcasters by region has been reported elsewhere (2).

These data clearly indicate an abnormal density of emitters in Italy (with regard to both the population and the surface) relative to other Countries. In the United States, for example, broadcasters amount to about 10,000; more precisely, 8,763 radio- and 1,030 TV-emitters were reported to be in operation in 1993 (3).

In spite of remarkable social differences among different areas of the Country, there is no clear distinction in the distribution of broadcasters in northern and southern regions. The differences seem mainly related to geographic conditions, and to the orography in particular.

Orography also plays a major role in the concentration of emitters on a local scale. Panoramic areas are in fact preferential sites for antennas, which may pose significant problems for exposure, due to the overlapping of radiation from multiple sources. A preliminary analysis of data for Lombardy shows that about 80% of emitters are located in alpine and sub alpine areas, 13% within the Province of Milan, and only 7% in plain provinces which cover about 30% of the surface of the region.

In the pilot study on Lombardy, an analysis has also been performed of the density of emitters with respect to the resident population (Table 1), which seems to be a rather good indicator of possible critical areas.

Table 1. Distribution of radio- and TV- broadcasting emitters, with respect to the resident population, among the municipalities of the Region Lombardy

Number of emitters per 10,000 inhabitants	Number of municipalities
< 1	292
1 - 5	157
5 -10	54
10 - 20	44
20 - 30	14
30 - 40	6
40 - 50	8
50 - 100	8
> 100	2

The density of broadcasters per 10,000 inhabitants exceeds the value of 50, for example, only in 10 out of the 585 municipalities of the Region. On-site experimental measurements have actually indicated that the exposure limits recommended by the IRPA/INIRC guidelines (4) are frequently exceeded in areas open to the public near clusters of antennas located at these sites.

CONCLUSIONS

The national archive of Italian radio- and TV-broadcasters is of fundamental importance to monitor the future development of installations not only from the point of view of the service, but also of the health and environment impact. The experience gained on limited analyses at local scale also indicates its relevance as a tool to identify areas where critical exposure conditions may occur and remedial actions are needed.

MAGNETIC RESONANCE SAFETY
BIOEFFECTS OF GRADIENT MAGNETIC FIELDS

Silvia A.A. Cenzano V.

Ente Nacional Regulador Nuclear (ENREN) - Buenos Aires - Argentina

ABSTRACT

From the safety point of view, there are areas to consider in operating a Magnetic Resonance (MR) facility. Time-varying magnetic fields, caused by the switched gradient on imaging systems, will induce currents in conductive pathways in the body. There are different thresholds for eliciting excitation for different tissues. Information was obtained from a MR research facility which could be bear in mind when a small sample is investigated although there are limitations upon the use of this information for biological tissues. Because a number of effects in man occur, there are recommendations made by the National Radiological Protection Board (NRPB) in the UK and the US Food and Drug Administration (FDA) has issued safety guidelines as well, which are considered in this work.

INTRODUCTION

MR involve exposure to three types of magnetic and electromagnetic fields. These are, the main magnetic field B_0 , the alternating magnetic field produced by the gradients and the radiofrequency field.

The aim of this work is to point out the effects in the body that may result from the alternating magnetic fields produced by gradients and the important factors which are responsible for inducing a physiologic response to an induced voltage.

During Magnetic Resonance (MR) imaging numerous gradient magnetic fields are turned on and off at rapid rates, for varying amount of times, and to varied peak gradient amplitudes. Placing the body within the MR system and rapidly switching the current on and off within the gradient magnetic field coils, two effects are produced, a) the creation of a gradient magnetic field b) the potential for induced voltages within the patient (and / or other electrical conductors) in the bore of the MR system.

There are potential bioeffects related to gradient magnetic fields from induced currents or voltages in the human body.

CAUSES AND EFFECTS OF TIME-VARYING MAGNETIC FIELDS

The production of eddy currents is a well known physical mechanism whereby time-varying fields can induce changes in biological systems. Biological tissues, containing ions in water, are conductive and it may be assumed that at certain rates and magnitudes of field changes, sufficient density of eddy current could be produced to affect the more sensitive biological tissue.

There are potential bioeffects related to gradient magnetic fields from induced currents or voltages in the human body. It is necessary to determine the amplitude of the induced voltages to know whether or not tissues will be affected by such induced voltages and currents. To calculate induced current densities, it is important to know the electrical resistivity of the induced current loop. This is determined by the tissue through which the induced voltage will attempt to produce a current flow (1).

Several factors are responsible for physiologic responses to induced voltages, including the strength of the static magnetic field, the orientation of the gradient magnetic fields being switched relative to the patient's tissue, the size of the greatest diameter of the patient's body, the frequency of the stimulus, the duration of the induced voltage, the shape of the waveform, the width of the pulse and the sensitivity of tissues. The magnitude of the voltages and /or currents induced within the patient will be determined by several factors as well, these include the electrical resistance in the circuit produced in the tissue, the cross-sectional area of the induced current flow, and the rate of change (versus time) of the gradient magnetic field itself. All induced voltages or currents will occur during the times that the gradient magnetic field strengths are changing - the rise and fall times of the gradients-. The greater the magnitude of the rise and fall times, the greater the induced voltage and current. There is a greater changing magnetic field over time (or dB/dt) as one proceeds further away from the centre and toward the ends of the gradient coils, where the time rate of change of the gradient magnetic fields is the greatest.

In MR, the health consequences due to time-varying magnetic fields in the extremely low frequency range are concerned with nervès, blood vessels and muscles that act as conductors in the body. Rapidly changing magnetic fields induce electric currents in tissue that could be sufficiently large to interfere with the normal function of neurones and muscle. The threshold current density above which the effects may occur varies according to the tissue involved, the pulse width and the pulse repetition frequency of the induced current (2).

Ventricular fibrillation is the most serious adverse response that may be anticipated during exposure to rapidly changing magnetic fields. The heart is most sensitive to stimulation at frequencies between 10 Hz and 100 Hz. 3 A m^{-2} rms is considered therefore to represent a conservative value for fibrillation threshold at frequencies outside this range. Significant disturbance of the heart beat (pump failure) may begin to occur above about 3 A m^{-2} rms.

The visual sensations are referred to as magnetophosphenes (3). Retinal stimulation is considered to be the most sensitive index of induced currents and it occurs when the peak rate of change of magnetic flux density is about 2 T s^{-1}.

EVALUATIONS IN A MR RESEARCH FACILITY

In a volume distribution of electrical current the parameter of importance is the current density (J). The biological system may be regarded as a loop and the important factors to consider is the current density induced in this loop, which can be calculated as:

$$J = 0.5\, r\, \sigma\, (dB/dt) \qquad [1]$$

where, r: the loop radius, σ: conductivity of the sample and (dB/dt:): the rate of change of magnetic field.
There are limitations upon the use of this equation for biological samples since biological tissues are not homogeneous. For example, the skeletal muscle, which acts as the main eddy currents conductor, is anisotropic. The presence of boundaries between different types of tissue will cause distortions to the idealised circular current path and alter the magnitude of currents. Bearing in mind these limitations, it is possible to obtain an estimated current density in the air inside the small gap of an MR research facility and from this, it could be possible to do an approximation of the threshold value in a small sample inside the magnet.

In the experimental work, X and Y flat rectangular gradient coils made by etching technique were used with a permanent magnet (B_0 = 0.59 T, gap: 18 mm). Trapezoidal waveforms were generated with 5V amplitude, rise time 480 µs, pulse width 20 ms, period 26 ms, (dB/dt)air = 4 T/s. Gap for sample: 15 mm (r = 0.0075 m) (4).
From equation [1], the current density in air , Ja, inside the gap of the magnet was calculated as: Ja = 0.037 x 10^{-14} A/m^2 with σa = 2.5 x 10^{-14} S/m and (dB/dt)a = 4 T/s. The current density in any sample is : Js = 0.5 r σs (dB/dt)s
The threshold value (dB/dt)s can be calculated as:

$$(dB/dt)s = (Js/Ja)\, (\sigma a/\sigma s)\, (dB/dt)a \qquad [2]$$

If σs = 0.3 S/m (2) and Js = 2.5 A/m^2 , the threshold value in a small sample will be: (dB/dt)s = 2222 T/s. This value can be compared with other estimations made for different authors. Thresholds values for different tissues and different density currents can be evaluated in this way bearing in mind the limitations of these approximations.

CONCLUSIONS

These last years there has been increased public concern about the bioeffects of gradient magnetic fields.
The health consequences are not related to the strength of the gradient field, but rather to changes in the magnetic field that cause induced currents. Because of this, it is important to obtain information concerning the pulse generation, to examine the conditions for the production of a detectable response and to obtain better understanding of biological effects involved.

This issue must be reconsidered as the maximum strengths and the rise time capabilities (dB/dt) of the newer and faster MR systems continue to improve.

Thresholds values for different tissues and different density currents can be evaluated for a small sample. The previous calculations can be carried out bearing in mind the limitations of these approximations, as was mentioned before. The threshold value obtained in this evaluation was, (dB/dt)s = 2222 T/s.

In view of the rapid progress in clinical imaging as a diagnostic aid, The National Radiological Protection Board recommends continue modifications to the original advise given in 1981. Some of these new recommendations are, (NRPB 1981,1983) (5), a) the root mean square value of rate of change of dB/dt should not exceed 20 Ts^{-1} for pulse widths above 10 ms, b) for periods of magnetic field change shorter than 10 ms: $(dB/dt)^2_{rms}\ t < 4$ where t is the duration of the change of the magnetic field in seconds.
For sinusoidally or other continuously varying periodic magnetic fields, the duration of the change can be considered to be the half period of the magnetic flux waveform.

The US Food and Drug Administration (FDA) has issued safety guidelines as well and suggested operating limitations for MR imaging devices regarding the gradient magnetic fields associated with MR imaging procedures Concerned with the rate of change of magnetic field, the limit patient exposure to time-varying magnetic fields with strengths less than those required to produce peripheral nerve stimulation, was suggested. An alternative is to demonstrate that the maximum dB/dt of the system is 6 T/s or less. There are other alternatives related to axial and transverse gradients (6).

Working with alternating magnetic fields the NRPB or/and the FDA recommendations must be considered.

THE EUROPEAN PRE-STANDARD ENV 50166 "HUMAN EXPOSURE TO ELECTROMAGNETIC FIELDS"

B. Kunsch

Austrian Research Centre Seibersdorf, Seibersdorf, A 2444

SCOPE AND CONCEPT

The CENELEC Prestandard ENV 50166 (1) deals with the prevention of adverse effects of human exposure to electromagnetic fields within the frequency range 0 Hz-300 GHz. It is based on the well-established short term effects, the stimulation of nerves and muscle tissue at low and heating at high frequencies. Reports on long term effects such as the induction or promotion of cancer have been scrutinised and it was found that the current available evidence had not established a connection. Basic restrictions, which must not be exceeded, are given for biologically relevant quantities and complemented by reference levels which are more readily measurable thus facilitating the checking of compliance. The Prestandard does not apply to the deliberate exposure of persons during medical research, diagnosis or treatment. Furthermore, safety hazards associated with the ignition of flammable materials or the triggering of explosive devices are not covered, and the interference of permissible fields with implants cannot be excluded.

LOW FREQUENCIES (0-10 kHz)

At low frequencies there are basic restrictions in terms of induced current density, contact current, electric field strength and static magnetic flux density. The ENV sets 10 mA/m2 as the basic restriction for workers within the frequency range 4 Hz-1000 Hz. The current density restriction is set inversely proportional to the frequency below 4 Hz and directly proportional to the frequency above 1000 Hz. This accounts for the specific stimulation characteristics of excitable cells. For the general population a precautionary factor of 2.5 was chosen. Harmful indirect effects are prevented by limiting the contact current, to 3.5 mA over the entire low frequency range for workers and to 1.5 mA for the general population.

High electric fields can make themselves felt through surface effects. To prevent annoyance a basic restriction is set for electric fields at 30 kV/m above 0.1 Hz (42 kV/m at 0 Hz). Similarly, a basic restriction for static magnetic fields at 2 T prevents vertigo and nausea.

Reference levels as limits for the electric and magnetic field strengths are derived from the basic restrictions using worst case assumptions for the geometry and position of the body and the relevant organs, with respect to external fields. Thus compliance with reference levels automatically ensures compliance with the basic restrictions on induced current density. However, reference levels may be exceeded if the basic restrictions are met.

HIGH FREQUENCIES (10 kHz-300 GHz)

The ENV uses the following quantities as basic restrictions in the high frequency range: Induced current density and contact current at frequencies up to 10 MHz and 3 MHz, respectively, the specific absorption rate SAR with different values for whole body, limbs, local heating and the specific absorption SA for pulses of a duration of less than 30 μs at frequencies above 300 MHz.

The current density is set for workers at f/100 mA/m^2, whereas the precautionary factor of 2.5 is maintained for the general public. Between 10 kHz and 100 kHz the contact current limit increases proportionally to the frequency and, between 100 kHz and 3 MHz, remains constant at 35 mA and 20 mA respectively.

At frequencies of around a few MHz the specific absorption rate SAR takes over from the induced current density to become the significant dosimetric quantity for establishing exposure limits. The threshold for effects which are considered detrimental to health is observed at 4 W/kg, averaged over a 6 min. time interval and over the whole body. This corresponds to a systemic temperature increase of less than 1°C at normal conditions. To derive the basic restriction for workers a safety factor of 10 is applied which gives an SAR of 0.4 W/kg. For the general public 0.08 W/kg was chosen. In the high frequency range both rms and peak values are set for the reference levels. Above 10 MHz, reference levels are also given for the mean power density.

DISCUSSION

Some European countries have already developed national standards or guidelines for the protection of the population from electromagnetic fields (2,3,4). The CENELEC Prestandard is the result of their national electrotechnical committees' harmonization effort. Problems to overcome were the questions whether a one tier

or a two tier structure of the standard should be adopted, and how to define the two levels of protection. For example Great Britain's NRPB guidelines give one set of limits which are valid for everyone whereas Germany's DIN/VDE Standard and Austria's ÖVE Standard distinguish between controlled/uncontrolled areas and workers/general public, respectively.

Beside CENELEC IRPA/ICNIRP and CEU have developed exposure limits at international level. The IRPA/ICNIRP limits are confined to 0 Hz, 50/60 Hz and the frequency range 100 kHz to 300 GHz (5,6,7). The limits of the CEU's draft Directive are related to workers only (8). The draft Directive defines exposure limits as upper limits as well as threshold values below which no adverse health effects are expected. In the region between threshold values and exposure limits there is a set of three action levels. These are not limits but rather field levels, the exceedance of which requires certain countermeasures. At the lowest action level, workers should be informed about their exposure situation, provived with protective gear and training. At the next action level a program for the reduction of exposure has to be developed and areas have to be marked off. Activities at levels higher than the 3rd action level are regarded as hazardous, authorities have to be informed and a systematic health surveillance has to be provided for exposed workers.

This discussion attempts to compare CENELEC's ENV limits with those limits given by IRPA and CEU, being aware that, particularly in the case of field strengths, such a comparison can only be approximate because of differing definitions.

		CENELEC	IRPA	CEU
induced current density , head and trunk	[mA/m^2]	10	10	10
electric field strength	[kV/m]	10	10	19,6; 12,3; 6.1
magnetic flux density	[mT]	1,6	0,5	0,64; 0,4; 0,2
contact current	[mA]	3,5		1,5

Table 1:Limit values of CENELEC ENV 50166, IRPA guidelines and CEU draft Directive at 50/60 Hz for exposure of workers over a full working day.

SA	[mJ/kg]	10		10
contact current (0,1 - 3 (100) MHz)	[mA]	35	(50)	50

Table 2: High frequency limit values of CENELEC ENV 50166, IRPA guidelines and CEU draft Directive for exposure of workers over a full working day.

Generally, the regulations of CENELEC, IRPA/ICNIRP and CEU are based on the same criteria. For workers there is full agreement between the basic restrictions of CENELEC, the basic criteria of IRPA/ICNIRP and the exposure limits of CEU for the induced current density and SAR, which are the starting points for deriving the respective field strengths (e.g. Tab.1 and 2). Differences exist between the contact current limits of CENELEC and CEU, established to control indirect effects.

Figure 1 shows the reference levels of the ENV in comparison with the electric field limits of the IRPA/ICNIRP guidelines and the medium action level of the draft Directive. Figure 2 displays the corresponding magnetic flux density limits. There is a satisfactory agreement between the three regulations. The differences however reveal that there is a need for harmonisation. The same holds true for the exposure limits for the general population as set by CENELEC and IRPA/ICNIRP. For details the reader is referred to the documents in the reference list.

ABSTRACT:

With the growing interest in induced current measurements and the presence in several international standards, several instruments for measuring induced currents are now commercially available. Comparing induced current measurements using differing measurement principles and instruments from different manufacturers with rule-of-thumb estimates and free-field measurements provides insight into variations in observed data.

Data is also presented using clamp-on induced current sensors to estimate contact currents.

Typical measurement situations using induced current measurements are presented in comparison with ICNIRP Guidelines on Protection Against Non-Ionizing Radiation and the IEEE C95.1-1991 Standard for Safety Levels with Respect to Human Exposure to Radio Frequency Electromagnetic Fields, 3 kHz to 300 GHz.

ASSESSMENT OF COMPLEX MICROWAVES OCCUPATIONAL EXPOSURE IN RADAR MAINTENANCE ACTIVITY

Răzvan Dănulescu

Public Health and Medical Research Institute, Iaşi, Romania

INTRODUCTION

The modern development of the society has determined the increase of thousand times greater than the natural fond of the humankind exposure to a complex combination of electromagnetic man-made fields and radiations of extremely various strength and frequencies (4).

A special contribution to this environmental change has had in the last decades the appearance and the explosive development of the microwaves generating appliances such as radars used in a great variety of military and civilian applications and which essentially contributes to the electromagnetic pollution (4,6,7).

In the above mentioned context which firstly interests the occupational environment, it is necessary to improve the exposure limits, as well as, the emission standards, in order to better protect the human health and well-being (7). From this point of view, the estimation of the microwaves occupational exposure risk constitutes, alongside the health status assessment, one of the priorities of the Occupational Health because the theoretical and practical problems related to the bioeffects of this kind of radiations are far to be clarified.

Our study has been carried out in a factory where one performs research, production and especially maintenance of microwaves generating devices.

OBJECTIVE

To thoroughly analyse the working conditions, both ergonomical and physical, and to colligate them in order to obtain a better exposure assessment for the improvement of the protection of the microwaves exposed workers.

METHODS

Ergonomical analyse has comprised the study of all the postures, movements, gestures, physical and psychological charges of the workload, as well as, the study of all the partial timing for obtaining reliable photographs of the day-time work. The technical features of the radars (constructive as well as functional) and the relative distances between them and the workers in every phase of the work have also been studied.

The assessment of the presence, frequency and the average power density of the microwaves has been performed by a Russian PO1 measuring instrument with a set of probes able to measure electromagnetic fields in the range 10 Mhz - 12 Ghz, the provided parameter being the average power density (mW/cm^2). Multiple measurements for each type of radar and for each position in the activity have been done according to the methods described in the NCRP Report No. 119 "A Practical Guide to the Determination of Human Exposure to Radiofrequency Fields" (1993), (3).

As a result of the correlation between the ergonomical studies and the physical measurements, average and local Specific Absorption Rates (SARs) have been assessed by using the methods and diagrams from the "Radiofrequency Radiation Dosimetry Handbook (Fourth Edition)", C.H. Durney,1986, (1).

RESULTS

The activity is performed in relative small work-spaces with glass walls in metal frames and there are multiple, unshielded and rather close microwaves generating devices.

The working position is generally sitting down at tables and benches, but also standing up and in bent position. The motor solicitation both static and dynamic is rather reduced with the preponderance of the gesture that requires precision. The psychological solicitation implies: the thinking, the constant attention, the memory, the visual and auditive perception.

The generators emit in the range 0.2 - 10 Ghz with mean emission powers from some watts to hundreds of kilowatts and the waves are usually modulated as impulses. During the tests the devices usually run at nominal parameters and the shielding carcasses are removed, so multi-directional and variable power leakages occur generating complex field distribution, with extremely various power densities and frequencies.

It is to be mentioned that the physical phenomena like reflection and dispersion of the microwaves favoured by the characteristics of the workplaces could determine sensible increases of the local fields up to four times owing to the stationary waves and/or to the multiple interferences. The work positions create exposures both in near and in far field which especially concern the hands, the head and the fore part of the trunk. The movements multiply the complexity of the exposure and make more difficult its appropriate assessment. Thus it is obvious that there are complex conditions of continuous (sometimes quick) variations in space and time of the frequencies and power densities with frequently potential additional effects.

The measurements in normal work conditions for 15 types of generators in each stage of activity are synthetically presented below in terms of the frequency.

For the frequencies 8-10 Ghz we have found average power densities between 0.01 and almost 10 mW/cm^2, with averages for the different points that define the workplace of 0.8-2 mW/cm^2. At frequencies around 2-6 Ghz, the average power densities were 0.04-0.5 mW/cm^2. At frequencies smaller than 2 Ghz the measured values were between 0.3-1 mW/cm^2. It is to be especially mentioned the found values of many mW/cm^2, that exists in accidental conditions at many devices but the weight of which during the worktime is difficult to be established.

Based on the photographs of the day-time work, and on the physical measurements, we have estimated a wide range of various whole body SARs: 0.01 - 2 W/kg. There is a great variation during the day-time work of the estimated SARs at the same subject, which shows on one side the complexity of the exposure conditions and on the other side the wide range of possibilities of interference of the microwaves with the human organisms. There are also many inter-individual differences depending of the device being repaired, of its situation in the workplace and of the specific phase of the activity.

Trying to calculate some time-weight averages of the whole body SARs, we have found values of 0.08-0.31 W/kg which are under the threshold considered by IRPA and WHO as a basis for the setting of the occupational exposure limits ().

The local peak SARs, even more difficult to estimate, were greater for the head (neck) and hands (wrists), their values being of few ten times greater than the average whole body SARs. However, there is a highly non-uniform spatial and temporal distribution of local SARs which reflects the same complexity of the exposure conditions.

CONCLUSIONS

The workload implies continuous and various movements with consecutive great variations of partial and total exposures to complex field distribution, with extremely various power densities and frequencies, generated in a close and small workspace by multiple unshielded generators.

Although we have found whole body SARs values of 0.08-0.31 W/kg which are under the IRPA threshold of 0.4 W/kg (2,5,6), we consider that the peak values of both whole body SARs and local SARs are quite important, as well as, the pulsed character of the emission and consequently we consider that supplementary limits for pulsed microwaves as recommended by the documents of IRPA and WHO, are to be further enhanced and implemented in national legislation.

Beyond its laborious characteristics, this method allows a rather reliable exposure assessment, which could be used in setting limits for special exposure conditions, in order to avoid hot spots and, consequently, to improve the protection measures.

PULSED RADIOFREQUENCY MICROWAVE FIELDS AROUND A QUADRUPOLE PARTICLE ACCELERATOR: MEASUREMENT AND SAFETY EVALUATION

R.N.Sachdev, G.Swarup, K.K.Rajan and Leena Joseph

Radiation Standards Section
Health, Safety & Environment Group
Bhabha Atomic Research Centre
Trombay, Bombay 400085, India

INTRODUCTION

Pulsed radiofrequency microwave radiation (RFMR) fields occur during the use of high power microwaves in plasma heating in fusion research, plasma and solid state diagnostics, particle accelerators and collidors, pump sources in lasers, material processing as well as in high power radars. This paper describes the experimental work done at Trombay for measurement of pulsed RFMR fields in the working area of a radiofrequency quadrupole (RFQ) accelerator with the use of a meter calibrated in continuous field and interprets the observed fields in the light of existing protection criteria for pulsed RFMR fields(1).

EXPERIMENTAL DETAILS

Experimental assembly of the RFQ accelerator and the asociated equipment is spread over an area of about 30 m^2. Figure 1 shows the layout plan of the assembly. The location marked R.F.chokes contains two chokes, RFC-1 and RFC-2. The radiofrequency microwave equipment operating at 55 MHz is confined along the west side wall of the hall housing the accelerator. The measurement of the electric field strength has been made using General Microwave Corporation, model 40, radiation hazard monitor. The meter is graduated to read continuous fields for frequencies ranging between 200 kHz and 40 GHz.

SALIENT OBSERVATIONS

The response of the meter has been corrected for the duty cycle(2). The duty cycle of the pulsed power is 1.6 percent. Table 1 lists out corrected power densities for pulsed fields. Of all the locations at which power density measurements have been made, those in the vicinity of two radiofrequency chokes RFC-1 and RFC-2 show maximum leakage in the present development stage(3). Pulsed field power densities over the working area have been depicted in figure 2 in the form of a three dimensional representation of the electric field strength around the RFQ accelerator. The distances shown, are on the floor along and at right angles to the entrance to the hall.

CONCLUSIONS

Observed fields in the working area of the RFQ accelerator at Trombay are much lower than the peak power limits recommended in their standards by world bodies like INIRC/IRPA, ANSI and NRPB to prevent high specific absorption associated with exposure to increasingly shorter pulse width high amplitude fields(4,5). However in view of the increasing use of these fields in nuclear energy and allied applications and inadequate present day understanding of the mechanism of interaction with human body, there is continuing need for such studies(6).

DESIGN AND CONSTRUCTION OF A BROAD-BAND ELECTRIC FIELD PROBE

A. Bahrami, M. Sohrabi and D. Farvadin

National Radiation Protection Department
Atomic Energy Organization of Iran
P. O. Box 14155-4494, Tehran
Islamic Republic of Iran

ABSTRACT

The design of a broad-band electric field probe based on a resistive film diode antenna on RT/Duroid substrate to measure the electric RF/MW fields as constructed at the National Radiation Protection Department (NRPD) of the Atomic Energy Organization of Iran (AEOI) are described in this paper. A square law diode detector with a matching circuit and also low pass filter have been used to produce a dc current proportional to the square RF voltage across the resistive antenna gap. A double-strip coplaner waveguide has also been designed to transfer this dc current to an amplifier with an output signal showing the electric field intensity in one direction. By using three mutually orthogonal resistive antennas, an isotropic electric field probe was made. All parts of this probe have been completely modeled and solved by the MATLAB computer program to determine the optimum values of the elements of the probe. The frequency response of the probe has also been theoretically found to be flat in the range 0.8 to 3 GHz. It was found to be quite satisfactory compared with those of similar probes commercially available. The probe is being used routinely in practice.

INTRODUCTION

Due to widespread applications of radiofrequency and microwave (RF/MW) sources in different disciplines, measurements of exposures from such fields are necessary for protection of workers and public. This requirement in Iran has been enhanced by the enforcement of regulations of the Radiation Protection Act of Iran (1). During the past two decades, significant advances have been made in instrumentation and techniques for measuring complex RF/MW fields applying resistive thin film screens (2) and resistive dipole antennas (3). These techniques have been investigated in this study both theoretically and experimentally for design and construction of a wide-band isotropic electric field probe using a three mutually orthogonal resistive dipole-diode. The design characteristics and performance of the probe as constructed at the National Radiation Protection Department (NRPD) are presented and discussed in this paper.

DESIGN CHARACTERISTICS AND EXPERIMENTS

By using a thin film technology, a resistive dipole antenna on an RT/Duroid substrate has been constructed with a design to have a wide-band antenna with a zero current at the end point and a maximum current at the center. A hyperbolic sinusoidal current distribution on the antenna was used to calculate the effective electrical length of the antenna and the open circuit RF voltage in the antenna terminal. A chip diode detector (which has an exponential characteristics) on the gap of the antenna was used. Whenever it operates in it's square law region, the dc component of the output current will be proportional to the applied squared voltage to the diode (4). Both the diode and the antenna impedance have dependency on the frequency so that the variation in frequency can affect them by a loading effect. Therefore, a matching circuit was used to cancel the loading effect (3). By this method, a relatively constant dc output for a constant amplitude of RF/MW exposure in different frequencies was obtained. To eliminate the ac component in the output of the diode and also to isolate the antenna and matching circuit from the other parts, a RC low pass filter was used. To transmit the

detected signal to the preamplifier, a resistive thin film symmetrical double-strip coplaner waveguide was used. This transmission line operated as a low pass filter and it provided an additional ac compensation (5). The dc output signal of the transmission line was amplified for monitoring of a high impedance meter. Figure 1 shows the circuit of one dipole-diode combination as designed and constructed in this work.

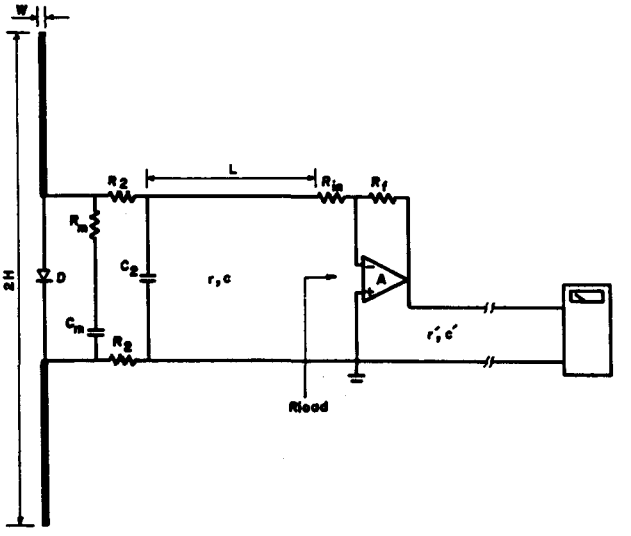

Figure 1. The circuit model of one directional dipole-diode combination RF/MW detector.

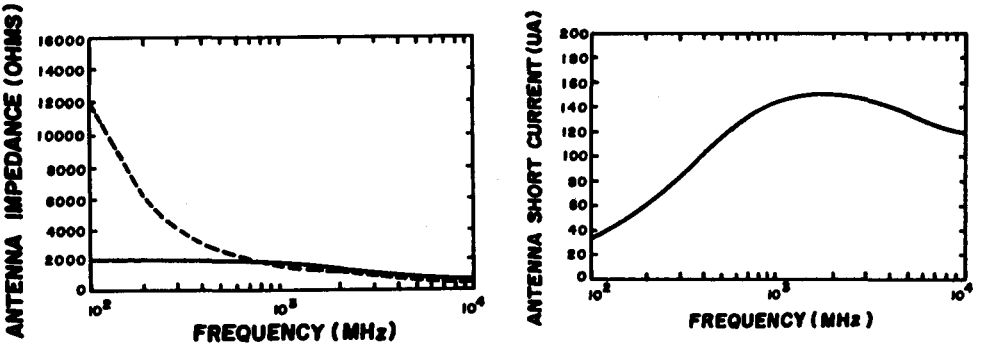
The electric field probe has been constructed based on a three orthogonal dipole-diode combination. Each dipole-diode is like the model shown in Fig. 1. A computer program was written using MATLAB to determine the optimum values of the elements of the probe such as antenna half length (H), dipole width (W), transmission line characteristics, etc. The output of the program for half length of the dipole was found to be 2 cm. The width and resistance of the dipole are parameters which limit the lower cut off frequency (2). A narrower width increases the lower cut off frequency but it makes the analysis easier. However, there is a trade off between the width of the dipole and the frequency of interest which was determined to be from 1 to 3 GHz. By running the program, the width of the dipole and antenna resistance were found to be respectively 0.1 cm and 3 kΩ per leg. Figure 2 shows the real and imaginary parts of the antenna impedance and it's short current versus the frequency.



(a) (b)

Fig. 2. a) The real and imaginary parts of the resistive dipole impedance; b) the antenna short current.

By modeling the diode and the other parts of the probe and by running the program at different frequencies of interest, the frequency response of the probe was determined, as shown in Fig. 3. It can be concluded that the probe has a response flat in the frequency range of 0.8 to 3 GHz which matches with our preset frequency range of interest. The probe was constructed based on the output results of the program as shown in Fig. 4. By comparative calibration of the probe, the RF/MW exposures in the environments of such fields and in the working areas were measured. The response of the probe was compared with those of other available field probes and it's response was acceptable.

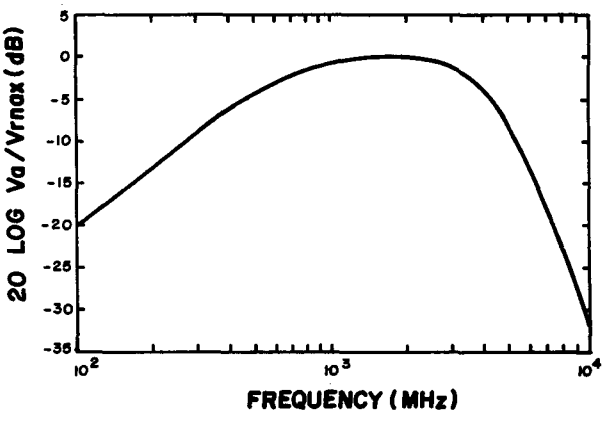


Figure.3 The frequency response of the probe.

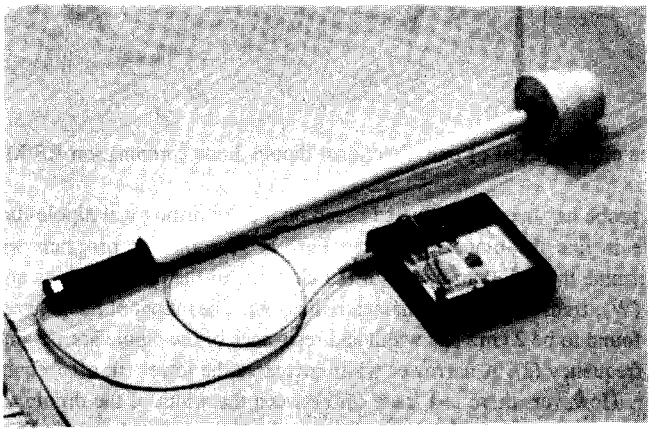

Figure 4. The electric field probe as constructed in this study.

CONCLUSION

In this study, a wide-band RF/MW measuring probe was designed and constructed which showed satisfactory performance characteristics and it has been applied in practice. Studies are underway to further upgrade the system.

BROAD BAND SENSORS CALIBRATION BY A GTEM CELL

G. Licitra[1], M. Pocai[2], F. Francia[1]

[1]Environmental Physics, Department of Health - Livorno, Italy
[2]C.I.S.A.M., Department of Defense - S. Piero a Grado (Pisa), Italy

ABSTRACT

Increasing interest of public for non ionizing radiation hazard and local authorities surveillance necessity demand for -easy to use, reliable measurement instrumentation [1]. Triaxial sensors, with their inherent large frequency response, are excellent candidates to reduce in field difficulties related to narrow band tools utilization, as antennas connected to spectrum analyzer. GTEM cell [2,3] is a relatively novel tool in EMC field, the use of which seems overcome some limitations of standard TEM cells [4] and antennas. The continuos improvement in theory of operation and manufacturing broadens its field of application from canonical electromagnetic compatibility radiated immunity and radiated emission tests [5,6]. The large operation frequency range (from DC to some GHz) and the compact design, well suited to laboratory use, offers the opportunity of conduct fast tests at a convenient location.

1. INTRODUCTION

A preliminary GTEM cell (EMCO 5302 model) characterization is presented in order to investigate its capability in broad band sensors calibration. VSWR, Electric Field Uniformity, etc., are measured and their values compared to specifications. A compact broad band electric field sensor is used to assess consistency and repeatability of measurements. Comparison between GTEM data and field strength values evaluated by this sensor, independently calibrated by manufacturer, is displayed and the optimum position of the sensor inside the test volume is investigated. In order to optimize test time and repeatability an *ad hoc* software is implemented to drive all used instrumentation. Finally, critical evaluation of GTEM performances is presented and suggestions are given to improve its reliability.

2. MATERIALS AND METHODS

In fig. 1 is presented a scheme of GTEM cell we investigated about. This model is sufficiently compact to occupy a modest room volume, and its weight is tolerable by common bench.

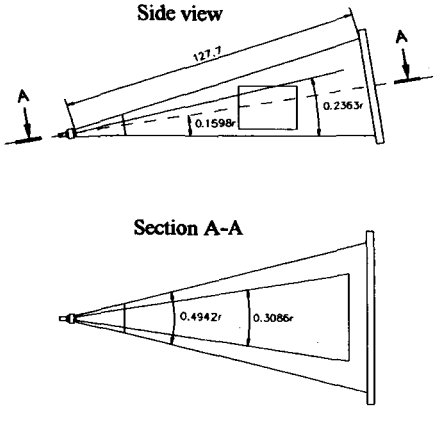

Fig. 1: Side and plant view of EMCO 5302 GTEM! model.

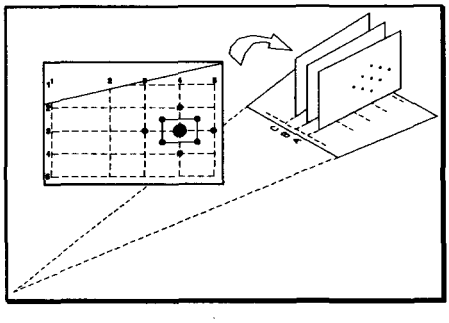

Fig. 2: Layout of measurement points. On each plane orizontal spacing is 4.5 cm and vertical spacing is 3 cm. Points in the inner surface were chosen midway closer neighbors. Planes separation ranges from 3 cm near the apex cell to 4.1 cm near the end cell.

After first evaluations was evident that results were not affected by door position, therefore it was removed to improve inside access. All measurements were so performed using lateral door aperture.

Field uniformity has been evaluated in three vertical planes bounding a volume of trapezoidal shape of approximately 8 (w) x 13.5 (l) x 14 (h) cm^3 (fig. 2). On each plane twenty-five measurement points were selected, even if only highlighted ones are presented. The central point is halfway septum height.

Experimental set up differs according to parameter to be measured. Time domain measurements were performed with a TDR HP 54121T and a RF Impedance Analyzer HP 4191A directly connected to cell input. Field measurements were performed using a HP 437B Power Meter, a Farnell PSG 1000 RF Source, a Kalmus 747LC 50W amplifier, a Werlatone 1795 coupler and an Alenia broad band Electric Field sensor 18RV1001-1. All instruments were driven by appropriate software LabVIEW based (National Instruments), developed by the authors, *via* a GPIB bus. In fig. 3 is shown a typical test set up.

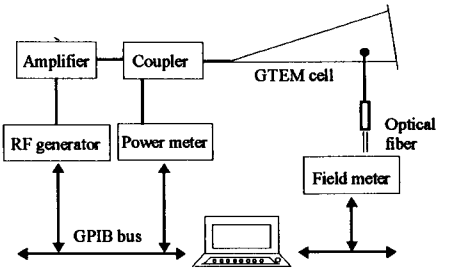

Fig. 3: Electric Field measurements test set up.

3. TDR MEASUREMENTS

Fig. 4 presents the TDR of cell in two different configurations. Traditional time axis is replaced with length axis to improve readability. Connector section shows most of the noise, as expected. Some variations are present in the transition zone where septum meets resistors. It is worth that, substantially, impedance does not exceed 54 Ω in the working region (approximately 78-105 cm far from apex). Various tests were made to assess influence of external factors on data repeatability and a negligible impedance variation is only present in correspondence with side aperture. As a matter of fact, TDR measurement with opened side door presents variation of about 1 Ω.

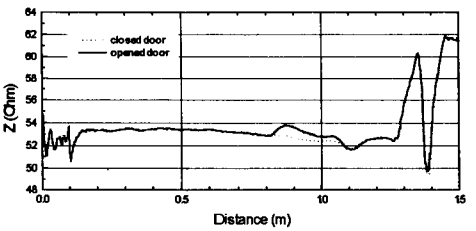

Fig. 4: TDR measurement of GTEM cell with closed and opened side door.

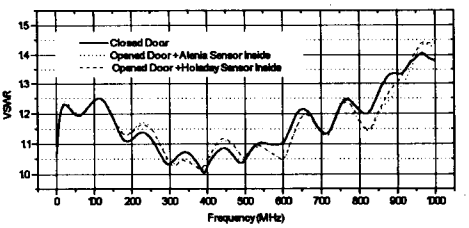

Fig. 5: VSWR measurement of GTEM cell: closed side door (continuum), opened side door with Alenia sensor inside (dotted) and opened side door with Holaday sensor inside.

Further analysis was made computing VSWR of the cell (fig. 5). Specifications declare a value (1.5:1) higher than our result, but manufacturer documentation includes a graph where VSWR is in substantial agreement with present data. Most range shows a value less than 1.2 while a maximum of 1.4 is found at 966 MHz.

Sensor insertion changes a little the shape, but not in a significant way. On the other hand, different sensors (e.g., Holaday STE sensor) were proved to identify eventual problems, but results show no significant differences.

4. FIELD MEASUREMENTS

Electric Field Strength measurements have been used to state field uniformity inside the cell. This parameter is relevant because it is related with the maximum DUT volume the cell can house. The generated fields were around 100 V/m with a 300 V/m full range.

In fig. 6 a comparison between the central point (position B[3,4]) and the rightmost one (position B[3,5]) is shown. The maximum difference is 2.7 dB at 940 MHz.

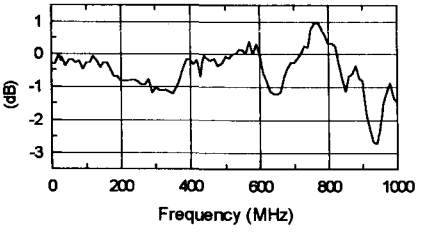

Fig. 6: Electric Field Uniformity on plane B between the central point (position B[3,4]) and the rightmost one (position B[3,5]).

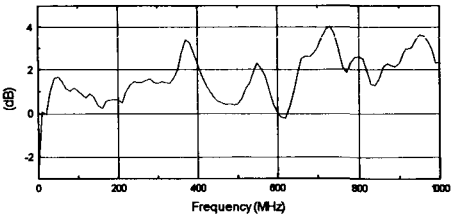

Fig. 7: Electric Field Strength difference between GTEM cell values and Alenia sensor at the central point position.

It is worth to point out that most of data differs for less than 1 dB. Analogue results hold for the other positions. These preliminary results allow a moderate optimism in the optic of a possible use of GTEM cell as sensor calibrator.

Fig. 7 shows the results of comparison between Electric Field Strength measured at position B[3,4] (central point) by the Alenia RV181001-1 sensor (calibrated by the manufacturer) and the Electric Field Strength as computed by geometrical GTEM parameters. The latter calculus was implemented by a dedicated software and correction for coupler insertion loss, coupler coupling factor and GTEM VSWR were taken into account. In the worst case the mismatch is comprised in 4 dB.

5. CONCLUSIONS

GTEM cell is becoming a valuable tool in performing some specific test up to now realizable only by means of different integrated approaches as TEM cells and anechoic chambers or large OATS sites. In particular, some interesting perspectives open in the field of sensors calibration. Drawbacks found at certain frequencies suggest that further investigations are required, but results in the most of frequency range are valuable ones.

Attention must be paid in frequency characterization of instrumentation in use. In our experience, common ten points often delivered with instrument by manufacturer are inadequate to probably describe the behavior in the full working range and interpolation is a rough expedient to solve the lack of data.

Effects of radar occupational exposure on the male fertility

Eugenia Danulescu, Razvan Danulescu, Doina Popa
Public Health and Medical Researches Institute, Iasi, Romania

Objective: The estimation of possible harmful effects upon the male fertility due to the occupational exposure to low and medium levels of pulsed microwaves.

Methods: 55 males occupationally exposed to microwaves have been studied compared to matched controls. Exposure assessment and consequently thorough investigation of the fertility have been made: complex fertility questionnaires concerning sexual dynamics troubles, reproductive history, pregnancy outcomes, time to pregnancy, spousal abortion rate, birth weight, gestational age, congenital malformations, etc. Serum testosterone analysis and seminal analysis (sperm count, volume, motility) have also been made.

Results: Exposure assessment has pointed out whole body SARs between 0.01 and 1W/Kg. Epidemiologic research has shown significant increase of sexual dynamic impairment, significant increase of time to pregnancy and decrease of the fertility. Low levels of serum testosterone, without statistical relevance, have been recorded. Slight but statistically significant decreases in sperm count and motility have also been found.

Conclusion: Since the exposed group dimensions are rather low, the statistical power of our study is somehow slight but, however, it must be considered at least an alarm signal and a stimulus towards further research in order to elucidate these found harmful fertility effects of the microwaves.

SPECIFIC FEATURES OF PSYCHOLOGICAL REACTIVITY IN PROFESSIONAL EXPOSURE TO PULSED MICROWAVES

Gh. Bălăceanu, R. Dănulescu

Public Health and Medical Research Institute
Iaşi, Romania

OBJECTIVE AND CHARACTERISTICS OF EXPOSURE

The literature contains controversed data concerning nervous and behavioral effects of chronic human occupational exposure to pulsed microwaves. Our paper follows some psychological changes in 49 occupationally exposed subjects, technicians and engineers with 38,9±3,2 years of mean age and 15,5±5,1 years length of service in activities of maintenance of radars in the vicinity of some generators unprotected by carcass or with inadequate protection, in a relative limited space with much and generally unshielded sources. The frequencies are from 0.2 to 10 Ghz with the mean power of density from 0.1 to above 2 mW/cm^2, with peak power density exceeding thousands times the mean power density. The estimated SARs are between 0.01 and 1-2 W/Kg, greater especially for head and hands.

METHODS

Both in exposed (E) subjects and control (C) subjects (36 Ss from the same enterprise with similar profession, mean age and length of service, without exposure), were used the followings tests:

- the Pointage Test (to punctuate the middle of 100 squares with the side of 1 cm);
- the Tapping Test (the sum of points tapped with the left and right hand in six seconds);
- the Bourdon-Amfimov attention test (the barrage of O and C letters in time of 10 minutes);
- the Praga Distributive Attention Test;
- the I_2 Intelligence Test (with the subtests: analogies, number series, useless words and antonyms);
- the Cattell Anxiety Questionnaire (5 PF);
- the Subjective Symptoms Questionnaire (from the Swedish Toxicopsychological Battery);
- an original test (Gh.Bălăceanu) that involve distributive attention, quickness, manual accuracy, simple discrimination of shapes and colours (the task is to place 36 cylindrical pieces with a drawed face in triangle square or circle coloured in red, yellow, blue or green, on a table with circles containing the same figures arranged at random);
- the reaction time test (series of 10 red or blue visual stimuli for each hand).

The subjects were examined in one session with pauses between tests. The comparisons between the exposed and control group were tested by using the "z" or "chi-square" test.

RESULTS

Tests	Measured variables	Mean results				Test of significance
		Exposed Ss	SD	Control Ss	SD	
Reaction time	time in ms	341.8	73.8	310.0	54.1	z=2.23 p<0.05
Pointage	time in seconds	58.2	16.9	46.9	11.7	z=3.56 p<0.001
Tapping	sum of points tapped with both hands	70.5	10.5	74.4	7.4	z=1.96 p=0.05
Bălăceanu	time in seconds	82.6	17.2	73.3	11.9	z=2.87 p<0.01
	imprecisions number	8.2	6.8	3.0	7.2	z=2.86 p<0.01
Bourdon-Amfimov	sum of correct barraged letters	450.3	97.3	471.8	84.8	NS

	- subjects with increased anxiety	19.6		5.9		z=1.97 p<0.05
	- subjects with normal C (ego strength)	80.4		94.1		z=1.96 p=0.05
	- subjects with normal O (paranoiac defence)	70.6		88.2		z=2.05 p<0.05
	- Ss with anxious/ inhibited ego	9.8		0		z=2.28 p<0.05

DISCUSSIONS

As we see, the exposed subjects have a significant increase of RT, reduced motor reactivity, reduced efficiency in tasks which involve distributive attention, manual accuracy, ability to reason with number series and categories of words. The increased time of solve the items of Intelligence Test put in evidence a reduced efficiency in cognitive tasks. The questionnaire of subjective symptoms points out the increase of extroversion symptoms, which correlated with the preference to participate to passional discussions (46.7% in exposed group vs 11.8% in control group, $z=3.26$, $p<0.001$), can indicate the increase of excitatory state which can subsequently induce inhibition and tiredness. This conclusion is supported by the increased percentage of subjects which relate frequent periods of strong tiredness (66.9% exposed subjects vs 47.1% control subjects, chi-square = 6.09 $p<0.05$) and on the other hand, as we have had seen, the reduced psychomotor reactivity and functional capacity of distributive attention. They have also more frequent troubles of recent memory (they forget what they recently think, 66.7% from exposed subjects vs 41.2% control subjects, chi-square = 7.7 $p<0.01$). The reduced percentage from exposed subjects which relate that they not dream (46.7% exposed subjects vs 75.5% control subjects, $z=2.65$, $p<0.01$) can also support the idea of increased tiredness and/or the trouble of recovery sleep. It was observed also the possibility to install an inferiority complex (55.6% exposed subjects vs 32.4% control subjects, $z=2.04$, $p<0.05$, relate that they have some difficulties to discuss about them with others).

The questionnaire of anxiety put in evidence increased percentage of anxious subjects in exposed group, more frequent increased anxiety, weakness of Ego, paranoiac defence (as compensatory factor), inhibited Ego, which can reduce the ability to cope with stress and crises and can develop neurosis or angst hysteria.

CONCLUSIONS

These findings support the idea of unfavourable influence of chronic occupational exposure to pulsed microwaves on psychological reactivity, reducing the individual resistance to stressful events, increasing the level of tiredness, reaction time, troubles of recent memory, inducing an excitatory state that subsequently can induce inhibition and tiredness. These psychological changes can have some repercussions on individual organic resistance to physical and/or psychosocial potential harmful factors on the one hand and/or on worsening of other psychoorganic affections, on the other hand.

MAJOR SCIENTIFIC TOPIC NUMBER 2.2 (see page 7)

ABSTRACT (See instructions overleaf)

Clinical and epidemiological studies of health of 80 people including the basic group of 30 people living for 5 years in the zone of daily SHF-exposure from 3 radars of 200, 1000, and 3000 MHz were carried out. The power density of SHF-radiation at the exposured sites ranged from 0,07 to 0,2 mW/cm2.

6 people (20%) of the basic group showed the complex of symptoms which are tipical for response on chronic SHF-irradiation: astheno-neurotic syndrome of various degree; disoders of the vegetative nervous system; neurogenic hyperventilation syndrom; thrombocytopenia and coagulopathy syndrome; myocardium function impairmehts: automatism (mainly, bradyarythmia), conductivity and excitability; changes in a number of biochemical blood characters and in T- and B-immune systems.

All the mentioned above allowed to conclude that the exposed people suffer from a chronic disease induced by radio-waves.

NATIONAL AND INTERNATIONAL STANDARDS ON THE MEASUREMENT OF ELECTROMAGNETIC FIELDS AND STATE-OF-THE-ART MEASUREMENT INSTRUMENTS

Hans-J. Foerster, Wandel & Goltermann, 72800 Eningen, Germany
Herbert Nowotny, Wandel & Goltermann, Baden, Austria
Bill Bean, Wandel & Goltermann, Raleigh NC, USA

INTRODUCTION

Exposure levels for non-ionizing radiation have been introduced world-wide on a technical basis. An ever growing number of countries tend to fix exposure levels on a political basis. These activities require measurement standards for both low-frequency and high-frequency measurement procedures and instruments. This standardization process has been started on different national bases but is not yet finished at an international level. I.e. in the low-frequency range, there are as yet no standardized measurement techniques in existence around the world. The result is that a large number of low-frequency devices are available commercially, but results from the different devices are not comparable. Moreover, there is no other branch of measurement technology where, in specifying technical data, so much information is either concealed or misrepresented. This is hardly acceptable in a field with major safety implications, as is the case with measurement of electromagnetic fields and waves.

GERMANY: VDE

When it stipulated its limits, the VDE also defined the necessary measurement techniques in DIN VDE 0848 (1). The VDE is thus an exception within Europe. These measurement techniques described in this standard are particularly valuable for the high-frequency range. However, precise specifications are lacking, along with requirements for test equipment. The standard leaves the choice of measurement technique to the person making the measurement, even though all errors and the influence of the frequency spectrum must be taken into account when determining the field strength values. The limit between high frequency and low frequency was set at 30kHz. For the low-frequency range, the norm is restricted to rudimentary guidelines for designing the test setup. Important is the restriction for the magnetic field probe, which is required to be a induction coil with an area of $0{,}01 m^2$.

EUROPE: EBU

At the European level, the EBU (European Broadcasting Union) has standardized measurement techniques, but they are tailored very specifically to the needs of the broadcasting industry (5). The effects of the various modulation techniques on the measurement results are documented in great detail.

INTERNATIONAL: IEC

In the eyes of the experts, the current situation is unacceptable: Limits have been stipulated, yet the measurement problem is left to the whims of the free market. The measurement techniques valid in Europe, particularly for verifying the limits of the two CENELEC norms (3, 4), were delegated to the IEC (International Electrotechnical Commission). IEC created two working groups with the aim of defining the test and measurement standards immediately under tight time constraints. The voting drafts of these papers are expected to circulate at the end of 1996. Both standards are focused to measurement procedures and measurement equipment with specific regard to human exposure. For the frequency range 100 kHz to 1 GHz, there is a draft dealing with radio communications (10). However, this standard has only limited use in industrial applications.

AUSTRALIA

In Australia, a newly revised version of the standard for measurement of high-frequency fields is now available in draft form (9). The original versions were highly practical documents, and the new standard is a continuation of this trend towards detailed description of test and measurement techniques. One new and innovative feature is the long-awaited description of a spatial averaging technique for avoiding excessive influence of RF hot spots and better recording of the whole-body exposure. Measurements are required at five points of a square (corners and center) having an edge-length of 300mm; the average of the five measured values is then displayed.

SWITZERLAND

The Swiss Federal Bureau for the Environment, Forests and Landscape (Bundesamt für Umwelt, Wald und Landschaft) has issued a recommendation with limits based on the IRPA values, including a detailed study of measurement of high-frequency fields (2). Here, the focus areas are error estimation in measurement and calibration, and investigation of measurement uncertainties. Radar signals are given special treatment. For low-frequency field measurements, the corresponding recommendation is not yet available.

USA

In the USA, the third revised version of the standard on measurement of high-frequency fields is now available (8). The fourth version is expected at the end of 1996. This standard will be used around the world as part of the standardization process at the national level, even if it is modified in each case. There is detailed coverage of three main areas: general test-related issues, instrumentation and actual measurements. In the fourth version, the section on instrumentation will most likely be revised since major technological advances have been made since the last version was published in 1991. A corresponding standard on the measurement of low-frequency electrical and magnetic fields is in preparation (7).

CONSEQUENCES FOR THE MEASURING DEVICES AND MEASUREMENT PROCEDURES.

It is a basic fact that the complexity of determining limits entails unusual problems for test equipment as well as for test personnel. One the one hand, the instruments must be simple to operate. However, the results must be precise, traceable and reproducible. Except for highly trained personnel in scientific and technical fields, the person making the measurements is generally uninformed about the theoretical and practical aspects of electromagnetic fields. In recent years, this problem has become more acute as the national and international limits recommendations have made their way into industry. This also explains the introduction of innovative measurement techniques for high-frequency as well as low-frequency applications (6). Due to space constraints, all of the requirements for field measuring devices cannot be considered here; this is a task for the IEC working groups. However, we will look at some of the most innovative advances in measurement technology over the past five years:

LOW FREQUENCY, ELF

3D-E-field measurement: When measuring electrical fields under high-voltage lines, the older one-dimensional technique was sufficient since it was possible to compute the field pattern in advance. However, the current standards of the VDE and Cenelec require measurement of the resultant field strength, regardless of application. Especially in industrial environments (switching fields, transformer stations, induction heating devices), the field pattern is a function of the installation and also varies over time, meaning that three-dimensional measurements are required. A setup of a state-of-the-art measurement device is shown in Figure 1 (12).

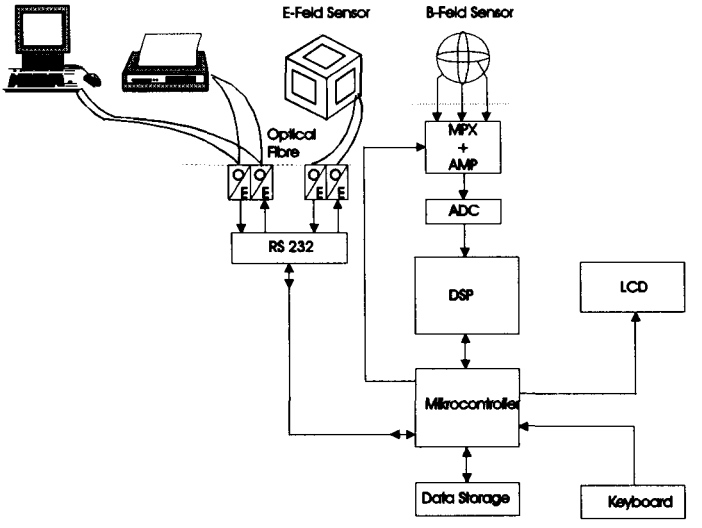

Figure 1 Setup of the EFA-3 measurement system for isotropic B- and E-field measurements

Tuneable filters: E-field and H-field measuring device must also allow selective recording of the field components since the international and national limits recommendations are all highly frequency dependent. Broadband equipment cannot handle this measurement when the frequency of the emitter is unknown and the existence of multiple signals cannot be excluded as a possibility. One example is an induction heating system, which simultaneously radiates 50/60 Hz fields with all their harmonics as well as heating frequencies in the 25 kHz range. Newer measuring devices are equipped with filter functions for handling such situations.

RF & MICROWAVE

Wide frequency ranges: Extremely broadband probes, primarily for applications in ISM areas and in telecommunications (AM & FM radio, GSM, TV) have been developed with frequency ranges from 100 kHz to 3 GHz and a negligible frequency response. Figure 2 shows the typical frequency response curve.

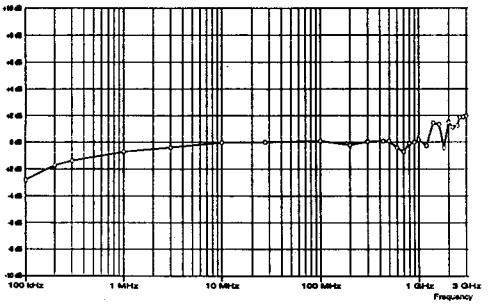

Figure 2 Typical Frequency Response of EMR-30 100 kHz to 3 GHz

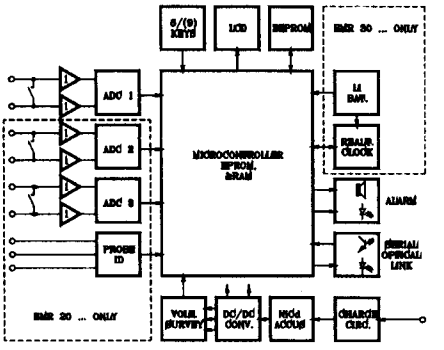

Figure 3 Triaxial digital axis processing for RF & Microwave measurements

Triaxial evaluation: Today, using trichannel digital evaluation of the individual axes of an isotropic sensor, it is easy to cover a dynamic range of 60 dB with a single probe (11). All of the limits stipulated in national and international standards can be covered without resorting to exchangeable probes with their associated calibration problems. Figure 3 illustrates the modular design of a triaxial digital system.

No auto-zero: Elimination of the need for an "auto-zero" function is another advance. Due to their extremely high-impedance input stages, field meters require continuing offset alignment. In the past, it was necessary to locate a field-free space for this procedure, thereby providing a typical trap for untrained personnel. Newer devices automatically perform this alignment even under field exposure.

CONCLUSION

This paper describes the international activities and policies for standardizing the measurement equipment for electromagnetic fields. Activities of the various countries, mainly Germany (VDE), USA (IEEE), Europe (IEC) and Australia (AS/NZS) as well as others are covered. Based on these reports requirements for measurement equipment are discussed and new designs for instruments especially developed for the measurement of electromagnetic fields with particular regard to human exposure are presented.

INTRODUCTION

Most laser safety documents advise the laser user that caution must be used in the evaluation of exposure to repetitively pulsed radiation since they are only limited data on multiple pulse exposure criteria. The empirical multiple pulse formula is based on some data indicating that there is generally a cumulative effect in multiple-pulse exposures. This effect is a reduction in the threshold energy per pulse relative to the single pulse threshold. The best fit to experimental data predicts that the threshold energy per pulse decreases in proportion to the fourth root of the number of pulses *n*. This model has been reported to be in agreement for exposures ranging from picoseconds to seconds. However, the very limited data reported in the sub-nanosecond domain of time were obtained with a low pulse ratio frequency. No data exists in the litterature concerning the effect on the retina of ultrashort pulses delivered with a high repetition rate. Also, it has been hypothesized that one cannot extrapolate from longer pulses width because the ultrashort pulse (single or multiple) induce effects which may involve fundamentally different mechanisms of damage. Moreover, laser exposure limits for a single-pulse duration less than 1 ns cannot be specifically provided by ICNIRP Guidelines or other publications on laser radiation because of a lack of biological data (1). The limit values for these exposure times has been derived by maintening the irradiances applicable to nanosecond pulses. With the goal in mind to obtain adequate data base for single and multiple ultrashort pulses, an experimental study has been directed toward determining the retinal damage thresholds induced by picosecond pulses emited in the visible spectrum.

METHODS

The experimental system is a dye laser pumped by a mode locked pulse compressed, frequency doubled Spectra-Physic Nd:YAG laser. A cavity dumper produces single pulses with an adjustable pulse repetition rate between single pulse and 1 million pulses per second (1 MHz). The wavelength at the output of the dye laser is 590 nm. A sample of the laser beam at 590 nm was deflected onto an autocorrelator which measures the pulsewidth and onto a photodiode and a calorimeter. The output signal of the photodiode, calibrated by the calorimeter, was converted with 8 bits resolution by a 100 MHz analogic-digital converter and was transferred to a computer. The animal used in the experiments was the rabbit Fauve de Bourgogne. Rabbits were used primarily because the average ocular transmission and absorption characteristics are very similar to the human ocular media for the visible spectrum and secondly to compare with the other experiments (2). The theorically expected spot size formed on the rabbit retina with the dye laser optical system was about 30 μm. To aid alignment of the animal's eye, a 1 mW HeNe laser was mounted co-axially with the main laser

beam path. Rabbits were anesthetized with intramuscular injection of ketamine hydrochloride (10 mg kg^{-1}), placed on a stand permitting us to produce in most cases retinal lesions aligned on the visual streak. The pupils were dilated before to exposure, and the eyelids were held open with a wire speculum. The treatment and procedures used in this study conformed to the European Community Guidelines on Animal Experiments. Two investigative methods were used. A direct ophthalmoscopic examination was made 15 mn and 24 h after the exposure using a fundus camera. Any presence or suspicion of lesion was photographed. Immediately after the direct ophthalmoscopy, all animals were examined using fluorescein angiography. Photographic recordings were made for each observation of fluorescein leakage.

RESULTS

The results were obtained for repetitive pulse trains varying from 1 000 to 200 000 pulses. The pulse repetition frequency (PRF) used were 10 kHz, 100 kHz and 1 MHz. Because the low energy characterizing a single pulse in our experimental laser configuration, no retinal injury has been observed for 1 MHz pulse train including less than 100 pulses. Similarly, few damages have been detected with lower PRF than 1 MHz and the data were not enough to calculate a probit regression line. In our experimental conditions, the lowest fundoscopic threshold levels were obtained 24 h after exposure with the direct ophthalmoscopic method; whereas using fluorescein angiography, the best time to detect an injury was immediately after the exposure. The experimental results are in good agreement with earlier works (3-4). After employing both investigative methods, we founds that fluorescein angiography appeared to be the most sensitive technique. These observations show that a fluid leakage is involved in the damage process. For each experimental condition, data were scored and processed by a method of probit analysis (5). The median effective dose (ED_{50}^{MP}) which is the energy expected to produce a retinal damage in half of the exposures is given in Table 1.

Number of pulses *n*		**100**	**1 000**	**10 000**	**20 000**	**100 000**	**200 000**
Time period (interval) (s)		1.10^{-6}	1.10^{-6}	1.10^{-6}	1.10^{-6}	1.10^{-6}	1.10^{-6}

* extrapolated value

Table I. Median effective doses calculated from fluorescein angiographic data obtained on rabbit retinas with multiple pulses trains (pulsewidth 8.10^{-12} s, $\lambda = 590$ nm).

DISCUSSION-CONCLUSION

The results show a slight additivity for pulses separated by less than one microsecond. The injury threshold per pulse decreases when the number of pulse *n* included in the train increases. The best equation fitting the relation between the energy threshold of the pulsed train and the number of pulse *n* is given by:

$$ED_{50}^{MP} = 0.01n + ED_{50}^{SP}$$

where ED_{50}^{MP} is the threshold value for a multiple pulses train of n pulses corresponding to a probability of 50% and ED_{50}^{SP} the threshold value for a single pulse with the same probability. The ED_{50}^{SP} extrapolated from our results, in the range of 1 000 to 200 000 pulses, is 55 μJ and the correlation coefficient r^2 is 0.9995. This energy threshold is higher than other values reported in the litterature (6-7) but the threshold value of 6 μJ reported by Birngruber et al (6) for Chinchilla Grey rabbits give the same fitting equation with our results and the correlation coefficient is 0.9984.

The severity of the damage does not seem to increase with the number of pulses. The damage observed was very similar after an irradiation of 100 or 200 000 pulses. No hemorrhagic lesion has been induced by a train of 200 000 pulses. Such lesions have been histologically observed at different delay post exposure (8).

Number of pulses n	**100**	**1 000**	**10 000**	**100 000**	**200 000**
Limit value ($n^{-1/4}$ formula) (μJ)	$4.8\ 10^{-10}$	$2.7\ 10^{-10}$	$1.5\ 10^{-10}$	$8.5\ 10^{-11}$	$7.1\ 10^{-11}$
ED_{50} per pulse of the train (μJ)	$6\ 10^{-8}$	$2.8\ 10^{-8}$	$2.2\ 10^{-8}$	$1.6\ 10^{-8}$	$1.5\ 10^{-8}$

Table II. Comparison between the results (ED_{50}^{MP}/n) and the corresponding limit values.

The comparaison of the data with the limit values of the guidelines (Table II) show that the empirical multiple-pulse formula, predicting that the threshold energy per pulse decreases in proportion to the fourth root of the number of pulses n, seems acceptable for picosecond pulses delivered with a high repetition rate. The safety marge is reasonable but is also variable depending the number of pulse. The empirical $n^{-1/4}$ formula is acceptable but does not describe specifically the mechanim of the repetitive-pulse injury thresholds.

Acknowledgments-This study was supported by contract 94/001 from the Direction des Recherches Etudes et Techniques du Ministère de la Défense.

PROTECTION FROM SOLAR ULTRAVIOLET RADIATION IN HONG KONG

John K.C. Leung, W.K. Ho and M.Y.W. Tso

Radioisotope Unit, The University of Hong Kong,
Pokfulam Road, Hong Kong

ABSTRACT

Increasing skin cancer rates in many countries have been attributed to increasing solar UV radiation due to global depletion of stratospheric ozone. The majority of the existing solar UV radiation monitoring stations are found in high latitude countries nearer to the 2 poles. We are building one such station in Hong Kong at latitude 22.5 °N. The station can provide information on solar UV irradiance, exposure limit, irradiance forecast and stratospheric ozone depletion in this region of the world.

Protection factors of fabrics and clothing for protecting against solar UV radiation have been determined and analyzed. The spectral transmittances of the fabrics in the wavelength range 250 to 400 nm were measured by means of a solar simulator and a double monochromator spectroradiometer. Effect of washings on the protection factors were simulated and determined.

INTRODUCTION

Depletion of stratospheric ozone by chlorofluorocarbons (CFC) was predicted more than 20 years ago and was first discovered in the late 1970s. Since then, ozone reductions were reported in many countries and the largest and deepest hole on record was observed in 1992 (1). It is believed that CFC will continue to increase in the stratosphere leading to more frequent and profound occurrence of the ozone holes (2). Many countries have set up networks of solar UV monitoring stations. But so far, the majority of them are located in high latitude countries nearer to the 2 poles. Little data are obtained near the tropic in South-east Asia. Hong Kong at 22.5 °N will provide data on solar UV exposure to one of the most densely populated cities in the world.

The solar UV emitted from the Sun is divided into 3 regions: the UVA (315 - 400 nm); UVB (280 - 315 nm) and UVC (100 - 280 nm). However, as a result of absorption by ozone in the atmosphere, no UVC and only about half of the UVB can reach the surface of the Earth. The irradiance is dependent on latitude and time of the day and year as well as on atmospheric conditions, such as cloud cover and atmospheric ozone content, that affect penetration of the radiations.

METHODS

1. Solar UV radiation

The biological response of the skin to ultraviolet radiation is very wavelength dependent. Various action spectra are proposed (3), (4) and they all show that UVB radiation is far more effective at producing erythema than UVA radiation. Between 300 nm and 315 nm, the response drops by three orders of magnitude. This drastic change in response requires a very precise spectral measurement of the solar spectrum or large error in the calculated biological response will result.

The station is located on the roof top of one of the buildings in The University of Hong Kong and is about 350 m above sea level. The site is away from the urban area and also far away from exhaust chimneys of other buildings in the University. The solar spectral irradiance is measured by means of a spectroradiometer (Model IL790, International Light Inc.) that uses a wide angle diffuser to provide a near cosine acceptance angle. The double monochromator contains two gratings blazed at 240 nm so that deep UV can be measured with a stray light rejection ratio of 10^6 to 1. The spectroradiometer is not used for continuous spectral irradiance measurement because of the complexity involved compared to other simple detectors. Instead, two UV-biometers from Solar Light Co. (Models 501 UVA & 501 UVB) are used to record the UV radiation 24 hours a day. One of the meters gives UVA irradiance in terms of mW cm^{-2} and the other gives UVB effective power in terms of minimal erythemal dose (MED) per unit time.

Atmospheric data including cloud cover, visibility and duration of bright sunshine are obtainable from the Royal Observatory of Hong Kong.

2. Protection factors for clothing

The protection factor (PF) is given by the ratio of effective UV radiation dose for unprotected skin to that of skin protected by the clothing (5), while both the UV spectral irradiance and the biological action spectrum are taken into account. Mathematically, PF is given by

$$PF = \frac{\sum_{250}^{400} E_\lambda S_\lambda \Delta_\lambda}{\sum_{250}^{400} E_\lambda S_\lambda T_\lambda \Delta_\lambda}$$

where E_λ = action spectrum given by IRPA (3)
S_λ = solar UV spectral irradiance in W m^{-2} nm^{-1}
T_λ = spectral transmittance of the clothing
Δ_λ = bandwidth in nm; and
λ = wavelength in nm.

A 1000 W solar simulator (Model 81191, Oriel Corp.) was used as the source and the spectral irradiance was measured by the spectroradiometer described earlier. The diffuser at the input of the monochromator collected both directly transmitted and scattered light from the clothing. The spectral transmittance was determined by noting the reduction in UV intensity when the clothing was placed in front of the monochromator.

RESULTS AND DISCUSSIONS

1. Solar UV radiation exposure

The two UV-biometers provide data every 15 minutes and the data are stored in a data-logger which can be transferred to a computer at any time. Daily variations of UVB MED and UVA irradiance are shown in Fig. 1. During a clear sky day, the change in UV intensity is fairly gradual, but in cloudy days, the intensity can change abruptly depending on cloud cover and atmospheric conditions. Basically, the UVB MED and UVA irradiance have similar variation throughout the day. At large zenith angles, it is noted that UVB radiation is absorbed more rapidly by the atmosphere than UVA radiation.

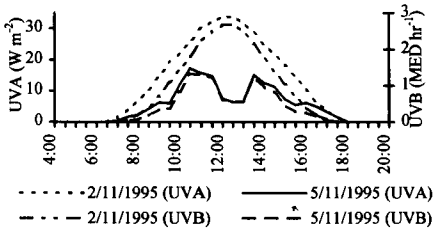

Fig. 1 Variation in measured UVA & UVB

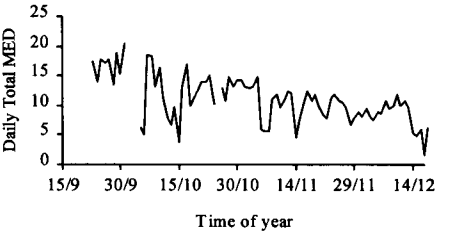

Fig. 2 Variation of the daily total MED

Since the UV-biometers were installed not long ago, measurement data before September 1995 were not available. Fig. 2 shows the total daily MED from September 1995 to December 1995. It ranges from a minimum of about 1 MED in December to about 20 MEDs in hotter months. It is expected that above 25 MEDs could be reached in June or July. The monthly average daily total MED is calculated for the few months in Table 1. The table also lists the duration of exposure to exceed 1 MED at solar noon under clear sky conditions. Since the limit could be exceeded easily around noon time, it is important that outdoor workers be protected with hats, sunscreens, sunglasses and clothing, particularly during Summer.

Table 1. Monthly average daily total MED and the duration of exposure for exceeding 1 MED at solar noon under clear sky conditions

Month	Average daily total MED	Time to exceed limit (min)
September	15.3	13.9
October	12.4	15.3
November	10.0	19.5
December	8.1	24.6

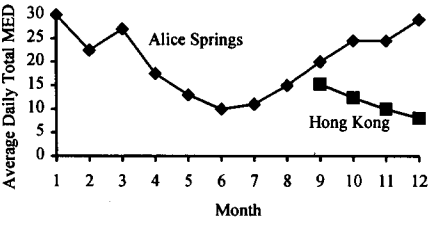

Fig. 3 Comparison of daily total MED with that in Alice Springs, Australia

Countries that have the same latitude should have comparable solar UV intensity in clear sky days. But countries that have equal latitude but in opposite hemisphere of the Earth will experience different solar UV intensity even in the same season because of the different relative position of the Earth and Sun. Fig. 3 shows the total daily MED measured in Alice Springs, Australia (23.5 °S) compared to Hong Kong (22.5 °N).

2. Protection factors for clothing

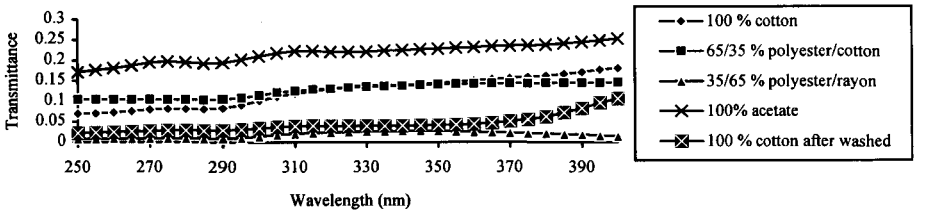

Fig. 4 Spectral transmittances of different types of fabrics

Samples of cloth were obtained from manufacturers and only thin and light samples were measured as the thicker ones would no doubt, have very high PFs. In general, the PF value depends on a number of factors such as weave, color, weight, stretch and water content (5). Typical spectral transmittances of some fabrics are shown in Fig. 4. The cloth samples were further tested for stability of the PF values by washing the cloths for a number of times. The cloths were stirred in a beaker of water with laundry powder for 15 minutes to simulate the action of a washing machine. They were then dried under an infra-red lamp to complete one washing cycle. 0, 1, 3, 7 and 13 washing cycles were repeated. Out of the 35 samples that have PFs less than 50, 71 % have PF increased, 6 % decreased and 23 % fluctuated or remained more or less the same with increased number of washes. The increase in PF is mainly due to shrinkage of the fabrics after the washes leading to a tighter weave of the fabrics. The largest change in PF was observed in a 100 % cotton fabric which increased by 3.2 times. The fabrics that have smaller PFs after the washings were not special ones, and the decrease was not more than 10 %, so it could be concluded that any decrease in PFs were mainly due to experimental errors.

Table 2. Protection factors of some combined fabrics

Sample no.	PF1	Composition 1	PF2	Composition 2	PF1 x PF2	Measured PF
1	8.5	100 % acetate	4.6	100 % acetate	39	30
2	4.6	100 % acetate	5.6	65/35 % polyester/cotton	26	26
3	8.9	100 % cotton	7.9	100 % cotton	70	36
4	4.6	100 % acetate	8.6	65/35 % polyester/cotton	40	35
5	4.6	100 % acetate	8.9	100 % cotton	41	30

Table 2 shows the combined protection factor of fabrics by putting two samples of cloth together and then measuring the combined spectral transmittance. Because PF is dependent on the spectral irradiance of UV radiation reaching the surface of the fabrics, and the second fabric underneath the surface one would receive a spectral irradiance quite different from the one incident on the surface fabric, therefore the combined PF of the two fabrics will not be equal to the product of the two individual PFs. A second more important factor that affects PF is that the combined transmittances for some types of fabrics differ quite significantly from the predicted transmittance as shown in Fig. 5. Though the measured PF value might be much lower than predicted, the actual difference in protection power is insignificant.

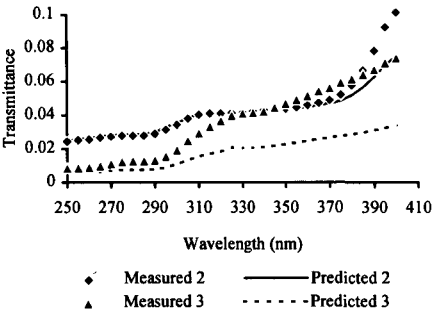

Fig. 5 Transmittance of combined fabrics (refer sample no. to Table 2)

UV-RADIATION INDUCED UDS IN HUMAN LYMPHOCYTES EXPOSED *IN VITRO* TO LOW LEVELS OF IONISING RADIATION

Mary N.Mohankumar and R.K.Jeevanram
Safety Research and Health Physics Group
Indira Gandhi Centre for Atomic Research,
Kalpakkam, INDIA

INTRODUCTION

It has been reported that lymphocytes of persons exposed to low doses of ionising radiation exhibit enhanced rate of UV radiation induced unscheduled DNA synthesis (1,2). Similar effects were observed in spleen cells of mice exposed to single or continuous exposures to low levels of radiation (3). This phenomenon has been attributed to radio-adaptive response (4). In order to eliminate the role of cell repopulating events and extra cellular factors it is necessary to check if the response exists when the priming dose is delivered *in vitro*. However, such an attempt was not envisaged due to the technical difficulties that will be encountered in delivering a chronic low dose irradiation to cells suspended *in vitro*. An attempt was therefore made to study the phenomenon by delivering a single low dose exposure to whole blood *in vitro*.

MATERIALS AND METHODS

a. Donors: Heparinised peripheral blood samples from 20 healthy non-smoking volunteers, aged between 25 and 45, who were employees of this centre and not engaged in radiation work, were collected in aseptic conditions at the Township Hospital and immediately transported to the laboratory. Blood obtained from each person was divided into three portions A, B and C (6ml each).

b. Irradiation: Portion C was exposed to a dose of 3 mGy with gamma radiation using a 185 kBq ^{60}Co source at a dose-rate of 12 mGy/hr at 37°C. During this period, the other two portions (A and B) were also maintained at the same temperature free from any radiation. Following this treatment, both irradiated and unirradiated portions were incubated at 37°C for three hours.

c. Lymphocyte separation: Lymphocytes were separated from all the portions using Histopaque (Sigma) and were washed three times in phosphate buffered saline and suspended at a concentration of about 3 x 10^6 cells per ml in PBS.

d. UV exposure: Lymphocytes obtained from portions B and C were placed in open petri dishes maintained at 4°C and exposed in dark to 30 Joules of 254 nm UV radiation emanating from a mercury lamp (Jarrel Ash) at a fluence rate of 3 J/m^{2}s.

e. Cell viability: The lymphocytes obtained were tested for viability by the trypan blue dye exclusion test immediately after separation and also after UV exposure.

f. Incubation: Immediately after UV exposure lymphocytes from all the three portions were suspended in RPMI-1640 (Sigma) culture medium supplemented with 20% autologous plasma, 5mM hydroxyurea (Aldrich), 1.85 MBq/ml tritiated thymidine (sp act 629 GBq/mmol BRIT,Bombay, India) and incubated for 90 minutes in complete darkness.

g. UDS assay : The incubation was stopped by the addition of cold thymidine and the lymphocytes were washed three times in PBS and finally suspended in 1 ml PBS. UDS was quantified by the method of Mitchell and Mirsalis (5). 0.8 ml was used for the estimation of DNA using diphenylamine reagent and the optical density at 601 nm was read spectrophotometrically (Hitachi, Japan). The minimum detection limit as per the study of Sandell (6) was found to be 4.6 μg DNA. The remaining 0.2ml aliquot was counted for its tritium activity in a liquid scintillation analyser (Packard, USA) having an efficiency of 68%. The Bq/μg DNA values were calculated and the results compared.

RESULTS AND DISCUSSIONS

The viability of lymphocytes measured immediately after separation and after UV exposure was >98 and >95% respectively. The DNA content in all test samples was greater than 8 μg. The Bq/μg DNA values obtained in these samples are presented in Table 1.

S.No	Sample	No. of Samples	Average Bq/μgDNA	P-Value (Student's t test)
1.	Control (A)	17	0.42 ± 0.11	
2.	UV exposed (B)	17	3.69 ± 2.03	< 0.001
3.	γ + UV exposed (C)	17	5.75 ± 2.23	< 0.01

Table 1. Incorporation of ^{3}H Thymidine in DNA of samples subjected to UDS

These results show that there is a significant increase ($p < 0.01$) in incorporated radioactivity in 17 out of the 20 samples that had received a prior 3 mGy exposure when compared to samples that had received only UV radiation exposure. The Bq/μg values for control samples ranged between 0.12 and 0.9 with an average of 0.42 ± 0.11. This activity is due to non-specific incorporation of tritiated thymidine. The values for UV exposed samples ranged between 1.4 and 7.76 with an average of 3.69 ± 2.03. This significant increase in activity is indicative of repair synthesis due to UDS. The samples exposed to gamma and UV radiation showed values ranging between 1.95 and 9.35 with an average of 5.75 ± 2.23. The significant increase in incorporated radioactivity due to the prior exposure of 3 mGy can be attributed to an adaptive response to ionising radiation. Similar results have been observed in cells exposed *in vivo* (5).

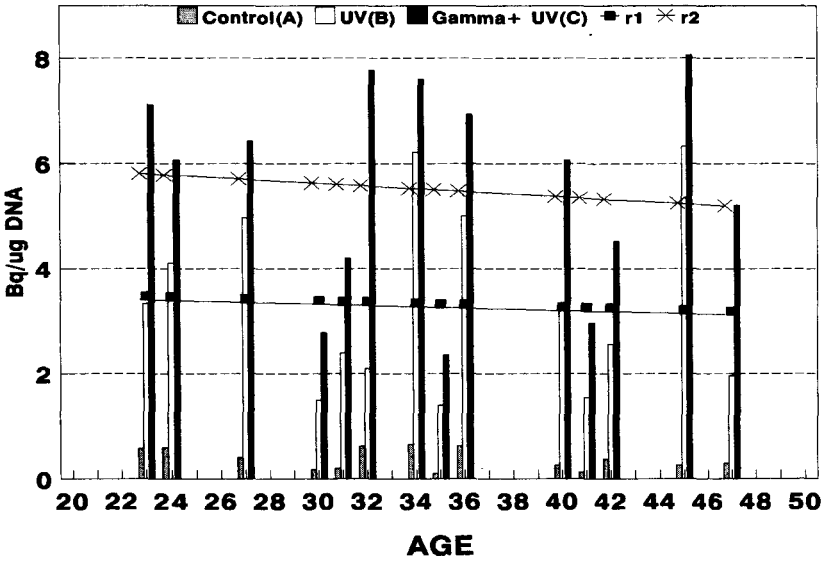

Fig. 1 UDS as a function of age

ıe UDS data as a function of age is shown as a bar chart in Fig 1. 14 out of the 17 were chosen since a few of the X values overlapped. (For example, the values l 9.35 do not appear in Fig.1). The response to UV radiation and that of γ+UV ns in these samples with respect to age did not show any correlation as shown by a ıon analysis. $r_1 = -0.0813$ for samples exposed to UV radiation and $r_2 = -0.099$ for s exposed to both gamma and UV radiation. The negative correlation suggests that UDS endency to decrease with age.

In the present study a time gap of about three hours between the priming and the nging dose was chosen since previous reports (7,8) suggest that such a time gap is ısary for the expression of adaptive response. Enhanced levels of poly (ADP) ribose nerase (9,10) and other inducible proteins produced during this time gap may have a ıounced influence in the expression of this response.

The variations observed in the Bq/μg DNA values among the 17 samples and the blunt ponse in 3 samples in this experiment could be attributed to the heterogeneity factors known to associated with adaptive response and to donor variations in their capacity to perform DNA pair (11,12).

ONCLUSIONS

The results obtained in this study indicate that

1. Enhanced rate of UV-radiation induced UDS can be evoked when a priming dose is delivered in-vitro.
2. A single low priming dose of 3 mGy delivered at a dose rate of 12mGy/hr is sufficient in inducing an enhancement in UDS.
3. A three hour interval between the priming and the challenge UV exposure seems sufficient to induce the phenomenon *in vitro*.
4. The significant enhancement in the rate of UDS in this study eliminates the ambiguity that the response may be dependent on extra cellular factors and cell repopulating events.

EXPOSURE TO UVR: RISK QUANTIFICATION FOR NON-MELANOMA SKIN CANCER

C. R. Roy, W. A. Cornelius and H. P. Gies

Australian Radiation Laboratory, Lower Plenty Road, Yallambie, Victoria, Australia 3085

ABSTRACT

Solar UVR has an acknowledged role in both non-melanoma skin cancer (NMSC) and malignant melanoma (MM). Episodic exposure to UVR, sufficient to cause erythema, has been shown to be a major risk factor for MM. For NMSC and for skin damage the lifetime cumulative solar UVR exposure is of more importance. A software package has been developed to assist in estimating a person's lifetime exposure.

INTRODUCTION

Long-term UVR exposure of the skin is generally accepted as the most important cause of NMSC. Much of our knowledge on the influence of solar UVR is derived from epidemiological studies of skin cancer. Such studies are greatly strengthened when the actual exposure of the subjects can be quantified. This is difficult and most studies use surrogates such as latitude, sunlight hours, or ambient UVR measurements for personal exposure. Within a given population the actual exposure will depend on many factors including place of residence, occupation, recreational activities, annual vacation, outdoor behaviour and most importantly the personal protective measures practised (1). This information together with a global solar UVR database are used in a windows-based software program which has been developed to generate monthly UVR exposure data for different anatomical sites over a person's lifetime.

For a given genetic susceptibility, the two most important factors in determining the relative risk of NMSC from solar UVR exposure are age and environmental UVR exposure. In the program, *UVRISK*, thegenerated UVR exposure data, is used in a simple power law relationship to calculate the cumulative NMSC risk. The program is used as an aid in the determination of pensions for chronic skin damage sustained as a result of armed forces overseas service. The lifetime exposure and risk is given for several different scenarios involving change in place of residence, employment and outdoor behaviour. The benefits of behaviour modification are clearly demonstrated.

EXPERIMENTAL METHOD AND RESULTS

Personal solar UVR exposure

The mid-month ambient UVR for a given location has been calculated by use of a modified Bjorn (2) model. The computed spectral power distribution has been weighted by the CIE (3) reference action spectra for erythema to give the effective irradiance. The data are then expressed in terms of minimal erythemal doses (MEDs) where one MED is 200 J m^{-2} of effective irradiance (4). Data have been calculated in 5° bands from 75°S to 75°N. The effect of long-term average cloud cover has been included and the results verified for Australia. Anatomical distribution and personal protection data are from published studies. The exposure calculation is performed for anatomical sites including face(cheek), hand(dorsum), back (shoulder), arm(upper) and leg. The effective dose to the skin for the given month and body site according to the following:

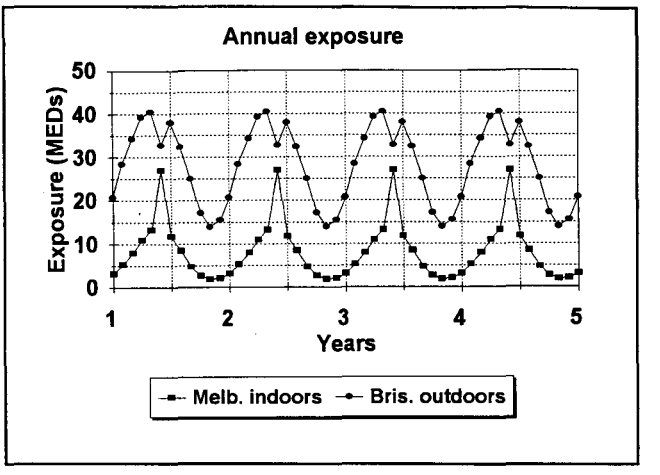
$$PAE(a,m) = \sum_{n=1}^{n=8} MAE\,(m,L_n) \cdot AF \cdot SF_n \cdot OF_n \cdot CF_n \cdot ESF_n \cdot W_n$$

where PAE(a,m), (personal ambient

exposure (in MEDs) for a specified anatomical site, a and month number, m); n (specified activity); m (month of the year); MAE(m,L_n),(daily ambient exposure for the middle of the month m in location L and activity n); AF, (body anatomical factor); SF_n, (site factor for activity n), OF_n (outdoor factor for activity n); CF_n(clothing factor for activity n); ESF_n(environment shade factor for activity n) and W_n(number of days in the month that the activity was performed). The cumulative personal ambient exposure for a specified anatomical site up to the evaluation age of T (months) i.e. $MED_{cum}(a,T)$ is determined by summing over T months.

Figure 1 shows the calculated annual exposure for two scenarios.

Figure 1. *Calculated annual exposure for Melbourne (37.8°S) indoor worker with 50% outdoor recreational exposure and for Brisbane (27.5°S) outdoor worker with similar recreational activities. At 40 years of age the Brisbane worker has had 3.4 times the effective UVR exposure of the Melbourne worker.*



The risk of NMSC from solar UVR exposure

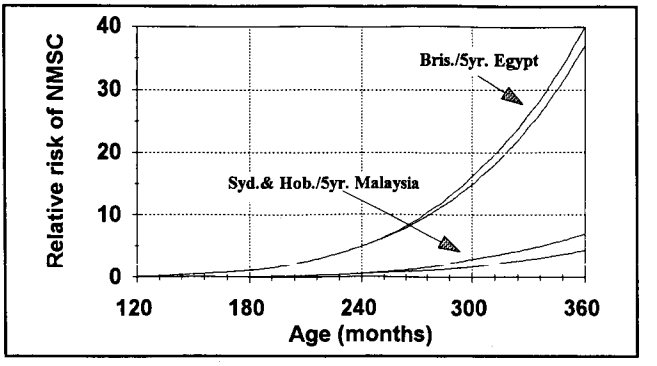
It has been shown that, for a group of subjects with a given genetic susceptibility, the two most important factors in determining the relative risk are age and environmental UVR exposure. A simple power law relationship { $Risk \propto (MED_{cum})^{\beta-1} (age)^{\alpha}$ } expresses the cumulative risk in terms of these factors (5) where α is a numerical constant associated with the age dependence of the cumulative incidence and β is a biological amplification factor. This relationship applies to the situation where the annual exposure received by an individual remains constant throughout life. Generally exposure does not remain constant - children often receive greater exposure than adults, adults can change their city of residence and their occupation. In order to take this into account this risk equation is modified (6) to estimate the risk of NMSC at age, T, for a given body site as:

$$Risk \propto [MED_{cum}(a)]^{\beta-1} \sum_{t=0}^{T} [MED_{ann}(a) \text{ at age } (T-t)]\ t^{\alpha-\beta}$$

where $MED_{cum}(a)$ is the cumulative effective UVR dose to the skin and $MED_{ann}(a)$ is the annual effective UVR dose to the skin, both being for a given body site. We assume (7) values of α=5 and β =2 as the result of combining the data for SCC and BCC and taking into account that BCCs are about four times more prevalent than SCCs.

Figure 2. shows the increased risk arising from 5 years of overseas service. For Egypt the increased risk of 8% arises from poor protection in a desert environment. For Malaysia (~4°S) the low latitude and poor protection accounts for an increased risk of 60%.

Figure 2. *Effect of overseas service on a veteran. Results show an increase in risk as a result of serving for 5 years in Malaysia or Egypt. Increase is due partly to the higher UVR environment but more importantly to the poor protection practices while serving.*



Protection and behaviour modification

Figure 3 shows that even for an outdoor worker large changes in both exposure dose and risk can be attained with the adoption of even modest behaviour and protection changes.

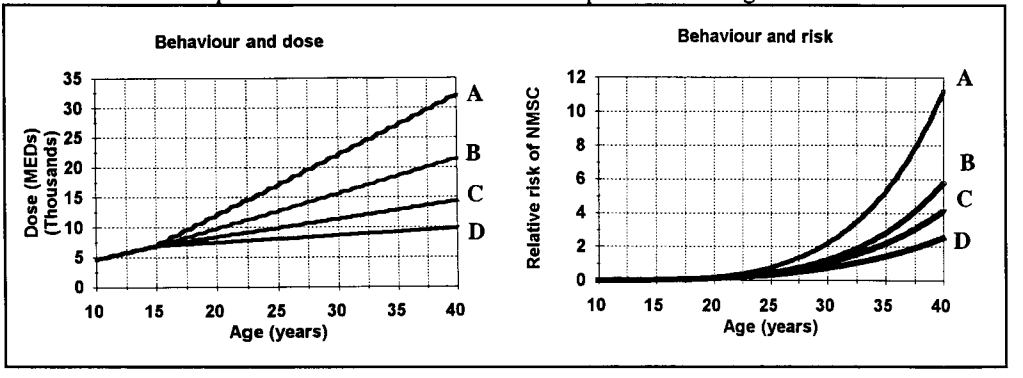


Figure 3. Effect of behaviour change on personal dose and risk of NMSC. A - 100% outdoor worker, unprotected during work and recreation; B - 50% outdoor worker, unprotected; C - as for B but SPF 5 protection during work; D - as for B but SPF 5 protection during work and recreation.

CONCLUSION

The program described has proven to be both user friendly and efficient in evaluating exposure doses and risk of NMSC. Changes in protection and behaviour are readily assessed. Further verification is planned.

THE INFLUENCE OF DOSE DISTRIBUTIONS ON THE RESULT OF UV-BIODOSIMETRY

A. Cabaj,[1] R. Sommer[2] and M. Kundi[2]
[1]Veterinärmedizinische Universität Wien, Austria
[2]Universität Wien, Austria

INTRODUCTION

Disinfection of drinking water with ultraviolet radiation has become a common method in Austria and in many other countries. The water usually is disinfected in flow through systems with low pressure mercury lamps as UV source, which emit predominantly UV radiation with wavelength 253.7 nm. Because of varying residence times of microorganisms and the spacial distribution of fluence rate in the irradiation volume, caused by different distances from the radiation source, by absorption of radiation in the water and by reflexion at the walls of the reactor, the microorganisms passing through in a turbulent flow, receive different fluences. In Austria UV-disinfection plants for drinking water must deliver a minimal dose of 400 Jm^{-2} for radiation of wavelength 253.7 nm (1,2). The fulfillment of this demand is proved during type testing. As dosimeter suspensions of bacterial spores are used whose UV-susceptibility has to be measured in a laboratory irradiation device. The dose, determined in this way, is called Reduction Equivalent Dose (3).

THEORY

If UV-inactivation of microorganisms used as biodosimeter follow first order kinetics their survival rate depends on dose in the following way:

$$\frac{N}{N_0} = e^{-a \cdot D} = 10^{-h \cdot D} \quad (a > 0, h > 0)$$

(N: Number of microorganisms after irradiation, N_0: Number of microorganisms before irradiation, a: UV-susceptibility of microorganisms (base e), h: UV-susceptibility of microorganisms (base 10), D: dose). The Reduction Equivalent Dose (RED) then can be calculated as:

$$RED(f(D),a) = -\frac{1}{a} \cdot \ln\left(\frac{\int_0^\infty e^{-a \cdot D} \cdot f(D) \cdot dD}{\int_0^\infty f(D) \cdot dD}\right),$$

where f(D) is the probability density of the dose distribution. If f(D) is distributed symmetrically, then the expectation value of dose E(D) is equal to the mean value μ of the distribution: $E(D) = \mu$. The expectation value of survival $E(\frac{N}{N_0})$ is:

$$E(\frac{N}{N_0}) = \int_{\mu-k}^{\mu+k} e^{-a \cdot D} \cdot f(D) \cdot dD = e^{-a \cdot \mu} \cdot \int_{-k}^{k} e^{-a \cdot u} \cdot f(u+\mu) \cdot du$$

or, for ξ between 0 and a:

$$E(\frac{N}{N_0}) = e^{-a \cdot \mu} \cdot 2 \cdot \int_0^k \cosh(a \cdot u) \cdot f(u+\mu) \cdot du = e^{-a \cdot \mu} \cdot \cosh(a \cdot \xi)$$

Because of $\cosh \geq 1$ follows:

$$E(\tfrac{N}{N_0}) \geq e^{-a\cdot\mu} \quad \text{and} \quad \mu \geq \text{RED}.$$

If the probability distribution of UV-dose is symmetric, the RED measured with microorganisms with exponential survival rate in general is smaller than the arithmetic mean of the dose distribution.

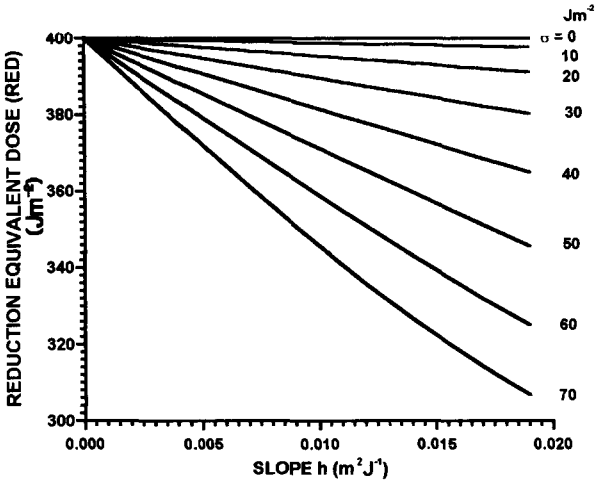

Figure 1. Dependence of RED from UV-susceptibility h of the biodosimeter (shoulder broadness = 200 Jm^{-2}) and from the standard deviation σ of the dose distribution (normal distribution, μ = 400 Jm^{-2}).

MODEL CALCULATIONS

The true shape of the dose distribution among the microorganisms passing a flow through UV-disinfection plant is unknown. Therefore we assumed the presence of normally distributed doses, from which follows:

$$\text{RED}_{\text{norm}}(h,\mu,\sigma) = -\frac{1}{h}\cdot\lg\left(\frac{\int_0^\infty e^{\frac{-h\cdot D}{\lg e}-\frac{(D-\mu)^2}{2\sigma^2}}\cdot dD}{\int_0^\infty e^{-\frac{(D-\mu)^2}{2\sigma^2}}\cdot dD}\right)$$

Integration was performed by numerical methods and in using survival curves with shoulder. We found a decrease of RED for incresing σ, that is for broader dose distributions and for more susceptible biodosimeters (increasing h). If the dose distribution is very narrow (σ very small) no difference exists between the Reduction Equivalent Dose and the arithmetic mean of of the dose distribution. These results are given in Fig. 1.

MODEL EXPERIMENT

In order to prove these theoretical considerations with an experiment we produced suspensions of spores of *Bacillus subtilis* ATCC 6633 with known dose distributions. The spores were cultivated with two different methods (4) resulting in different UV-susceptibilities

h of the microorganisms. The spores were irradiated in a laboratory irradiation device with doses from 200 to 600 Jm^{-2} and with an increment of 50 Jm^{-2}. Distinct volumina of these suspensions were mixed in order to get suspensions with known and symmetric dose distributions. The resulting discrete dose distribution is shown in Fig. 2.

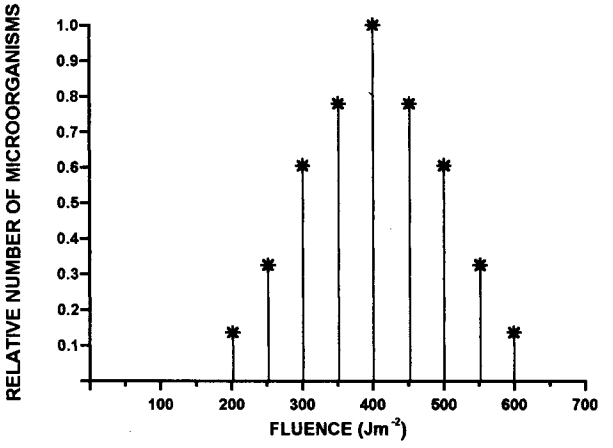

Figure 2. Experimentally produced discrete dose distribution with arithmetic mean $\mu = 400\ Jm^{-2}$.

The REDs following from the survival rate in the experiment were determined and compared with theoretical values. The results are given in Tab. 1. Within the accuracy of the method experimental and theoretical values showed good agreement.

ABSTRACT (See instructions overleaf)

Comparison of hazard evaluation meters and spectroradiometers for the measurement of short wavelength light sources

H. Brusl, N. Winker, K. Schulmeister, K. Duftschmid

In order to protect the health of workers in trade and industry, measurements of short wavelength light are required regularly. As the biological effect on the radiation is strongly wavelength dependent, spectroscopic measurements and subsequent multiplication with the respective action spectrum are performed to calculate effective irradiance. However the measurements are difficult to perform and measurement equipment is bulky and expensive. Instruments are available to measure effective irradiance directly, however in terms of dynamic range, influence of straylight and accuracy, the performance of these radiometers is poor compared to spectroscopic measurements. In order to characterise the usefulnes of hazard evaluation meters for workplace measurements, serveral typical UV and blue liegt sources found in industry have been measured with a double monochromator and the resulting effective irradiane values have been compared with valueus obtained with hazard evaluation meters. The comparison shows that great care has to be taken when performing short wavelength exposure measurements with hazard evaluation meters, as the measured effective irradiance values can differ substantially from the values as measured spectroscopically.

THE STUDY OF PHOTOTRANSFER THERMOLUMINESCENCE IN $CaSO_4$:Dy USING LASER AND ULTRAVIOLET NON-IONIZING RADIATION

Ademar J. Potiens Jr., Letícia L. Campos

Instituto de Pesquisas Energéticas e Nucleares - IPEN
Comissão Nacional de Energia Nuclear - CNEN
Caixa Postal 11049, Pinheiros, CEP 05499-970 - São Paulo, SP - Brazil

INTRODUCTION

Due to the growth of the use of ultraviolet (UV) and laser radiation in industry, medicine and university, the preoccupation with damages from these types of radiation has increased so much. In many establishments the control of health hazards of both laser and radioactive sources is made by the same group, and the possibility of using a TLD system to monitor laser radiation has been investigated (1). If thermoluminescent (TL) materials are preirradiated with known doses of ionizing radiations, the dosemeters are sensitive to laser radiation by phototransferred thermoluminescence (PTTL) and the laser dose can be measured (2). Like in many TL materials, $CaSO_4$:Dy irradiated with high dose of gamma radiation, annealed and exposed to UV and laser radiation, shows phototransferred thermoluminescence. The PTTL is a technique that was developed through the study of light effects in TL materials. The objective of this work is to study the PTTL in $CaSO_4$:Dy using UV and laser non-ionizing radiation The PTTL can be utilised for various dosimetric applications e. g., high dose dosimetry, dose reevaluation, UV and laser radiation dosimetry. The objective of this work is study different parameters of PTTL in $CaSO_4$:Dy using laser and UV radiation.

MATERIALS AND METHODS

Teflon pellets of $CaSO_4$:Dy produced at IPEN weighting 20 mg each,. with a 6.0 mm diameter and a thickness of 0.8 mm were used (3). The pellets were annealed at 300 C during 15 minutes before the gamma and laser or UV irradiations and thermally treated at 100 °C during 15 minutes after laser or UV irradiation.

A source of ^{60}Co with 15.0 TBq was used for sample irradiation. The samples were always irradiated under electronic equilibrium conditions, that is, the samples were placed between 3 mm thick Lucite plates.

The laser irradiation system contains a N_2 pulsed laser of 10 kW with pulse duration of 10 ns and wavelength of 337 nm. The UV irradiation system was composed by a Hg lamp Bausch & Lomb SP-200 and a Kratos GM-200 monochromator.

For the thermoluminescent measurement a Harshaw model 2000 AB TL reader was used. The linear heating rate was set at 10 C.s^{-1}, and the reading cycle was performed within 36 s, with a constant flux of N_2 of 4 l.min^{-1}. Light emission was integrated in the temperature interval between 200 and 360 C.

The pellets were first calibrated with ^{60}Co and selected at a range of 5 % of reproducibility.

Each reported value corresponds to the average of five measurements.

RESULTS

With respect to the laser radiation were studied two parameters:

- The PTTL response with a laser exposure time of 5 minutes as a function of gamma dose of ^{60}Co. It was measured between 10 Gy (10^3 rad) and 65 Gy (6.5×10^3 rad). The results are showed in Figure 1 and it is seen that the response is linear in this interval of measurements.

- The dependence of the PTTL response, using a gamma dose of 30 Gy (3×10^3 rad), with laser exposure time was studied from 5 to 20 minutes. It is seen in Figure 2 that the time of 15 minutes has the greater response and was found to reduce for the time of 20 minutes.

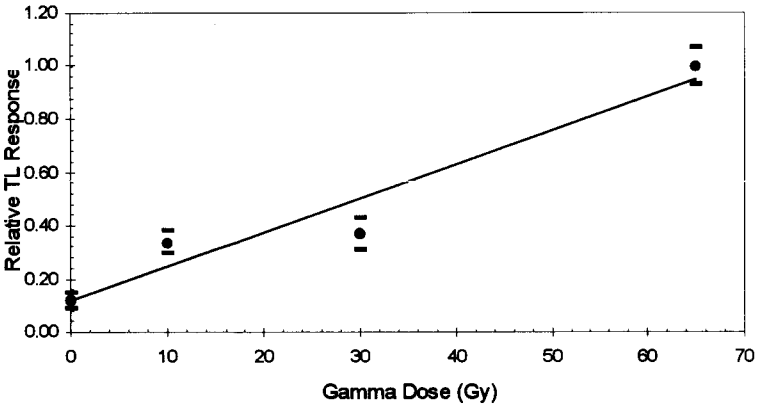

Figure 1. Dependence of TL Response as a Function of the Gamma Dose for $CaSO_4$:Dy

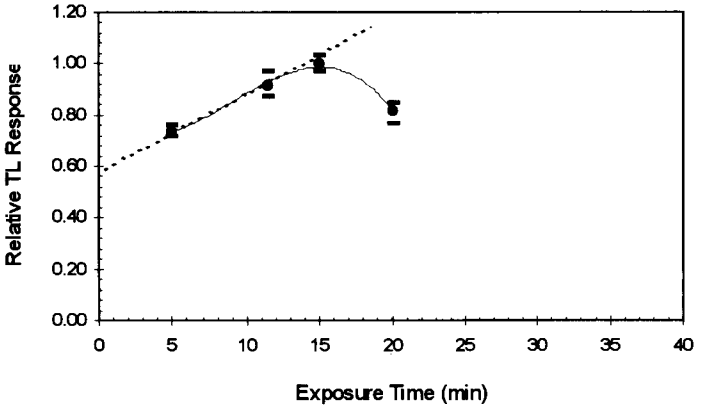

Figure 2. Dependence of TL Response as a Function of the Laser Exposure Time for $CaSO_4$:Dy

For the UV radiation was studied the dependence of the PTTL response as a function of UV exposure time. It was used a gamma dose of 10 Gy (10^3 rad) and a light wavelength of 310 nm and the time range studied was from 5 to 30 minutes. It is seen in Figure 3 that a better response was obtained for the exposure time of 20 minutes and was found to reduce for 30 minutes.

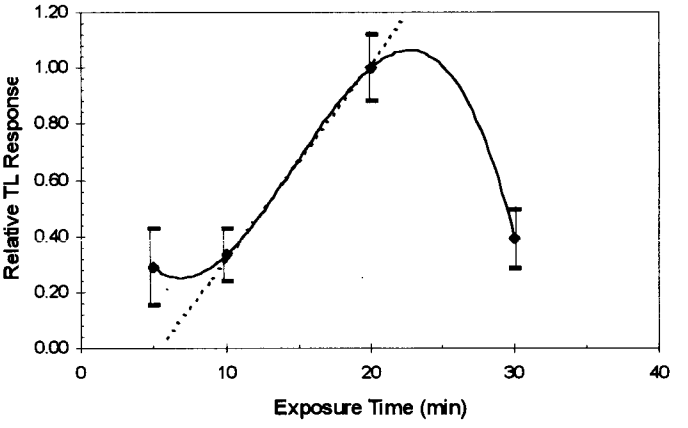

Figure 3. Dependence of TL Response as a Function of the UV Exposure Time for $CaSO_4$:Dy

The curves' behaviour of the figures 2 and 3 can indicate that there is an equilibrium between the population and depopulation of the traps placed in these temperatures. Comparing these two figures it can be seen that both curves are similar, presenting a linear and sublinear range, expected result considering their close wavelength (310 and 337 nm). It is expected that the lower limit for the laser radiation be similar to UV.

The objective of this project is to propose a theoretical model to explain this phenomenon and determine the minimum and maximum detection limits.

CONCLUSIONS

This work can be very useful to those institutions which work with non-ionizing radiation, as laser and UV and these preliminary results show that $CaSO_4$:Dy Teflon pellets present a good performance to PTTL to be used in laser and UV dosimetry and permits to continue this research.

COMBINED TL-ESR MgO DETECTORS FOR UV RADIATION

Vsevolod S. Kortov, I.Milman, A.Monachov

Ural State Technical University, 620002,
Ekaterinburg, Russia

INTRODUCTION

The ever-increasing demand for the control of radiation field parameters, including ultraviolet (UV) radiation, produces a set of problems among which is enhancement of reliability and validity of measurements over a wide dose range including emergency dose control. Real efficiency of the most popular materials used, for example, for thermoluminescence dosimetry, is restricted by the upper level of the measured doses, 10^2 to 10^4 Gy. However, the desired upper level of the dose interval can reach 10^8 Gy at ambient temperatures of up to 500 K (1,2). To solve this kind of problem by thermoluminescence dosimetry only is apparently not possible.

One of the most promising trends in this field is development of new working solid detector substances allowing one to obtain dosimetric information when measuring the parameters of several physical phenomena accompanying the interaction of the radiation with the detector's material. An example of such an aproach in the search for new materials has been given elsewhere (3). The basic physical phenomena used were thermoluminescence (TL) and electron spin resonance (ESR).

The purpose of this presentation is to study the dosimetric properties and operational characteristics of combined TL-ESR detectors for UV radiation on the basis of MgO:Mn, Fe crystals that have been subjected to a special thermochemical treatment (STT).

EXPERIMENTAL

MgO:Mn, Fe single crystals grown by the arc-fusion method contained 0.02 wt.% of Fe impurity. The samples were subjected to thermoreducing treatment in a vacuum oven with a graphite heating unit at 1000 to 2000 K for 1 to 10 h.

The detectors were irradiated using an deuterium lamp ultraviolet light using an interference filter with λ=250 nm or with X-rays from a Mo target tube operating at 55 kV and 15 mA.

After UV or X-ray irradiation the line with g=2.0037 appears in the sample ESR spectra (Fig.1). Lines g_1 to g_6 belong to Mn^{2+} impurity and line A corresponds to Fe^{3+} impurity ions. With thermally treated samples, line A is not observed before irradiation. After irradiation this line appears again and its amplitude increases with the increase of absorbed dose.

In MgO: Mn, Fe the ESR signal with g=2.0037 is known to correspond to the Fe^{3+} impurity ions (4). The TL maximum in the temperature range of 300 to 500 K is brought about by the recombination of thermo-ionizing electrons with Fe^{3+} impurity ions (5). At the same time, thermoreducing treatment of MgO crystals results in the emergence of Fe^{2+} ions and high concentration of electron trapping centers in the samples. During irradiation, electrons liberated from Fe^{2+} ions are captured by centers created as a result of the treatment, which leads to higher concentration of Fe^{3+} ions and, accordingly, higher ESR signals. When annealing thermo-ionizing electrons recombine with Fe^{3+} ions, this results in the ESR signal drop in the temperature range 350 to 450 K and appearance of the TL maximum. When the

anneal temperature increases to 950 K, the ESR signal drops rapidly in the temperature range 350 to 450 K and more slowly in the temperature range 450 to 950 K, until the signal disappears completely at 950 K.

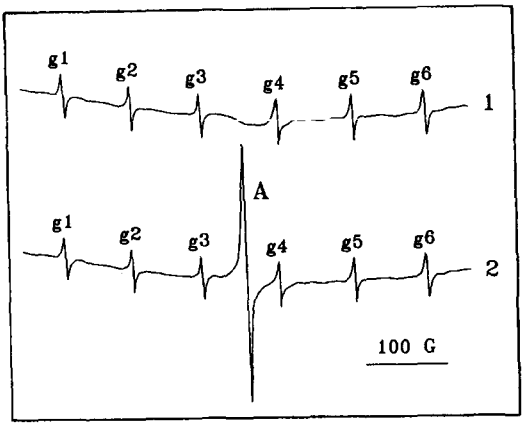

Figure 1. ESR spectra from virgin MgO:Mn, Fe single crystals (1) and crystals subjected to special thermochemical treatment (1) after (2) and befor UV or X-ray irradiation.

The ESR signal of Mn^{2+} ions does not change when irradiating and annealing. The fact that the ESR signal of thermally treated MgO:Mn, Fe crystals cannot be annealed even at high temperatures allows one to use them for measuring radiation dose at high temperatures. The dose dependence of the ESR signal of crystals irradiated at 570 K is linear in the range of 3 to 3×10^2 Gy. Under UV irradiation, the TL intensity dose dependence is linear in the irradiance range 10^{-1} to 10^3 $\mu J\cdot cm^{-2}$ (Fig.2, curve 1). The ESR signal is registered starting from irradiances of 2×10^2 $\mu J\cdot cm^{-2}$ and grows in a linear fashion with irradiance from 10^3 to 10^5 $\mu J\cdot cm^{-2}$ (Fig.2,curve 2). During the available time, the ESR signal did not reach saturation.

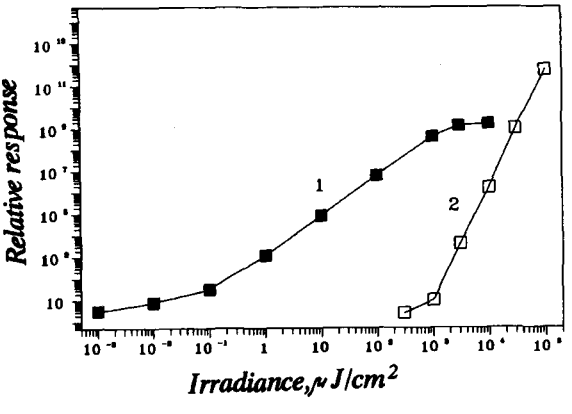

Figure 2. Irradiance dependence of the TL intensity (1) and ESR signal (2) of MgO:Mn, Fe single crystals due to UV irradiation.

Thus, MgO:Mn, Fe single crystals or ceramics can be used as combined TL-ESR detecting media after reducing thermochemical treatment.The main features of this material are the following:

1.High reliability and validity of dosimetric measurements due to readout of information from one and the same sample using two independ methods (TL and ESR).

2.Possibility of repeated reproduction of dosimetric information by the ESR signal after TL readout and influence of high temperatures ($T < 800$ K) on the sample.

3.High sensitivity and wide range of registered doses for dosimetry of UV radiation. The total range of registered irradiances using ESR and TL exceeds 8 orders of magnitude (the low level is 10^{-3} $\mu J \cdot cm^{-2}$; the upper level is greater than 10^{5} $\mu J \cdot cm^{2}$).

4.Possibly of enhancing the accuracy of dosimetric measurements for the ESR signal registration when reading out information by the ratio of the intensity of the Fe^{3+} ion line to the intensity of Mn^{2+} ion lines, whose parameters remain stable when irradiation and annealing.

5.Possibility of pre-adjustment of the TL reading devices, according to the results of ESR measurements.

6.Possibility of evaluating the current dose by the TL output and dose accumulated over a longer period of time (month, year) by the ESR output.

CONCLUSION

It can be said that the combined TL-ESR MgO:Mn, Fe detector can cover irradiance ranges of particular interest, such as erythermal dose for skin (16 $mJ \cdot cm^{-2}$) or also lower values which can be used in biological research.

INTRODUCTION

The current laser safety standards do not define the exposure limit values for pulsewidth less than one nanosecond. It has been hypothesized that one cannot extrapolate from longer pulse widths because the ultrashort pulse contains high peak power and may induce non linear effects. These effects may involve fundamentally different mechanisms of damage particularly for repetitively ultrashort pulses (1-2). Most laser safety documents advise the laser user that caution must be used in the evaluation of exposure to repetitively pulsed radiation since they are only limited data on multiple pulse exposure criteria. The empirical multiple pulse formula is based on some data indicating that there is generally a cumulative effect in multiple-pulse exposures. No data exists in the litterature concerning the histological effects on the retina of ultrashort pulses delivered with a high repetition rate (3). The aim of this work was to study the evolution of single retinal lesions after exposure to trains of picosecond laser pulses. The experimental approach we have developped corresponded to :
1) observation of 100 µm thick and to characterize lesions by fluorescence microscopy after different specific stainings,
2) epoxy resin embedding of lesion areas for further studies by light and standard electron microscopy.

METHODS

The experimental system is a dye laser pumped by a mode locked pulse compressed, frequency doubled Spectra-Physic Nd:YAG laser. The pulsewidth was 8.10^{-12} s. The pulse repetition rate used in these experiments was 1 million pulses per second (1 MHz) and the number of pulses included in the train was 200,000 pulses. The wavelength at the output of the dye laser is 590 nm. A sample of the laser beam at 590 nm was deflected onto an autocorrelator which measures the pulsewidth and onto a photodiode and a calorimeter which measure the energy. The animal used in the experiments was the rabbit Fauve de Bourgogne because the average ocular transmission and absorption characteristics are very similar to the human ocular media for the visible spectrum (4). The theorically expected spot size formed on the rabbit retina with the dye laser optical system was about 30 µm. To aid alignment of the animal's eye, a 1 mW HeNe laser was mounted co-axially with the main laser beam path. Rabbits were anesthetized with intramuscular injection of ketamine hydrochloride (10 $mg.kg^{-1}$), placed on a stand permitting us to produce in most cases retinal lesions aligned on the visual streak. The pupils were dilated before to exposure, and the eyelids were held open with

a wire speculum. 3 to 5 lesions were produced in each eye which were distributed over about 1 cm^2 area to overcome interactions. Animals were killed 4.5, 24, 48 and 96 hours after exposure. Retina were fixed overnight with 2% glutaraldehyde 2% paraformaldehyde in buffered solution (0.1 M cacodylate pH 7.3) after gradual dissection of the eye immersed in the fixative. The exposed area was cut, treated during at least 2 hours in the buffer containing 10% saccharose and 10% DMSO before freezing. Nuclei were stained with propidium iodide (PI) which allows to identify easily condensed DNA in apoptotic cells and a O-Gal residues were stained by bandeiraæ simplicifolia lectin labelled with FITC which visualizes blood vessels and macrophages (5). The treatment and procedures used in this study conformed to the European Community Guidelines on Animal Experiments.

RESULTS

Light microscopy

Injuries induced by higher energies (Total intraocular energy > 3 mJ) could produce damaged areas larger than the retinal spot size of the laser beam. The swelling and rising of the retinal layers permite to identify easily the damaged area (6). The common observations are:

- the Brüch's membrane appears undamaged,
- the retinal pigment epithelium is disturbed: the repartition of the melanin granules is inhomogeneous,
- the outer plexiform layer is dammaged with an area of vacuolization.

At the opposite, for smaller energies, the damaged area corresponding to the threshold values cannot be easily determined because pathologic changes are very subtles.

Confocal microscopy

The retinal image diameter of the beam was 15-30 µm whereas the diameter of the early œdema detected by fluorescein angiography during the first hour post treatment was 150-200 µm.

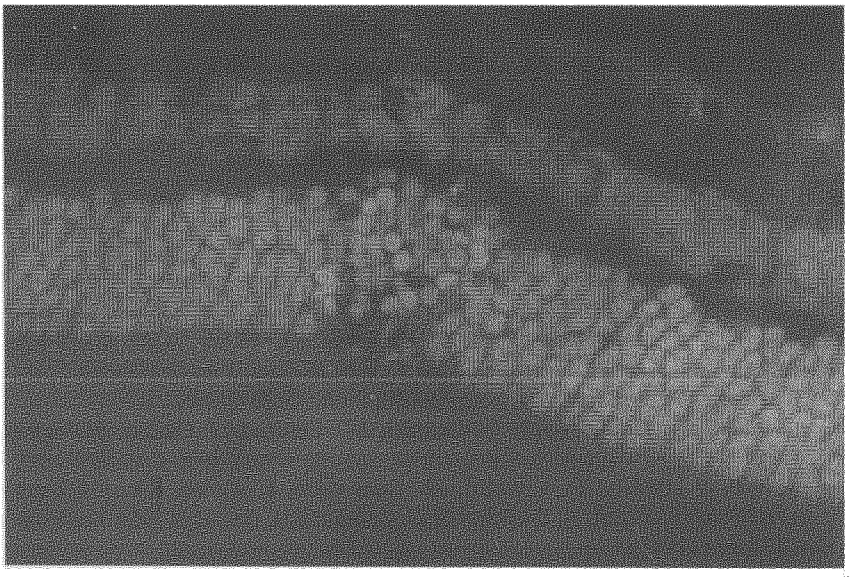

Figure1. Retinal damage induce at the outer nuclear level detected by confocal microscopy with propidium iodine staining (590 nm 200,000 pulses, 1 MHz, TIE ≈ 3 mJ).

Lower injuries can be detected within 50 to 100 µm thick. The technical choice of specifical stainings permited to visualize the damage induced to the inner grannular layer, the pigment epithelium and the choroid. The mixture PI-Lectin permited to observe picnotic or apoptotic nuclei. Preliminary results are given in the Table I. The homogeneously distributed apoptotic cells were confined to focal lesions in the outer nuclear layer after 4.5, 24 and 48 hours respectively. Macrophages were the only inflammatory cells in these lesions and were mainly involved in tissue repair by phagocytosis of apoptotic bodies and altered segments after 24 and 48 h. Only a few macrophages were encountered per lesion (<10).

Delay post irradiation	4h 30	24h	48 h
Diameter of the lesion	78 to 87 µm	84 to 100 µm	45 to 54 µm
Number of macrophage	0 to 1	0 to 1	2 to 4
% Apoptosis	20%	80%	10%

Table I. Evolution of the lesional parameters at different delays post laser irradiation.(590 nm 200,000 pulses, 1 MHz, TIE ≈ 3 mJ)

Electron microscopy

Each lesion were studied by confocal microscopy and some of them thereafter by electron microscopy. Inflammatory process could be induced by ultrashort pulses laser irradiation. Inflammatory cells such monocytes, polynuclear cells were observed at the junction of inner and outer segments. Cellular alterations were detected in the outer nuclear layer very similar to those observed during the cellular death induced by apoptosis (5). Electron microscopy allowed to characterize at 4.5 h pigmented epithelial cell alterations and to observe intralesional unphagocyted material up to 48 h. No lesion were detected after 96 hours suggesting a nearly complete repair.

Acknowledgments-This study was supported by contract 94/001 from the Direction des Recherches Etudes et Techniques du Ministère de la Défense.

ABSTRACT (See instructions overleaf)

With laser materials processing, direct exposure to the laser beam is usually not the main hazard. The high power laser beam is enclosed up to the surface of the workpiece and the workstation is usually shielded. Secondary hazards such as UV-radiation, ozone and fume produced by the laser-workpiece interaction are more serious due to the every-day, long term exposure of the worker.

In this paper, results of spectroscopic measurements of the secondary optical emissions associated with CO_2 laser welding of steel and aluminum will be presented. Spectral measurements of the plasma emission at a distance of 50 cm showed that the allowed dose for UV-radiation and short wavelength visible light ("blue light hazard") per work day can be exceeded in as short as a few seconds and tens of seconds, respectively. Particularly high exposure levels were found when the welding process became instable and plasma shielding occured. Model calculations showed that the plasma temperature is at the order of 13,000 K, hence the maximum of the spectral irradiance is in the UV region. The visible part of the radiation is relatively low, which could cause a feeling of false security, because it possible to look into the plasma without closing the eyes.

BIOLOGICAL RESPONSES OF NIH 3T3 TO 193 NM EXCIMER LASER IRRADIATION. COMPARISON WITH 254 NM IRRADIATION.

1. INTRODUCTION

During conventional UV radiations, activation of genes is tightly linked to the presence of DNA damages. At 254 nm, the major cellular chromophore is the nuclear DNA, with cyclobutane pyrimidine dimers being the major photoproduct (1,2). At 193 nm, DNA is more strongly absorbing than at 254 nm. However, the quantum yields of the photoproducts induced at these two wavelengths are different (3) and damage to cellular DNA in the form of pyrimidine dimers or single-strand breaks was reported to be only marginal or undetected (4,5). Peptide bonds, many amino acid side chains, insaturated lipids, esters, and other cellular molecules absorb at 193 nm (6,7). Consequently, the most of the energy is thought to be absorbed by proteins, leaving the DNA shielded. About 60 % of the radiation can apparently be blocked by 1 µm of cytoplasm (8). However, exposures of cultured human fibroblasts to subablative doses of 193 nm laser radiation resulted in changes of genes expression such as collagenase, metallothionein and *c-fos* (9). The mechanisms by which the 193 nm radiation affects gene expression are not known. The site of primary interaction of the radiation could be different from the site of the genetic response. Thus, the signal transfer could pass through the cytoplasm via the nucleus. One hypothesis is that cytokines may regulate the transduction pathway event. By example, the TNF-alpha which is induced by UV-radiations (10). More, it can activate transcription factors such as AP-1 or *c-fos* and stimulate the growth of normal fibroblasts (11). Moreover, TNF-alpha plays a major role in the inflammatory processes by enhancing the remodeling of extracellular matrix (12,13) in which mainly matrix metalloproteinases and collagenase participate. Besides, matrix metalloproteinases are responsive to cytokines and particularly the 92 kDa gelatinase (gelatinase B or metalloproteinase 9 or MMP 9) is induced and regulated by TNF-alpha (14).
To understand the cellular response to high energy laser radiation, we investigated cell proliferation and cell activation. The results showed a decrease of the cell proliferation and an increase of the cell activation. These variations are more marked after the irradiation at 193 nm. In addition, we have quantified the variations of TNF-alpha and gelatinase B in supernatants of fibroblasts irradiated with 193 nm laser radiation or 254 nm conventional UV radiation. The results showed that both wavelengths caused increased rate of TNF-alpha and of the gelatinase B (expressed under two forms, latent and active) but the laser was significatively more efficient.

2. MATERIAL AND METHODS

2.1. *Cell cultures*

The mouse fibroblasts NIH 3T3 cells obtained from American Type Culture Collection were grown in RPMI 1640 medium containing 10% of decomplemented fetal calf serum (FCS - Boehringer Mannheim), 20 mM L-glutamine and 100 µg of antibiotic mixture (penicillin, streptomycin, neomycin - Gibco-BRL) at +37°C in 5% CO_2. Two days before irradiation, $1.5 10^6$ cells were plated into 8.5 cm diameter plastic tissue culture dishes (Falcon). Prior to irradiation, the medium was removed and the cells rinsed with phosphate-buffered saline (PBS-Boehringer Mannheim). Irradiations as well as sham exposures of controls (zero dose) were performed in the absence of any solution, with plates held either vertically in the case of laser irradiations or horizontally in conventionnal UV irradiations. After irradiation, cells were plated for 8 hours into 96-well plates at 10^5 cells /well, with 200 µl medium per well.

2.2. Irradiations

Laser irradiations were performed with a SEL 520 SOPRA excimer laser at 193 nm (ArF), with nominal pulse duration of 13 ns. Laser beam was defocussed to illuminate an 8.5 cm diameter cell culture plate (56.7 cm^2) held vertically. The energy per pulse, measured with a joulemeter Molectron JD2000 detector, was 57 mJ/pulse, corresponding to a peak irradiance of $7.7\ 10^8$ W/m^2. Cells were exposed to fluences of 10, 50 and 120 J/m^2 by varying the number of pulses delivered with 1 Hz repetition rate. Irradiations at 254 nm was performed with a Bio-Sun system (Vilbert-Lourmat) where UV energy, delivered by 3 UV-VL20 lamps with a constant irradiance of 4 W/m^2, is controlled by microprocessor.

2.3. *Cell proliferation*

Cell proliferation was assessed by (methyl-^{3}H) thymidine incorporation.

2.4 *Cell activation*

A tetrazolium colorimetric assay, using the dye MTT [3-(4,5-dimethylthiazol-2yl)-2,5-diphenyltetrazoliumbromide], measures the reducing ability of mitochondrial enzymes.

2.5 *Quantification of total proteins*

Total proteins was quantified according to the sensitive method described by Bradford (15).

2.6 *Quantification of TNF biological activity in culture medium*
TNF-alpha secretion was measured by a biological activity test using actinomycin-D-treated L-929 cells as described by Fish and Gifford(16).
2.7. *Gelatin zymography*
Gelatinolytic activity was performed in cell supernatants as described by Heussen and Dowdle (17).
2.8. *Statistical analysis*
It was performed according to Student'st-test for unpaired data (StatView II software, Abacus concept Inc., Meylan, France). $p < 0,05$ was considered significant.

3. RESULTS
3.1. *Number of cells*
The number of cells was measured immediately and 8 hours after the irradiation. At 193 nm, the number of cells decreased sharply in a dose-dependent manner. The most pronounced decrease was observed 8 hours after the exposure. At 254 nm, a similar dose-dependent decrease was measured 8 hours after irradiation. A high mortality of cell (36%) was detected at 120 J/m^2 at 193 nm just after the irradiation, a smaller one was seen (15%) 8 hours later at the same dose. In opposite, at 254 nm no mortality was observed at any dose just after the irradiation and 8 hours post-irradiation, the cell mortality detected was at 8%.
3.2. *Cell proliferation and activation*
The proliferation of NIH 3T3 cells is markedly reduced, reaching about -75% at 120 J/m^2 after each kind of irradiation. In return, both wavelengths induced a dose-dependent cell activation in irradiated cells but the augmentation was about 2.4-fold greater after 193 nm laser exposure than after 254 nm irradiation at 120 J/m^2.
3.3. *Quantity of total proteins*
The wavelength of 193 nm induced a dose-dependent increase of the amount of total proteins in irradiated cells. Even though at 254 nm the increase was not significant between 50 and 120 J/m^2. The increase was 1.6 times greater after 193 nm laser irradiation than after 254 nm at 120 J/m^2. Irradiations induced cycloheximide-dependent increase amount of protein.
3.4. *TNF-alpha and Gelatinase B activity* (Figure 1)
A large dose-dependent increase was observed after 193 nm irradiation. In contrast after 254 nm irradiation, no increase was detectable except for the fluence of 120 J/m^2 but the TNF activity was 2 times lower. Both irradiations at 193 and 254 nm cause a significant and dose-dependent increase of both latent and active forms of excreted gelatinase B. The proportion of the two forms was identical but the augmentation was about 2.1-fold greater after 193 nm laser exposure than after 254 nm irradiation at 120 J/m^2.

4. DISCUSSION
To our experimental conditions, an important cell mortality is induced only by 193 nm laser radiation. This suggests that radiation damage induced by laser 193 nm exposure differs from that of 254 nm radiation. At 193 nm, the maximal contribution of radiation injury to cell death was observed immediately after irradiation. Cells either are too injuried and died within minutes, or are not damaged enough and survive after repair. At 254 nm, a wavelentgh which is known to produce DNA damages, no immediate cell death was observed and mortality was still low 8 hours later. The nuclear damages occuring at 254 nm irradiation do not induce an immediate cell death. Then, the cell mortality observed within minutes after irradiation may likely originate from an alteration of the cell membrane. The high absorption by cytoplasm and membrane proteins may account for the damages induced by 193 nm photons and the high cell mortality observed immediately after laser exposure. The decrease of the cell proliferation is important after 193 nm radiation. Cell activation which was really important after 193 nm irradiation, as shown by the cycloheximide dependent increment of total proteins. This suggests that cells have tried to repair their damages. This effect on cell activation is different from the one published by Kochevar and al, (18) who found a dose-dependent inhibition of the MTT reduction. Cell activation is increased and could be due to the increment of TNF-α which is involved in gene expression regulation and proteins synthesis. Indeed TNF-α ellicit a rapid induction of *fos* mRNA (19) and, it is well known that activation of *fos* is part of a typical response of mammalian cells to UV-C light (20). Our results confirm this *fos* induction which occur in fibroblasts following irradiation at 193 nm. The level of TNF-α could be considered as a parameter permiting to evaluate the damaging effect of 193 nm photons on the plasma membrane because it may be related to the change of arachidonic acid metabolism occurring in the altered plasma membrane (21,22). Kochevar and al, (18) have demonstrated an increase in cell membrane permability associated with a release of arachidonic acid within 15 minutes after exposure to 193 nm radiation whereas exposure to 254 nm radiation did not cause this release. They suggest that plasma membrane damage induced by 193 nm radiation was obvious from the release of arachidonic acid. This release of arachidonic acid observed by Kochevar and al, and the secretion of TNF-α in cell supernatants measured in our experiments seem to occur at approximately the same fluences (23) shown that arachidonic acid which is also released in response to TNF, induced *c-fos* mRNA. Furthermore Gelatinase B, involved in the degradation process of basement membrane, is more expressed after laser exposure, supposed to be changing the cell adhesion process. The results indicated that the 88 kDa active form which is involved in the TNF-α activation was specifically increased after 193 nm laser irradiation. However, the quantification of TNF-α biological activity in cell supernatant could be originated from the membrane compartment release from

damaged cells by 193 nm photons. The Gelatinase B increase could be also induced by extra cellular TNF-α but cell activation observed with the lowest fluence suggest that the origin of the quantified TNF-α did not only issue from membrane compartiment of dead cells. Moreover, the 88 kDa active form of Gelatinase B contribute to increase the quantity of TNF-α produced in surviving cells.
Thus, the results suggest that the plasma membrane is the site of the primary damage in cells exposed to 193 nm laser radiation. The mechanism of interaction between 193 nm photons and the plasma membrane is unknown but the primary effects of the 193 nm radiation are a cell activation, a more important expression of Gelatinase B and of TNF-α. This latter cytokine could be the signal of induction from the plasma membrane to the nuclear transcription factors of genes whose expression was specifically changed by 193 nm laser radiation.

Quantitative risk assessment - an alternative approach to laser safety?

Bob Gardner [1]
Peter A Smith [2]

[1] Directorate of Defence Health and Safety, MOD, Aquila, Golf Road, BROMLEY, BR1 2JB, UK
[2] Defence Research Agency, Centre for Human Sciences, FARNBOROUGH, Hants, GU14 6TD, UK

Introduction

The current international laser safety standard (IEC 825) gives a system of laser classification based solely upon the laser parameters without reference to the intended use. The procedure makes pessimistic assumptions to arrive at a "safe" classification related to the maximum hazard.

Hazard [1] *A hazard is something with the potential to do harm*

The manufacturer's requirements and the user guidance go on to manage the hazard by mitigating the potential for harm of higher classifications by introducing interlocks etc. Risk management is not considered in current laser safety standards.

Risk [1] *Risk expresses the likelihood that the harm from a particular hazard is realised*

It can be argued that the classification should also be based upon the intended use to which the laser will be put. The basis for this type of hazard analysis would have to be a risk assessment. Such a system of classification has an obvious advantage in that it would allow a wider variety of products to fall into the lower classes by virtue of their low risk.

This idea is attractive but the authors have reservations about its practicability. There are many different possible methods for making a risk assessment which vary in complexity and in the criteria used. It is difficult to see how a laser standard could adequately specify risk assessment techniques which are suitable for use in any and all situations. Furthermore, labelling would have to ensure that the intended use was unambiguously identified.

Such a system can only be necessary if classification is used as an overriding indicator of "safety", which currently it is not. It is risk that indicates the level of safety, being related to both the harmful consequences and the likelihood of occurrence.

Legislation and Risk Assessment

In 1974 the Health and Safety at Work etc Act (HSWA) came into force in the UK. This Act places duties on employers in respect of their employees and other persons (eg visitors and the general public etc) affected by work activities. The UK Ministry of Defence (MOD) is not exempt from this Act or Regulations which are made under it.

These impose on UK employers a "duty of care" to their employees (in the case of MOD this includes its sailors, soldiers and airmen) and the requirement to provide "a safe place of work" under HSWA. In addition they have to abide by the specific Regulations. MOD can seek exemptions from these on grounds of national security. However, it is policy to use this provision sparingly and only where truly essential and not for administrative convenience.

A European Union (EU) Directive caused the Management of Health and Safety at Work Regulations 1992 to be made in the UK. These require employers to assess all risks in the workplace even where specific Regulations do not exist. Similar regulations should also exist in all EU member states. In making such assessments MOD conforms to national or international standards and guidance wherever practicable. The assessment must be recorded if the risks are "significant". Assessments are open to inspection by the enforcing authority for the legislation, in the UK this is the Health and Safety Executive (HSE). After inspection HSE may instruct the MOD to make improvements or prohibit the practice.

In most cases quantitative risk assessment (QRA) will not be required to demonstrate safety. The deterministic methods used in current laser safety standards will be quite adequate. However, in some cases, deterministic methods lead to unrealistically large, and therefore unduly restrictive, hazard areas [2]. Where these exist QRA may be justified depending upon the complexity and the resources needed to carry it out.

Quantitative risk assessment - an example

Current laser safety standards are based upon preventing an exposure above the level of a Maximum Permissible Exposure (MPE). There is an implicit assumption made therefore that circumstances can be arranged such that this can be guaranteed.

When one considers a class 3B laser rangefinder, being operated from an aircraft, the opportunities for failure make such a guarantee is difficult to give. Figure 1 illustrates the off axis angular limits of a forward firing laser rangefinder being used with the Nominal Ocular Hazard Distance (NOHD) to sweep out a deterministic laser hazard area trace (LHAT).

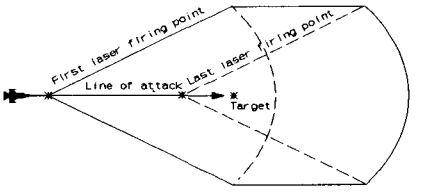

Figure 1 - Deterministic Laser Hazard Area Trace

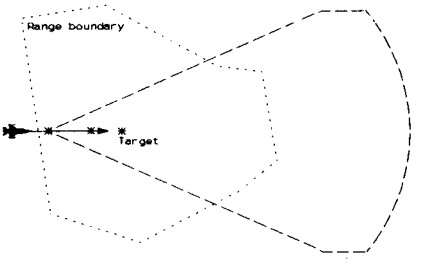

Figure 2 - Deterministic LHAT and range boundary

Often the deterministic LHAT may extend beyond the range boundary, Figure 2, and thus appear unacceptable. This certainly occurs in the UK and Europe, but perhaps not in the US or where ranges cover larger areas.

Under these circumstances a question needs to be answered - "what is the risk?" MOD uses QRA[3,4] to investigate the probability that the laser would in fact point at anything other than the target and the consequences if this should happen.

The elements used in the QRA are:

- equipment performance and fault condition parameters
- an eye damage model for the wavelength concerned
- atmospheric models for scintillation and absorption
- population models for the areas around the range

Since the MPE is an exposure at which no harm is caused it is more appropriate to use another criterion to assess the risk of harm. The eye model therefore uses the "minimum ophthalmoscopically visible lesion" (MOVL).[5]

Using a risk of 1 in 10^8 MOVL per attack the LHAT obtained is typically of the form shown in Figure 3. It has 2 components made up of a fault-free LHAT and a fault condition LHAT.

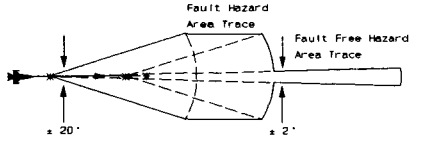

Figure 3 - Components of a QRA LHAT

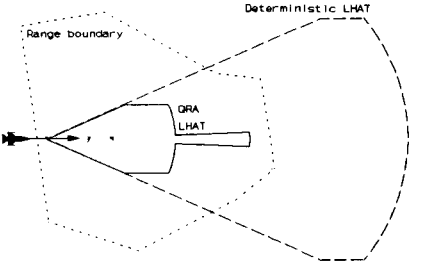

Figure 4 - Deterministic and QRA LHATs compared

It is usual that the QRA LHAT obtained by combining both the fault and fault-free LHATs is contained within the range boundary. Figure 4 illustrates this by overlaying the range boundary with both the deterministic and QRA LHATs.

Consideration of the Extended NOHD and the equivalent probabilistic modelling are beyond the scope of this paper. Never the less, the possibility of persons using binoculars is modeled and contained within the overall

risk criterion endorsed by MOD of 1 in 10^8 of achieving a MOVL per attack. Particular attention is paid to areas where the probability of binocular use is high, e.g. bird sanctuaries etc.

Tolerability of risk

The risk of 1 in 10^8 MOVL compares favourably with some other figures quoted by HSE[6], particularly as it is non-fatal:

Levels of fatal risk per annum (average figures, approximated)

1 in 100	risk of death from five hours of solo rock climbing every weekend
1 in 1000	risk of death due to work in high risk groups within relatively risky industries such as mining
1 in 10 000	general risk of death in a traffic accident
1 in 10 000	risk of death in an accident at work in the very safest parts of industry
1 in 1 million	general risk of death in a fire or explosion from gas at home
1 in 10 million	risk of death by lightning

or indeed the results from practical examples of QRA:[7]

- 1 in 10^6 per 8 h shift for failure of 3 safety interlocks on an injection moulding machine (usually non-fatal)
- fatal risk of 1·5 in 10^9 per hour of winding of a coalmine elevator (carried out after an accident caused 18 fatalities and which caused improvements to be made)

It might be suggested that the figure of 1 in 10^8 MOVL is impossibly small to be used as a practical estimate of risk. The authors tend to agree, but argue that while it may not be useful as an absolute measure, it is useful as an quantitative indicator of relative risk. So although it may not be combined with other estimates of risk, eg aircraft crash probability, to give an overall mission risk, it does indicate that laser safety is a minimal factor. In a similar way the authors would argue that such an assessment cannot and indeed should not seek to include factors for deliberate or negligent misuse of the laser. Consideration should certainly be given to the prevention of such occurrences and measures may need to be taken to prevent them, ie by adequate pilot/navigator training and supervision, backed by good design. However, unless they are shown to be reasonably foreseeable, they should not form part of the laser safety risk assessment.

The future

Current legislation and the regime of enforcement in the UK are adequate to enforce laser safety. QRA as a technique to assess the tolerability of risk is in use by both MOD and UK industry in various areas of safety.

The enforcing authority, HSE, recognise this and give guidance on its use:[8]

> "Assessing risks is necessary in order to identify their relative importance and to obtain information about their extent and nature. .....
>
> Risk assessments should be carried out by competent people, and professional health and safety advice may be necessary in some cases, especially in the choice of appropriate QRA techniques and the interpretation of results."

Specific laser safety legislation based solely upon MPEs would therefore, in our opinion, be too restrictive. If proposed EU legislation[9] on physical agents continues to call solely upon the European Standard or anything similar, MOD must seek to ensure that its current techniques and safe practices are not unduly affected. The authors suggest that industry and other users might also wish to preserve the flexibility of approach offered by risk analysis which does not either degrade or prevent the improvement of laser safety.

MODIFICATION OF RADIATION-INDUCED MEMBRANE AND CELL DAMAGES BY HALOGEN-CONTAINING COMPOUNDS (HCC)

A.V. VOROBEY, S.V. PINCHUK, N.A. SHUKANOVA Institute of photobiology, Academy of Sciences of Belarus, Minsk,Belarus

It was found a strong increase in UV-radiation (270-300 nm) induced destructive damages of proteins, lipids, and isolated membranes of blood cells and lysis of the cells in the presense of some HCC polluting the environment.The investigations carried out on model systems (tryptophan and protein in solution) indicated that HCC promote the photo-induced breakdown of indol ring. According to chromatographic and spectral characteristics the products formed under such conditions are distinct from earlier known those of tryptophan destruction. The studies on artificial lipid and cell membranes showed that under absorption of UV-radiation of ecological range (λ > 300 nm) they are capable to play a role of"inside" photodynamic sensitizers.In the presence of HCC non-connected with the products indicated an increase in photo-induced oxidation of lipids also takes place. This effect was observed on native membranes, but not on liposomes. The form and maximum position of the action spectrum of this process evidence the involvement of protein tryptophan residues and a certain contribution of photodestruction of α-tocopherol. Similar increase in cell membrane damage in the presence of HCC was registered under ionizing radiation action.The problems of potential danger of discovered modification of radiation-induced damages of cell membranes in functioning cells and organisms under conditions of technogenic environment pollution, augmentation of near-UV component of solar radiation reaching the earth surface and increased radiation background are discussed.

NON-IONISING RADIATION: EXPERIENCE OF COMMUNICATING THE HAZARDS

R Hill
National Radiological Protection Board, Chilton, Didcot, Oxon, UK

ABSTRACT

Scientific advice relating to non-ionising radiation protection, partly through necessity, contains a degree of scientific terminology. The advice has to be directed at a variety of audiences including users and members of the public, many of whom may not be familiar with scientific terminology. This paper presents NRPB's practical experience of effectively conveying this advice to the various audiences.

INTRODUCTION

The study of human interactions with non-ionising radiation and the determination of any deleterious health effects which may arise as a result of this interaction is complex, involving scientists from a wide variety of disciplines. In such a multi-disciplinary scientific environment the language used to communicate ideas and express opinions must, through necessity, be technically precise and rigorous. It is perhaps to be expected that when such a community concludes its work, reaches a considered opinion and proposes its views as best current scientific advice, the advice is phrased in the same language. Here lies a basic problem. If communication, whether written or verbal is to be effective it must be understood by its audience; and specialist scientists form but a small part of the overall audience.

The National Radiological Protection Board is responsible for the provision of advice to Government Departments of the United Kingdom, to corporate bodies and to members of the British general public in relation to protection against the hazards of both ionising and non-ionising radiation and it is with this large audience that the Board must communicate. Resources are finite and must be used in the most effective manner. This requires the various audiences and their needs to be clearly identified. The Government is perhaps the focus for the Board's formal advice on standards, but this paper focuses on three audience groupings; the radiological protection community; the general public and the users (employers and employees), principally the latter group. A number of approaches will be explored as will the interaction between these audiences.

RADIOLOGICAL PROTECTION PROFESSIONALS

Radiological protection professionals are in the best position to receive advice from the Board in its formal advice format. The Documents of the NRPB is the current route by which the Board promulgates its formal advice on non-ionising radiations (1-3). These publications are supported by the NRPB Report and Memorandum series where the research results are more extensive, and by peer-reviewed scientific papers in the open literature. These and various specific meetings provide the mainstream, of communication for those at the forefront of non-ionising radiation work. However, account also has to be taken of the radiological protection professionals whose background and training has focused on ionising radiations and who have had their area of expertise extended either by design or evolution to include non-ionising radiations.

Training can be a very effective form of communication, whether by directly training the individual or by training the trainers. The Board offers two professional-level training courses: the Advanced Radiological Protection (ARP) course aimed at the seasoned radiation safety professional, and the Post Graduate Radiological Protection (PGRP) course aimed at meeting the early training requirements of those embarking upon a career in radiation protection. Board staff, and invited speakers, communicate directly with the radiological protection community, influencing current thinking, promoting consistency and the development of a common approach in addressing radiological protection matters. Whilst still dominated by ionising radiation matters, the non-ionising radiation content is increasingly important.

The Board also provides a series of scientific seminars and produces a monthly Radiological Protection Bulletin, in which non-ionising radiation topics figure prominently.

GENERAL PUBLIC

Before looking at what may appear to be the next logical group, the users, it is necessary to first consider the general public. This is because the users, ie the employers and employees, are of course also members of the general public and will often reflect the generally held perceptions.

The public receive most of their information about non-ionising radiation and its potential health effects from the media. The information will be acquired by the media from press releases, high profile activities arising from litigious matters and from published scientific reports and papers. Again we come back to the basic problem that the source material is in a highly technical form and needs to be translated into plain language that allows the public to relate the potential hazards to their own experience. This process may be helped through press releases and briefings, and by providing radio, television and press interviews. This can be resource intensive, but it is necessary in order to provide a careful blend of scientifically accurate information and summaries in plain language. How this is used is another matter; the media has its own priorities that sometimes lead to selective presentation of information, sometimes producing a skewed or alarmist view of things. Nevertheless there are many balanced and thoughtful articles and programmes. Wishing away the bad bits is unproductive: we simply have to recognise realities and continue to influence the media in as honest a way as possible.

With non-ionising radiation issues we have the advantage of being able to learn from the pitfalls encountered previously in the ionising radiation field. However there is also the very large disadvantage of the word "radiation" and the pre-conception in the public's mind that this is automatically associated with cancers. Often the message to be communicated is that the possible health effects are different and that the hazards are significantly lower than the public's perception. However one can have equal difficulties getting over the message that common practices are more hazardous than generally accepted. A recent example has been the Board's advice on ultraviolet radiation (3) and the hazards associated with direct exposure to the sun and to sunbeds. This is perhaps not a message that many in the general public want to hear, as it directly affects their lifestyles, but it is an important matter and one that will be a challenge to our communication skills over a number of years.

The Board has put a lot of effort into another communication medium, namely a series of "At-a-Glance"leaflets. These are aimed at the interested layperson and are produced in both graphical and pictorial form utilising colour to enhance the visual impact. Relevant information, statistics and facts are presented in bullet point style. Each leaflet covers a particular subject area, for example Radon, Nuclear Emergencies, Medical Radiation, Transport of Radioactive Materials, Natural Radiation, Non-ionising Radiation, Ultraviolet Radiation and Electric and Magnetic Fields from the Use of Electricity. The At-a-Glance series has proved to be very successful with over one million copies distributed to date.

The Board receives a steady stream of telephone calls and letters from members of the public and following media coverage of non-ionising radiation matters this increases. Many enquiries can be dealt with by a package of information including reprints from the Board's journal, the Radiological Protection Bulletin and the At-a-Glance series. However, many questions require further input from scientific staff. Whilst there is clearly a need for a national body to be in a position to answer such questions in this way, it is resource intensive and that is one of the reasons for focusing effort on the more cost effective routes of media communication and leaflets.

THE USERS

Whilst there are some documents available that give specific guidance to users of non-ionising radiation, these are not as extensive as those for ionising radiation, partly due to the developing nature of the subject and partly due to the lack of hazard specific legislation. It is perhaps an area for improving communication in the future.

One area that has developed significantly over the past couple of years is the range of training courses available to communicate at this level. These have to be focused, both on the audience, eg safety professional, management, staff etc; and on the specific use of non-ionising radiation. The latter vary considerably: for example, from the localised nature of manufacturing uses of RF, such as heat sealing of PVC, to the communications industry where RF radiation is radiated from antennas; and for lasers from simple low power laser pointers through medical laser scalpels to fully interlocked high powered lasers. The direct needs of safety professionals are often easily addressed in straightforward lectures, however at the other end of the scale many trainees will not have been in a classroom environment since leaving school. For the latter group the use of good visual representations and practical demonstrations and measurements are essential. They can also be very useful to the safety professional in suggesting ways they may pass on understanding to a wider audience.

To address these needs the Board runs a range of training courses and has also collaborated with Loughborough University in developing laser safety training that addresses not just the radiation hazard but others such as electrical and fume hazards.

Many practical situations require measurements of non-ionising radiations as part of an overall assessment, whilst others are standard situations that have been previously well documented. Even in the latter case, measurements of non-ionising radiations as part of consultancy work may be necessary to allay fears of the workforce. For example in recent years concerns have been expressed in some quarters over the exposure to electromagnetic fields from visual display units (VDUs). Although the scientific evidence suggests that employees will not be harmed by these fields (4), enquiries are still received by the Board. Copies of publications and telephone reassurance may be sufficient to reassure some employees. However, in some cases this may not be sufficient and an employer may be in the situation where a number of employees are refusing to work at VDUs, or wishes to confirm that there is nothing wrong with a particular VDU. Under these circumstances it may be necessary to visit the premises to carry out measurements for reassurance purposes. These should confirm that the emissions from the VDUs are below the Board's investigation levels. However, if the results are presented in a written report, the employee and possibly the employer, may be overawed by the formal nature of the document. A more successful approach is to carry out a series of measurements with the concerned employees and trade union representatives present. They can be asked to read the meters on the measurement instrumentation (with care to ensure they do not influence the measurement results) and compare these measurements with the investigation levels. Any questioning can then be in the small group or on a one-to-one basis. Most employees are trusting of professionals who are prepared to go through this very open and direct process.

CONCLUSIONS

As in other areas of safety the development of scientifically sound advice is just one component of developing radiation protection for non-ionising radiation: resources to effectively communicate that advice are essential. The means of communication and the level of delivery must take account of the various audiences. This is not a new message, but one we should routinely remind ourselves of.

ABSTRACT (See instructions overleaf)

Lately, a new type of the consequence caused by radiation have received much attention. It was found that tumor cells exposed to fractionated ionizing irradiation, with a high total dose, may become resistant to chemotherapeutic agents. The aim of the present study was to determine whether the same phenomenon will occur in human normal and tumor cells after exposure to a low total dose of irradiation divided in a small number of fractions. Since c-*myc*, c-Ha-*ras* and *p53* oncogenes are involved in both drug-resistance and neoplastic transformation, we also examined their expression in normal preirradiated cells.

Primary human lung fibroblasts or human cervical carcinoma HeLa cells were irradiated five days with daily dose of 0.17 Gy of gamma rays. The sensitivity of preirradiared cells (after 5 or 10 γ-ray-fractions) to different cytostatics was determined by colorimetric MTT dye assay and compared to the sensitivity of control cells. The expression of c-*myc*, c-Ki-*ras* and *p53* oncogenes in control and preirradiated cells was detected immunocytochemically. The results show that preirradiated cells became resistant to vincristine and vinblastine, but did not change their senisitivity to doxorubicin, 5-fluorouracil, mitomycin C or cisplatin. The expression of examined oncogenes was the same in normal preirradiated and control cells.

Our results suggest that irradiation of human cells with multiple small doses of gamma rays may change their susceptibility to chemical agents. These data may have practical application to radiation protection determination.

RELATION BETWEEN RADIO-ADAPTIVE RESPONSE AND CELL TO CELL COMMUNICATION

Keiichiro Ishii

Central Research Institute of Electric Power Industry, Tokyo 201, Japan

INTRODUCTION

Ionizing radiation has been considered to cause severe damages to DNA and do harm to cells in proportion to the dose, however low it might be. In 1984, Wolff et al. showed that human peripheral lymphocytes adapted to the low-dose radiation from ^{3}H-TdR added in culture medium and became resistant to the subsequent irradiation with high-doses of X-rays (1). This response, which is called radio-adaptive response, is also induced by X-rays and gamma-rays in human lymphocytes (2) and Chinese hamster V79 cells (3). However, the mechanisms of and conditions for adaptive responses to radiation have not been clarified. With an objective of clarifying the conditions for adaptive responses of cells to radiation, we examined how the cell to cell communication is involved in the adaptive responses. We irradiated normal human embryo-derived (HE) cells and cancer cells (HeLa) in culture at high density with low-dose X-ray and examined their radio-adaptive responses by measuring the changes in sensitivity to subsequent high-dose X-ray irradiation using the Trypan Blue dye-exclusion test method. We also conducted experiments to examine the effects of Ca^{2+} ions and Phorbol 12-Myristate 13-Acetate (TPA) which are supposed to be involved in cell to cell communication.

MATERIALS AND METHODS

(1) Dose-dependency of Preliminary Irradiation Effect

Four hours after the start of culture of HE cells, the cells were irradiated with low doses of X-ray ranging from 0 to 20 cGy. Similarly, HeLa cells were irradiated with X-ray ranging from 0 to 40 cGy. The cells were cultured for another four hours, then subjected to high-dose irradiation of 200 cGy. After high-dose irradiation, the cells were cultured for five days before the number of viable cells was counted. The relative growth ratios of the respective groups were determined. The control groups received mock treatments for both the low-dose irradiation and high-dose irradiation.

(2) Effects of Calcium Ions and TPA

Four hours after the start of the culture of the HE cells, the regular culture medium was replaced by Ca^{2+}-containing Hank's Balanced Salt Solution (HBSS) or Ca^{2+}-free HBSS. Then each group received irradiation of 13 cGy or mock treatment. Ten minutes after the irradiation

or the mock treatment, the HBSS were replaced by the regular medium. Then the cells were cultured for four hours before receiving a high-dose irradiation of 200 cGy. TPA was added to the culture medium at a concentration of 100 ng/ml at 3 hours and 40 minutes after the start of culture of HE cells, then the cells were irradiated with 13 cGy 20 minutes after the addition of TPA. The culture medium was removed 20 minutes after irradiation at 13 cGy, the cell sheet was rinsed 3 times with PBS, and the regular culture medium was poured to the culture flask. The cells were cultured for 4 additional hours, and then irradiated with 200 cGy. After that, the cells were cultured for five days, and the numbers of viable cells were counted to determine the relative growth ratios of the cultures. The control groups were treated in the same manner as the irradiated groups except that both the low-dose irradiation and the high-dose irradiation were mock treatments.

RESULTS AND DISCUSSION

(1) Dose-dependency of Preliminary Irradiation Effect

The results are shown in Fig. 1. When a high-dose irradiation of 200 cGy was given to HE cells, the growth ratio of the living cells decreased to 37 % of that of the control. When a preliminary irradiation of 10 to 20 cGy was given to HE cells four hours before the irradiation of 200 cGy, the relative growth ratio significantly increased to 45-53 %; and a peak was reached at a preliminary irradiation dose of 13 cGy. In HeLa cells, however, preliminary irradiation by the entire dose range from 0 to 40 cGy did not affect the relative growth ratio after 200 cGy irradiation.

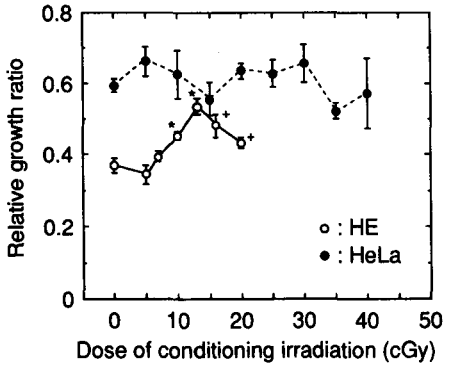

Fig. 1 Changes in relative growth ratio of pre-irradiated human embryonic cells and HeLa cells after receiving the challenging irradiation of 200 cGy, as a function of pre-irradiated conditioning dose. Relative growth ratio = growth ratio of irradiated cells / growth ratio of sham-irradiated control. Each point is the mean ± SD of six independent determinations. $^{*}p<0.01$, $^{+}p<0.05$ by paired t-test.

(2) Effects of Calcium Ions and TPA

The results are shown in Fig. 2. When the HE cells were given an irradiation of 200 cGy without any preliminary irradiation, the growth ratios of the living cells decreased to 31-37 % of those of the control groups irrespective of the presence or absence of Ca^{2+} in the HBSS

which replaced the regular medium. When an irradiation of 13 cGy was given to the HE cells in the Ca^{2+}-containing HBSS four hours before the 200 cGy irradiation, the relative growth ratio of the living cells increased significantly to 53 %. However, when the HE cells were given an irradiation of 13 cGy in the Ca^{2+}-free HBSS, the relative growth ratio of the living cells was about 32 %.

When TPA was added to the culture medium at 100 ng/ml during preliminary irradiation, the relative growth ratio of HE cells significantly decreased to 42%.

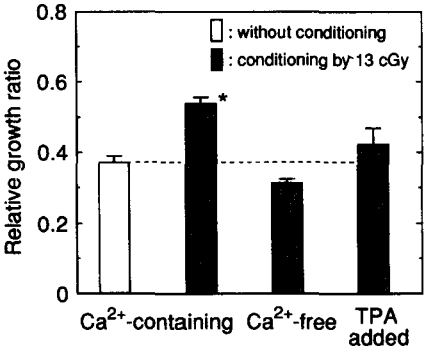

Fig. 2 Changes in relative growth ratio of pre-irradiated human embryonic cells after receiving the challenging irradiation of 200 cGy by the presence or absence of calcium ions and TPA in the medium during the conditioning irradiation. Each point is the mean ± SD of six independent determinations. *$p<0.05$ by paired t-test.

In the present study, to examine how cell to cell communication is involved in the adaptive responses of cells to radiation, we irradiated normal cells (HE) and cancer cells (HeLa) with low-dose X-ray and examined changes in their sensitivity to subsequent high-dose X-ray irradiation. As a result, the preliminary irradiation of the HE cells by low-dose X-ray moderated the decrease in the growth ratio of the cells due to the subsequent 200 cGy irradiation, and increased the radioresistance. This adaptive response was not observed in HeLa cells. When the HE cells were suspended in a Ca^{2+} ion-free medium or TPA added medium while receiving the conditioning irradiation, the adaptive response was not observed. The above-mentioned findings suggest a good possibility that low-dose irradiation enhances the radio-resistance of normal cells. The results also show that there is an optimum dose range for inducing the radio-adaptive response. This radio-adaptive response seems to involve cell to cell communication maintained in the normal cells (4).

ABSTRACT (See instructions overleaf)

The effect of ^{137}Cs γ-quanta on the chromatin conformation was studied by the method of anomalous viscosity time dependence. A few different cell types were exposed: VH-10 human fibroblasts, BALB\C mouse splenocytes, Sprague-Dowley rat thymocytes. The cells were irradiated within the 0.1-50 cGy dose range and then lysed for viscosity measurements. It was established for all types of cells that exposure to low doses of 0.5 cGy resulted in a statistically significant reduction of viscosity peaks. This reduction reached a maximum value approximately 40-60 min after irradiation. The reduction of viscosity was revealed at doses up to 4 cGy for human fibroblasts with the maximum effect of about 2 cGy. The opposite response, increase of viscosity, was observed after cell exposure to 10-50 cGy doses. From the linear approximation of this dose dependence, the increase of viscosity started at a dose of about 3±1 cGy. The effect of increased viscosity disappeared with time after irradiation, with kinetics similar to that of DNA repair. Repair of the chromatin conformation depended strongly on temperature in the 0-37°C range. To the contrary, kinetics of the 0.5 cGy effect did not depend on temperature. Thus, two different types of the chromatin response were observed in mammalian cells after low (0.5 cGy) and high (50 cgy) doses of irradiation. This study provides new evidence that doses as low as 0.5 cGy cause significant changes of the chromatin conformation in different types of mammalian cells.

BIOPHYSICAL ANALYSIS OF RADIATION-INDUCED CHROMATID AND CHROMOSOME ABERRATIONS AT LOW DOSES AND DOSE RATES

Werner Hofmann,[1] Maria Nösterer,[1] Peter Eckl,[2] and Johanna Pohl-Rüling[1]

[1]Institute of Physics and Biophysics, University of Salzburg, A-5020 Salzburg, Austria
[2]Institute of Genetics and General Biology, University of Salzburg, A-5020 Salzburg, Austria

INTRODUCTION

In the present study, two sets of experimental data have been analyzed: (i) *in vitro* and *in vivo* exposures of human blood lymphocytes to alpha particles from short-lived radon decay products (1,2), and (ii) *in vitro* irradiation of rat hepatocytes with gamma radiation (with and without pre-irradiation) (3). The biophysical multi-stage model for radiation-induced chromosomal damage used in these analyses is derived from earlier models for radiation-induced transformation (4,5) and liver carcinogenesis (6).

BIOPHYSICAL MODEL

A biophysical model for the production of radiation-induced chromatid and chromosome aberrations as a function of dose or dose rate has been developed, which is based on experimentally observable cellular mechanisms, such as the formation of single and double strand breaks or cellular inactivation. In this multi-stage model, a sequence of five states is assumed in the development of a cell from the initial unirradiated level (state 0) to a cell exhibiting chromosomal damage (state 4) (Figure 1). The intermediate steps in this sequence of events are: production of an unspecific DNA single strand break (rate k_{01}); production of a second specific DNA single strand break (k_{12}); interaction of both DNA single strand breaks to form a double strand break (rate k_{23}); division-related fixation of the DNA double strand break thereby producing chromosome aberrations (rate k_{34}); and, division-related fixation of two single strand breaks leading to chromatid aberrations (rate k_{24}=m). Single and double strand break formation may be reduced by adaptive mechanisms, while actual breaks may be repaired (rates k_{10}, k_{21} and k_{30}). Cells in the various states can be removed by radiation-induced cell death (rate k_d) and apoptosis (rate k_a), and increased by mitosis (rate m). In case of alpha irradiation, double strand breaks can also be produced by single alpha particle intersections (rate k_{03}). The values for the transition rates between the various states in this model were derived from *in vitro* cellular experiments.

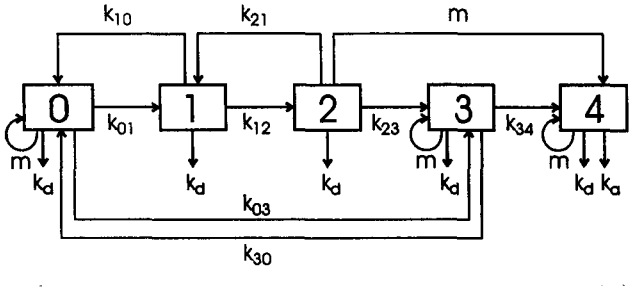

Figure 1. Biophysical multi-stage model for the analysis for radiation-induced chromatid and chromosome aberrations produced by alpha and gamma irradiation. Transition rates are described in related text.

ANALYSES OF EXPERIMENTAL DATA

In the first analysis, chromosome aberrations in human blood lymphocytes were exposed to short-lived radon decay products under *in vitro* irradiation conditions (1). Blood samples were irradiated by ^{214}Po alpha particles at doses between 0.02 and 26.9 mGy. The aberration data were collected from 11 experiments conducted during the period 1984 to 1992; a total of 64816 metaphases was scored in eight collaborating laboratories. Figure 2 illustrates the total chromosomal aberrations (dicentrics, rings, interstitial and terminal deletions) as a function of dose for blood samples taken between 1984 and 1986, i.e., prior to the Chernobyl accident. The data plotted here are based on 10687 scored metaphases. After a steep linear increase at very low doses, the aberration frequency gradually drops with increasing dose. The comparison between with these experimental data and our model simulations indicates that the biophysical model developed here is capable of reproducing the functional form of the experimentally observed dose-response curve.

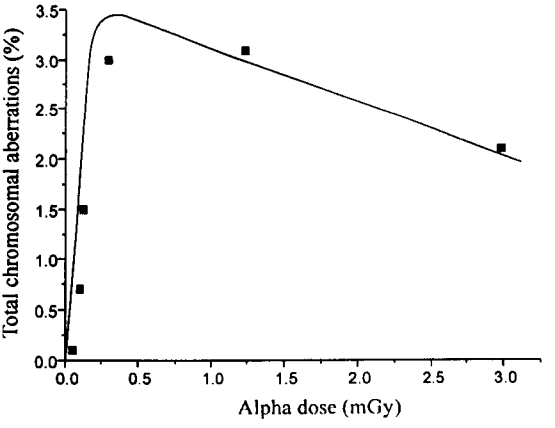

Figure 2. Total chromosomal aberrations (dicentrics, rings, interstitial and terminal deletions) in human blood lymphocytes for low dose *in vitro* alpha particle irradiation. The full squares refer to the experimental data, while the full line represents the model simulations.

A similar dose-reponse relationship has been reported for low dose and dose rate *in vivo* radon progeny irradiation of blood lymphocytes in miners and medical staff working in the Badgastein thermal gallery: total chromosome aberrations first rise linearly with dose up to about 7 mGy/year and then decrease with increasing alpha dose (2).

In the second analysis, primary cultures of adult rat hepatocytes were irradiated with ^{60}Co gamma radiation at much higher doses of 0.01, 0.1, 1 and 5 Gy at a dose rate of 33 Gy/h (3). In order to study potential effects of adaptive response mechanisms, the same set of doses was also applied to hepatocyte cultures pre-irradiated with 2.5, 10, 100 and 200 mGy 24 hours prior to exposure. As shown in Figure 3, induction of chromosomal aberrations for both normal and pre-irradiated cells rises sharply with dose in the low dose region and then remains level at higher doses. Most importantly, however, all pre-irradiation doses caused a significant reduction of chromosomal aberrations, which was highest for a pre-irradiation dose of 2.5 mGy. Our theoretical predictions of the shape of the dose-response relationship as well as of the effect of the induction of adaptive response mechnisms by pre-irradation are consistent with the experimental evidence.

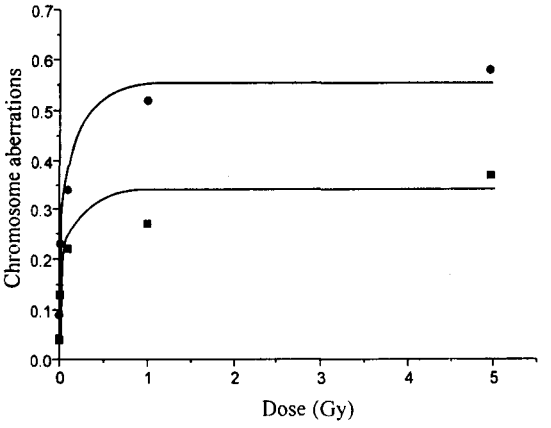

Figure 3. Total chromosomal aberrations in primary rat hepatocytes by *in vitro* gamma irradiation. The full circles (without pre-irradiation) and full squares (2.5 mGy adaptive dose) denote the experimental data; the full lines refer to the corresponding model simulations.

CONCLUSIONS

The three sets of experimental data analyzed in this study cover different dose regions (very low, low and high), cell types (lymphocytes, hepatocytes), radiations (alpha, gamma) and irradiation conditions (*in vitro*, *in vivo*, pre-irradiation). Despite these differences, a consistent pattern emerges. If chromosome aberrations are plotted as a function of dose, four distinct regions can be observed: First, at the lowest doses, no chromosomal damage can be statistically detected; above a certain dose level, the frequency of aberrations increases almost linearly with dose; following the induction of adaptive mechanisms, the dose-response may either exhibit a plateau or even decrease, depending on pre-exposure and dose rate; and, finally, chromosomal damage rises again at sufficiently high cellular doses.

Comparing our theoretical results with these three sets of experimental data, we may conclude that our model correctly predicts both the shape of the dose-response curve as well as the action of adaptive response mechanisms induced by pre-irradiation.

INTRODUCTION

Actuality of the tritium biological effect researches is caused by its wide spreading due to accumulation of technogenic tritium in biosphere as well as the possibility of increasing of persons working with this nuclide because of real perspective of the thermonuclear energy production. Information about tritium effect in conditions, that is closely like the real conditions, i.e., under chronic isotope intake, is especially important.

The materials of many-years work of authors' group have been generalized in this paper on the kinetics of forming of early and late effects following the prolonged influence of tritium in broad range of doses including low level.

MATERIALS AND METHODS

Studying the chronic influence of tritium oxide (HTO) has been conducted for two species of laboratory animals on the different levels of integration (from molecular to population) by using the radiobiological, biochemical, hematological, cytogenetic, immunological, and pathomorphological methods. Animals were received the HTO during 3-6 months (dose rates of β-exposure ranging from 0.1 to 27 cGy/day, and absorbed doses ranging from 0.1 to 25 Gy).

RESULTS AND DISCUSSION

The study of tritium behaviour kinetics in chromatin of hematopoietic tissues under the prolonged HTO injections by 370 kBq/g per day has shown that 70-80% of nuclide were incorporated into DNA, and 20-30% of those were incorporated into chromatin proteins. The half-period of accumulation of tritium in DNA of hemopoietic tissues was 15-25 days. The excretion of label was being during two time period: 60-70% of label for 5-8 days; 30-40% of label for 12-18 days. Effectiveness of including tritium into carbon relations of DNA from water was 0.5-0.8, and if taking into account the easily exchanging tritium and tritium of 8th carbon of purine, it is approximately 1. Activation of the hematopoietic tissue proliferation (hemolytic anemia) did not influence on both the level of tritium incorporation into DNA and the effectiveness at the nuclide equilibrium period.

The common radiation burden on hemopoietic tissues as well as tritium inclusion into chromatin led to changes of DNA structure and reparation depending from dose, and also to nucleic acid metabolism changes. For prolonged injection of tritium oxide (37-1850 kBq/g per day, the absorbed doses of 1.2-28 Gy), the strong damages of DNA primary structure (by content of double-stranded DNA, and by single-stranded DNA molecular mass) were determined at and of nuclide injections in the animals, only which received moat amount of nuclide. The findings relate to DNA reparation at moment of tritium oxide intake in animals. The residual damages of DNA were remained after the intake end, and were found by additional test-exposure.

Content and rate of DNA biosynthesis depended from the dose rate and the absorbed dose. At first two months of β-exposure to incorporated tritium in dose range of 1-12 cGy/day, the DNA concentration in hemopoietic tissues was on subnormal

level, and that for high dose was on decreased level, despite the increase of absorbed dose. This was because of dose-depending activation rate of DNA synthesis from 14th day and practically during all period of nuclide injecting. However, under high values of rate of beta-exposure (the absorbed doses of 12 Gy), the decreasing of DNA content was indicated for studied tissues (thymus - 65% of control) at end of influence. After short-time recovery of this index, when radionuclide intake has finished, the secondary decreasing of DNA content was observed in animals of this group. The significant decrease of this index in hemopoietic organs corresponded the increasing of substances (polydeoxyribonucleases), that indicated to the DNA destruction, and reflected possibly the cell elimination with non-reversible radiation damages.

The DNA structure damage and their reparation developed to chromosome aberration. Cytogenetic studies of *Wistar* rats found the high sensitivity of myelocariocyte chromosomes to tritium damaging effect. During HTO injection (3.7-370 kBq/g per day, dose rates of 0.12-12 cGy/day, and absorbed doses of 0.24-25 Gy), the chromosome damages were mainly the aberrations of chromotide type in animals of all groups. The aberrations of chromosome type were being appeared with increasing the absorbed dose, which were mainly symmetrical exchanges. The time points of their appearance and frequency depended on the dose rate, and for maximum rate these damages began to be observed in 60 days after influence. At relatively later period the chromosome type aberration appearances and the absence of significant increase of chromosome damage in animal groups, when absorbed doses were being increased, evidence that there are adaptive processes under prolonged intake of tritium. The stable aberrations of chromosome type were being kept up to end of observation after cessation of HTO injections in animals, and the cell clones with atypical chromosome were determined for most of rats that were received the higher doses.

The nucleic acid metabolism changes developing under chronical effect of HTO in hemopoietic tissues made a basis for shifts of cell population kinetics in these tissues. It was found the dependence of hemopoiesis damages from nuclide dose burden under prolonged β-exposure to incorporated tritium with different dose rates (for rats -- 0.12-12 cGy/day, and for mice -- 0.04-4.4 cGy/day). The difference of tissue reactions of animals, which received the different HTO amounts, were expressing as different rates and depopulation. It was shown high sensitivity of multipotent and committed cells, that are precursors of myelo- and lymphopoieses, to tritium in comparison with morphologically recognized hemopoietic cells. The erythropoiesis damages under chronic effect of HTO was more clear, than granulocytopoiesis.

The clear dependence of character and fullness of recovery from radiation effect level was shown for bone marrow and lymphoid tissues after finishing of HTO injection. The recovery of cell content in these tissues of animals exposed to beta-radiation in dose of 12.5 Gy (dose rate of 12.0 cGy/day) was in 1-3 months later than after lower doses of exposure. The value of non-reversible decreasing of multipotent precursor compartment was being higher with increasing the absorbed dose. On this background, the recovery of lymphopoiesis, especially T-cell production, was defective. The population of committed precursors of T-lymphocytes stabilized on 40-60% level in comparison with B-lymphocyte precursors whose population reached the values of age norm in 3-6 months after the end of HTO intake. Also, the recovery of cellular structure in thymus and lymphatic nodes, which cells were mainly T-lymphocytes, was not full, and at the same time the cell content in spleen (B-cells) was being increased up to control level in 6-9 months.

HTO-induced changes of lymphopoiesis at different stages were being developed as the dose-depending damages of humoral and cellular immunity. During excretion of tritium oxide by amount of 370 kBq/g per day (mice, rats), the antibody production

was being lower up to 50% of control. Suppression of humoral response on the antigene at earlier time periods was caused mainly by insufficiency of T-helpers, and later of B-lymphocytes. Under prolonged intake of HTO by less amount, the antibody production changed during short-time period (for 185 kBq/g per day), or kept on level of age norm (for 37 kBq/g per day). The reliable dependence was obtained between the absorbed dose and the character and fullness of recovery of humoral and cellular immunity after the end of β-emitter intake. Antibody production, activity of normal killers, and T-inactivating lymphocytes recovered in 1-3 months after exposure to radiation in doses of 3-4 Gy, and in 9-12 months after the accumulated dose of 8.7 Gy (*CBA* mice).

The relative biological effectiveness (RBE) of tritium oxides in respect with γ-radiation (^{137}Cs) was determined basing on dependence of dose-effect after one-time injection of nuclide under the absorbed doses of 0.5-14.5 Gy. Taking into account the indexes of lymphoid organ's mass, the cell content in hemopoietic tissues, the damages of DNA structure and of nucleic acid metabolism, it may be indicated that RBE of tritium increased under decreasing of absorbed dose, and was 4-6 under minimum doses. The $DL_{50/30}$ value of RBE of tritium corresponded 2.32.

The late effects of tritium oxide intake are most important for assessment of its danger, particularly its cancerogenous influence. The publications on blastomogenous effects of tritium do not present the precise dose-depending outcome of malignant tumours at different sites (1,2). The late effects of prolonged beta-exposure to tritium incorporated were studied by us for following doses: 0.24; 2.02; 12.5; and 25.3 Gy. The frequency of malignant tumours in exposed *Wistar* rats exceeded the control level at 1.5-2.5 times. Revealed neoplasm at different sites may be divided on three categories by character of dose-effect dependence. Tumours of first category had the positive correlation with dose (leukaemia, lung cancer, skin cancer, osteosarcoma, and mammary gland cancer), at the same time tumours of second category had (lymphosarcomas of lung) were characterized by negative dose-dependence. The malignant tumours of endocrine organs, testicles, kidneys and urethra, gastro-intestinal tract did not have the reliable dependence on dose (3d category).

The difference of dose-effect dependence for frequency of different neoplasms induced by tritium makes the difficulty to use this criterion, as character of radiation danger. The non-stochastic index of dangerous effect for organism, such as lifetime shortening, is more integral and universal. The prolonged injection of tritium oxide by minimum amount (dose of 0.24 Gy) increased the mean lifetime (MLT) of animals by 12%, and in cases of injection of large amount of nuclide (dose of 2.02 Gy) the lifetime of animals did not differ from value of control. The further increasings of radiation dose up to 12.5 and 25.3 Gy led to decreasing of MLT of animals by 18% and 23%, respectively. However, decreasing of the MLT of animals was the same either in rats with malignant tumours, or in other animals. The absence of priority of malignant tumours for decreasing of the MLT makes possibility to think that there is single mechanism of thanatogenesis either for nature senescence, or for its acceleration, in particular, by radiation exceeding the specified level.

ABSTRACT (See instructions overleaf)

A lot of territories was contaminated with radionuclides (mostly ^{90}Sr and ^{137}Cs) after Chornobyl accident. The level of external γ-radiation in the Chornobyl region is from 1 to 40 mR/h at different lots. Some coniferous species (pine and spruce) form many different morphological abnormalities under these conditions of chronic irradiation. The changeability of needles' length during some vegetation periods is one of them. So, pine needles become essentially shorter (2-3 fold) in some years. Spruce trees have both lengthened and shortened needles as well as needles with normal length on the same tree. It was shown previously that the size of cells in abnormal needles is also different from the normal one. Since the cell size is closely connected to cytoskeleton functions so it was supposed that ammount of cytoskeleton proteins in modified cells must be different from the normal one. Such difference can be caused by changes in synthesis of cytoskeleton proteins as well as by changes in cell genome. Significant changes in protein spectrum and in individual proteins (actin, α- and β-tubulin, hsp70 etc.) were registered with immunochamistry and SDS-PAGE. With the aim to study genome of modified cells, DNA from them was examined with restriction fragment length polymorphism method, dot- and Southern-hybridization with β-tubulin gene. Some changes in DNA from abnormal needles were observed. It was supposed, that chronic irradiation could affect the genome stability of coniferous plants.

THE RADIOPROTECTIVE ROLE OF TYASTIME ON CHLOROPLASTS OF PHASEOLUS VULGARIS L.

Rodica Dumitrescu, Dumitru Popescu
Institute of Biology, Spl. Independetei
nr. 296, PO-Box 56-53, Bucharest, 79651
Romania

Introduction.

There are numerous studies about the effects of low doses of gamma ionising radiation. Unfortunatelly the probabilistic nature of interaction and the existence of too many parameters characterizing the interacting parts make difficult the appearance of reproducible results. In this work we present a part of our results regarding the action of gamma ionising radiation on both chloroplasts ultrastructure and pygments dynamics from Phaseolus vulgaris L. (1) Also, the radioprotective action of Tyastime was discussed.

Materials and method.

The Phaseolus vulgaris L. seeds were treated with Tyastime solution of 0,5‰, 1‰ and 1,5‰ concentration.

Using a Co^{60} source, the each sample of treated seeds was supposed to theree gamma irradiation doses of 10 Gy, 30 Gy and 50 Gy in two rates. (D = 10 Gy/min., D = 3,33 Gy/min.)

The ultrastructure modifications werw studied by electron microscopy and the dynamics of assimilating pigments, in two succesive generations (M_1, M_2) was observed using the H. H. Strain and A. A. Svec technique (2)

Results and discussion.

1. The Tyastime radioprotective effect on chloroplast ultrastructure

At irradiation rate of 3,33 Gy/min., no important changes of Chloroplasts ultrastructure were observed.

The tylacoidal system was destroyed and a large number of amilophere inclusions appeared at the irradiation rate of 10 Gy/min., especially at 30 Gy absorbed dose. (fig. 2).

Tyastime 1‰has not an efficient radioprotection at 30 Gy.

The granes have a different thylacoides per grana, and thylacoidal system from stroma were broken by the appearence of both amiliferes inclusions and plastoglobules. (fig. 3)

The most efficient radioprotective role was observed at the samples treated with 1,5‰ Tyastime and irradiated at 30 Gy, when the chloroplasts (fig. 4) have a nearly identical structure with the control sample. (fig. 1)

2. The Tyastime radioprotective effect on assimilating pygments dynamics.

The Assimilating pygments were studied after 1‰ Tyastime treatment followed by irradiation at D = 10 Gy/min.

From the Table I, it can see the strongly effect of irradiation on the first generation of Phaseolus vulgaris L., plants (M_1) and the radioprotective effect which appeared only at the second generation
(M_2).

The processe of pygments accumulation and the ratio chloropyl "a" / chlorophyl "b" have similar changes in the two generations.

According to the Lohman model (3), Tyastime contribute to the membrane stabilization owing to - SH groupes.

MAJOR SCIENTIFIC TOPIC NUMBER 2.1 (see page 7)

ABSTRACT (See instructions overleaf)

Stress proteins (metalothioneins 1 and 2, and heat shock protein 70) induction for 14-days *Pisum sativum* seedlings has been investigated under different stress factors. Acute and chronic irradiation, growth of seedlings in Cu^{2+}, Cd^{2+} and ^{137}Cs salt solutions, and high temperature were used as stress factors. Dependence of stress proteins synthesis of plants from different physical and chemical factors were investigated by the methods of Laemmli-electrophoresis and western-blotting with antibody against MT-1, MT-2 ad HSP-70. The stress proteins participation in the protection of plants from different enviromental conditions are discussed.

FAST NEUTRON IRRADIATION EFFECTS ON LIVER CHROMATIN STRUCTURE

B. Constantinescu[1] and Liliana Radu[2]

[1] Cyclotron Laboratory, Institute of Atomic Physics, P.O.Box MG-6, Bucharest, Romania.
[2] Department of Molecular Genetics, Victor Babes Institute, Spl. Independentei, 99-101, Bucharest 76201, Romania

EXPERIMENTAL

The growing interest in neutron therapy requires complex studies on the mechanisms of neutron action on biological systems, especially on chromatin (the complex of deoxyribonucleic acid-DNA with proteins in eukaryotic cells).

The chromatin was extracted from a normal tissue-livers of Wistar rats-and from a tumoral tissue-Walker tumour maintained on Wistar rats. For chromatin separation, the method indicated in (1) was used, with a supplementary nuclei's purification through a passage on 1M sucrose, and the obtained purity verified by an absorption test (2). Suspension of cells-5×10^6 cells/ml concentration-from Wistar rat livers and from Walker tumours were also isolated. Irradiation doses from 5Gy to 100 Gy by fast neutron intense beams produced via d(13.5MeV)+Be (thick target) reaction at Bucharest U-120 Classical Cyclotron were used (3).

To study the post-irradiation effects, various methods were employed. So, the variation in the 260nm absorbency in chromatin thermal transition was pursuit (E_0-before and E-after transition). The chromatin-ethidium bromide complexes fluorescence with λ_{ex}=480nm and λ_{em}=600nm was analysed. To determine chromatin DNA strand breaks a fluorimetric method (4), with cells' suspensions as starting material was used. This method requires a partial treatment with alkali, producing three components: T-estimating the total fluorescence of DNA double helix, P-assigning the untwisting rate and B-the blank, where DNA is completely unfolded. The percentage of DNA double strand,-D-, remaining after this treatment, is:

$$\%D=100\times(P-B)/(T-B)$$

The intrinsic chromatin fluorescence was determined for tyrosine (λ_{ex}=280nm, λ_{em}=305nm), specific for basic chromatin proteins, and for tryptophane (λ_{ex}=290nm, λ_{em}=345nm), specific for acid chromatin proteins. Polyacrylamide gel electrophoresis was performed as indicated in (5).

The double fluorescent labelling of chromatin was realised with acridine orange for DNA and with dansyl chloride for chromatin proteins (6). Fluorescence intensity determinations were done with λ_{ex}=505nm, λ_{em}=530nm for acridine orange and with λ_{ex}=323nm, λ_{em}=505nm for dansyl chloride.

A Pye Unicam SP 1800 spectrophotometer and a Aminco SPF 500 spectrofluorimeter were employed.

RESULTS AND DISCUSSION

For normal chromatin, a diminution of the negative fluorescence intensity for chromatin-ethidium bromide complexes with the increasing of neutron dose (from 0.98 at 5Gy to 0.85 at 100Gy) was observed. This fact reflects chromatin DNA injuries, with the decrease of double helix DNA proportion. As is known, single and double strand breaks are produced under fast neutron action. The quantity of the remaining DNA double strand, determined by fluorimetric analysis of the unwinding DNA, also decrease with neutron dose.

A reduction of intrinsic fluorescence intensities with neutron dose was also observed (approximately 1.5 times from 5 to 100Gy), denoting a destruction of chromatin proteins' structure. The energy transfer efficiency also decrease under neutron action (from 0.224 at 5Gy to 0.135 at 100Gy), indicating a more unstable tertiary structure of chromatin.

For tumour chromatin, some results are presented in figures 1, 2, 3. So, in figure 1 are represented the relative absorbencies (E/E_0) obtained for the thermal transitions of chromatin samples versus fast neutron dose, lower values indicating a damaged chromatin DNA (with a smaller proportion of double helix).

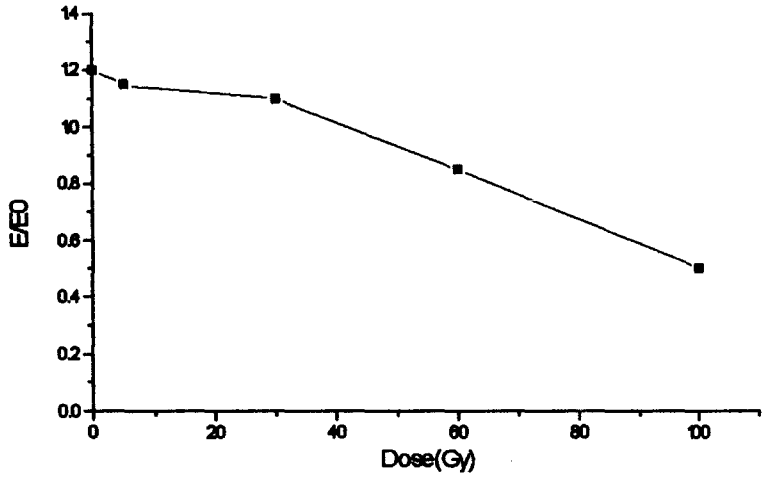

Figure 1Thermal transition of chromatin samples exposed to fast neutrons.

Figure 2 presents the fluorescence intensities of chromatin-ethidium bromide complexes versus fast neutron dose. Lower values also denote modifications in chromatin DNA structure, so that intercalation of ethidium bromide between pairs of superposed DNA bases takes place in a lesser degree.

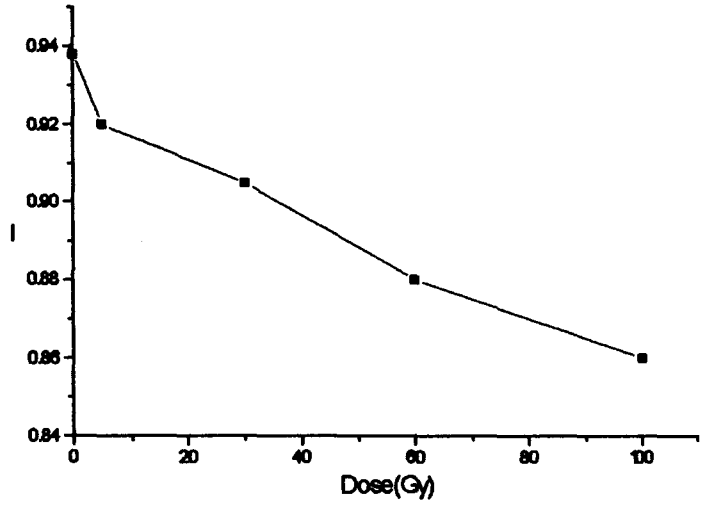

Figure 2. Chromatin-ethidium bromide complexes relative fluorescence versus fast neutron dose.

Intrinsic fluorescence of chromatin tyrosine and of chromatin tryphtofane versus fast neutron dose is presented in figure 3, the diminution of their values indicating a destruction of chromatin proteins.

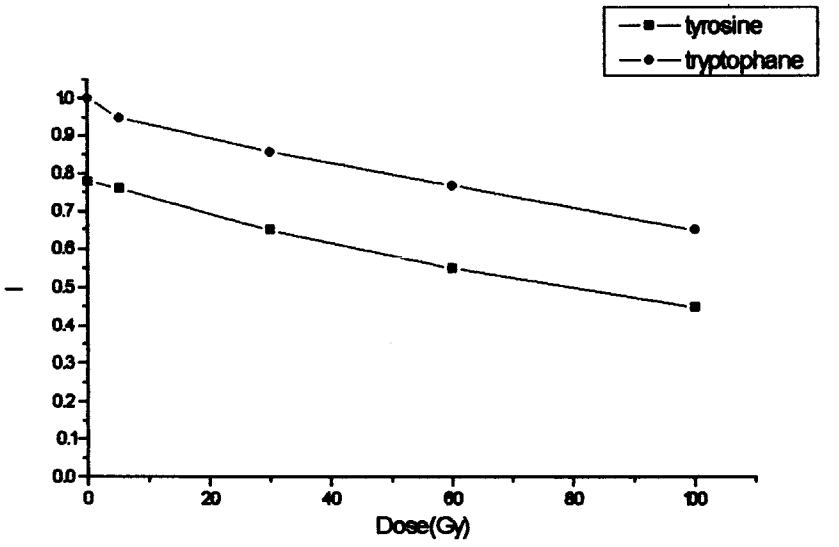

Figure 3. Chromatin tyrosine and tryptophane relative fluorescences versus fast neutron doses.

To study the influence of thyotepa, thyroxine and D_3 vitamin treatments on fast neutron radiolysis in tumour chromatin, 10mg/kg of anticancer drug thyotepa, 40μg/kg of hormonal compound thyroxine and 30,000 UI/kg of D_3 vitamin were administrated separately or associated to Wistar rats bearing Walker carcinosarooma. Similar studies on chromatin modifications as mentioned below were effectued. Preliminary results indicate that the association of thiotepa with thyroxine and D_3 vitamin produce a diminution of chromatin lesions induced by cytostatics and, consequently, differences in chromatin fast neutron radiolysis. Such results could constitute an indication for associated chemotherapy-radiotherapy scheduled in clinical applications. This research is in progress.

PRESENTING AUTHOR (IF DIFFERENT)

MAJOR SCIENTIFIC TOPIC NUMBER 2.1 (see page 7)

ABSTRACT (See instructions overleaf) In the study there are consideral some food-interest enzymes, like: proteases, α-amylases, pectic enzymes.
The enzyme preparations were irradiated in dry state and normal conditions(ambient temperature, pressure and humidity); by γ-rays and electron - accelerated beam. The γ - irradiation was performed to a Co - 60 source with approximately 105 TBq activity, in the dose-range of 1 - 50 kGy at different dose-rates between 0.3-1.5 kGy/h. The e - beam irradiation were performed on a liniar accelerator with the next main parameters: electron mean energy 7 MeV; mean beam current 5 μA, pulse perriod 3.5 μS; frequency 100 Hz, at the same doses, with dose-rates between 0.5-1.5 kGy/min

There were investigated, comparatively, the kinetical behaviour of the enzymes in terms of the reaction speed, v; Michaelis - Menten constant K_M and enzyme activity A_e versus irradiation dose.

These is observed a significant influence of the irradiation on the enzyme kinetical parameters, especially for the high doses.

To understand both γ- ray and e-beam effects on the enzymes, their action is described in dose-response terms and equation.

INFLUENCE OF FREE 5-BROMODEOXYURIDINE ON SCE INDUCTION IN HUMAN LYMPHOCYTES IRRADIATED AT THE PRESYNTHETIC STAGE

T. Kondrashova, N. Luchnik

Medical Radiology Research Centre, Obninsk, Russia

INTRODUCTION

Published data on induction of sister chromatid exchange (SCE) in mammalian cells by gamma-irradiation at the G_1 stage contain a contradiction: irradiation at the G_1 of the first replication cycle in the presence of 5-bromodeoxyuridine (BrdU) did not induce SCE (1, 2), while irradiation at the G_1 of the second cycle enhanced its frequency significantly (3, 4). Explanations of this controversy suggested either that chromosomes containing no BrdU were insensitive to gamma-rays, contrary to those BrdU-substituted; or that DNA lesions formed in the first cycle induced isolocus SCE both in the first and in the second cycle, these exchanges annihilating each other. However, an attentive analysis of the published works shows that in all cases BrdU was added to the culture just before the onset of the S stage of the first cell cycle; thus, the cells were exposed in absence of BrdU at the G_1 of the first cycle, and in its presence at the G_1 of the second cycle. In an earlier paper (5) we have shown that this difference in the experimental protocols, which seemed to escape notice in interpretations of the results, was very likely the reason of the above discrepancies. Here we describe the results of experiments directly addressed to this problem.

SCE INDUCTION BY IRRADIATION AT THE G_1 STAGE OF THE FIRST CYCLE

Fig. 1 shows the data on SCE frequencies induced in cultured human lymphocytes at the G_1 stage of the first post stimulation cycle by 2 Gy ^{60}Co gamma-rays for different schedules of BrdU addition to the culture. The cells were irradiated either immediately after PHA-stimulation (early G_1), or after 10 (middle G_1) or 20 h (late G_1) incubation. BrdU (final concentration 9×10^{-5} M) was added either at 23 h after PHA-stimulation (i.e. just before the onset of the S phase), or simultaneously with PHA, or immediately after irradiation. The cells were harvested at 59.5 h after PHA-stimulation. The comparison of the left (grey) columns between four groups displayed in the diagram shows that irradiation in the absence of BrdU did not induce SCE. From the comparison of the dark columns it is evident that, provided BrdU was present in the culture from the very beginning, irradiation enhanced SCE frequency reliably. Moreover, the control frequency was significantly higher in the latter case

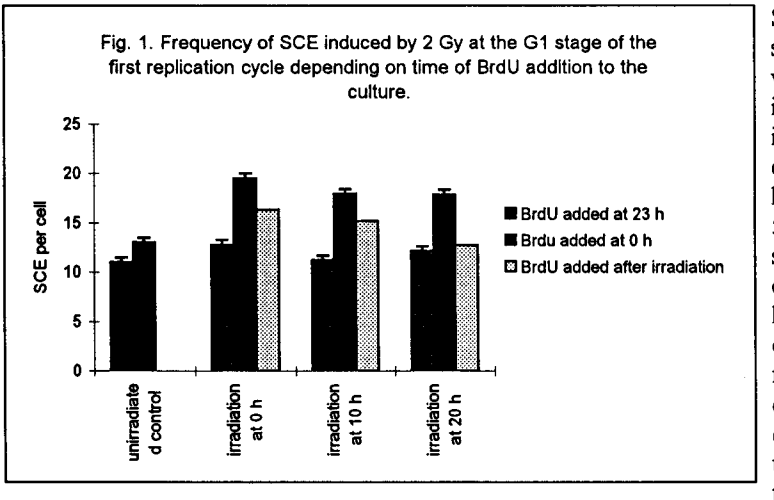

Fig. 1. Frequency of SCE induced by 2 Gy at the G1 stage of the first replication cycle depending on time of BrdU addition to the culture.

than in the former (see the first pair of columns). Comparison between light-coloured columns in three groups and comparison between light and dark columns in each group implies that presence of BrdU in culture medium was essential for SCE formation both at the moment of irradiation and during postradiation incubation of cells.

SCE INDUCTION BY IRRADIATION AT THE G_1 STAGE OF THE SECOND CYCLE

The other set of experiments was aimed to study SCE induction by irradiation at the G_1 stage of the second replication cycle of lymphocytes. BrdU was added to the culture simultaneously with PHA. Three variations of experimental protocol were employed: (1) the cells were irradiated immediately after washing off BrdU; (2) quite the reverse, BrdU was washed off immediately after irradiation; (3) BrdU was washed off 1h after irradiation. It was important to choose the time of BrdU removal so that the bulk of cells would pass only one replication cycle in its presence and the subsequent cycle without it. Under this condition, the time of BrdU removal and that of irradiation being very close to each other, one can be sure that the metaphases with differentially stained sister chromatids, which are to be analysed, are those very cells which were irradiated at the G_1 stage of the second cycle. In preliminary experiments this time was determined as 40 h after PHA-stimulation. Cells were harvested at 62 h after stimulation.

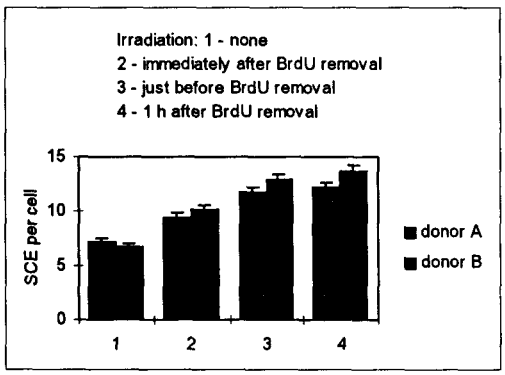

Fig. 2. Frequency of SCE induced by 2 Gy at the G_1 stage of the second cycle depending on time of BrdU removal from the culture.

The results obtained for two donors are illustrated in Fig. 2. Unlike the data for cells irradiated in the first replication cycle, exposure at the G_1 of the second cycle induced SCE even in the absence of BrdU (comparison of the first pair of columns to the second). This may be associated either with the different composition of chromatids (they did not contain BrdU at the G1 of the first cycle, but contained it at the G1 of the second one) or with rather prolonged presence of BrdU in the culture medium before irradiation in the second cycle. However, consideration of all the four groups shown in Fig. 2 evidences that, like in the case of irradiation in the first cycle, the presence of BrdU during the irradiation in the second cycle (and during an hour post irradiation) reliably increased the frequency of radiation induced SCE.

CONCLUSIONS

Irrespective of the number of replication cycle (the first or the second) and of the extent of thymidine substitution with BrdU in chromosomal DNA, irradiation in the presynthetic stage induced significantly more SCE in the presence of BrdU in culture medium than without it. Presence of BrdU was essential for SCE formation both in the moment of irradiation and during postradiation incubation of the cells. It should be underlined that this effect cannot be associated with a direct modification of chromosome radiosensitivity by BrdU, because we are dealing with the presynthetic stage. The influence of free (not incorporated into chromosomes) BrdU can probably be explained by its interplay with mechanisms of repair of initial genetic changes (or lesions). The biochemical possibility of such an interplay had been described (6). Evidences indicating a regular repair process taking place in the G_1 stage were accumulating

over a period of years (see (7) for references) and seem to find a further substantiation recently (8).

RECOMBINANT PLASMIDS CARRYING MUTANT LOCI *GAM* INCREASE RESISTANCE OF *ESCHERICHIA COLI* WILD TYPE CELLS TO IONIZING RADIATION

Valeri N. Verbenko, Helena P. Krupjan, Lili V. Kuznetsova and Vitali L. Kalinin
Petersburg Nuclear Physics Institute, Russia

To undestand factors limiting repair system of *Escherichia coli* wild-type strain mutant loci *gam* were cloned from hyperradioresistant mutant of *E. coli* Gam^r444 using vector MudII4042.

The recessive *gam12* mutation results in constitutive expression of heat-shock regulon as we tested with *lacZ* gene under control of heat-shock promoter p_{htpG}. On the other hand, induction of abnormal protein (human prourokinase) titrating the DnaK increases radioresistance of *E. coli* wild type cells harboring pUK-O2pmO.

Dominant mutation *gam18* compensates defect in *uvrD* gene partly. Random insertions of mini-Tn10-Km^r transposon into pGam18 by hop-transposition from λ_{1105} vector were obtained and plasmid which had lost Gam^r phenotype was selected. Transduction of *kan* marker by Kohara phages revealed homology of plasmid-borne allele with helicases which have 3'→5' polarity. Dominant plasmid of another type pGam43 leads to RecA-independent inhibition of post-irradiation DNA-degradation. Unknown inhibitor is produced constitutively because relative efficiency of plating of T4 2^- mutant phages appeared to be as high as in *recB* strain.

Our data show that enhanced radioresistance of *E. coli* wild type cells harboring recombinant plasmids with mutant loci *gam* is due to unusual involvement of heat-shock proteins in repair and encreased activities of SOS-repair system and specifically RecF-way of recombination-repair.

ACUTE SKIN LESIONS DUE TO LOCALIZED "HOT PARTICLE" RADIATION EXPOSURES*

J.W. Baum, A. L. Carsten, D.G.L. Kaurin, and C.W. Schaefer
Brookhaven National Laboratory, Upton, NY 11973-5000

ABSTRACT

The purpose of these studies was to determine the incidence and severity of lesions resulting from very localized deposition of dose to the skin from small (< 0.5 mm), discrete radioactive particles. Hanford mini-swine were exposed to localized doses from 0.2 to over 600 Gy (averaged over 1 cm^2 at 70 μm depth) from isotopes having maximum beta particle energies from about 0.3-3 MeV. The incidence of erythema and scabs (indicating ulceration) were scored routinely for up to 71 days post-irradiation.

The responses followed normal probability distributions, and thus, no true threshold could be defined. Ten and 50% incidence rates were deduced using probit analyses. The lowest dose which produced 10% incidence was about 1 Gy for exposures to Yb-175 (0.5 MeV maximum energy) beta particles. The severity of lesions was estimated by analyzing the results in terms of their diameters and persistence. From preliminary considerations of the probability of induction, size, and persistence of acute lesions, a special limit for hot particle exposures in the range of 5-50 Gy may be reasonable, with an action level between about 1 Gy and the limit.

INTRODUCTION

Exposure to workers to small radioactive particles, typically ranging in size from one micron to a few hundred microns in diameter has been identified as a problem in the nuclear power industry. These particles have become known as "hot particles" due to their relatively high specific activity and small size. When deposited on the skin or inhaled, they can cause intense local irradiation of small areas of tissue and may cause reddening, ulceration, necrosis, and a possible increase in the risk of skin cancer.

In December 1989, the National Council on Radiation Protection and Measurements (NCRP) published a report which reviewed the effects of exposure to hot particles in a human volunteer, in monkeys, and pigs (1). Based on this review, a recommended limit of 10^{10} beta particles (75 μCi h; 10 GBq s) emitted from a "point" particle or a particle of less than 1 mm in diameter was suggested for particles in contact with the skin. This limit was intended to prevent "deep" ulceration but, admittedly, might allow transient effects which frequently disappear in less than a week, as observed by Hopewell et al. (2). For beta particles from activated fuel, this exposure causes a dose of about 5 Sv averaged over 1 cm^2 at a depth of 70 μm in tissue. The risk of skin cancer following irradiations of the skin by hot particles was deemed less than that when extended areas of the skin are irradiated due to the small number of cells exposed and the greater potential for cell killing from the localized beta particle dose.

In 1987, an International Commission on Radiological Protection (ICRP) Task Group reviewed much of the same material reviewed by the NCRP. However, the Task Group based its recommendations on preventing acute transient ulceration and recommended restricting to 1 Sv the dose delivered within a few hours over an area of 1 cm^2 measured between depths of 100-150 μm (10-15 mg/cm^2) (3). The latest recommendations of the ICRP, nevertheless, retain the limit of 500 mSv averaged over any 1 cm^2, at a nominal depth of 7 mg/cm^2, regardless of the area exposed (4). The objectives of this work were to provide additional scientific data to use in the decisions and recommendations of these committees and the regulatory agencies.

MATERIALS AND METHODS

Hanford mini-swine were exposed to four types of particles at Brookhaven National Laboratory (BNL): 1) activated UC_2 particles of 250 μm diameter for comparisons with the data of Forbes and Mikhail used in NCRP Report 106 (1); 2) Tm-170 particles with dimensions of about 230-500 μm for comparisons with Hopewell et al's data used extensively by the ICRP Task Group (3); 3) Yb-175 particles with dimensions of 280-500 μm and maximum beta particle energy of 0.5 MeV (to simulate Co-58 which emits a 0.47 MeV positron); and 4) Sc-46 with beta and gamma emissions very similar to those of Co-60. Cobalt-60, Co-58, and activated fuel are the commonest sources of hot particles in nuclear power plants. Scandium-46 was used rather than Co-60 because its shorter half-life and lower density allowed the production of particles that simulated 100-μm-diameter Co-60 particles with much shorter activation periods. UC_2 particles were 252-μm-diameter spheres coated with 18.5 μm of pyrolytic graphite. Other particles were cut from foils of thickness 258 μm (Tm), or 130 μm (Yb and Sc). The largest dimension of the latter pieces was 535 μm.

*This work was supported by the U.S. Nuclear Regulatory Commission. C. Schaefer was supported by the Health Physics Fellowship Program, administered by Oak Ridge Institute for Science and Education for the U.S. Department of Energy.

Irradiations were made within tattooed grids on the flanks of anestisized pigs. Sources were mounted on styrofoam blocks to minimize backscatter. Exposures of 45 s or less were made using a hand-held cone/rod jig with the source fastened to the end of a styrofoam cone, 8 cm long, attached to a plexiglass rod 22 cm in length. Longer exposures were made using a cloth harness with elastic straps which flexed as the animal breathed, yet held the source in a fixed position for up to two hours.

UC_2 and Tm-170 particles were employed both touching the skin and slightly above the skin to test the hypothesis that more beta particles might be required to induce ulcers in the latter case which minimizes particles on clothing. Animals ranging in age from 3.8 to 15 months were exposed to see if age at exposure had any effect on the outcome. Various scoring procedures were explored to test the sensitivity of results to the number of observations per week, the number of number of observers, and the number of days of observation post-exposure. The sensitivity of results to background corrections also was studied. In addition, the diameter of any lesion and area of erythema was measured, using an overlaid scale, and their persistence recorded.

The following were the scoring procedures for erythema and scabs:

Method A, which detected the most lesions, is a modified Hopewell et al. (2) method in which the mini-swine were scored twice per week for 28 days using two or sometimes three observers (Hopewell, personal communication). To model this scoring criterion, we eliminated data from one of the three weekly observations for the first 21 days post-irradiation. Thereafter, BNL observers made only two observations per week, which was similar to the Hopewell scoring schedule. The BNL lesion-scoring criteria were as follows. If two observers scored an area as a lesion on the same day, or if two observers scored the area as a lesion on one day and one observer scored it as a lesion on the successive day, or visa-versa, the area was scored as one-half of a lesion. If two observers scored the area as a lesion on two consecutive days, then it was considered to be a full lesion.

Method B, or "4-of-6/4-of-4," gave fewer lesions than Method A. For the first three weeks in which the mini-swine were scored three times per week, a lesion was considered to be radiation-induced if two independent observers each scored an area as a lesion a minimum of twice in one week. This method was called 4-out-of-6, since there were two observers and three observation periods, giving six possible outcomes, and four scorings of a lesion were required out of the six possibilities, with each observer seeing the lesion at least twice. After the first 21 days, the pigs were scored twice per week, and a lesion was considered to be radiation-induced if two observers each scored a lesion on two consecutive observation days--which was called 4-out-of-4.

Method C, or "6-of-8/5-of-6," was the most restrictive scoring technique used, and was designed to minimize any spurious apparent background. A lesion was considered radiation-induced if two observers scored an area as a lesion three times each out of a possible four consecutive scoring periods for the first three weeks. After three weeks, when the pigs were only scored twice per week, and a lesion was considered radiation-induced if one observer scored an area as a lesion a minimum of two times and another observer scored the same area as a lesion a minimum of three times in three consecutive scoring periods.

RESULTS

Analysis of the results as a function of the animal's age at exposure revealed no single pattern of changes with age. There was greater variability in the results for specific doses in animals over about 10 months of age, however, individual differences in response were as large as those due to age.

Biopsy samples of normal skin were taken from animals of ages 3.8 months to 15 months. The thickness of the keratin layer ranged from 18-33 μm at ~3 months and increased to 48 μm in pigs aged 15 months. The depth of the basal layer varied from 56-92 μm for these young animals and was 100 μm for a single sample at 15 months of age.

The period of observation (28, 48, or 71 da) was very important. Deduced ED_{50} values (50% incidence of a barely detectable lesion or erythema) were 1.5 to 4 times higher for observations that continued for only 28 days compared to those continued for >71 days. The method of scoring (A, B, or C) typically caused differences of factors of about two, with Method C generally giving higher ED_{50} results; this is attributed to better discrimination against background, or the false positive results obtained using scoring Method C. Background effects (scabs in unexposed areas) were typically about 3%, but varied from 0-14% with large statistical uncertainties due to the small number scored (e.g., 1 of 28 spots). Correcting for background events typically caused 5-10% changes in ED_{50}, and 10-20% changes in ED_{10} results using scoring Method C.

Extrapolation of scab diameter results to the zero diameter intercept to arrive at an apparent threshold yielded results for UC_2 exposures of 4.4-9.1 Gy for exposures to particles on the skin. This compares to about 15 Gy for the related Forbes/Mikhail results. These results are approximately equal to the ED_{10} value of 8.5 Gy derived from the UC_2 incidence results, summarized below.

Table 1 summarizes the percentage scab incidence for the four particles studied here and compares them to the work of Hopewell (5) and Reece et al. (6). The most effective particle in our studies was Yb-175 with maximum beta particle emission of 0.47 MeV that yielded an ED_{10} value of 1.3 Gy (0.36 - 2.6 Gy at 95% confidence). Approximately equal ED_{50} values were obtained for Yb-175 and Tm-170 (0.97 MeV), 5.5 and 5.9 Gy, respectively. These values also are close to the value derived from Hopewell's studies (4.5 Gy) using Tm-170. Both Sc-46 and activated UC_2 had higher ED_{50} values, 12 Gy and 11 Gy, respectively. The ED_{50} values reported by Reece et al. (6) for Co-60,

Table 1. Comparison of the Findings of Hopewell et al., BNL, and EPRI*

Isotope	E_{max} (MeV)	E_{avg} (MeV)	Hopewell		BNL		Reece
			ED_{10} (Gy)	ED_{50} (Gy)	ED_{10} (Gy)	ED_{50}(Gy)	ED_{50} (Gy)
Pm-147	0.22	0.062	2.7	3.9			
Co-60	0.31	0.096					40

Tm-170, and activated U particles were 3-4 times higher than the corresponding results for Sc-46, Tm-170, and UC_2 from our studies and those of Hopewell et al. (5).

DISCUSSION AND CONCLUSION

The lesions being scored in this type of study at low doses are small (e.g., about 1- to 2-mm diameter), and transient (e.g., 1-2 weeks). These lesions are not open festering wounds, but rather, barely noticeable scabs. The question to answer is how should this detriment be weighted in comparison with the debilitating effects normally being avoided in setting limits for deterministic and stochastic risks.

In these studies, over 1,100 individual spots were exposed to hot particles. About 560 of these developed detectable scabs which were assumed to result from a break in the integrity of the skin, and therefore, may lead to infection. Only two of the exposed sites became infected -- these after exposures near 500 Gy. One was treated topically with ointment for a few days and the other was treated topically and systemically with an antibiotic since the lymph nodes seemed to be infected. These large exposures leading to infection certainly are not acceptable detriments and a limit should be set to avoid them. However, the low incidence of infection for animals living under typical experimental conditions, and lack of other serious effects, suggests that a limit set to avoid persistent ulceration may be acceptable even if small transient scabs are produced.

A dose limit could be based on the product of the probability of scab formation, the diameter of the scabs and their persistence. From a preliminary evaluation of our data, for doses in the range of 1-200 Gy, this value is about 1-4 scab-mm-da/Gy. Alternately, a limit could be based on the number of days a scab is expected, regardless of its diameter. For example, preliminary analysis in terms of the number of scab-days for exposures between 0.1 and 50 Gy indicates that an average value for all sources is about 1.6 scab-days/Gy with somewhat higher values at lower doses and perhaps twice as many scab-days per Gy from Tm-170 compared with other sources.

These results together suggest that a limit in the range of 5-50 Gy may be appropriate to avoid effects that are more nearly comparable with other detriments at the dose limits. Based on these results and the relatively small harm associated with the production of lesions by hot particles, it seems reasonable to set a special hot particle limit in the range of 5-50 Gy (dose averaged over 1 cm^2 at 70-μm depth in tissue). In addition, an action level for persons receiving doses in the range 1 Gy to the limit selected could be established involving weekly checks for possible lesions; any ones detected then could be treated to avoid infection.

MAJOR SCIENTIFIC TOPIC NUMBER

The experiment was performed on not pedigree male rats weighing 220-280 grams. A section of the animal's back measuring 4.0 x 4.0 cm was exposed to radiation dose of 5000 and 10000 rad on the RUM-140 device. Hairs on that section were removed before the irradiation. Radiation burn developed in 10-14 days. This burn closed up in 3 months and after 4-6 months complete recover of hairs was observed.

Regimens of hyperbaric oxigenation /GBO/ (1 and 3 ATMs hour daily during 8-10 weeks) showed no harmful influence on animals behavior. These GBO regimens promoted more auspicious wound process and more rapid healing of the skin.

Application of GBO straight away irradiation before the development of visible manifestations of radiation lesions was conductive to tardy development of radiation wound and more mild course of wound process. Thus obtained results testify that GBO have prospects in the treatment of radiation skin lesions.

EARLY EFFECTS OF RADON PROGENY EXPOSURE IN ANIMALS

Clare G Collier, Sean T Baker, Toni M Eldred and John C Strong

Biomedical Research Department, AEA Technology, B551, Harwell, Didcot, Oxon, OX11 ORA, UK.

INTRODUCTION

Life-span carcinogenicity studies are currently being conducted in rats at AEA Harwell to investigate the effects of exposure conditions on lung tumour induction following exposure to radon and radon progeny. Chronic exposures to radon/radon progeny are performed under well defined conditions, in a specially constructed exposure facility (1). Groups of animals have been exposed to levels between 175 and 3000 WLM, at an exposure concentration of 1000 WL. Further studies will investigate the effect of dose-rate on lung tumour incidence at both high and low total doses. Life-span carcinogenicity studies in the rat are expensive and time consuming. In addition, determination of the radiation dose to the lungs is not simple. Various approaches to reduce the time-scale and assess the radiation dose to the lung are being investigated. In France the CEA group have used 5-6-Benzoflavone to increase the incidence of preneoplastic changes and tumours and to reduce the latency period for tumour induction following exposure to radon and radon progeny (2, 3). At AEA, studies on the early effects of radon progeny exposure, namely cell proliferation and induction of chromosome aberrations are being conducted to determine whether these early effects can provide predictions for lung tumour induction. This approach may allow the effects of different exposure conditions to be determined far more rapidly and may also give some insight into the mechanisms of lung tumour induction by radon progeny.

METHODS

For these studies, epithelial cell proliferation and induction of nuclear aberrations in alveolar macrophages were studied in male Sprague Dawley rats 14 days following exposure to radon and radon progeny. Earlier studies (4) indicated that the peak response for these effects is observed at this time, regardless of exposure duration (2-15 days).

Following exposure (duration 1-20 days), animals were housed under standard conditions with food and water available *ad libitum*. At 14 days after the end of exposure, the animals received an intraperitoneal injection of 5-bromo-2'-deoxyuridine (BrdU, Sigma) (4 ml, 5 mg/ml). Four hours later they were killed with an intraperitoneal injection (400 mg/kg) of sodium pentabarbitone (Sagatal, RBM, Animal Health Ltd, Dagenham) followed by exsanguination via the abdominal aorta.

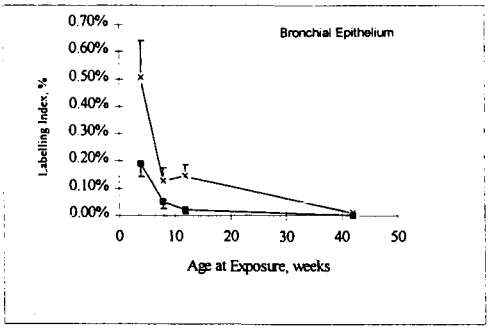
Where measurements of nuclear aberrations were to be made, the lungs were lavaged and cytocentrifuge slides prepared from the lavage fluid (4). Differential cell counts on at least 2000 cells selected at random were made on the these slides. Nuclear aberrations in alveolar macrophages were scored as cells containing micronuclei, binucleated cells, cells containing both types of aberration and cells containing multiple fragments of nuclear material in addition to the main nucleus. Identification of micronuclei was as described previously (4).

For the assessment of epithelial cell proliferation, following lavage, the lungs were fixed, sectioned and serial sections stained for BrdU and with Hand E as described previously (4). For each animal at least 20 fields on the BrdU stained slides were observed and the number of BrdU labelled cells counted. At least 10 fields on the H and E stained slides were observed and the total number of epithelial cells counted. The labelling index was expressed as the percentage of total epithelial cells incorporating BrdU.

EFFECT OF AGE ON RADON INDUCED CELL PROLIFERATION

Before beginning the main life-span studies, the effect of animal age on early effects resulting from radon/radon progeny exposure was investigated. Other groups studying the effect of radon progeny exposure have used animals of widely varying ages. The TNO group in the Netherlands have used animals as young as 4 weeks at exposure (5), whereas the CEA group in France have generally used animals which were 3 months old (6). Groups of 4 animals which were 4, 8, 12 and 40 weeks old were simultaneously exposed in the AEA facility to a total dose of 440 WLM, over 5 days. Groups of similar aged animals were maintained under normal (non-exposed conditions) to act as controls. For each animal, cellular proliferation in the alveolar and bronchial epithelium was determined using BrdU uptake at 14 days post exposure (Figure 1). The youngest animals (both exposed and control) showed the highest proliferation rates (at least 10 fold higher than the adult animals). In both the exposed and control animals, the elevation of proliferation above that in adults, fell with age, and by 12 weeks of age at exposure, proliferation levels were as for the 40 week old animals. Generally, for all age groups and both exposed and control animals, epithelial cell proliferation was low in the bronchial region (less than 0.5% even in the youngest radon exposed animals) and about 3 times higher in the alveolar region. Taya et al (4) found that the bronchial region showed a similar extent of proliferation to that in the alveolar epithelium. Exposure to radon/ radon progeny resulted in an increase in proliferation of between 2 and 6 fold in all age groups. The study demonstrated that the use of animals less than 12

weeks of age may not be appropriate for dosimetric studies and raised doubts about their suitability for life-span studies as the higher proliferation rates could result in higher cell death and lower tumour incidences.



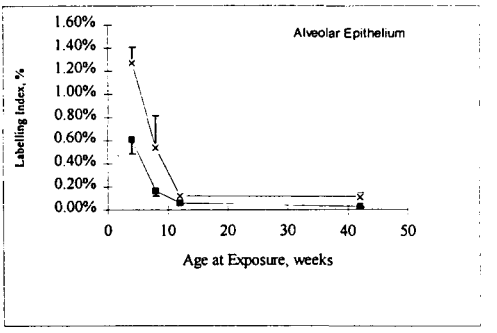


Figure 1. The effect of animal age on epithelial lung cell proliferation, following and without exposure to radon progeny. (x-radon exposed ■-unexposedMean incidence of proliferating cells % ± SEM).

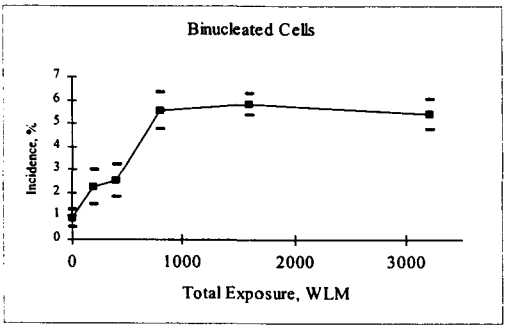
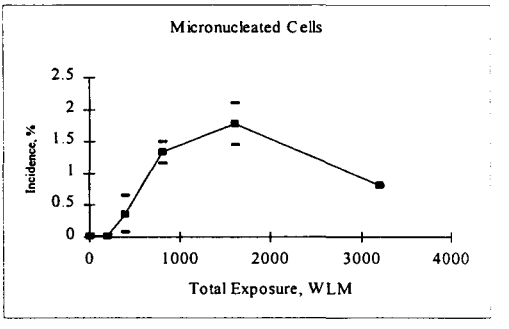
THE EFFECT OF DOSE ON CELL PROLIFERATION AND NUCLEAR ABERRATION INDUCTION

A study to investigate the effect of dose on lung tumour induction is currently being conducted. Fourteen groups of animals were exposed at a constant dose rate (1000 WL) over varying time periods to give total exposures of 200 to 3200 WLM. From each exposure group, 2 animals were killed 14 days after exposure to assess early effects (epithelial proliferation and nuclear aberration induction). The incidences of the three principal types of nuclear aberration are given in Figure 2.





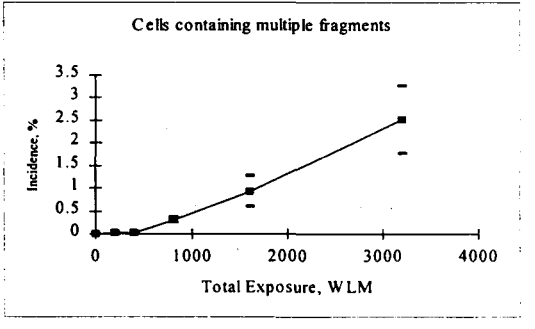


Figure 2. Incidence of nuclear aberrations in alveolar macrophages following exposure of rats to radon progeny at different cumulative doses (Mean incidence % ± SEM).

Cell proliferation was measured in the alveolar and bronchial regions from each of the animals (Figure 3). Alveolar epithelial cell proliferation rose with increasing dose up to 800 WLM. It then fell to levels below that

of control animals at doses of 3200 WLM. In the bronchial region, proliferation peaked between 200 and 400 WLM and also fell to levels below those of control animals at the higher doses.

Early effects (various types of nuclear aberration and cell proliferation) generally showed a dose response with increasing radon/radon progeny exposure levels. For all effects other than multiple micronucleus induction (possibly representative of apoptosis), beyond a peak response dose, the dose response relationship was not maintained and effects either fell at higher doses or remained level. The dose at which peak response was observed was different for different effects. The most sensitive effect was epithelial cell proliferation, with peak responses in the alveolar and bronchial regions occurring at 800 WLM and 200-400 WLM respectively. Aberration induction appeared to be less sensitive and peak responses were observed at 800 and 1500 WLM for binucleus and micronucleus formation.

CONCLUSIONS

The validity of these early effects to accurately predict long term lung cancer incidences will not be known until the current life-span studies are completed. However should one or a combination of the assays used prove to be successful in predicting long term effects from radon exposure, the duration and costs of studies to investigate the effect of exposure conditions on the induction of lung tumours by radon progeny could be significantly reduced. In all future exposures for life-span studies at AEA, animals are being taken to study these early effects.

EFFECT OF RADON-222 AND ITS DAUGHTER INHALATION ON REPRODUCTION IN RATS EXPOSED UNDER NATURAL CONDITIONS

Stela Râmboiu[1], E. Bordàs[1], Adriana Olinic[2]

[1]Medical Center, Health Services and Management, 3400 Cluj-Napoca, Romania
[2]Universtity of Medicine, 3400 Cluj-Napoca, Romania

INTRODUCTION

Radon-222 and its short-lived progeny inhalation is strongly related with a high incidence of lung cancer /1/. The literature did not reveale any other effect produced by Radon-222 and its decay products /2/.
The aim of the study is to present data about sterility induction in rats exposed under natural conditions ia a uranium mine to high level of Radon-222 and Radon-222 progeny concentrations in air.

MATERIAL AND METHOD

The experiments were performed on 60 adult Wistar rats. The animals were devided into 6 groups:

- grups I an II (female and male) exposed for 52 days in a uranium mine to an average concentration of 28,638 Bq/c.m. Radon-222 and 2.76 Working Level of Radon-222 progeny;
- control groups III and IV (female and male) kept underground in the same mine, in the same conditions of temperature and humidity as groups I and II; Radon-222 and Radon-222 progeny concentration were at the level natural background;
- control groups V and VI (female and male) kept in vivarium conditions.

The Kusnetz' and Rock' methods were used to measure Radon-222 and its daughters concentrations in air /3, 4/. The externalgamma dose rate was also measured with a Curiemeter VA-J-100.
All groups were devided into two subgroups; the fertility index was calculated at the end of the expoosure and ten months later, by mating unexposed rats with exposed ones. The weight of the reproductive organs were evaluated and the histological sactions were analysed.

RESULTS

Immediately after exposure and mating of exposed females with unexposed males and unexposed females with expsed females the fertility indices were 82% and 85%, respectively; the histological sections of reproductive organs presented a normal aspect.

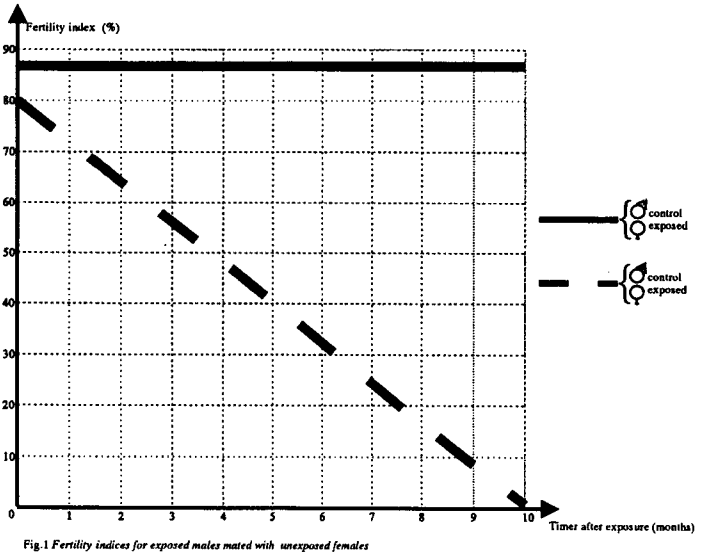

Fig.1 *Fertility indices for exposed males mated with unexposed females*

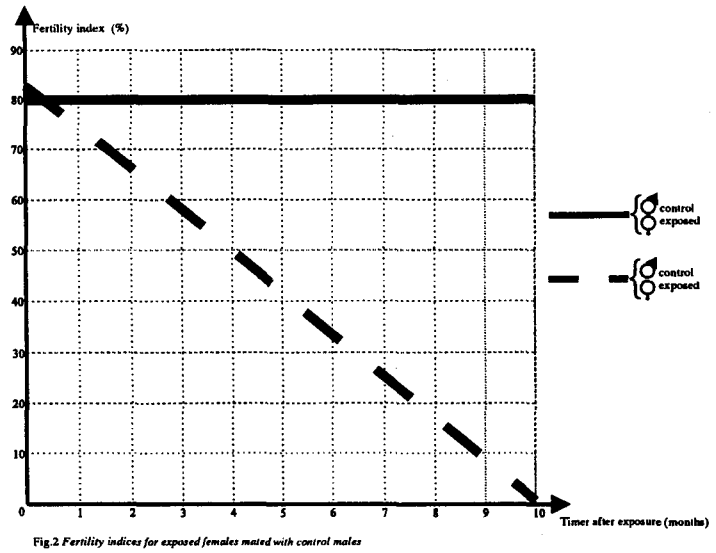

Fig.2 *Fertility indices for exposed females mated with control males*

After a latency period of 10 months the animals presented severe lesions of the reproductive organs manifested by cellular and follicular distrophy at level of the ovaries and atrophy of the germinative epithelium of testis (Fig. 3). Concomitantly to these morphological lesions the fertility index became crossed mating of the exposed and control animals (Fig. 1 and 2). There were no diferesces between the fertility indices of exposed animals mated with underground control groups and vivarium control groups, respectively.

Fig. 3 *The histological section of testis 10 months after exposure*

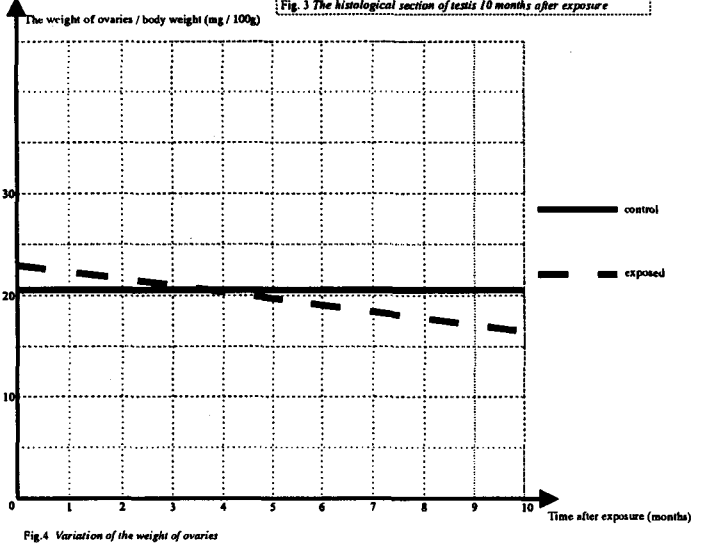

Fig.4 *Variation of the weight of ovaries*

The weight of ovaries for exposed and unexposed rats did not present significant variations in time (Fig. 4 and 5). The weight of testis / 100g body weight was significantly lower ten months after the end of exposure (160 mg/100g. body weight) compared with control underground group IV (476 mg/100g. body weight). (Fig. 6)

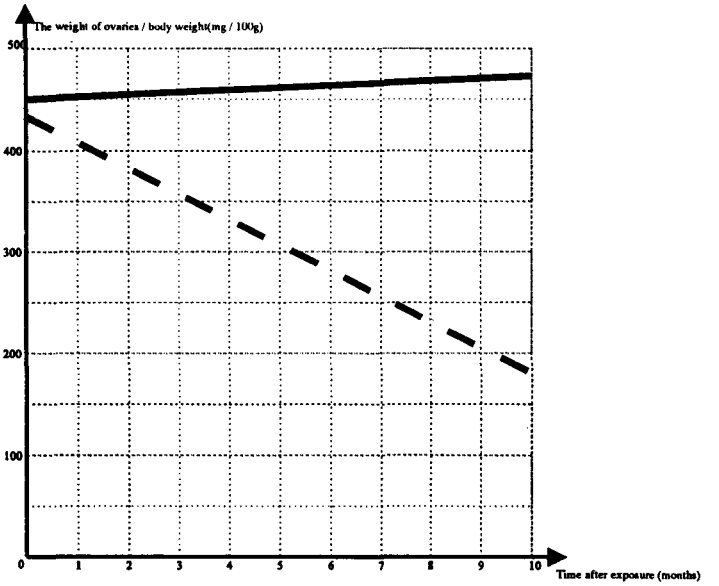

Fig.5 Variation of the weight of ovaries

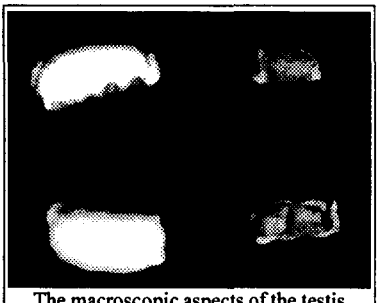

The macroscopic aspects of the testis 10 months after the exposure compared with control groups

CONCLUSION

As the gamma dose values were too low to produce the rats sterility, the only possible explanation is the inhalation of short - lived Radon-222 progeny.

Osteosarcoma induction in mice by the alpha-emitting nuclides, plutonium-239, americium-241 and uranium-233

M Ellender, JD Harrison, HE Pottinger and JM Thomas
National Radiological Protection Board, Chilton, Didcot, Oxon. OX11 0RQ, UK.

Introduction

Following either occupational or environmental exposure of individuals to alpha-emitting isotopes of plutonium (Pu), americium (Am) or uranium (U), their entry into the bloodstream will result in long-term retention in the skeleton and a consequent risk of osteosarcoma and leukaemia. The International Commission on Radiological Protection (ICRP) has recently adopted models for the behaviour of radionuclides in the skeleton which take account of the physiological processes of bone remodelling and growth (1,2). The models treat Pu and Am similarly, allowing for burial of surface deposits during mineral deposition and transfer to the marrow and release to the circulation during bone resorption (1). Thus, the models predict that ^{239}Pu and ^{241}Am are similarly effective in inducing osteosarcoma and leukaemia. Uranium behaves more like calcium and the alkaline earth elements and the model assumes more rapid transfer from surfaces to bone volume (2). Because a greater proportion of alpha energy from U isotopes is deposited harmlessly in bone mineral, they are predicted to be less effective in causing malignancy. No changes have been made to the assumptions that the sensitive cells for osteosarcoma induction are uniformly distributed on endosteal bone surfaces and those for leukaemia induction are uniformly distributed through red bone marrow. Furthermore, radionuclides are assumed to initially deposit uniformly on endosteal bone surfaces.

A number of finding are at variance with model predictions. Experimental studies using rats (3) and mice (4) have shown that ^{239}Pu is about three times as effective as ^{241}Am in inducing osteosarcoma per unit average skeletal dose. Autoradiographic studies of mouse (5) and rat (6) bone have shown differences in the initial distribution of ^{239}Pu, ^{241}Am and ^{233}U as well as their subsequent behaviour. The induction of osteosarcoma but absence or very low incidence of leukaemias in humans given radium isotopes suggest that alpha irradiation from bone surfaces may be ineffective in causing leukaemia, possibly due to heterogeneity in the distribution of sensitive cells in the marrow (7).

This paper presents results from a study of the comparative toxicity of ^{239}Pu, ^{241}Am and ^{233}U in mice, comparing tumour incidence and the distribution of alpha dose within the skeleton. Completed results for osteosarcoma induction are reported; leukaemia diagnoses are not yet complete.

Materials and Methods

Male CBA/H mice were obtained from the Medical Research Council (MRC) Radiobiology Unit, Chilton, Didcot, Oxon, OX11 0RD. This strain a very low spontaneous incidence of osteosarcoma and leukaemia. Groups of 5 mice were housed together. Food (type RMI Expanded, Special Diet Services, Witham, Essex) and water were freely available at all times. Animal care and handling conformed to the UK Animals (Scientific Procedures) Act 1986.

Groups of 12 week old mice (50-100) were given intraperitoneal injections of ^{239}Pu, ^{241}Am or ^{233}U as the citrate complexes. Each nuclide was administered to three groups of animals at levels of activity estimated to give average bone doses of about 0.2-0.3 Gy, 0.5-1.0 Gy and 1.3-1.6 Gy, calculated to 500 days after administration; a further control group (100) were given inactive solution. To avoid chemical toxicity to the kidneys from ^{233}U, each nuclide was administered as 9 injections over a 3 week period. All groups were treated similarly. The mice were followed for their life-span and either died or were killed when moribund or a visible tumour was present. Osteosarcomas were identified by x-ray examination of the skeleton at death and the tumours confirmed by histological examination. Other organs and tissues were taken for histological examination as appropriate.

Results

Table 1 summarises tumour diagnoses for each group of animals, counting all observations including cases where individual animals were shown to have more than one tumour or tumour type. High incidences of liver and lung tumours were observed for all experimental groups and the control group, as expected with this mouse strain (8,9). A variety of other soft tissue tumours were identified with low incidences (see footnotes to Table 1). Small numbers of blood cell tumours were also observed; final diagnoses are in progress.

Table 1. Number of tumours by type

Group	^{239}Pu			^{241}Am			^{233}U			Control

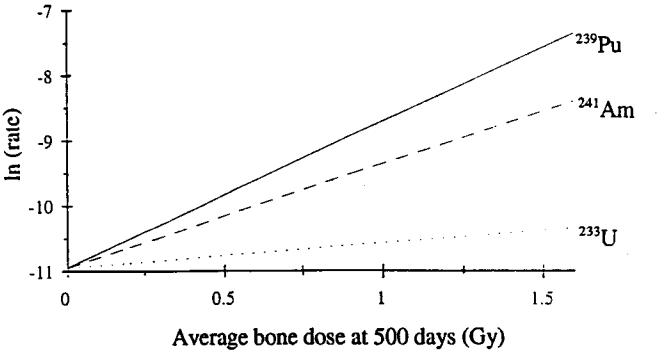

Figure 1. Incidence of osteosarcoma following administration of ^{239}Pu, ^{241}Am or ^{233}U

Osteosarcoma was seen in 2%, 8% and 18% of mice in the 0.2 Gy, 0.5 Gy and 1.3 Gy ^{239}Pu groups (5, 15 and 25 kBq kg^{-1}), respectively. The corresponding incidences of osteosarcoma in ^{241}Am groups were 0, 4% and 18%, respectively, and incidence in each ^{233}U group was about 2%. Only the highest dose groups had animals with more than one osteosarcoma, with one animal having two tumours in each nuclide group and 2 animals having three tumours in the ^{239}Pu group. A difference was apparent in the location of osteosarcomas in the highest dose ^{239}Pu and ^{241}Am groups in that about 70% in the ^{239}Pu group were in the appendicular skeleton, mainly femur, while a similar proportion in the ^{241}Am group were in the axial skeleton, mainly vertebrae. Osteosarcoma incidence as a function of dose was assessed using Poisson regression (Figure 1). Significance was tested by comparing changes in deviance with a χ^2 distribution. Dose was found to have a significant effect on incidence (change in deviance = 20.34 on 1

$p<<0.001$). However, the effect differed significantly between nuclides (change in deviance = 16.21 on 2 d.f.; $p<0.001$). There was evidence for a difference in regression slopes for ^{239}Pu and ^{241}Am (change in deviance = 3.86 on 1 d.f.; $p=0.05$) and a single slope for ^{239}Pu and ^{241}Am differed significantly from a slope for ^{233}U (change in deviance = 12.35 on 1 d.f.; $p<0.001$). For ^{233}U, the slope was consistent with no effect of dose. A further analysis will take account of ages at death and competing causes.

Discussion

The observed incidences of ^{239}Pu induced osteosarcoma in male CBA/H mice are consistent with reported incidences in females of the same strain of 7.5% and 30% after administration of 6 kBq kg^{-1} and 19 kBq kg^{-1} of ^{239}Pu, respectively (8), and the observation that females were more sensitive than males to osteosarcoma induction by a factor of 3 - 4 for ^{239}Pu and 4 - 6 for ^{226}Ra (9). It is considered that the difference may be due to greater turnover of bone in females. The observed difference in osteosarcoma induction by ^{239}Pu and ^{241}Am was smaller than reported previously. Bensted et al (4) reported that 17 out of 22 male rats given 108 kBq kg^{-1} ^{239}Pu developed osteosarcoma compared with 4 out of 19 given 92 kBq kg^{-1} ^{241}Am. Using small groups of animals (10 - 20), Taylor et al (3) showed a significantly greater incidence of osteosarcoma in male and female C57Bl/Do black mice given 105 kBq kg^{-1} and 32 kBq kg^{-1} of ^{239}Pu than in comparable groups given 102 kBq kg^{-1} and 30-34 kBq kg^{-1} of ^{241}Am. Similar studies using C57BL/Do albino mice showed greater osteosarcoma incidence with ^{239}Pu than ^{241}Am in female mice but no difference in male mice.

Autoradiographic studies have shown clear differences in the initial distribution of ^{239}Pu and ^{241}Am on bone surfaces in rodents (5,6). While ^{239}Pu is concentrated mainly on endosteal surfaces of trabecular and cortical bone, ^{241}Am is more widely distributed on bone surfaces including periosteal surfaces and internal cortical bone surfaces. Previous reports of greater sensitivity to osteosarcoma induction by ^{239}Pu than ^{241}Am have been attributed to greater doses from ^{239}Pu to trabecular surfaces (10). It is possible that differences in distribution and osteosarcoma incidence were accentuated by increased bone turnover caused by the deposited nuclides which is apparent, according to Loutit et al (9), at administered activities of 20 kBq kg^{-1} and greater.

Uranium has been shown to deposit initially on bone surfaces, including endosteal and periosteal surfaces, concentrating on growing surfaces (5,6). The low toxicity of ^{233}U compared with ^{239}Pu and ^{241}Am is consistent with more rapid burial of surface deposits, reflecting the chemical similarity of the uranyl ion and those of the alkaline earth elements, including calcium.

In conclusion, it would appear that the observed osteosarcoma incidences, although showing small differences between ^{239}Pu and ^{241}Am, are broadly consistent with ICRP model estimates of equivalent toxicity of ^{239}Pu and ^{241}Am and lower toxicity of ^{233}U.

RADIATION-INDUCED CHROMOSOME ABERRATIONS IN BONE MARROW CELLS LEADING TO ACUTE MYELOID LEUKEMIA IN MOUSE

Nobuhiko Ban and Tomoko Kusama

The University of Tokyo, Tokyo, Japan

INTRODUCTION

It is well known that radiation-induced acute myeloid leukemia (RI-AML) in mice is characterized by deletion and/or rearrangement of chromosome 2 (1-5). While chromosome 2 has been suspected to be a target of RI-AML, radiation-sensitive site of the chromosome might be implicated in the leukemogenesis (3,6). There were few cytogenetical studies, however, focusing on chromosomal rearrangements shortly after irradiation, and little was known about the frequency and pattern of chromosome 2 aberrations during the early period. In this study, metaphase samples were prepared from whole-body irradiated mice 24 hours after irradiation, most of the cells considered to be in the first mitotic stage. Distribution of chromosomal breakpoints on the metaphase samples were analyzed to study the relationship between chromosome aberrations and RI-AML.

MATERIALS AND METHODS

Eight-week male C3H/He mice were exposed to a single dose of 3 Gy of γ-ray from a ^{137}Cs source, and sacrificed 24 hours after irradiation. Bone marrow cells were extracted from femurs, and metaphase samples were prepared without cultivating process. Chromosome banding was achieved by double staining with DAPI [4',6-diamidino-2-phenylindol] and actinomycin D, which enhances contrast of Q-band with DAPI (7). Banded metaphases were photographed and negatives were scanned with a film scanner connected to a Macintosh computer. Incorporated metaphase images were karyotyped on the Macintosh using Adobe Photoshop software. Chromosome-type aberrations were scored for 5 mice, and breakpoints were identified according to standard idiogram of the banding patterns (8).

RESULTS AND DISCUSSION

Table 1 shows frequencies of chromosome-type aberrations. A total of 250 metaphases was analyzed for 5 mice, and 232 breakpoints were observed in 101 aberrant cells. As an average,

Table 1. Frequencies of chromosome-type aberrations.

Mouse No.	Metaphases analyzed	Metaphases with structural aberrations	Number of breakpoints	Brekapoints per metaphase
#1	50	27 (54%)	70	1.40
#2	50	16 (32%)	43	0.86
#3	50	21 (42%)	46	0.92
#4	50	15 (30%)	29	0.58
#5	50	22 (44%)	44	0.88
Total	250	101 (40%)	232	0.93

approximately one breakpoint per cell was detected.

Number of the breakpoints in each mouse was graphed in Figure 1, where breakpoints on chromosome 2 were distinguished from the other chromosomes. Although there are statistical errors, Mouse #5 seemed to have more breaks on chromosome 2 than the other mice. Hence data of Mice #1 to #4 were pooled, and Mouse #5 was analyzed separately.

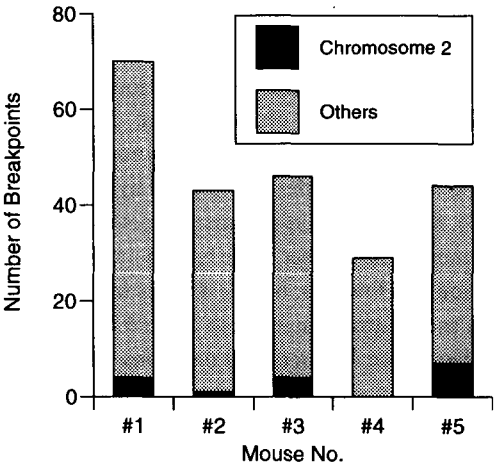

Figure 1. Number of chromosomal breakpoints in each mouse

Figure 2 shows the number of breakpoints in each chromosome for Mice #1 to #4 and Mouse #5. Data of Mouse #5 includes 32 metaphases additionally analyzed. The difference between two graphs is evident, and chromosome 2 of Mouse #5 is conspicuous. Mouse #5 had 13 breakpoints on chromosome 2 in 82 metaphases while Mice #1 to #4 had 9 in 200, 3.5 times higher in relative frequency.

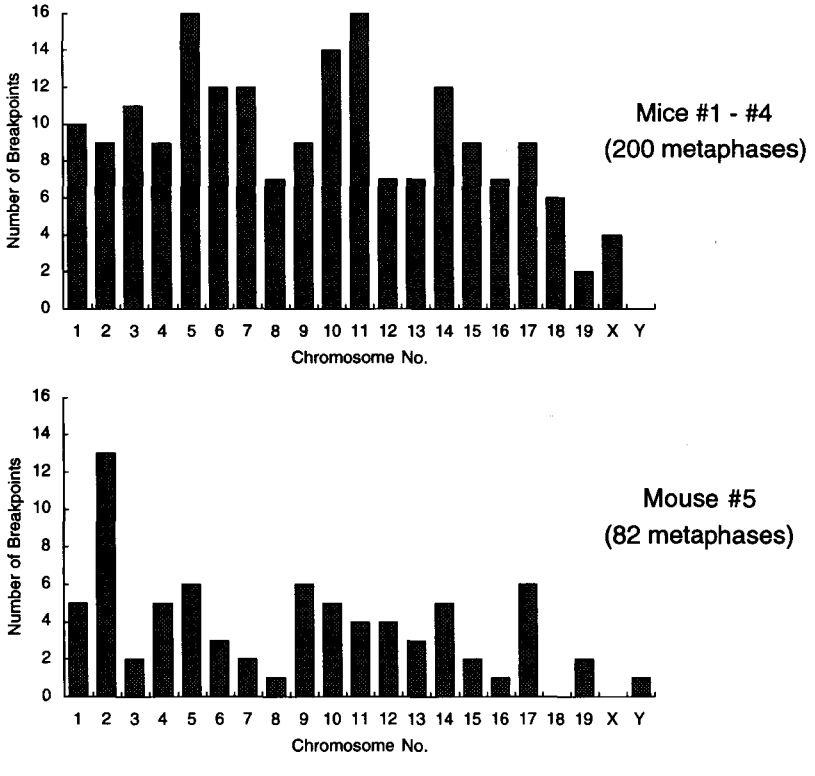

Figure 2. Number of chromosomal breakpoints in each chromosome

Figure 3 illustrates distribution of the breakpoints on chromosome 2. The breakpoints were classified into three aberration categories as described by Savage (9). So far, any sort of cluster is not evident although the number of the breakpoints is not enough. However, Mouse #5 was involved in more intrachanges than Mice #1 to #4. These were all interstitial deletions, typical aberration category of chromosome 2 in murine AML (1-5).

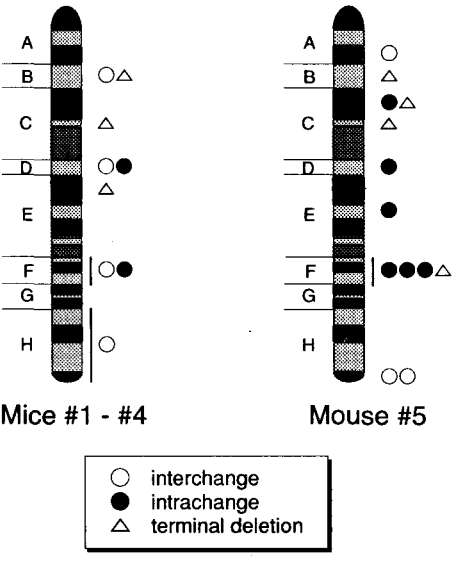

Figure 3. Distribution of breakpoints on chromosome 2

CONCLUSION

Our experiment detected a chromosome 2-sensitive mouse out of 5 mice studied. The result indicates inter-individual difference in chromosome aberration exists even in an inbred strain. It is inferred, if radiation-induced chromosome aberrations are responsible for murine leukemogenesis, there might be AML-sensitive individuals.

ABSTRACT

Clinical and hematological changes in pigs after one-time acute radiation by high-energy-X-rays were described.

The radiation of animals was performed by using the linear accelerator of industrial type, with X-rays of 4 MeV, with semi-lethal dose (LD 50/30 = 3,20 Gy) bilaterally (50% of the dose from each side).

The radiation syndrome in pigs developed through 4 stages of the disease: the prodromal stadium (1-3 days), the latent stadium (3-7 days), the stadium of expressed clinical symptoms (7-18 days) and the stadium of recovery (after 25 days). The basic characteristic of the disease was a strong haemoragic diathesis with expressed blood spots on the skin and bleedings from the nose and the anus as well as a rush decrease of blood elements (leukocytes and trombocytes) already 24 hours after radiation.

INTRODUCTION

The studies on the acute radiation syndrome (ARS) in pigs is of great importance because a certain number of morphological lesions are similar to those in people in the same radiation conditions. This refers particularly to the clinical picture and pathomorphological changes on the skin and haematopoietic organs of the breeds of "white" pigs (1-3).

The aim of our investigations was to study the effects of semilethal radiation doses on the manifestation of the radiation syndrome in pigs.

MATERIAL AND METHODS

Six pigs of the "Landras" breed were used in the experiment. They were of both sexes, 4 months old and with average weight of 40 kg. The animals were irradiated with the semilethal dose of high-energy-X-rays (3,20 Gy) on a linear accelerator of industrial type. The irradiation was performed one time bilaterally (50% of the dose on each side). In the course of the 30 post-irradiation days the animals were clinically observed every day and their haematological status was followed on days 1, 3, 7, 14, 21 and 28 after irradiation.

RESULTS AND DISCUSSION

Clinical manifestations of the radiation syndrome in semilethally irradiated pigs can be divided in 4 phases: the prodromal phase, the latent phase, the phase of expressed clinical symptoms and the phase of recovery.

The prodromal phase begins immediately after irradiation and lasts to day 3. It is characterized by slight apathy, inappetence and conjunctivitis of lower degree.

The latent phase attach to the prodromal phase and lasts to day 7. It is characterized by absence of visible clinical symptoms, animals look illusory healthy and consume feed and water normally.

The phase of expressed clinical symptoms begins approximately on day 7 after irradiation and lasts the next 12-15 days. It is characterized by strong apathy, animals mostly lie, refuse feed and water, diarrhea appears, which obtains a profuse character with jelly and blood, the temperature rises and also bronchopneumonia with expressive cough attacks appears. Between days 7 and 10 after irradiation, a strong erythema and hyperaemia occur on the skin of animals, which, in the later phase, transform into dermatitis that has sometimes a pustulous character. Dermatitis is mostly expressed on ears, on the back, on the inside of extremities as well as on the stomach. About day 15, bloody spots and diffused bleedings appear, the skin aches when touched and breaks easily. In their further development, skin lesions convert into bloody stained dark crusts that give a "sooty" appearance to the whole change. In this phase also bleedings from the nose and the anus are manifested and on day 18 the first deaths were noticed.

The phase of recovery begins after the day 25 in animals that survive. It is characterized by a gradual disappearance of symptoms that were expressed in the previous phase, but even after day 30 the survived animals couldn't be characterized as clinically healthy.

The frequency and the period of appearance of clinical symptoms of the radiation syndrome are shown in figure 1.

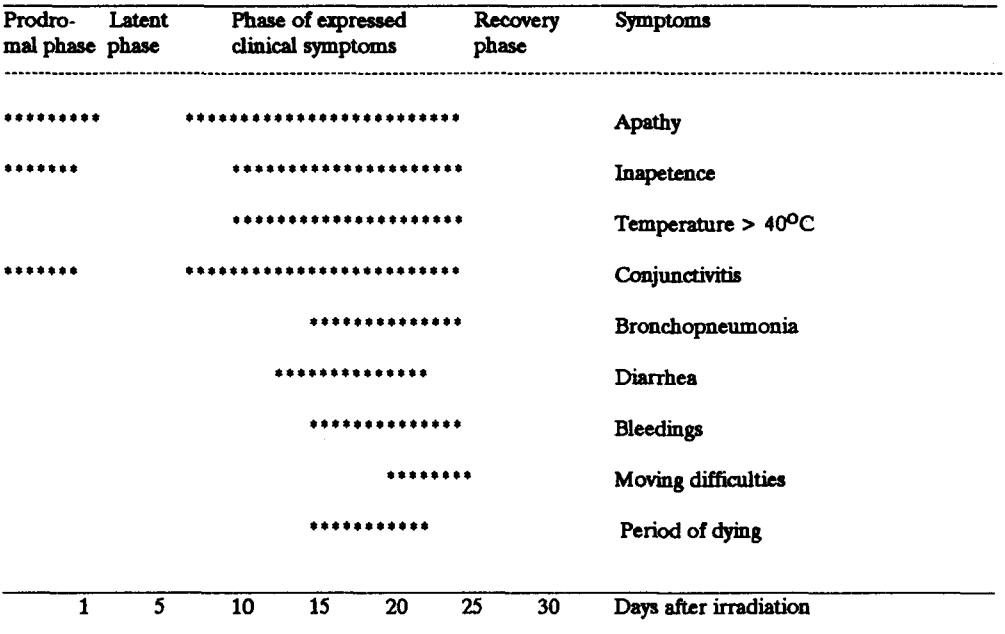

Figure 1. Frequency and period of appearance of clinical symptoms in semilethally irradiated pigs.

Table 1. Relative values of leukocyte and trombocyte number in semilethally irradiated pigs.

Days after irradiation	Relative number of leukocytes, % in relation to the normal	Relative number of trombocytes, % in relation to the normal
0	100	100
1	70	80
3	50	60
7	40	45
14	20	15
21	30	20
28	40	35

Haemathological changes were reflected in a rush decrease of the formed blood elements (leukocytes and trombocytes) already 24 hours after irradiation (table 1).

CONCLUSION

The main characteristic of the radiation syndrome in semilethally irradiated pigs was a strong haemorrhagic diathesis with expressed bleedings on the skin and from the nose and the anus. The changes on the skin were manifested by strong hyperaemia, erythema and dermatitis, especially on the inside of thighs and on the stomach. In the later phase, blood spots and diffused bleedings on the skin and from the nose and the anus appeared. Changes in the haemathological status were obvious already 24 hours after irradiation, with a drastic decrease of leukocyte and trombocyte number. On day 14 after irradiation, the leukocyte and trombocyte number decreased to only 10-20% of their normal value.

ABSTRACT (See instructions overleaf)

The problem of choosing the optimal conditions using drugs is a cardinal one for any experimental research. Basing on principles of mathematical theory of experiments, optimal doses and periods of drug administration were determined using both the rate of survival at day 30 following as response indices.

The ability of Ukrain (Uk), a cytostatic and immunomodulating semi-synthetic compound of thiophosphate-modified alkaloids of Chelidonium Majus L., to modify the effects of irradiation was studies in CBA mice.

The doses of irradiation from 6.0 to 7.5 Gy at the dose rate of 1.5 Gy/min, the dose of Uk from 0.2 to 10 mg/kg and time: from 24 h before t
o 24 h after irradiation of its administration were chosen as the most significant factors that may influence the survival of irradiated animals. The drug (0,2 -1,4 mg/kg) was found to increase the survival rate of mice by 50 - 60 persent at irradiation doses from 6.00 to 6.75 Gy with no effect at the dose of 7.50 Gy. Maximal increase in the survival rate of the mice was noted when the drug was administreted within the interval from 6 h before to 3 h after irradiation.

To conclude, the main outcome of the work presented is the finding that Ukrain is capable of modifying the effects of irradiation when applied in both prophylactic and curative regimes. The drug was also found to be able of modifying the effects of prolonged irradiation with the cumulative dose of 8.75 Gy (LD 85/30) at the dose rate of 0.02 Gy/min.

AUTOIMMUNE PROCESS IN CNS UNDER Cs-137 INNER IRRADIATION

N.I.Lisyany, L.D.Liubich

Institute of Neurosurgery, Academy of Medical Sciences of Ukraine

INTRODUCTION

Autoimmune hypothesis as to the development of radiation-induced brain injuries stands high among the concepts of the CNS post-radiation damage pathogenesis.

To study the changes occurring in a living organism affected by a small-dose radiation due to incorporated radionuclides as well as to create adequate models are of critical importance in the post- Chernobyl period.

The effects of chronic small-dose inner radiation on the development of autoimmune responses were evaluated by determining the level of the CNS proteins and protein-induced antibodies to the CNS components.

MATERIALS AND METHODS

Forty eight ordinary mice weighing 140-180 g were used throughout the experiments. The mice were kept on isocaloric diet in vivarium and received 600 Bk of Cs-137 with food daily. The control group mice (n=16) were kept under similar conditions out of isotopic unit being given similar food free of Cs-137.

The tests were performed after 1,3,6,9 months since the beginning of experiments and in 3 months after a 6-month Cs-137 intake has been terminated.

After 1,3,6,9 months the animals were decapitated, and the blood were taken for serum. In the serum of experimental mice we studied the content of autoantibodies to neurospecific proteins (NSP): MBP, S-100 and NSE (neurospecific enolase) as well as the availability of blood-circulating MBP and NSE. NSP were obtained from calf brain. MBP was isolated using Palladin et al.(1970) technique while S-100 and NSE were isolated after G.A.Berezhnoy (1978). Antibodies to NSP were determinated by the Voller et al (1979) method modified by T.M. Cherenko (1989) using indirect immunoferment technique. To determine the MBP content in the blood serum standard ELISA modified by T.M.Cherenko was used. NSE serum concentration was measured using a set of reagents for NSE assay in human blood serum (NSE EIA <DIAplus>, F.Hoffman-La Rosch & Co., Basel, Switzerland).

RESULTS AND DISCUSSION

Analysis of mean levels of antibodies to MBP shows that at the initial stage of inner ionizing radiation their concentration holds low. However, starting from 3-6 and 9 month particularly, it increases definitely. Titres of autoantibodies to S-100 and NSE were seen to grow gradually within 1-9 months.

In mice with a 3-month interval after a 6-month radiation exposure mean levels of antibodies to all the three NSP have reached control values. The level of autoantibodies to MBP in these mice slightly exceeded the control values, whereas levels of autoantibodies to S-100 and NSE were indefinitely lower.

The most statistically confident autoantibody accumulation against standard value was observed within 6 months (to S-100) and 9 months (to MBP and NSE).

While studying the development of neurosensitization it appeared that autoantibodies to the three NSP: glia markers, neurons and myelin were identified not in every mouse. Out of the mice

having a 1 - month Cs-137 intake only 30 % revealed autoantibodies to NSE and S-100. In this period autoantibodies to myelin structures are not yet registered.

After 3 months of radiation exposure autoantibodies to MBP are also revealed in 80 % of animals. In 9 months autoantibodies to all the three NSP are identified. Practically half of the animals under test exhibit autoantibodies to MBP and NSE while autoantibodies to S-100 appear less frequently.

Thus, it may be concluded that: 1) Not all the animals develop autoimmune responses; 2) Autoantibodies to different antigens are revealed with different frequency. Throughout all experimental periods autoantibodies appear mostly to glia and neuron proteins, whereas autoantibodies to MBP are seen in more prolonged time (from the 3-rd month), being found, however, in the majority of mice.

In early period (1 month) autoantibodies appear not to all antigens which fact allows a suggestion that immune responses to different brain structures are triggered step-by-step. This may evidence for a stepped character of the brain damage under small-dose radiation. The most sensitive brain structures (glial and nervous cells) are the first to suffer, while less sensitive ones (myelin and oligodendroglia) undergo damage later.

Of particular interest are data obtained as to specificity of autoimmune responses in mice having a 3-month interval after a 6-month radiation exposure. 66 % of this animals reveal autoantibodies to NSE, whereas only 16,7 % show autoantibodies to MBP, this value being lower than that in the group receiving isotopes during 9 months.

Thus, autoimmune responses remain to exist after isotopic exposure and nuclide withdrawal from the blood and brain, acquiring the features of a chain reaction.

Different frequency of autoantibody appearance in the groups of animals receiving and not receiving isotopes testifies to the dynamical character of the process and its relatioship with the brain and immune system injuries. The fact that autoantibodies to NSP were identified not in all but in a part of the animals under test points to the existence of an individual sensivity (threshhold) to inner radiation. It cannot be excluded that such a sensitivity is controlled by histocompatibility gens or by other censor systems.

Considering the reasons why autoantibodies are inavailable in some animals" blood the following assumptions can be made: 1) Autoantibodies are almost entirely bound to the blood-circulating antigens; 2) Autoantibodies are produced through the immune system suppression; 3) There exists either cell or humoral inhibitor to slow down the development of immune responses, and whose nature is to be studied farther on.

To understand more completely the mechanisms of radiation effects on the brain structure and function, we determined the serum content of MBP. The results tell of a wave-like protein content in the blood. After a month of radiation exposure the highest MBP content amounted to 258 ng. Later on the MBP level decreased and remained within 100-123 ng.

The data obtained may be compared to the level of autoantibodies to MBP. In early period (1 month) no autoantibodies to MBP are seen in the animals" blood, although this is a period of the highest MBP concentration. In more prolonged periods there appear autoantibodies which bind and remove the antigens from circulation thereby reducing their content in the blood. It may be suggested that in early periods (1-st month) radionuclides destroy nervous cells most actively. Then the compensatory mechanisms are triggered to prevent further brain damage and antigen outflow into the blood. Both mechanisms are likely to be involved: on the one hand the processes of primary and secondary brain damage are taking place, and on the other hand the compensatory mechanisms are being triggered.

Of special interest seem to be the data on the MBP content in the animals' blood after a 3-month restoration period when the animals received no radionuclides. The MBP content in these animals was found to lower practically to the control values pointing to regenerative processes and destruction intensity decrease.

When determining the NSE content, its level was noticed to grow after the 6-th month of radiation exposure reaching maximum after 9 months. In the group of animals having a 3-month interval after a 6-month Cs-137 consumption this level was lower than in the group exposed to radiation during 6 months but higher than in the control group, this fact being probably indicative of the onset of reparative processes in the brain.

CONCLUSIONS

After 1,3,6 and 9 months of Cs-137 dietary intake 50-60% of experimental animals releaved the availability in the blood of antibodies to the brain structures as well as blood-circulating neuroantigens MBP and NSE, this evidencing for the development of destructive processes in the brain due to incorporated radionucludes.

The antibody level was found to grow gradually and continuously from the 1-st to the 9-th month. However, a 3-month interval after 6 months of Cs-137 intake involves statistically significant decrease of neuroantibody and autoantigen blood levels as compared to the animals fed with Cs-137 without intervals, this testifying to reparative processes in the brain.

Inner radiation disturbs blood-brain barrier permeability, allows the brain transbarrier tissues to contact the immune system thereby enabling a stopped autoimmune process to be developed in the CNS. It follows that autoimmune responses to the brain antigens may prove the existence of the brain organic damage because of inner radiation due to incorporated radionuclides.

ABSTRACT (See instructions overleaf)

A key role for nitric oxide (NO) has been postulated in the pathogenesis of brain damage following acute insultes. To ascertain the relationship of NO to glutamate neurotoxicity and its correlation with morphological and biochemical changes observed after prenatal exposure to ionizing radiation, an animal model was used.

Fetuses of Wistar rats were irradiated intra-utero on 13th day of gestation with 0.4 Gy, 0.7 Gy and 1 Gy with gamma rays, and sacrificed at postnatal days 3 and 10.Brain samples were taken for histopathological and biochemical studies: superoxide dismutase (SOD), catalase, guanylyl ciclase, D-T diaphorase and NO-sinthase activities and lipoperoxides and DNA levels.

It was observed a dose-dependent loss in neuronal density and a decrease of total brain DNA. Correlated changes in oxidative stress were found. We report here an increased production of NO and higher guanylyl ciclase, NO sinthase and D-T diaphorase activities at the higher dose.

These data suggest that the NO and the intracellular signaling molecules may play a possible role in the radioinduced damage in developing brain.-

MECHANISMS OF NEURO-ENDOCRINE REGULATION IN THE CONDITIONS OF SMALL IRRADIATION DOSES AND POST-CHERNOBYL RADIATION SITUATION

E.F. Konoplya

Institute of Radiobiology of the Academy of Sciences of Belarus

Study was held of function of thyroid, parathyroids, gonads, pancreas, adrenal and pituitary glands, transport of hormones in blood, interaction with membrane, cytoplasma and nuclear receptors of different in radiosensitivity and hormone-dependency tissues under the action of small doses of acute and chronic external and internal irradiation. The state of central and peripheral neuro-humoral regulation of cardiovascular system was assessed. The analogous researches were carried out in the conditions of radionuclides pollution after the Chernobyl accident. The obtained data reveal an expressed disturbance of processes of formation, regulation, transport, reception of hormones and neuromediators, which is conditioned by the character, dose and time period after the irradiation. The results serve as the basis of formation of nearest and remote radiation effects and pathology.

NEUROREGULATORY PROCESSES IN THE CNS STRUCTURES LONG AFTER CHRONIC EXPOSURE TO LOW DOSES OF IONIZING RADIATION AND LEAD AND CORRECTION OF THE DISORDERS

GOURINE V.N., DUDINA T.V., YELKINA A.I., KANDYBO T.S.

Institute of Physiology, Academy of Sciences, Minsk 220725, Belarus, tel: 0I72-39546I, fax: 0I72-394773

In experiments on mature Wistar male rats exposed to different modes of ionizing radiation at relatively low doses and in combination with chronic probe-assisted application of lead acetate (5 mg/kg daily) we found changes in the intensity of neuronal uptake of some neurotransmitters that characterize the functional state of the corresponding synaptic formations of the diencephalic region and other brain structures long after radiation. A decrease in the functional activity of the mediobasal hypothalamus was accompanied by disorders of neurohumoral regulatory mechanisms in the hypothalamus-pituitary-adrenocortical system and hypothalamus-thyroid system. Application of therapeutic doses of neurotropin (Nipon Zoki, Japan) and thymaline 3 months after cessation of radiation and lead stimulated an increase in specific binding of glucocorticoids by brain structures, activation of the hypothalamus-pituitary-adrenocortical system, and some normalisation of neurotransmitter relations in centres regulating autonomic functions 6 months after.

A NEW CONCEPT ON THE BASIC MECHANISM OF EFFECTS OF PRENATAL EXPOSURE IN THE DEVELOPING NERVOUS SYSTEM OF A NEW ORGANISM.

I.V.Filyushkin and A.I.Ignatov

The State Research Center of Russia - Institute of Biophysics.

INTRODUCTION

Congenital nervous deficiency is known to be the only meaningful teratogenic end point ascertained in prenatally irradiated children, for instance, in survivors of atomic bombing [1]. Similar effect is known to be the aftermath of prenatal exposure to alcohol [2] or lead [3]. Besides, an opinion exists [4] that prenatal exposure to any agent affecting physical development can have such a consequence. Consequently, any proposed mechanism through which exposure of an embryo (to radiation) produces alterations of nervous system function of a newborn must disclose the nature of this "overall" vulnerability of the nervous reactivity of a newborn to any prenatal exposure.

We have found such a mechanism theoretically and then verified it in animal experiments.

A BRIEF THEORY OF EFFECTS OF PRENATAL IRRADIATION

Teratogenic action of prenatal exposure starts from impinging upon proliferative and other characteristics of embryo cells. Embryonic development is stabilized by morphogenetic homeostasis, so that this impingement induces homeostatic (adaptive) response aimed at normalization of the development. An irradiated embryo consists of cells with decreased proliferative capacities and increased variety of all their characteristics. Systemic analysis shows [5] that under these conditions, a certain overdevelopment of the endocrine component of regulation of a growing organism is produced by adaptive response to normalize the process of the development. If this endocrine "overregulation"remained to be noncompensated in the course of the subsequent development, a certain overdevelopment of the entire neuroimmunoendocrine regulation in a newborn could occur, therefore further adaptive response induces coadaptive underdevelopment of nervous and immune components of regulation which are ontogenetically later than the endocrine component. These side effects of the adaptive response appear to be just this power systemic motivity for producing nervous (and immune) deficiencies in a newborn. So, induction of the nervous deficiency appears to be an element of the normal adaptive response to embryo cells damage, and this fact is just an explanation of the overall vulnerability of nervous system of a newborn to any deleterious prenatal exposure.

According to this mechanism, prenatal irradiation can induce malformed structure of neuroimmunoendocrine regulation in progeny (e.g. the existence of excess endocrine regulation accompanied with nervous and immune deficiencies), even if it occurs during the pre-implantation stage of embryogenesis. This statement stands in a strong contradiction with the common scientific opinion [6] that irradiation at this stage leads to "all or none effect": it can result in an embryonic death, however those that survive appear to be normal. Hence, the proposed mechanism would be proved if regulation effects of pre-implantation irradiation are found in alive progeny.

RESULTS OF VERIFYING EXPERIMENTS

We have found just these effects in progeny of pregnant Wistar rats exposed to 2 Gy of gamma-irradiation protracted at the initial 6 days of pregnancy. Comparatively to controls, increased body mass and fatness of irradiated in utero progeny was observed from 42-th day of postnatal life and later, with these patterns being decreased from birth up to 28-th day. So, an endocrine overcompensation of the aftermath of radiation damage occurred in the late period of postnatal life of progeny. After acute gamma-irradiation at the 100-th day of postnatal life, irradiated *in utero* progeny had much more profound body mass loss than controls did. Decreased systemic response to acute irradiation is known in animals having an obvious endocrine regulation deficiency [7]. In light of this fact, more profound response which appeared to be characteristic for those irradiated *in utero* is a clear indication that pre-implantation irradiation had really induced excess endocrine component of regulation. Hence, predicted existence of "endocrine regulation imprinting" of damaged properties of embryo cells have met the experimental corroboration.

The question is: has this endocrine imprinting been accompanied with the production of alteration of the nervous system function?

First, comparatively to controls, increased relative mass of adrenals on 42-th, 49-th and 120-th days of postnatal life was observed in irradiated *in utero* animals. It is an indication that syndrome of chronic adaptation have been induced. Second, these animals had the increased level of autoantibodies to S-100 brain protein. It is an indication of their diminished training abilities. Hence, alteration in the nervous reactivity was induced by irradiation at the pre-implantation stage of embryogenesis.

However, some more surprising is the fact that pre-implantation irradiation also altered immune reactivity of progeny.

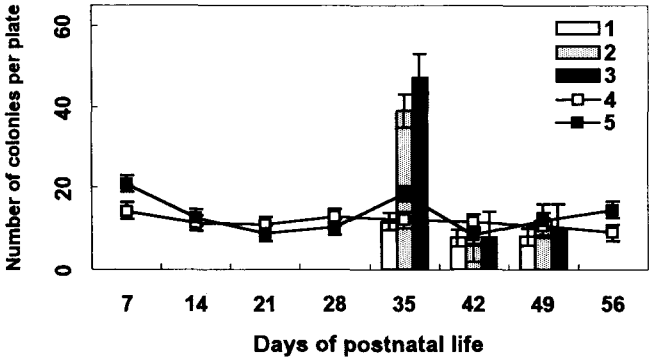

Figure 1. The temporal dynamics of automicrophlora in control animals and those irradiated *in utero* at the pre-implantation stage of embryogenesis.

1 - Control animals. 2 - Animals irradiated *in utero*.
3 - Control animals injected with ram erythrocytes or horse serum.
4 - Animals irradiated *in utero* and injected with ram erythrocytes on 28-th day of postnatal life.
5 - Animals irradiated *in utero* and injected with horse serum on 28-th day of postnatal life.
Vertical bars represent 95-% confidence intarvals.

First, the titre of antibodies in irradiated animals in response to injection of ram erythrocytes or horse serum was increased comparatively to controls. Second, abnormal temporal dynamics of skin automicroflora was observed in irradiated *in itero* progeny after its weaning on 28-th day of postnatal life, especially if weaning was

accompanied with injection of ram erythrocytes or horse serum (see Fig 1). Thirdly, peritoneal anaphylaxis test has shown that increased vulnerability to allergy was characteristic for prenatally irradiated animals.

Significant correlation of distorted immune regulation patterns was ascertained. Thus, in the full accordance with the proposed systemic(!) mechanism of induction of immune deficiency, observed alterations in immune reactivity were credible to belong to the unique pathological process launched by pre-implantation irradiation.

CONCLUSION

Ectopic gray matter is known to be the major brain defect responsible for nervous deficiency induced by prenatal irradiation in humans [1] and rodents [8]. This defect is also known to be induced by in utero action of alcohol [2] being a cytotoxic agent. It seems incomprehensible that similar brain defects are due to in utero exposure to agents having absolutely different mechanisms of primary action at (embryo) cells: radiation is a typical genotoxic agent. But this fact appears to be just corresponding with the proposed systemic mechanism of induction of the nervous deficiency. Ectopic gray matter is known to be due to arrest in migration of immature neurons. Instead of being an aftermath of the direct damage, this effect is much more credible to be an end point of a certain systemic response of a growing organism aimed at diminution of potencies of the nervous system of a newborn.

The proposed mechanism has predicted effects in immune systems of alive newborns due to irradiation at pre-implantation stage of embryogenesis. Immune deficiencies were never observed before as (radiation) teratogenic effect. Nevertheless, we have observed such effects in experiment. This means that our concept appears to pass through a "difficult examination" in the light of the world's radiobilogical knowledge.

ENHANCED FREQUENCY OF ABNORMAL SPERMATOZOA AFTER COMBINED X-RAYS-ACRYLAMIDE EXPOSURE

M.M. Dobrzyńska and A.K. Gajewski*

National Institute of Hygiene, 24 Chocimska Str, 00-791 Warsaw, and *Academy of Physical Education, 36 Marymoncka Str, 01-813 Warsaw, Poland

Living organisms are exposed to a various types of radiation and different types of chemicals. Combined X-rays-acrylamide exposure is possible in industry and in scientific laboratories. Study was performed using sperm morphology test. Male mice were treated with 0.25 Gy of X-rays, 75 mg/kg bw of acrylamide (AA) and with combination of both agents. All stages of spermatogenesis were exposed. Spermatozoa were examined and classified as normal, banana like, lacking in hook, amorphus, folded and twin tailed forms.

Acrylamide induced sperm-head abnormalities after exposure late spermatids and early spermatocytes. X-rays clearly increased the frequency of abnormal spermatozoa after exposure spermatozoa, late spermatids and spermatocytes. Combined X-rays-AA treatments increased the frequency of misshapen sperm head after exposure all stages of spermatogenesis except late spermatocytes and spermatogonia.

Effect observed after combined exposure even in low doses significantly exceeted the sum of effects produced alone by the agents.

MAJOR SCIENTIFIC TOPIC NUMBER 2.1. (see page 7)

ABSTRACT (See instructions overleaf)

When considering risks for radiation protection purposes the embryo\foetus is considered as an especially sensitive subgroup. To establish radiation risk estimates for the embryo\foetus relevant organ systems, exposed to ionising radiation at low doses, need to be studied. There are data for low LET radiation, but the sensitivity of the foetus and, more particularly, foetal haemopoietic cells to high LET radiation has not been fully investigated. This scenario has assumed some importance in relation to discharges into the environment.

The experiments presented here, part of larger carcinogenesis study, were designed to evaluate the effect of intrauterine exposure to ^{239}Pu on foetal haemopoietic cells. Groups of pregnant mice were infused with ^{239}Pu at concentrations of 0, 80, and 160 kBq\kg throughout gestation. Both these activity groups resulted in doses to the foetus considerably higher than that received from environmental contamination but at a dose rate much less than used in other reported work.

Cell culture studies have shown that, up to 1 year post partum the cellularity of the femoral bone marrow was undisturbed. The number of stem cells, myeloid cells and microenvironmental fibroblasts - as measured by CFU-A, CFC and CFU-f respectively - were also unaffected. This study will be compared with those which have shown that a single injection of ^{239}Pu or ^{241}Am during gestation led to significant alterations in haemopoiesis (Van Den Heuvel, 1990, Int. J. Radiat. Biol., 57, 103; Mason et al, 1992, Int. J. Radiat. Biol., 61, 393.).

DOSE ESTIMATION OF ENRICHED URANIUM IN TESTES ON INDUCTION OF DOMINANT LETHALITY AND SKELETAL ABNORMALITIES

Shou-peng Zhu, Ming-yue Lun
Faculty of Radiological Medicine, Suzhou Medical College,
Suzhou, China

INTRODUCTION

Enriched uranium is one of the principal fuels of nuclear power stations (1). Since now in the sphere of radiological medicine what is concerned about the environmental pollution and damage to human beings by nuclear fuels and its fission products released by nuclear tests and plants. Especially in recent years nnuclear power stations are increasing rapidly, the production and consume of enriched uranium expand year by year. Consequently, observations of its harming effect on environment and in the body become a significant task. Especially its action on induction of dominant lethality and skeletal abnormalities showed a close relation on retentive peculiarity in testes. So we paid attention to the relationship between the cumulative absorption dose and the incidence of the dominamt lethality and skeletal abnormalities in the offsprings.

EXPERIMENTAL METHODS

(1) Radiation dose estimation of enriched uranium in testes.

According to the retention function rs(t), with respect to time accumulation of 28d, the cumulative activities $A_s(t)$ (Bq) of enriched uranium in testes were obtained:

$$A_s(t) = \int_0^t A_0, s. rs(t). dt$$

Here A_0, S=early radioactivities of enriched uranium in testes.

Again from the cumulative radioactivities of enriched uranimm in testes calculated the absorption dose (2, 3). Dose estimation may be according to the formula as follows:

$$D_r = 1.6 \times 10^{-10} \sum_s \sum_j [A_s \Sigma SE(T \leftarrow S)_i] \text{ (Gy)}$$

Here $SE(T \leftarrow S)_i = \dfrac{Y_i E_i AF_i (T \leftarrow S)}{M_T}$ [(MeV/g/nucleus conversion)

Y_i=produce of α radiation

E_i=average energy of α particles

M_T=mass of the organs

$AF_i(T \leftarrow S)$=absorption fraction=1

So that the cumnlative absorption dose may be calculated by contribution of three uranium radionuclides.

(2) The rate of dominant lethals and skeletal abnolmalities induced by enriched uranium.

Sexually mature male and virgin female BACB/c strain mice, 10 weeks old and weighing 21±1g, were used in this study, Experimental animals received intratesticular internal irradiation by enriched uranium with doses of 0.4, 2, 10, 20,

40 and 60ug. After 13 days treatment, each male was allowed to mate with 2 virgin females for a period to 49 days. The females were killed 18-20 days after the beginning of the mating, and the number of corpora lutea, as well as living and dead embryos were counted. So that the rate of dominant lethals were calculated.

Then living and dead embryos are taken out of the mating females, and are fixed in 95% ethyl alcohol for 7 days. One after another are turned into 1% KOH solution for 6 days (5). After a while embryos are stained with 0.05% of alizarin red for 1 day. Experimental specimen are infiltrated with a miscible liquid with ethyl alcohol-glycerin-KOH for 8 days. Dominant skeletal mutations were detected in the skeleton specimen.

EXPERIMENTAL RESULTS

(1) Contribution of the cumulative absorption dose in testes by three uranium radioisotopes

Uranyl fluoride containing ^{235}U of 18.9% (60mg/ml) was used in this study. Sexually mature male BALB/c mice, 10 weeks old and weighing 21±1g, were randomly divided into 6 experimental groups. There were 5 mice in each group. Animals treated by single intratesticular injection(4) with different doses of enriched UO_2F_2 ranging from 0.4 to 60ug. We estimate the cumulative absorption dose of the three radioisotopes of the experimental enriched uranium with 18.9% abundance through 28d. It was deducted from the data shown in Table 1.

Table 1. Contribution of the cumulative absorption dose through 28d in testes by three uranium radioisotopes after injection of enriched uranium with different doses.

Injected	Cumulative absorption dose in testes, Gy			
doses, ug	^{234}U	^{235}U	^{238}U	Total
0.4	8.639×10^{-5}	2.903×10^{-6}	2.103×10^{-6}	9.140×10^{-5}
2	4.320×10^{-4}	1.451×10^{-5}	1.052×10^{-5}	4.570×10^{-4}
10	2.160×10^{-3}	7.257×10^{-5}	5.257×10^{-5}	2.851×10^{-3}
20	4.320×10^{-3}	1.451×10^{-4}	1.052×10^{-4}	4.570×10^{-3}
40	8.639×10^{-3}	2.903×10^{-4}	2.103×10^{-4}	9.140×10^{-3}
60	1.304×10^{-2}	4.354×10^{-4}	3.154×10^{-4}	1.380×10^{-2}

It should be noted, that the contribution of total α radiation by ^{235}U was only <5% and >90% fraction of total α radiation came from ^{234}U. Although the content of ^{234}U in natural uranium is less, but physical half life of ^{234}U is comparatively shorter, and then the α radioactivity is higher. Therefore the contribution of α radiation is chiefly by ^{234}U.

(2) The rate of dominant lethals induced by enriched uranium

Experimental results indicated, that therateofdominant lethals induced byenriched uranium was elevated with the increasing doses of enriched uranium.

Table 2 gives the distribution of the females according to the number of living and dead embryos induced by different doses of enriched uranicum. It shows that the increase in the mean number of dead embryos is the result of an increase of the radiation dose of enriched uranium. Our present results show that doses of

euriched uranium given to mouse mainly increase the rate of intrauterine deaths. Whereas the mean number of implantations is only slightly altered.

Table 2. The rate of dominant lethals induced by different doses of enriched uranium

Injected doses, ug	Pregnant females(%)	Live embryos/♀	Dead embryos/♀	Ratio with 1 dead embryos/♀	Ratio with >2 dead embryos/♀
0	83	7.00	0.63	0.5	0.13
0.4	100	7.50	1.25	0.75	0.38
2	100	6.22	1.33	1.00	0.33

60	71*	4.60*	2.60**	1.00	1.00

*p>0.05 **p<0.01

(3) The rate of dominant skeletal abnormalities induced by enriched uranium.

In mutation-rate experiments, dominantskeletal mutations were confirmed by breeding tests. Skeletal abnormalities were detected in the skeletons of some of the sons of irradiated males. Table 3 summarizes certain parts of the skeleton appear to be especially subject to change by dominant mutations such as ribs fusion, extra rib on one side, and extra ribs on both sides,as well as extra point ribs. Especially gaps in skull, and spine defect, were foundby large doses of enriched uranium.

Table 3 The rate of dominant skeletal abnormalities induced by different doses of enriched uranium

Injected doses, ug	Total embryos	Embryos with dominant skeletal abnormalities				Rate of sheletal abnormalities
		Extra rib on one side	Extra ribs on both sides	Extra point ribs	Other	
0	55	2	8	0	0	18.2

ABSTRACT (See instructions overleaf) The purpose of this work was to study the action of radiomodifying drugs of detoxicators (gluconeodes) and immunomodulators (interleukin-1β) classes on reparation (a model of regenerating liver). Outbred white male rats weighing 160-200 g were used in the experiments. The animals were irradiated at a dose of 6.75 Gy using IGUR-1 source at a dose rate of 1.58 Gy/min. 1,4,24 or 72 hours after irradiation the left and central lobes of the liver of the animals have been removed. The intensity of regeneration was judged by insertion into their DNAs of ^{3}H-thymidine, wich was administered to the rats 20 hours after hepatectomy. As a result of the experiments, it has been established that hepatic regeneration in irradiated rats with hepatectomy having been performed 1 or 4 hours after radiation exposure has been completely inhibited. One day following radiation exposure, the intensity of regeneration was 60% of the norm. On day 3 after radiation exposure, the rate of regeneration normalized. Single administration of gluconeodes for therapeutic purposes led to an insignificant acceleration of the regeneration process as compared to irradiated control (with hepatectomy 1 and 4 hours after irradiation). A significant effect of this agent (after single or 3 times a day administration) has been revealed on days 1 and 3 of radiation sickness when the rate of hepatic regeneration 1.5-2 times exceeded the norm. Similar effect has been revealed after a single dose of interleukin-1β (25ug/kg). Thus, the mechanisms of action to different classes of compounds have a similar positive effect on the processes of regeneration.

ABSTRACT (See instructions overleaf)

The aim of this study was to investigate the effects of internal contamination with lethal amount of bone-seeking isotopes P-32 on mineral metabolism and alkaline phosphatase activity for detecting the damage caused by P-32 on the chicken's organism. The experiments were carried out on a fifty-day old hybrid chichens of "JATA" breed on both sexes. The concentration of calcium, magnesium and inorganic phosphorus as well as activity of alkaline phosphatase were determined in blood plasma. Obtanined results have shown as follows:

1) magnesium concentration was significantly reduced on the first and the seventh day after contamination,
2) two significant drops of calcium values on the first and the third day after contamination,
3) the phosphorus concentration was significantly reduced on the seventh day after contamination, and
4) alkaline phosphatase activity was significantly increased on the first day after injection of P-32.

ABSTRACT (See instructions overleaf) A strain of Monascus ruber from the Collection of the Institute of Food Research, ICA 3.250 and another two radioinduced mutant strains, ICA 3.250 M_1 and ICA 3.250 M_2 were used.

Culture was performed from the stock culture on corn flour-solid media with intermittent stirrings for 7 - 10 days at 30°C and the pigments were extracted by Et - OH.

The pigment biosynthesis on liquid media was performed using the synthetic medium containing 4 % glucose; 0,1 % KH_2PO_4; 0,05 % $MgSO_4$. 7 H_2O; 0,05 % NaCl and 0,01 % $FeSO_4$. 7 H_2O in the shaker - type incubator (240 rpm), at 30°C for 6 days. The samples were analysed by UV - VIS spectrophometry.

The irradiations were performed at a Co - 60 source with an activity of approximately 105 TBq, the irradiations being carried out statically, in a cylindrical geometry, in the dose range of D = 1 + 10 kGy, at 1 kGy/h dose - rate.

There was determined the viability percentage versus the unirradiated (control) sample, separately for every irradiation dose, to obtain the dose-effect curves, the radiosensitivity parameters and the optimum mutagenesis dose range.

There were obtained two mutants (at 4 kGy and 6 kGy) which were analysed for pigment biosynthesis.

RADIOSENSITIVITY OF THE GUINEA-PIG OOCYTE AT DIFFERENT STAGES OF FOLLICULAR DEVELOPMENT

INTRODUCTION

Recently, we have shown that the guinea-pig represents an excellent model for studies on genetic hazard of radiation in man (1). We also developed techniques for culturing oocytes of this species and preparing their meiotic chromosomes for cytogenetic examination (2). In the experiments reported here, we examined the radiosensitivity of oocytes at two different stages of maturation, separated by only one week.

MATERIAL AND METHODS

In a first series of experiments, ovaries of adult females were X-irradiated with 1 or 2 Gy on day 3 of the 17-day estrous cycle. Their meiotically competent oocytes were punctured from the growing follicles on day 10. They were cultured for 6 h to the MI stage, and fixed for cytogenetic analysis.
In a second series of experiments, ovaries were irradiated with the same doses on day 10 of the estrous cycle. In this case, oocytes were collected and cultured either immediately after irradiation, or at various time intervals thereafter.

RESULTS

As shown in Table 1, important differences were found in the yields of chromosome aberrations, according to the time of the estrous cycle at which irradiation had occurred.
Irradiation at the beginning of the cycle induced low numbers of translocations and slightly higher numbers of other aberrations. These effects were dose-dependent. The frequency of oocytes showing translocations was about 1.5 Gy^{-1}, a value comparable to that obtained after irradiation of the immature oocyte (3).
When irradiation was delivered one week later, and oocytes were collected and cultured immediately thereafter, the frequencies of oocytes showing chromosome anomalies revealed much higher. This was true for translocations as well as for other types of chromosome aberrations. Multivalents implied variable numbers of chromosomes and in many cases the number of chromosomes implied could not be determined. These highly damaged metaphases were frequently associated with chromatid breaks. The frequency of oocytes carrying translocations was 30-35 % Gy^{-1}.

In some experiments, oocytes which had been irradiated on day 10 were collected and cultured one day later. Surprisingly, MI preparations revealed impossible to obtain: all fixed oocytes were already in MII, whether they had been irradiated with 1 or 2 Gy. This phenomenon was studied more in details, using various doses of X-rays and different times of culture.
It appeared that most if not all oocytes which were in MII on day 11 had been stimulated to divide *in vivo*, before removal of the ovaries. The lowest dose of radiation which was able to induce such a rapid stimulation of the first meiotic division in meiotically competent

oocytes was apparently in the range of 0.25- 0.50 Gy. Further experiments showed that all MII oocytes had been eliminated from the ovaries by day 15, i.e. 2 days before ovulation, and been replaced by others that were contained in smaller follicles at the time of irradiation. Those were in diplotene and were able to evolute normally to the MI stage, when cultured for 6 h.

Dose (Gy)	Day of irradiation	Oocytes examined	N^{ber} abnorm. (%)	N^{ber} with transloc. (%)	N^{ber} with break/frag. (%)
0	-	78	0 (0)	0 (0)	0 (0)
1	3	132	5 (3.78)	2 (1.51)	4 (3.03)
2	3	147	15 (10.20)	5 (3.40)	11 (7.48)
1	10	122	50 (40.98)	44 (36.06)	27 (22.13)
2	10	120	89 (74.16)	76 (63.33)	53 (44.16)

TABLE I
Chromosome aberrations detected in metaphase I oocytes irradiated on days 3 or 10 of the estrous cycle (examination 1 week or directly after irradiation).

DISCUSSION

Our data evidenced a dramatic increase in the radiosensitivity of the guinea-pig oocyte during a time interval of only 1 week : oocytes irradiated at the beginning of the estrous cycle (day 3) had a low frequency of chromosome aberrations, while those irradiated at the middle of the estrus cycle (day 10, when growing Graafian follicles are clearly visible at the surface of the ovaries) exhibited heavy chromosome damage.
Earlier, Oakberg and Clark (4) noted a marked decrease in the number of large oocytes, during the first ten days following irradiation of guinea-pig ovaries by 2 Gy. In agreement with this, we found that oocytes irradiated at the middle of the estrous cycle were eliminated from the ovaries in a few days, after their evolution to the MII stage. The stimulation of the first meiotic division by radiation required less than 24 h after doses of 1 or 2 Gy, and was probably due to a very rapid killing or inactivation of follicular cells which normally exert an inhibitory effect on this process. When examined on day 15 of the estrous cycle, i.e. 2 days before ovulation, ovaries of animals irradiated on day 10 again showed high numbers of growing Graafian follicles. Oocytes contained in those were in diplotene, and behaved normally in culture, reaching the MI stage after 6 h. Thus, the ovaries had apparently compensated for the loss of all large follicles by an acceleration of the maturation and growth of smaller oocytes.
An increase in the number of corpora lutea per female was noted by Cox and Lyon (5), in guinea-pigs irradiated with 4 Gy (the only dose tested) between days 6-12 of the cycle and mated at the first estrous post-treatment. This effect was attributed to the ovulation of abnormally high numbers of oocytes in irradiated animals ("superovulation effect"). Concommitantly, there was an apparent increase of the preimplantation loss in these animals, an effect possibly resulting from the induction of dominant lethals by radiation. It will be important, therefore, to have a precise idea of the level of chromosome damage present in oocytes surviving an irradiation near the middle of the estrous cycle, and able to reach ovulation after an accelerated growth. Such study is in progress in our laboratory.

Data on the mouse indicated that, in this species, the radiosensitivity of the oocytes is low during weeks 1-2 before ovulation, if one excepts the 12 hours immediately preceding ovulation (6,7). On the basis of our results, it can be concluded that the radiosensitivity of the growing guinea-pig oocyte (1 week before presumed ovulation) is clearly much higher than that of the corresponding stage in the mouse, both in term of sensitivity to killing and to induction of chromosome aberrations.
Recent results have also shown that the mouse immature oocyte was sensitive to the induction of translocations and other chromosome aberrations by radiation (8-10), and data obtained in our laboratory allowed to extend this conclusion to the immature oocyte of the guinea-pig (3). However, the results of Straume et al. (10) suggested that the radiosensitivity of the mouse immature oocyte should be rather high, while our data indicated that the radiosensitivity of the guinea-pig immature oocyte is rather low.

All together, our results suggest that important differences exist between the mouse and the guinea-pig, with regard to the radiosensitivity of their female germ cells. This underlines the necessity of performing studies in other mammalian species, in order to better define the genetic risks associated with an exposure of women to radiation.

ABSTRACT

Evidence exists for increased fluid and chloride secretion induced by ionising radiation. Acetylcholine via stimulation of muscarinic epithelial receptors may be implicated in such increases. This study addresses the question of whether ionising radiation modifies cholinergic muscarinic receptors.
Male Wistar rats were exposed to total body gamma irradiation (8 Gy; 1.3 Gy.min^{-1}; ^{60}Co source). Plasma membranes were prepared from small intestinal mucosal scrapings and marker enzyme activities (sucrase, Na+/K+-ATPase) measured. Muscarinic receptor binding characteristics (Kd, Bmax) were determined using the non-selective muscarinic antagonist ^{3}H-QNB (quinuclidinylbenzilate).
Sucrase and Na+/K+-ATPase activities are maximally decreased 3 and 4 days (D3, D4) post irradiation (3 fold). Myeloperoxidase activity is markedly reduced (10 fold at D4) and is still lower than control values 21 days after irradiation (5 fold). Two ^{3}H-QNB binding sites are observed for control rats. For the high affinity site, Kd is decreased up to 7 days after irradiation with a maximum at D4 (4 fold decrease) whereas Bmax is unchanged. For the low affinity binding site, both Kd and Bmax are reduced. The significance of these sites remains unclear.
The increase of the affinity of the high affinity binding site is in agreement with an increased response to cholinergic stimulation, and so with increased fluid and chloride secretion. These results suggest a possible implication of a dysfunction of cholinergic regulation in irradiation-induced diarrhoea. Thus it is of interest to determine the mechanisms by which radiation can modify muscarinic mucosal receptors.

INTRODUCTION

Acetylcholine, released from parasympathetic nerve endings, has a major role in the control of intestinal function. In particular, increased stimulation of muscarinic epithelial receptors may result in fluid hypersecretion. (1). Several reports show that ionising radiation induces intestinal fluid and chloride secretion (2,3).
In addition Otterson (4) observed a decrease of the amount of acetylcholine esterase (degradative enzyme) in the mucosa after irradiation. This suggests that irradiation may alter cholinergic regulation of mucosal functions so leading to increased fluid and electrolyte transport.
This study addresses the question of whether ionising radiation modifies the characteristics of cholinergic muscarinic receptors in the mucosa of rat.

METHODS

Male Wistar rats (Laboratory C.E.R.Janvier), weighing between 280 and 300g, were exposed to whole body gamma irradiation and received a dose of 8 Gy (1.3Gy.min^{-1}, ^{60}Co source). Control rats were sham-irradiated during the same period. The small intestine was removed under anaesthesia (sodium pentobarbital: 60mg.kg^{-1}) up to 21 days after irradiation and animals euthanised following an overdose of anaesthetic. Small intestinal plasma membranes were prepared from mucosal scrapings (both ileum and jejunum were pooled for each rat) and kept at -80°C. Enzyme activities were determined by spectrophotometric assays : Sucrase (5), Na^+/K^+-ATPase (6).

Determination of muscarinic receptor characteristics was performed using a non-selective muscarinic antagonist ^{3}H-QNB (quinuclidinylbenzilate). Membrane (200µg protein) were incubated with increasing concentrations of ^{3}H-QNB ranging from 50pM to 15nM. Non specific binding was determined in the presence of atropine (50µM). Separation of bound and free ligand was by rapid filtration. The experiments were performed 1, 3, 4 and 7 days after irradiation on either irradiated or sham-irradiated rats.

Analysis of binding data was by Scatchard analysis.

Statistics: A one way Anova test was used to test populations of control rats and for enzyme activities experiments, and a one way Anova Dunnett's test for binding experiments. (ns = non statistically significant; * = $p<0.05$)

RESULTS

Determination of enzyme activities

Sucrase is an enzyme associated with the apical membrane and is essentially located on the top of the villi. The results presented in the Table 1 show that sucrase activity was greatly decreased to 17% of control values 3 and 4 days after irradiation ($p<0.05$). Nine and 21 days after irradiation the sucrase activity went back to control values (ns). In parallel, the activity of the basolateral enzyme, Na^+/K^+-ATPase was determined and it is clear that irradiation modifies the Na^+/K^+-ATPase activity with a time dependent pattern similar to the pattern observed for the sucrase. Na^+/K^+-ATPase activity was unchanged at D0 but falls to 66 and 60% of basal level 3 and 4 days after irradiation respectively ($p<0.05$), and returned to basal values at D9 (ns). At D21 a second decrease in activity of 72% is observed.

Table 1: Determination of sucrase and Na^+/K^+-ATPase activities

Day after irradiation or sham irradiation	Sucrase (U/mg protein)				Na+/K+ ATPase (U/mg protein)			
	control rats	Irradiated rats	n	p	control rats	Irradiated rats	n	p
D0 at 6hours	1.26 ± 0.12	1.02 ± 0.13	2	ns	0.98 ± 0.06	0.99 ± 0.04	2	ns
D3	(n=19)	0.22 ± 0.08	5	*	(n=19)	0.33 ± 0.14	5	*
D4		0.22 ± 0.02	4	*		0.39 ± 0.06	4	*
D9		1.01 ± 0.08	6	ns		0.73 ± 0.09	6	ns
D21		0.79 ± 0.09	4	ns		0.27 ± 0.09	4	*

Characterisation of muscarinic receptors

Analysis of 3H-QNB binding data of control rats indicated the presence of 2 binding sites, one of high affinity and low capacity and one of lower affinity but higher capacity. No difference was observed for control animals during the 7 days following the simulation of irradiation (ns) and the results obtained for all control rats were pooled.

Figure 1 summarises the results obtained for binding characteristics tested up to 7 days after an 8 Gy irradiation. The Kd of the high affinity binding site (Kd1) is decreased to 24.4% of the basal value at D4 after irradiation. This decrease is still observed at D7 (25.8, $p<0.05$). No significant change in the number of sites (Bmax1) was observed for this high affinity binding site (ns) even 4 and 7 days after irradiation. For the lower affinity binding site, both Kd (Kd2) and Bmax (Bmax2) were decreased at D4 (11.5% for Kd and 14.1% for Bmax). Seven days after irradiation only the Kd2 of this site was significantly decreased (13.1%, $p<0.05$).

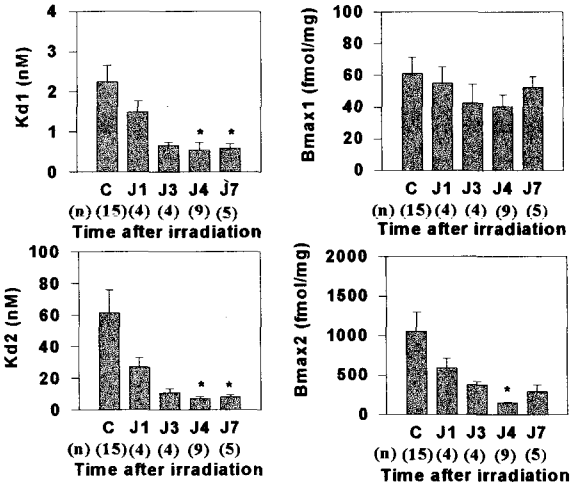

Figure.1: Characterisation of 2 muscarinic binding sites

CONCLUSION

The present data show that gamma irradiation markedly attenuates both apical (sucrase) and basolateral (Na^+/K^+-ATPase) enzyme activities. This may reflect a decrease of number and size of villosities linked to mucosal denudation (7). Such changes may explain decreased nutrient absorption following irradiation.
The modification of muscarinic receptor characteristics, in particular the effect on the high affinity binding site is in agreement with an increase of sensitivity of the small intestine to cholinergic regulation. Thus irradiation may affect regulatory processes of water and electrolyte transport. The effect on the second binding site is more difficult to interpret in terms of increased sensitivity. More experiments are required to see whether changes in both sites are also related to increased fluid and electrolyte transport after irradiation. To this end further experiments are in progress in order to test the functional capacity of muscarinic receptors using isolated intestine placed in Ussing chambers.

INTRODUCTION

Exposure to ionising radiation induces gastrointestinal dysfunction. These injuries may be classified into two main categories: the initial syndrome characterised by acute effects such as nausea, vomiting, anorexia and diarrhoea observed during the first 24 h after irradiation for doses as low as 1 Gy. Later effects and the onset of the gastrointestinal syndrome (GIS) are seen at higher doses (>10 Gy) and include intestinal haemorrhages, diarrhoea and septicaemia, the severity of which depends on the nature of irradiation and on the dose received. These modifications of digestive system function are associated with a general deterioration in the epithelial cell-lining resulting in loss of functional capacity and integrity (1). In addition epithelial ion transport is modified inducing an electrolyte imbalance with a decrease in water absorption combined with excessive secretion and loss of sodium and chloride (2). On the other hand, ionising radiation dramatically affects gastrointestinal motility resulting in modified frequency and amplitude of contractions (3). The precise contribution of each of these factors in the manifestation of irradiation-specific effects like radio-induced diarrhoea is not known. The aim of this study was to investigate the effects of whole body gamma irradiation on neurotensin (NT), a gastrointestinal neuropeptide implicated in gut electrolyte transport and motility regulation. This study carried out in the rat, focused on plasma NT levels as well as on colonic smooth muscle NT specific receptors.

METHODS

Male Wistar rats (250g) were exposed to whole body gamma (^{60}Co source) irradiation with doses ranging from 1 to 8 Gray (Gy) at a dose rate of 0.25 Gy.min^{-1} or sham-irradiated. Peripheral blood samples and the colon were removed under anaesthesia (sodium pentobarbitone 60mg.kg^{-1}) from 1 to 10 days after irradiation. Plasma NT was measured by radioimmunoassay (Amersham) and plasma membranes were prepared from the colon smooth muscle after removal of the mucosal layer. Analysis NT receptor binding sites was carried out on these membranes 3 days after irradiation and the Kd and Bmax determined using ^{125}I-labelled NT in the presence of increasing concentrations of unlabelled NT. Specific binding was measured from the difference between ^{125}I-NT binding in the presence and absence of 1µM unlabelled NT.

RESULTS

Plasma NT levels increased rapidly 24 hours after gamma irradiation with a peak of 32.2 ± 7.6 fmol/ml ($n=6$; $p<0.01$) for a dose of 8 Gy as compared with sham-irradiated animals (5.9 ± 1.0 fmol.ml^{-1}) . The maximal secretion was observed 2 days after irradiation and remained elevated for 4 days following a dose of 6 Gy (42.7 ± 3.5 fmol.ml^{-1}; $n=6$; $p<0.005$). The NT levels decreased progressively and returned to basal values at day 7 for all doses (Figure 1).

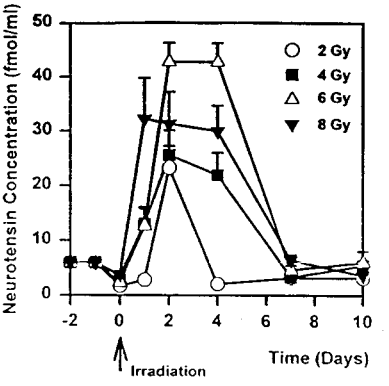

Figure 1: Variation in blood neurotensin levels after gamma irradiation in the rat. The NT concentration was measured by radioimmunoassay after irradiation in the dose ranging from 2 to 8 Gy. Results are means ± SEM; n=6

Increased plasma NT levels appeared to be dose dependent at day 2 in the dose range 2-8 Gy (Figure 2).

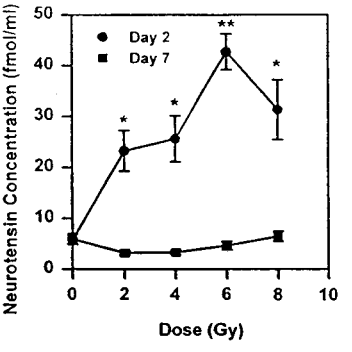

Figure 2: Dose response curves for blood neurotensin levels.
Results are means ± SEM; n=6; *p<0.005, **p<0.001

In parallel, NT receptor binding in colonic smooth muscles was modified. Three days after 6 Gy irradiation, NT specific receptors were characterised by the appearance of a second class of site of low affinity and high capacity. An increase (3 fold) of the total capacity of binding sites was observed as compared with controls (Table 1).

Table 1: Binding sites capacity

	Control	6 Gy Day 3
Affinity Kd (nM)	Kd=0.66 ± 0.04	Kd1= 0.28 ± 0.03 Kd2= 4.05 ± 0.38
Capacity Bmax (fmol.mg^{-1})	Bmax= 86 ± 4	Bmax1= 60 ± 9 Bmax2= 316 ± 36

Data are expressed as mean ± SEM; n=3

CONCLUSION

Whole body gamma irradiation of rats in dose range of 2 to 8 Gy results in a dose dependent increase in plasma NT levels. Variation of gastrointestinal peptide plasma profiles may provide new and better site specific indicators of irradiation induced gut damage. This increase is concomitant with and may be related to a modification of NT specific receptors in colonic smooth muscle. These new observations demonstrate that ionising radiation at doses of less than 10 Gy induces modifications of some gastrointestinal peptide functions.

INTRODUCTION

Both glial and mesodermal cells participate in the formation of scar tissue after injury in the adult central nervous system. According to most authors, the glial response to brain injury is present in fetus and new born animals but incomplete. The mature scarring would be effective only on day 8 after birth in rat (1). The GFAP+ (Glial acidic Fibrillary Protein) cells in the rat fetuses cortex were first detectable on day 19 (2). Are there, early in gestation, target cells sensitive to the deleterious effects of irradiation?

MATERIAL and METHODS

Irradiation (1 Gy) were carried out on 15 or 21 days pregnant rats or on nerve cells just after the beginning of culture. On day 1 after birth, the cortex cells were isolated and cultured in medium with 10% fetal calf serum (FCS) until 30% of confluency. The cells were synchronized in the G1 phase of the cell cycle by a 48 hours culture in medium with 0.1% FCS. This arrest was verified by BrdU incubation. The medium was then replaced by one with 10% FCS for the cells to enter the S phase and 20 hours later ^{3}H thymidine or BrdU were added for 6 hours. The radioactivity was measured in washed cells and BrdU+, GFAP+ cells by immunohistochemistry were counted on 5 microscopic fields. The MTT survival test was carried out on all cultures.

RESULTS

The culture with 10% FCS promoted the survival of astrocytes (GFAP+) which represented 99% of the cells. After irradiation, the GFAP+ cells survived (MTT test) as well as the controls (figure 1). The cell cycle arrest with 0.1% FCS was effective as only 7% of cells were BrdU+. After return to 10% FCS, 35% of control glial cells were BrdU+. The proliferative activity of cells from fetuses irradiated on day 15 was increased by 100% and on day 21 to about 50% of the control

values (figure 2). The proliferative activity of the cells irradiated *in vitro* was similar to the control values.

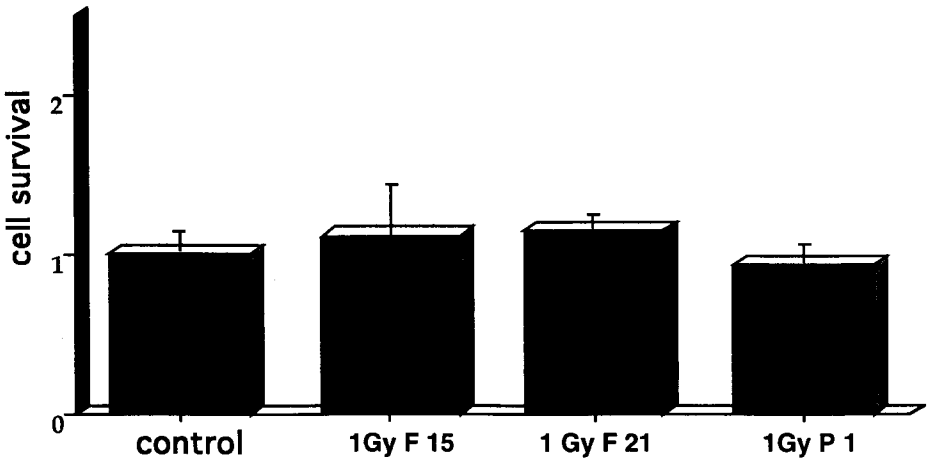

Figure1: Cell survival measured by MTT test relative to control survival. P 1: isolated nerve cells irradiated on day one postnatal; F 15 or F 21: nerve cells isolated from 1 day old animals exposed when they were 15 or 21 day old fetuses

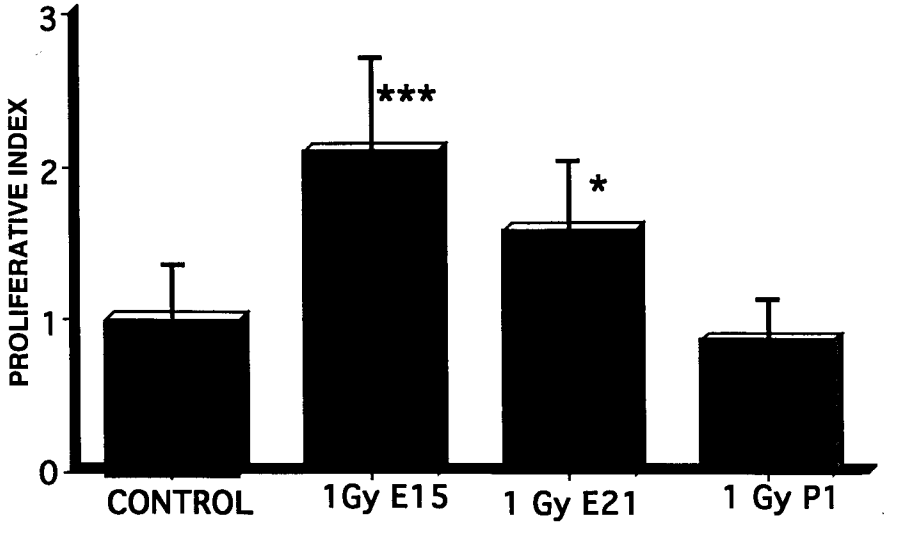

Figure 2: GFAP+ glial cells proliferation relative to the control one.

DISCUSSION

The neurons death induced by irradiation was most effective on gestational day 15 when these cells were dividing actively (3) but glial cells present as progenitors were radioresistant (unpublished results) . On the other hand, few neurons were dividing on day 21 and few were killed by irradiation. In spite of glial cells division from progenitors, these cells were rather radioresistant in comparison with the proliferative neurons (unpublished results). The increase of proliferative activity induced by the irradiation on day 15 of gestation was very interesting because at that time the glial cells were mainly as progenitors. The increase in proliferative activity was lower on day 21 when glial cells started dividing. The progenitors of glial cells could be the target of ionizing radiation to induce proliferation. We can hypothetize that the exposure on day 15, the most radiosensitive period for the cortex neurons, kill a great number of these cells which may release directly or indirectly (via mesenchymal cells) factors like FGF (4) that stimulate progenitor glial cells to proliferate. On day 21pc, the decrease of both neurons radiosensitivity and the number of progenitor glial cells (sensitive to released growth factors) could explain the lower increase of the proliferative activity of the glial cells. On day one after birth, no change was observed with the cells irradiated *in vitro*. This could be either the consequence that glial cells and neurons had lost their close relationships or glial cells could not respond to irradiation at this age.

CONCLUSION

This increase of proliferative activity after prenatal irradiation is very important because:

- the gliomas incidence could be enhanced
- a postnatal brain injury could recruit more reactive glial cells to proliferate.

RADIATION-INDUCED ALTERATIONS OF CELL MEMBRANES AND BLOOD CELLS: THE PHYSIOLOGICAL CONSEQUENCES AND DIAGNOSIS VALUE

I.D. Volotovski, A.V. Vorobey. Institute of Photobiology, Academy of Sciences of Belarus, Minsk, Belarus

The blood-forming organs and blood are the most sensitive targets to radiation damage. A number of structure-function parameters of the cells of blood and blood-forming organs in different time intervals after acute sublethal doses and chronic irradiation during one year under the background of radioactive iodine and cesium injections were determined. These were the intensity of intrinsic fluorescence of cellular components closely related to the metabolic activity of the cells; the fluorescence intensity of membrane-bound probes, pyrene, ANS and merocyanine 540 (Imc) which characterize the properties of the membrane structure; Con A binding and velocity of lectin-induced agglutination of the cells (Vagg) which were changed in bone morrow cells (BMC), splenocytes, thymocytes and peripheral blood lymphocytes (PBL) after irradiation. The changes in Imc and Vagg were revealed at lover doses than it was found for other parameters. BMC and PBL were the most sensitive to either acute or chronic irradiation.
The analysis of the data obtained testify that the observed changes are mainly due to their shifts in population composition of the cells. The perspective of application of the spectral methods for early elucidation of radiation-induced cancerous and immunodeficient changes in the organism are discussed.

CHANGES OF STRUCTURAL AND FUNCTIONAL PARAMETERS OF BLOOD AND BLOOD-FORMING ORGANS CELLS MEMBRANE UNDER IRRADIATION OF ORGANISM

N.A.SHUKANOVA, E.S.LOBANOK. Institute of Photobiology, Academy of Sciences of Belarus, Minsk, Belarus

Cell membranes are one of the high sensitive to radiation targets. In this study structural and functional changes of membranes of rat thymocytes, splenocytes and peripheral blood lymphocytes (PBL) after acute treatment of animals by γ-irradiation in doses 0,25-2,0 Gy were investigated. For fluorescent intensity of membrane probe merocyane 540 (IMc),binding with cells of concanavalin A (Con A) and velocity of Con A-induced agglutination (*V*agg) double-phase dependencies on time after irradiation was shown for all types of cells. In first 1-3 days after irradiation IMc, *V*agg and lectin binding to cells were increased, but in 5-10 days they turned to norm. Under lowering of irradiation dose the effect values decreased and terms of their appearance increased. Both strongly pronounced effects on PBL and correlations among immunological characteristics and biophysical test give the opportunity to use the last one for express-control functional-important radiation changes of immunocompetent cells. From comparison of the data described with results received in vitro we can make a conclusion that observed changes were caused by the influence of radiation on population composition of lymphocytes. Therefore, the fluorescent-microscopic study of cells seems to be very perspective for the early detection of radiation damages in blood system. Application of the method gives an opportunities for carrying out of high-sensitive express-control for blood system state during radiation influence and efficiency of used radioprotective means.

β-CAROTENE AND VITAMIN PROTECTION OF MOUSE THYMUS AGAINST RADIATION EFFECTS

V.A. Khorokhorina, B.P. Ivannik, N.I. Ryabchenko, R.V. Sinkova, V.I. Ryabchenko

Medical Radiology Research Centre, Obninsk, Russia

Devastation of lymphoid organs is the promptest and the most sensitive response of organism to ionising radiation. Lympholytic action of this factor is followed by violation of immunity system (1), thus increasing the hazard of various diseases. An analysis of effects protective against degradation of lymphoid tissue is a promising test in a search for effective means enhancing the resistance of organism to radiation action. It has been reported that β-carotene, a provitamin A having antioxidant properties, is very promising as a radioprotector (2). As β-carotene is water-insoluble, it is preferable to use its water-dispersed forms with addition of α-tocopherol, tocopherol acetate (vitamin E), ascorbic acid (vitamin C) and its derivatives, proteins and emulsifying agents. These additions allow to achieve the stability of the water-dispersed form and improve the assimilation of β-carotene in organism (3). Below we describe the data on radioprotective ability of β-carotene and vitamins.

White mice (genetical type Swiss, males, weight 18-22 g) were exposed to ^{60}Co γ-rays at 100 rad/min. 24 h later, the mice were sacrificed, and the number of cells in thymus was determined. As a radioprotector, we tested Vetoron, a water dispersed commercial preparation (AQWA-MTD, Moscow, Russia) containing 2% β-carotene and vitamins E and C, each in concentration of 0.67%. The animals were fed with Vetoron enriched feed for 7 days prior to irradiation. The Vetoron enriched feed (31.2 mg of β-carotene per 100 g of the feed) was prepared daily.

The obtained data are shown in the Figure. At 24 h post exposure, a dose-dependent decline of the number of cells in thymus was observed. This dependence can be described, in semilogarithmic co-ordinates, by the equation

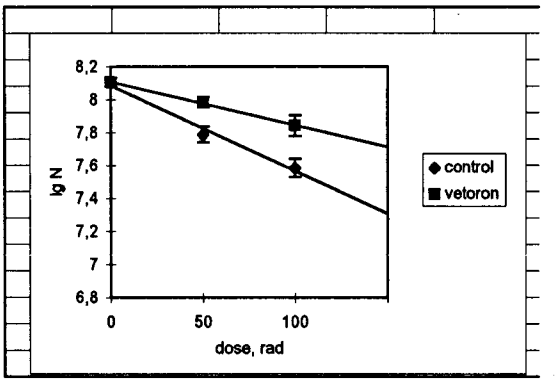
$$\lg N = (8.102 \pm 0.026) - (0.0053 \pm 0.0007)\, R$$

where N stands for the number of cells in thymus of exposed control animals, R is radiation dose (in rads). Preliminary feeding of mice with the Vetoron enriched feed exerted a significant ($P<0.05$) protective action. The dose dependence of thymus devastation value obtained for this case can be described, in semilogarithmic co-ordinates, as

$$\lg N_v = (8.106 \pm 0.025) - (0.0026 \pm 0.0006)\, R$$

where N_v stands for the number of cells in thymus of exposed animals fed with Vetoron enriched feed, R is radiation dose (in rads). Comparison of the slopes of the dose curves obtained for control animals and for animals fed for a week with Vetoron enriched feed shows that this preparation reduced the radiation induced decrease of the number of cells in thymus by 50%.

Data on β-carotene induced increase of viability of irradiated animals can be found in literature (4, 5). Also it has been shown that decrease of concentration of β-carotene and other antioxidants, including vitamin C, in blood enhanced the hazard of cancer and cardio-vascular diseases (2, 6). Our results, together with these data, allow to conclude that composite water



Action of the Vetoron preparation on the number N of cells in thymus of the irradiated mice.

dispersed preparations containing β-carotene and vitamins E and C can be used for protection of organism against action of radiation and other unfavourable environmental factors.

INTRODUCTION

The prophylactics of late effects of exposure is the actual medico-social problem, because now there are large groups of persons who were exposed during occupational contact and living on territories contaminated by radionuclides. Most probable consequences of external and internal chronic influence of radiation may be the increase of malignant tumour frequency, the development of secondary myelo- and immuno-depressions, the earlier forming of sclerous and destructive processes, and the acceleration of senescence. The role of damages in immune system was not yet understood in pathogenesis of the late effects of radiation, but there are evidences that the decreasing of the immunologic supervision in period of forming the consequences of radiation influence enables to realize the cancerogenic effect of radiation (1,2).

The purposes of this investigation are to decrease the frequency or to prevent the development of radiation consequences dangerous for health and life by using the method of modification of radiogenic damages in hemopoietic and immune systems by applying the pharmacological preparations with immunomodulating effects. The ivestigation tasks include: the study of modifying influence of pharmacological substances with different mechanisms of effect: myelopid (immunomodulating, and regulatory), β-carotin, *Calendula officinalis* (immunomodulating, and antioxidant), lipamid (detoxicating); the separate or complex applications of these substances; and the development of the optimum medico-prophylactic schemes. The advantages of these indicated preparations in comparison with the known (T-activin, thymogen, cytokines, etc.) are the absence of contraindications and the possibility to use *per os*.

MATERIALS AND METHODS

The work was conducted on 2 species of laboratory animals (*Wistar* rats, and *CBA* mice) under three models of chronic radiation damages, following the incorporation of plutonium-239 (polymer nitrate or citrate, single injection by amount of 92.5 kBq/kg), and of tritium oxide (HTO, daily drinking water intake, total dose of 9 Gy for 6 or 3 months, dose rates of 4.5 and 9.2 cGy/day), or the long-time fractionational external γ-exposure to cesium-137 (dose of 6 Gy for 6 weeks, or for 3 weeks with dose rate 20 cGy per day for 3 hours, the exposure during 5 day per week with interval of 3 or 10 days.

The medico-prophylactic courses were begun in 0.7, 2, or 5 months after beginning of external exposure; in 1 or 6 months after HTO intake; and in 0.2, 2, or 6 months after plutonium-239 intake. Myelopid (MP), produced at the Immunology Institute, Moscow, was injected hypodermicly one-time per week or per month giving 0.6 mg/kg or 2.0 mg/kg, respectively, and making 3-14 injections per 1 or 2 courses. β-carotin (produced by "Vitamins" SPJ, Moscow) was received by animals together with foods (curds, olive oil) in amount of 7 mg/kg during 4 months. The *Calendula officinalis* was received with drinking water by mice in amount of 12 ml/kg, and by rats in amount of 5.6 ml/kg. The tablets of lipamid were taken with the crude for mice in amount of 15

mg/kg per day, and for rats in amount of 7.2 mg/kg per day. The complex of myelopid, lipamid, and Calendula was received by animals in the same amount, as separately.

The evaluation of modifying effects of medicinal preparations was conducted after exposure and 1 or 2 courses of immuno-therapy for the following criteria: the number of stem cells (SFU_{s-8}, SFU_{s-12}); of karyocytes in bone marrow and in immunity organs; of T- and B-lymphocytes, plaque-forming units in spleen (PFU - integral index of humoral immunity); of peritoneal macrophages, by taking the functional activity of lymphocytes, macrophages, natural killers, RBTL, the content of leukocytes in blood as well as by results of autopsy study after animal death.

The processing of data was conducted by general statistical methods with estimate of statistical reliability of differences equal to $p \leq 0.05$, as threshold of unerring prognoses.

RESULTS AND DISCUSSION

Chronic radiation damage under indicated models of influence may be characterized as having the phases. The traits of damages in hemopoietic and immune systems depended from kinds of ionizing radiation or from plutonium compositions, dose rate, and the total dose of exposure, the duration of influence, evenness of exposure. The development of myelodepression, hypoplasia of lymphoid organs, and immuno-deficiency state were being observed under impact of HTO or plutonium-239 polymer nitrate. It was found out the deep suppression of humoral immunity (decrease of PFU up to 10% of intact control), the decreasing of activity of cellular immunity effectors by 10-30%. The damages of immune processes were less expressed, and recovered to normal values in 3-6 months of observing in case of external exposure or of plutonium citrate injection. For all kinds of ionizing radiation, the most deep and stable changes (up to 10% of norm and below) were indicated in the stem cell compartment under considering all studied models of radiation damage, and full recovery of these cells' number was not registered for period of observation.

Leukopenia was not long after all kinds of radiation influence, the lymphopenia and hypoplasia of lymphoid tissue depended from the decreasing of population of both T- and B-lymphocytes. The value of proliferative ability damage increased with increasing dose of even exposure.

The application of pharmacological preparation under long-term influence of radiation allows to decrease the depth of immuno-deficiency and myelodepression, and all the tested medicinal preparations have immunomodulating effect: the increase of stem cell content at 1.5-2.5 times; the increase of the antibody-producers at 1.5-4 times; the decrease of hypoplasia of lymphoid organs at 1.5-2.5 times; the increase of functional activity of cellular immunity effectors by 10-50% in comparison with exposed animals that were not treated). The stimulating effect of immunomodulators was more expressed under significant damage of radiosensitive organs and tissues, but the same effect was indicated in case of using substances when there was full recovery of immune reactions. It was found out that the indicated modulating effect of preparations was pronounced mainly in 2-3 months after medico-prophylactic course, and more constant influence of medicinal substances on recovery processes was registered in the stem cell compartment. The regulatory effect of myelopid was being observed during the recovery of immunity indexes, and it was higher than for the intact control. The most expressed effect was determined in case of complex application of preparations (myelopid, *Calendula officinalis*, and lypamid; or myelopid and β-caratin) for both external and internal exposures. Chronic effect of incorporated tritium or plutonium polymer nitrate caused the decrease of the average lifetime (ALT) by 10% and the increase of malignant tumour frequency at 2 times due to mainly the increasing

of outcomes of myeloleukemia, lung cancer (HTO), liver tumour, and ostersarcoma (plutoniume-239).

The medico-prophylactic course of myelopid provided the decrease of common number of malignant tumours at 1.5 times ($p<0.05$), including the frequency of lung cancer that decreased at 1.7 times up to spontaneous level; the myeloleukemia decreasing at 3.6 times; and tumours of liver and ostersarcomas decreasing up to the spontaneous level. The receiving of β-carotin enabled to decrease at 1.5 times (lower than spontaneous level) the frequency of lung cancer, and at 3 times the myeloleukosis induced by tritium. In case of fractionational γ-exposure (dose of 3 Gy), the decrease of ALT was not find out, however, the malignant tumour frequency increased at 6 times due to the increase of leukemia and liver cancer. Myelopid applications, separately or in complex with β-carotin, led to the decrease of leukemia frequency up to spontaneous level, and of liver cancer at 2.5 times.

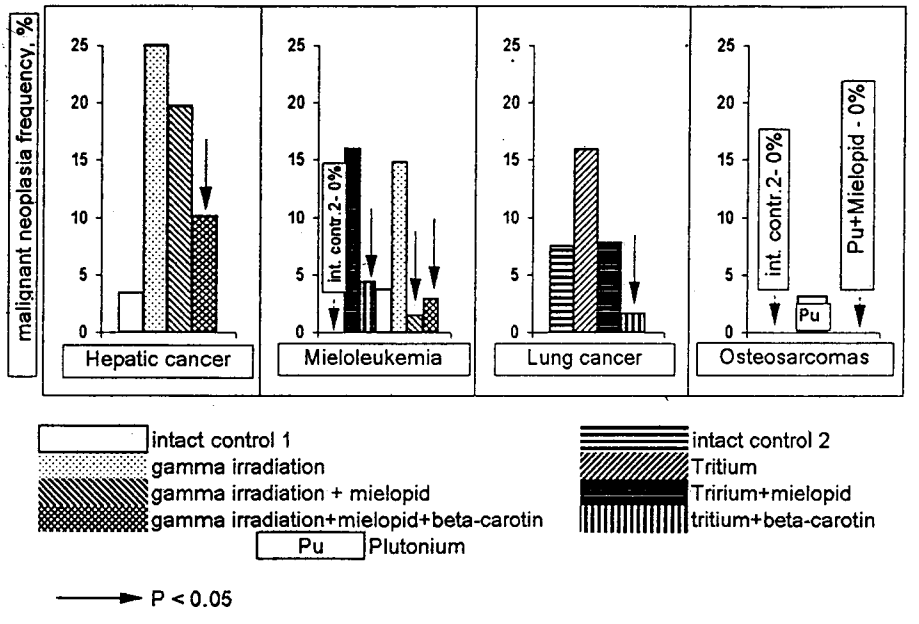

Figure 1

Pharmacological prophylaxis of malignant neoplasia after internal (Pu and Tritium) and external (Cs-137) irradiation in mice

Thus, pharmacological preparations with immunomodulating effect may decrease the level of damages of immunity organs, promote the more full recovery of hemopoietic and immune systems, and these functions, increasing the immune control that allows to decrease the malignant tumoural growth or to prevent the developing of the radiogenic malignant neoplasms.

The key mechanism responsible for producing oxidative damage by ionizing radiation are free radicals and H_2O_2 formation. Our recent findings suggest that supplementation with selenium enriched yeast (SeY) could in rats exposed to ionizing radiation increase survival and prevent or minimize changes in content and distribution of Se, Cu, Zn and Mn in most of the rat tissues, as well as oxidative changes in blood. The exception is changes in tissue Fe content and distributions induced in SeY supplemented irradiated rats, that are not unidirective. Other studies indicate that Se compounds may initiate formation of reactive oxygen species and manifest toxicity when oxidative damage exceeds antioxidant defenses or the ability to form selenoproteins, selenoethers or elemental Se.

To study the effects of supplementation with SeY on oxidative stress induced by ionizing radiation and antioxidative defense systems we employed erythrocytes. Since erythrocytes are constantly circulated through tissues producing higher magnitude of free radicals and H_2O_2 flux they require a relatively high level of selenium containing enzymes, glutathione preoxidase (GSHPx), that is the main H_2O_2 catabolizing enzyme in them and other antioxidative enzymes. Male Wistar rats received selenium (0.5 μg/d) as SeY or pure yeast (Y) for 28 days before exposure to gamma rays (single dose of 4.2 Gy and 8.6 Gy from ^{60}Co source). Erythrocytes were analyzed for changes in the content of trace elements (Se, Cu, Zn, Mn and Fe), thiobarbituric acid reactive substances (TBARS), reduced (GSH) and oxidized (GSSG) glutathione, as well as the activity of enzymes, GSHPx, glutathion reductase (GR), catalase (CAT) and superoxid-dismutase (SOD) 8 and 30 days after the exposure.

Taking into account all the studied parameters in erythrocytes of the rats, it may be concluded that supplementation with SeY may reduce the changes induced by ionizing radiation in trace elements and alteration of the antioxidative defense. The ratio of reduction caused by supplementation with SeY depends on the involvement of enzymes in initiated antioxidant defense, related to the dose of radiation obtained and time.

ABSTRACT (See instructions overleaf)

EFFECTS OF SUPPLEMENTATION WITH SELENOUS YEAST ON RADIOPROTECTION

[1]Jozanov-Stankov O., [2] Djujic I., [1]Demajo M., [1] Mandic M., [2] Prijovic Z.

[1] Institute of Nuclear Sciences "Vinca" P.O.Box 522, Belgrade, Yugoslavia.

[2] IHTM - Department of Chemistry, Njegoseva 12., Belgrade, Yugoslavia.

Ionizing radiation induced in the living system an increased production of free radicals, mainly oxygen reactive species, that could cause unrevesible damage of biomoleculs. Endogenous antioxidant defense system (AODS) developed in the aerobic cell with the role to protect against damaging reactivity of oxyradicals. Essential element Selenium is an important part of AODS.

In our study we investigated weather the supplementation with Se in a form of protein bound element, could exert an protective effect against harm of whole-body irradiation. A groups of male Wistar rats were exposed to gamma rays (single dose of 4.2 Gy from Co-60 source) and supplemented with Se-enriched yeast (0.5 ug/d for 4 weeks before and whole time after irradiation) or with pure yeast - controls . We analyzed the alterations in : amount of reduced (GSH), oxidized (GSSG) glutathione, Selenium, malondialdehyde-like products; activities of enzymes catalase (CAT), glutathione peroxidase (GSH-Px), superoxide dismutase (SOD) in red blood cells of rats 8, 30, 150 days and 8 months after irradiation.

The obtained results suggest that Se supplementation reduced changes in AODS, helping the organism to overcome harmful effects of ionizing radiation.

THE EFFECT OF SELENIUM AND GREEN ALGA MOMOTARU E-25 ON RADIATION CARCINOGENESIS AND LEUKAEMIA IN RATS EXPOSED TO IONIZING RADIATION

V. A. Knizhnikov, N. K. Shandala, V. A. Komleva

Institute of Biophysics, State Research Centre of Russsia,
Zhivopisnaya 46, 123182 Moscow, Russsia

INTRODUCTION

During the past decades several studies of radioprotective agents indicated that the antioxidative properties of selenium provide protection against free radical damage resulting from peroxidative conditions or ionizing radiation.

SELENIUM EXPERIMENT

In a long-term study four groups of 80 white mongrel rats each were exposed to radiation following the Chernobyl pattern. A control group of 80 animals was not irradiated. The fodder for three of the irradiated groups was supplemented with selenium containing yeast (1) to ensure a selenium content of 0.5 mg/kg, 1.5 mg/kg and 5 mg/kg, respectively.

During the 2.5-year study, the total cancer incidence was 7 (8.75%) cases in the control group. There were 53 (66.25%) cancer cases in the irradiated but not treated group, whereas there were 21 (26.25%), 16 (20.0%) and 19 (23.75%) cancer cases, respectively, in the selenium supplemented groups (Figure 1).

Over the same period there were 2 (2.5%) cases of leukaemia in the control group. In the irradiated but not supplemented group leukaemias totaled 13 (16.25%), while in the supplemented groups there were 4 (5.0%), 1 (1.25%) and 5 (6.25%) cases, respectively (Figure 2).

Radiation is mediated through formation of free radicals. When tissues are exposed to high energy radiation, most of the energy is absorbed by cell water. Radiation causes one of the oxygen-hydrogen covalent bonds in water to split, creating hydrogen and hydroxyl radicals. The hydrogen radical is the most reactive one known in chemistry, it can readily cause DNA damage. The selenium depending enzyme, glutathione peroxidaze, is supposed to be the endogenous scavenger of the hydroxyl radical (2).

Recently, an anticarcinogenic activity of beta-carotene and some other biological agents of vegetable origin has been reported. This effect is, however, unlikely to be associated directly with antioxidants. Besides, there is no evidence of any superiority of these substances to selenium as means of cancer prophylaxis.

In the study to follow we wished to investigate possible effects (synergism, antagonism) of selenium and Green alga Momotaru E-25, a biologically active strain obtained in Japan, when used in combination.

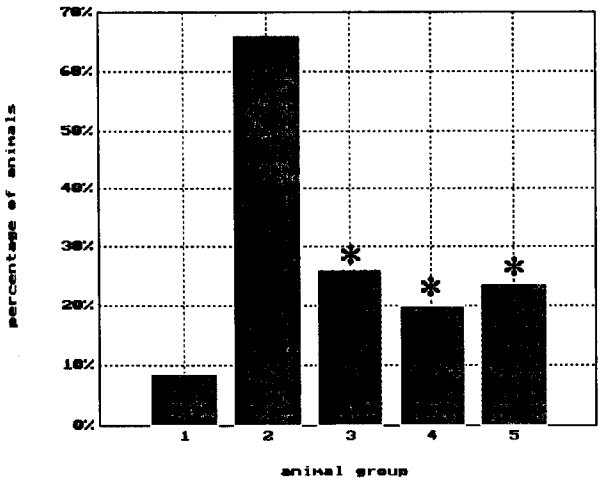

Figure 1. Total cancer incidence (pituitary, thyroid, breast, lung, ovary, uterus, kidney, liver plus leukaemia).
* $P < 0.05$ for comparison with group 2.

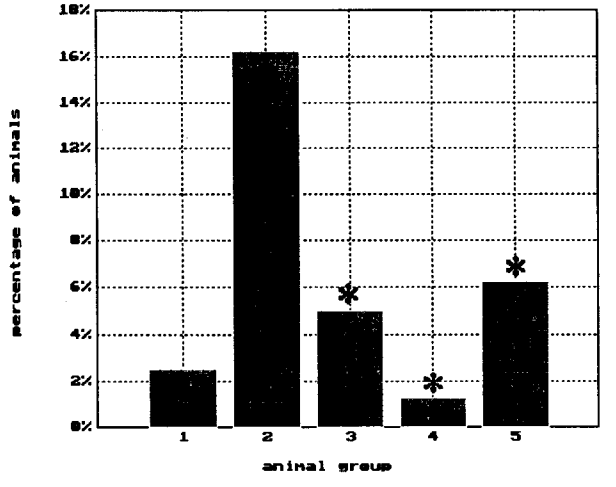

Figure 2. Leukaemia incidence.
* $P < 0.05$ for comparison with group 2.

SELENIUM PLUS GREEN ALGA MOMOTARU E-25 EXPERIMENT

The experiment involved 200 white rats divided into four groups. Group 1 was given a standard diet and no treatment (control). Groups 2, 3 and 4 were exposed to 6.5 Gy of gamma radiation and to incorporated iodine-131. After external irradiation was completed, groups 3 and 4 began to receive Momotaru E-25 and group 4 additionally got Selena (a Finnish preparation) at a dose of 30 ug selenium a day per capita. The animals were followed up for 2.5 years till their natural death. The exposed rats from groups 2, 3 and 4 had leukaemias, cancers and benign tumours, with the death rate increased.

Selenium supplementation of the diet (group 4) resulted in a longer lifespan (Figure 3). No antagonism between selenium and Momotaru E-25 was observed.

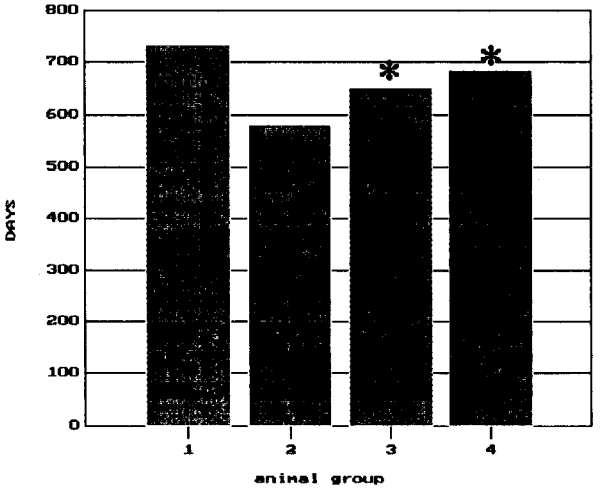

Figure 3. Rat lifespan.
* $P < 0.05$ for comparison with group 2.

CONCLUSION

A diet enriched with non-toxic doses of selenium and Momotaru E-25 caused a longer average lifespan and a 2 - 4 fold decrease of leukaemias and other malignancies, e.g. breast, thyroid and lung cancers, etc., at late times. In the groups with selenium and Momotaru E-25 supplementations, latent periods were longer than in the exposed control given no preparations.

The anticarcinogenic effect of selenium doses applied is on the average equal to the prevention of excess tumors from an effective dose equivalent of at least 1.0 Sv.

INTRODUCTION

In recent years as the result of nuclear testing and accidents at nuclear power plants such as Chernobyl, etc. radiation exposure has become a major issue in various parts of the world. Experience of recent nuclear accidents has shown there is no effective treatment for patients exposed to doses of radiation that result in fatal hematopoietic failure and/or secondary infections (1). Therefore, agents that are effective when administered after irradiation, are of great interest.

In this study, the possibility of using biotechnological agent MD2 after lethal total body irradiation (TBI) and radiotherapy has been demonstrated. In addition, the considerable radioprotection without toxic effect can be obtained.

MATERIALS AND METHODS

Mongrel male mice were ip. injected with the 20% solution (in PBS) of MD2, 25 ml/kg, (0.5 ml/20 g mouse). Control mice were ip. injected 0.5 ml PBS per mouse. Dogs (18±2 kg) were orally administered with MD2, 1ml/kg, twice a day for 15 days following irradiation. The 20 year old patient admitted to the KMMA, was operated in 1976. Diagnosis: hard tissue sarcoma with desintegration localized on VI-VIIth ribs near the spine. The operation involved the resection of VI-VIIth ribs. The patient was orally administered with MD2, 0.4 ml/kg, three times a day. In addition, MD2 was applied to the skin. This supporting therapy lasted 3 months and was repeated after one year. *Irradiation.* Mice and dogs received 7.5 Gy (0.7 Gy/min) and 3.3 Gy (0.3 Gy/min) cobalt-60 TBI, respectively. Some of these experiments were carried out in 1976. The patient received 60 Gy/15/3 weeks on to hem after the operation. When 45 Gy was given, MD2 was administered. *The production of MD2* (polycomponent liquid, pH=5) is a high-technology biotehnological process which includes the bacterial fermentation of barries and vegetables (2). MD2 contains all essential amino acids; vitamins: "D", "B"; nicotinic, lactic and acetic acids; glucose; metals: Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}, Fe^{3+}, Cu^{2+}; E-coli and lactobacillusis (2, 3). The agent has been used in the food (to increase bacterial fermentation), pharmaceutical industry, and in stock-raising in the former Soviet Union (4).

RESULTS

In the mice treated with MD2 (0.1 ml/mouse), no animals showed signs of impending toxicity during the 1-24 h preceding irradiation, and no signs other than those attributable to radiation damage were apparent subsequently. Maximum protection was attained after a single injection

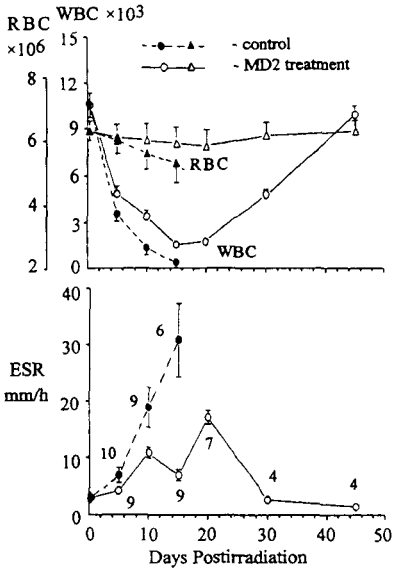
Table 1. Survival of TBI mice after treatment with ip. administered MD2.

Pre-TBI conditioning	No. of mice	No. of mice (%) Alive on Day 30-post TBI	Thymus, mg	Spleen, mg
PBS	80	4 (5)	21±4	98±15
MD2 1 h before TBI	40	18 (45)*	37±3*	210±36*
MD2 5 h before TBI	40	23 (57)*	43±4*	207±24*
MD2 24 h before TBI	43	13 (30)	-	-
MD2 1 h after TBI	30	7 (23)	-	-

* - $p < 0.05$ compared with saline.

of MD2 1-5 h before TBI (Table 1). Administration of MD2 24 h before or 1 h after TBI was less effective. Protected mice remained healthy until day 30 post-TBI when they were killed for examination of their thymus and spleen. These organs were preserved by MD2 because in protected mice the thymus and spleen were twice as heavy as those in the control (Table 1).

To assess the toxic effect of MD2, mice were injected ip. with the intact agent undiluted. The dose of MD2 at which about 50% of the mice died within 30 days was 200 ml/kg (4 ml/mouse). Consequently, the therapeutic index is equal to about 40 (4/0.1).



In the treated dogs with MD2 45-day survivors were 44% (n=4/9, the median survival time (MST) was 17.4±1.6 days), whereas in the control - 0% (n=0/10, MST was 14.7±1.5 days). With increasing rates of survival, MD2 administration ameliorated leukopenia, reduced the intensification of erythrocyte sedimentation rate (ESR) (Fig. 1). Post-TBI MD2 administration reduced the decline of white blood cells (WBC) and the gradual normalization of WBC was evident from day 20 onward. In addition, red blood cells (RBC) remined virtually unchanged. The treated dogs died on 15 day post-TBI, the day of nadir for WBC, when MD2 administration was stopped. In addition, ESR of survivals increased by 2.4 times on 20th day post-TBI and then decreased without MD2 administration. All dogs that survived lived at least one year. Finally, treated dogs had a better appetite, were much more active and their hair was not as badly damaged as in the control.

Fig. 1. WBC, RBC and ESR in irradiated dogs. Figures are the No. of dogs.

As for the patient, 14 days after surgery (29/09, 1976) a course of radiotherapy was carried out (13/10 to 5/11, 1976). The doses were increased during radiotherapy resulting in a decrease

Table 2. Changes in peripheral blood in patient admitted to the KMMA in 1976.

Date of examination	21/09	6/10	19/10	26/10	28/10	31/10	4/11	12/11	15/11

ESR (mm/h)	3	23	15	9	8	8	8	10	13

in the number of lymphocytes in the blood (Table 2). This effect was most pronounced. During radiotherapy the patient complained of fatigue, general malaise, loss of appetite, and some days before MD2 administration, of aggravated pain that was not relieved by drugs. To ameliorate the patient's state MD2 was administered (2/11, 1976). Two days later, sleep and appetite had normalized, lymphocytes had increased considerably (Table 2) and the pain had abated. On 14th day after MD2 administration (16/11, 1976), the patient was discharged home and continued to use MD2 according to the scheme mentioned above during the following 2,5 months. Then this course was repeated after one year. Now, 19 years after intervention with radiotherapy, the

patient feels well and does not complain of any long-term complications associated with radiotherapy or with the original disease. The patient graduated from Unversity immediatively after the operation, is now working, and continues to be mentally active.

DISCUSSION

At present, the majority of effective radioprotectors, e.g. WR 2721 or WR-3689 with DRF about 2-3, cannot be widely used, especially in humans, because of their toxicity (5). In contrast, MD2, having a therapeutic index of about 40, is not toxic at doses relevant to radioprotection. Doses of about 1-5 ml/kg body wt did not induce undesirable side effects such as diarrhea or nausea either in animals or in humans. Furthermore, as previously revealed, these doses both enhanced physical performance in mice and in humans, and improved the functional state of the central nervous system of the latter (6).

It should be noted that MD2 prevents hematopoietic organs from radiation-induced damage and appears to recover hematopoietic cells since post-TBI treatment with MD2 leads to a slower decline in cells of both myeloid and erythroid origin (Fig. 1). Nevertheless, the mechanism(s) underlying the MD2-mediated radioprotective effect is at present not understood and is a matter of speculation. On the one hand the fact that MD2 contains bacterial endotoxin, a well known radioprotector (5), may in part account for the radioprotective property of this agent. However, in contrast to MD2, the endotoxin is most effective when adninistered 24 h before irradiation and provides slight protection when administered shortly before or after radiation exposure (5). On the other hand MD2 has immunomodulator and bactericidal activity (3). This may account for the extreme effectiveness of post-irradiation MD2 adminstration. As an immunomodulator, MD2 may induce cytokines which are protective, and therapeutic agents against radiaton (1). Additional experiments are necessary to find out. Nevertheless, it is clear that other factor(s) are involved in the MD2-mediated therapeutic effect, because cytokines are not effective after lethal TBI (1) and have no bactericidal properties. It should be noted that MD2 displays antitumor activity (3) that makes this agent useful in clinical radiation therapy, as shown above.

At the cellular level, it is proposed that protein kinase C (PKC) is the target of MD-like agents (2). In contrast to known activators of PKC (phorbol esters, bryostantin) MD1, analog MD2, induces calcium-release from intracellular stores which is necessary for full cellular response (2). Furthermore, it was recently revealed that MD1 reduced MN formation in human lymphocytes with DRF=1.4, and the accumulation of cells in the G2-phase, when MD1 was added 1 h after irradiation (4). In the case of MD2 these effects may underlie the preservation or recovery of hematopoietic cells. This remains to be seen.

CONCLUSIONS

1) When administered before sublethal TBI, MD2 protects mice without toxic effects.
2) The advantage of MD2 is the possiblity of its use after lethal TBI. The effectiveness of post irradiation therapy depends on the duration of MD2 administration.
3) MD2 may be administered per os and applied to the skin.
4) MD2 protects and causes a recovery in hemopoiesis at hematopoietic syndrome.
5) MD2 may be used in clinical radiation therapy to ameliorate the patient's condition.

ABSTRACT (See instructions overleaf)

The goal of the study was to determine the radiosensitivity modification effect of lectins. Experiments were performed on mice following mathematically planned scheme.

Animals were observed after intraperitoneal injection of Pisum sativum lectin (PSA), Ricinus Communis agglutinins (RCA), Glycine soja lectin (SBA), Arachis hypogaea (AH) in a single dose 0.1 - 5.0 mg/kg b.w. to check differences in lethality and survive time.

The lethal doses (LD16, LD50, LD84) in mice found respectivly for PSA at the rate of 1,5; 1,8 and 2 mg/kg b.w.; for RCA - 4,3; 4,6; 4,8 mg/kg b.w.. Intraperitoneal administration of SBA and AH in dose 0.1 - 2 mg/kg b.w. does not produce a significant increase of lethality.

Further, four groups of animals were exposed to LD 80-100/30 (6.5-7.5 Gy, 1.5 Gy/min) gamma-irradiation at 24 h time-point after administration of the lectins in a single dose 0.1 - 1 mg/kg b.w.

The collected data showed that lethality, induced by LD80 radiation exposure, gets in PSA-pretreated group 30% shift downward. In case of LD100 radiation exposure, there were no significant differences in the rate of lethality to compared with non-treated irradiated (LD100) control.

No radiosensitivity midification effect had been found in the cases of SBA- , AH- and RCA-pretreatment no matter of a dose and a time-point of lectine administration.

ABSTRACT (See instructions overleaf)

IPI is a criterion of radioprotectors efficiency. Its biological essence is to determine a share of "protected" (according to a selected index) biological objects over the given dose range while using one ore another preparation. In this work the mortality of experimental animals was used as a radiation injury index.

White nonbred mice were irradiated with 5.25 - 7.5 Gy that is with doses which result in 50 - 100 % mortality. In all cases intraperitoneal administration was used. In preliminary multifactorial experiments the doses and time of radioprotector administration were determined as optimal.

On the base of IPI values the radioprotecors investigated were ranged according to their radioprotective efficiency in the following manner: high-efficient preparations (Actovegin, Naphazolin, Cystamine, Thimogen, Limphokinin) and low-efficient preparations (Prodigiosan, Polyribonate).

MAJOR SCIENTIFIC TOPIC NUMBER 4 or 6 (see page 7)

ABSTRACT (See instructions overleaf) The paper is devoted to the study of the possibility of using interleukin - 1β as a therapeutic drug in acute radiation sickness. Mice were irradiated at a dose of 6.0 Gy ($LD_{70/30}$) and dogs at a dose of 2.9 Gy ($LD_{70/45}$). The drug was administered to the mice intraperitoneally at a dose of 50 or 500 ug/kg 1 hour following exposure, whereas the dogs received an intravenous dose of 2 ug/kg 3,24,48 and 72 hours following exposure. The use of the drug has accelerated the recovery of hemopoiesis in mice. Even at day 7 after radiation exposure, the number of leukocytes in treated animals ($0.74 \pm 0.10 \cdot 10^9/l$) was higher than the critical level, whereas severe leukopenia ($0.30 \pm 0.09 \cdot 10^9/l$) was still noted in controls. The drug had a positive effect on the content of myelocaryocytes and granulocytes. The process of bone marrow cells maturation was more intense. A group of treated dogs differed from the controls by the slow development of leukopenia and the high content of granulocytes in the blood at 1-3 days after irradiation. This effect may be associated with the enhanced recruiting of mature cells from the medullary reserve. During the height of the disease, the intravascular aggregation of thrombocytes in treated dogs and the outer indications of hemorrhagic diathesis were significantly less pronounced as compared to the control. It is conceivable to use interleukin as a therapeutic agent in combination with other classes of drugs.

FUNCTIONAL APPROACH TO THE STUDY OF ANIMALS POPULATIONS (RODENTS - ADAPTATIONS TO HARMFUL FACTORS).

E. GRIGORKINA, G. OLENEV

Institute of Plant & Animal Ecology, Ekaterinburg, Russia

Radiosensitivity problem is the part of problem of biological variability and physiological individuality, adaptation and total adaptability. But ionizing radiation influence prognosis is not beyond the theoretical studies yet [1, 2] and hasn't been developed even for external irradiation (acute and chronic) and known dose loads. Information concerning the responses of variety of organisms to radiation exposure is required to make an assessment of potential environmental impact. There are many data about a various small mammals' radioresistance, but all of them were fulfilled without the account of the functional status of animals.

The possibility of two alternative pathways of growth and development regularly realized during ontogenesis (single-phase and biphase growth) was demonstrated in a natural bank vole (Clethrionomys glareolus Screb.) population (South Urals, South taiga subzone). The functional approach, offered by Olenev [3, 4] and used in the zoological investigations, is based upon the functional status (the functional condition, associated with the specificity of growth, development, reproductive condition and succession in time). It has been suggested that three Physiological Functional Groups (PFG) should be distinguished.

FIRST PATHWAY OF ONTOGENETIC DEVELOPMENT. (corresponding to PFG 3).Youngs of year breeding during their Year of Birth are characterized by monophasic rapid growth, reaching an average body weight of 25 g, and enter breeding. Initial stage of formation of true roots started at 65-75 days of age [4]. The high level of metabolic processes . Rapid aging (by our data on age changes in teeth), life span is 3-5 months. These animals serve to provide the increase in numbers during their year of birth.

SECOND PATHWAY OF ONTOGENETIC DEVELOPMENT.(corresponding to PFG 2). Youngs of the year, which do not breed during the Year of Birth are characterized by biphase growth. At approximately one month of age, at a body weight of 16-18 g, growth is suspended, and the first phase of growth is concluded. The initial stage of formation of true roots in them is noted at age of 120-130 days. Activity of metabolic processes is reduced. Lifespan the Youngs of the year (with regard the second phase of growth) is 13-14 months. Aging is delayed as compared to PFG 3 by almost two times. The spring period of "conservation" is concluded by short-term growth and maturation within the course of two-three weeks, and body weight reaches 24-27 g during this. Almost all animals. which overwintered, mature. Activated processes of metabolism are similar in level to those for PFG 3 individuals. although according to absolute age animals are much older than representatives of PFG 3.

It is known that radioresistance to a considerable extent depends on previous to irradiation functional organism condition, the most significant indices of which are CNS and immune system condition, metabolism and energy processes level and also hormonal status of the organism. So the study aimed to reveal the peculiarities of the PFG 2 and PFG 3 radioresistance.

MATERIAL AND METHODS

The laboratory experiments were carried out it the two intrapopulational functional groups of bank voles (Cl. glareolus), captured from the natural environment in Southern Urals. Voles were subjected to acute total gamma-irradiation ^{137}Cs in the range 9,0 - 15,5 Gy (exposure rate of 110 s Gy/min). The lethality, average lifespan and effects of radiation on the haemopoietic system (bone marrow from femur and blood) were estimated after the dose 12.7 Gy, chosen so that it would cause the enough high level mortality of animals. The quantity of leucocytes and granulocytes of bone marrow were determined at various postirradiation intervals on 1, 4, 8, 16, 30 days from 7 different voles in each functional groupings. These experimental values were also obtained from 10 unirradiated control voles of the same grouping for making a comparison. A total of 307 individuals was utilized in this study: 177 animals from PFG 2, 130 from PFG 3. All hematological tests were measured by the standard micromethods. All animals were maintained in our laboratory conditions under the constant temperature and humidity during 30 days observation period.

RESULTS AND DISCUSSION

LETHALITY.

It is apparent from Table 1 that PFG 2 voles are more radioresistance than those of PFG 3 (LD 50/30 -13,2 ± 0,2 Gy and 12,7 ± 0,2 Gy, relatively, p≤0,05) [5]. It should be noted, the range of doses when the death of PFG 2 animals was observed is 12,7 - 15,5 Gy, while for PFG 3 voles is 11,0 - 14,0 Gy. The mortality of the breeding year's youngs were almost in 3 time greater than the nonbreeding year's young after the exposure by the dose 12.7 Gy.

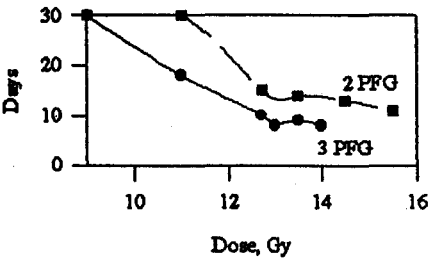
AVERAGE LIFESPAN.

The lifespan from the moment of exposures to the death during 30 days of observation is a criterion of radiation effect' assessment [6]..It is well known that this indicator is inversely proportional to quantity the dose. This seems to be supported by the data from Tabl.1 which demonstrated that after irradiation by dose 12,7 Gy the lifespan of PFG-3 voles is 9.8 days and period of death with 4-th to 12-th days whereas the lifespan of PFG 2 animals is 13,5 days (the difference is significant) and period of lethality with 11-th to 18-th postirradiation days. Dose 14,0 Gy causes 100% mortality of animals PFG 3, while the 100% level of lethality for voles PFG 2 are registered after dose 15,5 Gy (Fig.1).

Tab. 1. Lethality and average lifespan of different PFG voles, subjected to irradiation by 12.7 Gy.

Parameters	PFG 2	PFG 3
Number of animals	34	41
Number of dead animals	6	22
Lethality, (%)	17.6	53
Average lifespan	13.5±0.7	9.8±1.0

Fig. 1 The relationship between dose and average lifespan of intrapopulational bank voles groupings.



A features of the of radiation sickness among animals different functional groupings are noted. The intestinal symptoms such as diminished food and water intake, diarrhoea, loss of fluids, and another clinics manifestation, such as a decreased activity, conjunctivitis were expressed more stronger for animals PFG 3. has already been noted, part of voles PFG 3 were died in early period (within the first 7 days following exposure). It may be believed, that the main couse of their lethality is the damage to the gastro-intestinal tract. But animals PFG 2, were died in more late period. Therefore, one can suppose, that their death was occured by the bone marrow syndrome.

REACTION OF THE HAEMOPOIETIC SYSTEM:

Radioresistance of mammals depend upon the radiation damage of radiosensitive systems, such as the haemopoietic system and the gastro-intestinal mucosa. The stem cells are most radiosensitive and thus predominately influence radiation response. Symptoms occur when lack of replacement of end cells occur [7]. The kinetic of a leucocytes and bone marrow cells quantity, demonstrated in the Fig.2, shows the essential differences between the two investigated groupings by the depth of parameters decreasing. The rate and the level of recovery of the nonbreeding year's youngs were also significantly greather. Our experimental data correspond to a literature ones that cells systems, undergoing to continual renewal or rapid growth, are likely to exhibit the greatest radiosensitivity . It can assume the radioresistance of the nonbreeding part of a population are conditioned by minimizing of a metabolism processes and a reducing of the energy supplying.

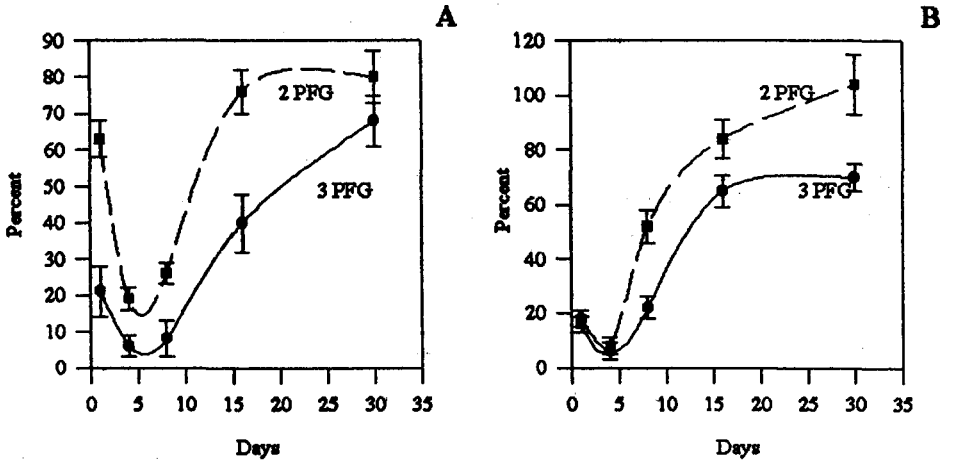


Fig. 2 Comparative haemopoietic cytokinetic in two intrapopulational functional groupings of bank voles exposed to the dose 12.7 Gy. A - LEUCOCYTES, B - BONE MARROW CELLS.

CONCLUSIONS

1. Specimens of the same absolute age, but of a different functional status , are differed essentially in the response to the radiation' action by the next criteria: LD50/30, the average lifespan, the reaction of the haemopoietic system. In the natural environment (exemplified on a rodents populations) it can change the relation between breeding and nonbreeding parts of the population and, thus, its density.

2. It seems reasonable to apply the functional approach in the practice of radioecological investigations. It permits substantial reduction of errors and provides a more precise methodological basis for analyzing of the radioresistance of a natural animals populations, for a conducting of experimental investigations and also for the health protection.

[3]Department of Biochemistry and Biophysics, Silesian Medical Academy, Katowice, Poland

INTRODUCTION

Radiocontamination of biosphere results in chronic influence of ionizing radiation in low doses on large groups of living organisms, including human populations.

Earlier we have revealed that melanin was able to reduce the percentage of different mutation types induced by acute irradiation in animals (Drosophila, mice)(1,2). Our experimental data have also shown that melanin decreases the mutation load accumulated in Drosophila populations as a result of X-ray irradiation for 115 generations (3). The investigation of melanin possibility to influence chronic irradiation effects was very important and urgent. It was interesting to study melanin action in human cells too.

METHODS

The influence of melanin isolated from animal hair on genetic effects of irradiation in mice and human lymphocytes has been studied. Mice males of 2.5 months and 22g weight were used. The starch gel or melanin suspension in it were injected into stomach every day with a special needle. Melanin was supplied in concentrations from 0.3 to 30 mg/kg. Mice were exposed to 1-3 Gy of γ-rays of Cs^{137} at the dose rate of 0.007Gy/h (chronic irradiation) and 420Gy/h (acute one). Animals were killed 2.5-3.0 months later when the exposure was stopped. This interval was necessary for repairing irradiated spermatogonia. The levels of reciprocal translocations in metaphase of spermatocytes were analysed cytologically by the method (4) which is a modified Ivens' method (5).

Human cells were cultured according to a standard method. The culturing time was 52h at 37°C. Colchicin was injected 2 hours before cells fixation with ethyl alcohol and glacial acetic acid mixture. Blood was taken from practically healthy people of 25-45 years old in special medical hospital.

Melanin was added to culture media at G_1 and G_2 stages in the following concentrations: 0.1; 0.3; 1.0; 3.0; 10.0; 30.0 mg/l. Human cells were exposed to acute irradiation (0.5Gy of γ-rays) 40 min after melanin injection. The cytological test included dicentric-ring- and fragment- analysis.

RESULTS AND DISCUSSION

Investigations of melanin influence on spontaneous mutation level in mice has demonstrated that melanin itself doesn't possess a mutagenic activity in all concentrations used, even being supplied for 30 days.

Melanin in all concentrations was shown to reduce effectively mutagenic action of acute γ-irradiation. The melanin influence on genetic effect of chronic irradiation was even more effective. The data presented in fig.1 show that the pigment in the concentration of 3 mg/kg greatly reduced the percentage of induced mutations at different doses of chronic irradiation. The same effects were shown if melanin was supplied in other concentrations - it was revealed that melanin activity doesn't depend on concentration used.

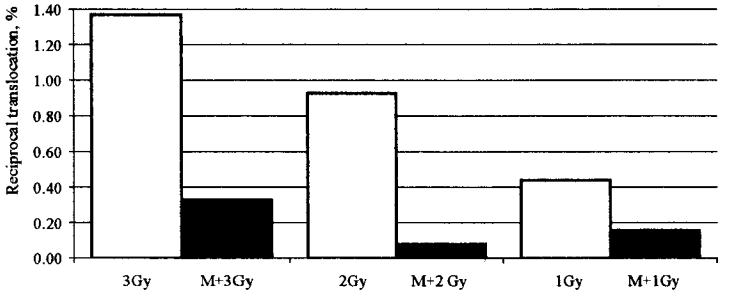

Figure 1. The melanin influence on chronic irradiation induced mutation frequency in mice germ cells (M - melanin).

It's very difficult to compare antimutagenic activity of melanin under acute and chronic irradiation because in the first case one injection of melanin has been used, but in the second case melanin has been injected many times (once a day for 10-20 days). Nevertheless it is possible to draw a conclusion that melanin is no less and even more effective under chronic irradiation than under acute one.

Radioprotective action of this pigment is connected with its high ability to accept and to give back electrons and with anti-radical activity (6,7). It's clear that when low-dose irradiation is used, the possibility for melanin to catch free radicals or electrons is better.

The investigations of melanin action in human lymphocytes have shown, that the aberration frequency in intact cells (control) was ranging from 0.42±0.19 to 1.0±0.3%. These values agree with the literature data. It means that melanin doesn't increase the control level of aberration and has no mutagenic ability.

The study on radioprotective action of melanin has demonstrated, that it is effective in reducing of aberration frequencies, induced by radiation. It was shown, that melanin in all used concentrations (from 0.3 to 30 mg/l) was able to decrease the mutation level (fig.2), but not so effectively as in mice. Strict concentration effect correlation was not observed either in human cells or in mice. There are some proofs that only small amount of melanin can penetrate into cells, and melanin quantity inside cells doesn't increase with rise in outside melanin concentration - this fact can explain absence of such correlation.

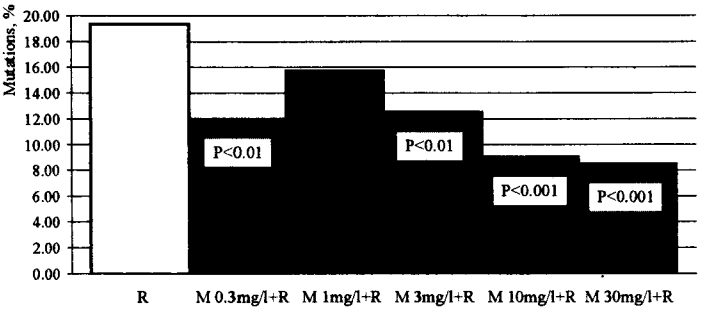

Figure 2. The influence of melanin on radiation induced mutation frequency in human lumphocytes (R - radiation, M - melanin).

Antimutagenic effect of melanin has been revealed to be the same under irradiation at G_2 stage as at G_1 one. These results demonstrate that melanin action doesn't depend (or little depends) on the repair system. The same conclusion was drawn earlier, when melanin had been investigated in drosophila and mice (1, 2).

Complete toxicological tests have been conducted. Melanin could be used in medicine for people protection against genetic consequences of long-term irradiation. We are ready to present this pigment for clinical tests.

CONCLUSIONS

The pigment melanin is not toxic and doesn't possess a mutagenic activity. It reduced the level of mutations, induced by chronic irradiation with low dose rate even more effectively than by acute one. Melanin radioprotective effect is more pronounced in vivo (drosophila, mice), than in vitro (human lymphocytes). Melanin could be used in medicine for people protection.

EXPERIMENTAL DEVELOPMENT OF COMBINED TREATMENT FOR ACUTE RADIATION SICKNESS

K.S.Chertkov, I.Ye.Andrianova, V.N.Andrushchenko, and L.A.Vernigorova

Institute of Biophysics, State Research Centre of Russia, Moscow

INTRODUCTION

A wide application of nuclear energy in various areas of human activity and a growing number of workers occupationally exposed to radiation increase the risk of emergency (1-3). The most severe impact results from nuclear power plant accidents, especially those with a reactor core damage, as in the case of Chernobyl accident, the largest one, when many persons received doses which caused acute radiation sickness. Complicated and varied pathogenetic mechanisms of acute radiation sickness as well as the fact that there are certain stages in its course suggest that a combined treatment is required. Our studies aimed at mitigating the cardinal symptoms of acute bone-marrow radiation syndrome were carried out for years along several lines:

- development of drugs and procedures for early treatment to be effective within the first 24 h postirradiation;
- search for drugs to intensify hemopoietic recovery when used in the latent period;
- investigation of drugs for prophylaxis or incidence reduction of infectious syndrome
- in the agranulocytosis period.

The practical results of the studies are presented in this paper.

MATERIALS AND METHODS

Animals: Male and female mongrel dogs, 1 to 5 years old, weighing 10-20 kg and maintained under the vivarium conditions on a standard diet.

Irradiation: A single uniform total-body exposure to ^{60}Co gamma-rays from the experimental generator EGO-2 at a dose rate >0.6 Gy/min and doses of 3.46 Gy (LD_{90}) and 3.65 Gy (LD_{95}). In special series of experiments to assess the preventive agents for early radiation syndrome, radiation doses were 8 Gy and 20 Gy.

Remedies investigated for modification of radiation damage manifestations: Dimetcarb and dixaphen, complex drugs comprising dimetpramide - an antiemetic, and sydnocarb or caffeine with ephedrine - central nervous system stimulators; prodigiosan, a lipopolysaccharide obtained from *Bacterium prodigiosum*; proteus vaccine; derinate, a DNA-based drug; estradiol dipropionate; hemosorption, a detoxication procedure; and an anti-infectious complex including broad-spectrum antibiotics and vitamins.

Efficiency criteria: The severity of acute radiation sickness and its symptoms, changes in the peripheral blood (erythrocytes, hemoglobin, reticulocytes, ESR, thrombocytes, leukocytes, differential blood count), 45-day dog survival.

Statistical processing: ^{2} test, Student's t-test, Wilcoxon-Mann-Whitney test.

RESULTS AND DISCUSSION

Early radiation responce shows as nausea, vomiting, hypodynamia,asthenia, undue fatiguability. To prevent these symptoms, dimetcarb and dixaphen were used. In the dog experiments, at a dose of 8 Gy which causes 91% nausea, dimetcarb orally administered 1.5 h before or immediately after irradiation led to a 40% reduction, with less pronounced hypodynamia. The other drug, dixaphen, was injected intramuscularly. It is more efficient, having the ability not only to prevent but also to stop actual vomiting in 50-60% of animals at a dose of 20 Gy.

To decrease the early postradiation intoxication symptoms and to mitigate the subsequent acute radiation sickness course, the hemosorption efficiency was studied, with optimal application conditions specified. The results clearly demonstrate the procedure to be appropriate within the first 24 h postirradiation. Hemosorption makes the damage far less severe and increases the dog survival by 50% at LD_{95} (3.65 Gy).

The detoxicating effect of hemosorption manifested itself, in particular, in removal from the exposed dogs' blood of potential radiotoxins, medium-molecular compounds of peptide nature, their amount growing substantially in the early postradiation period. Special experiments showed that isolated polypeptides suppress the hemopoietic precursor cell pool at the level of granulocyte-macrophage committed cells. Hemosorption treatment resulted in a significant increase of these cells in the bone marrow and peripheral blood at the acute stage of radiation sickness as compared with the control.

Acute bone marrow syndrome was treated for with the drugs we combined into a group called "early therapy agents". These can stimulate cytokine production, step up repairing the initial radiation injuries, intensify restoration of the hemopoietic stem cell count and microenvironment. The drugs are efficient when used in the first 24 h postradiation. The dog experiments demonstrated that the drugs which belong to high-molecular compounds (derinate) or proteolypopolysaccharides (proteus vaccine, prodigiosan) mitigate distinctly the radiation sickness course and promote the peripheral blood reconstitution following a single subcutaneous or intramuscular injection in 24 h after irradiation. At a dose of 3.46 Gy (LD_{90}), the survival rate exceeded that of the control by 31-60% ($p<0.05$). In addition to higher survival, the treated dogs exhibited a much lower incidence of severe forms of acute radiation sickness (40-50%, with 96% in the control), less pronounced hemorrhagic syndrome and a less profound drop in some peripheral blood parameters than the control did. The best results were obtained for proteus vaccine: it was also efficient at a higher radiation dose (3.65 Gy), close to the lowest absolute lethal one, with a survival rate of 50-60% (5% in the control).

It is known that the principal critical point in the bone marrow of acute radiation sickness is the hemopoietic system and its status determines the outcome. Investigated as a stimulator of postradiation hemopoietic recovery was estradiol dipropionate, a steroid hormone involved in the regulation of hemopoiesis. It was injected intramuscularly every other day starting from the midlatent period, i.e. from 5 to day 19 postradiation. With this scheme, estradiol raised the survival rate up to 47% at LD_{95} ($p<0.05$), slowed down a drop of leukocytes and promoted their clear-cut earlier restoration compared to the control, thus shortening the agranulocytosis period. At the height of disease, 20 days postradiation, the leukocyte count was 0,5 10^9 and 1,0 10^9/l blood ($p<0.05$) in the control and treated animals, respectively.

The leukopoiesis-stimulating effect of estradiol is associated with increased number of myeloid series cells in the bone marrow, due to mature and young divisible cells, and of granulocyte-macrophage precursor cells in the bone marrow and peripheral blood.

To prevent agranulocytosis-related infectious complications, we developed rational complexes by combining antibiotics of different classes to be used in cycles. The application of these complexes of systemic-action antibiotics or poorly absorbed aminoglycosides with delayed administration (starting from day 6-7, twice a day) for microbial decontamination of the intestine alongside with vitamins increases the dog survival up to 60-100% at LD_{50}-LD_{90}. At the absolute lethal dose the effect drops down to 30-40% (Fig.). The antibiotic therapy significantly reduced the severity of clinical symptoms, successfully prevented infections and mitigated the course of complications developed. However, the treatment produced little or no beneficial effect on the damaged hemopoiesis.

With one of the drugs under investigation (derinate, proteus vaccine, estradiol) or hemosorption included into the antibacterial complex, the efficiency grew from 30-40% to 70-90% at a near-absolute lethal dose and the length of antibiotic therapy was shortened (Fig.).

This is of great importance since the therapeutic agents applied together with antibiotics reduce an adverse effect of the latter on hemopoiesis and immunity by shortening their use. Our data indicate that a combined application of the remedies studied and an antibiotic complex not only mitigated the damage but also enhanced hemopoiesis. The difference was most prominent for estradiol used in combination with antibiotics.

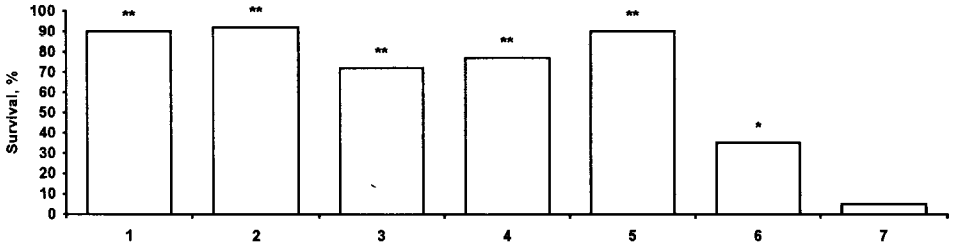

Figure. Efficiency of different remedies used in combination with antibiotics in dogs irradiated at a dose of 3.65 Gy (LD_{95}): 1 - hemosorption; 2 - proteus vaccine; 3 -prodigiosan; 4 - derinate; 5 - estradiol; 6 - antibiotics; 7 - control. Each group includes at least 10-12 dogs.
* significant difference from the control ($p < 0.05$);
** significant difference from antibiotics ($p < 0.05$).

Thus, the studies have demonstrated the efficiency of various remedies which should be included into the antibacterial complex to make it more effective in the treatment of acute radiation sickness. The results obtained conform with the evidence (4) that multiple administration of a cytokine (CSF) to exposed dogs adds to the antibiotic efficiency. The early therapy agents capable of stimulating the endogenic cytokine production and of enhancing the natural body resistance have the advantage of a single intake which facilitates essentially their practical application.

If the early therapy agents or hemosorption cannot be used within the first 24 h postradiation, we would recommend, as an alternative, that a hemopoietic stimulator (estradiol) should be included into the antibiotic complex starting from the midlatent period. The symptomatic drugs (dimetcarb or dixaphen) are also shown to be appropriate for prophylaxis and cure of early radiation response manifestation.

MAJOR SCIENTIFIC TOPIC NUMBER

It is known, that acidi glutaminici and its derivates have wide biological activity, directly take part in the regulation of energy, protein and lipid changes in human being in some pathological and stress conditions.

On the othes hand pharmaceutical industry produces somi drugs with acidi glutaminici for treating sone desorders. Beside this Natrii glutamat is used in food industry.

In this report there are data about toxical and antiradiation beateres of acidi glutaminici and its derivates: glutamini, glutamat Kalii and Calcii, Magnii, Lizine in experiments on small laboratory animals.

Natrii glutamat was used as food adition in total gamma-radiation.

At first an antiradiation activiti of the drug was investigated in different combinations: during 15 days before, after, before and after the radiation. At the second turn of experiments such groops of animals were influenced with acute radiation in subletal doses 600 and 750 rad.

The conditions of prolonged radiation with low pawer were investigated too.

The results allow to consider that Natrii glutamat in experiments on small animals in conditions with acute or prolonged radiation increase their survival with different doses on 35-40%.

To make final conclusions we must experiens Natrii glutamati on big laboratory animals - dogs.

ANTIRADIATION EFFECTIVENESS OF THE CHLORINE C

O.M. BUBNOVA, I.I. GRECHKA, V.V. ZNAMENSKY
State Research Centre of Russia - Institute of Biophysics, Moscow

INTRODUCTION

At present ever more attention of the experimenters in the field of search of high-effective antiray means - is directed to development of preparations from bio-active substances of a natural origin. In this connection all greater interest is caused by researches of antiray activity of these compounds, distinguished, as a rule, from known preparations of synthetic manufacture of low toxicity, absence of expressed collateral effects and possibility of course application.

It has biological (antiray) activity in dozes 5-10 mg/kg and clorine C which is derivative of chlorophil A. At present it passes tests in oncology.

Porphyrines (synthetic and natural) are recently subjected to wide study as potential medicinal means (1-2), due to their ability to be accumulated in bodies of the reticulo-endothelial system and proliferous tissues (3), as well as their physical-chemical characteristics (fluorescence, photosensitizing action, colouring).

All this testifies for the benefit of perspective use of porphyrin for treatment and diagnostics of tumors (4). According to the abovedescribed properties of porphyrines there is that fact, that for some of them radioprotective properties are revealed during the injections as well as before and after radiation treatment (5).

The abovesaid has formed the basis for study of antiray properties of the chlorine C during the experiments on small-sized laboratory animals.

The researches of sharp toxicity of chlorine C were conducted on white non-bred and linear (CBA x C57 Bl) F1 mice of both sex weighing 20-26 g. Chlorine C has been injected once (intraperitoneally, intramuscularly, subcutaneously and per os) in a wide range of dozes, registering death of the animals during 7 days after the injections. Parameters of sharp toxicity (LD_{16}, LD_{50}, LD_{84}) were defined by the method of Lichfield and Wilcocson.

Facts on sharp chlorine C toxicity are indicated in the Table.

Table Sharp chlorine C toxicity in experiments on mice.

Mice	Way of injection	LD_{16} (mg/kg)	LD_{50} (mg/kg)	LD_{84} (mg/kg)
non-bred	intraperitoneally	105	200	340
(CBA x C57 Bl) F1	intraperitoneally		270	
	intramuscularly		1100	
	subcutaneously		1400	
	per os		2000	

The facts, submitted in the Table show that toxicity of chlorine C is considerably below at the injection per os, subcutaneously and intramuscularly, than intraperitoneally. These facts permit to relate chlorine C to substances of the average toxicity.

Antiradiation effectivity of chlorine C was studied on the mice (CBA x C57 Bl) F1. Chlorine C was applied in a wide range of dozes with its' use in 3 variants: before radiation treatment, after radiation treatment, combined (before and after radiation treatment).

Studing radioprotective effectiveness of clorine C the mice have been subjected to general radiation treatment on Y-installation " IGUR " with capacity 1.68 Gy/min. 30-days-long survival of mice, dynamics of their death, changes in their weight as well as average duration of life of dead ones depending on a doze of clorine C, time and way of the injection before radiation treatment in the doze of $LD_{90\text{-}95/30}$, that has made for sharp radiation treatement 9 Gy, has been studied.

Experiments have shown, that chlorine C possesses high radioprotective àctivity in experiments on mice during intraperitoneally injection 15-60 minutes before radiation treatment in dozes, close to minimum absolutely lethal. At the injection 90 mg/ kg 15-60 minutes before the radiation treatment antiray effectiveness was 63 % and 45 %, accordingly (control - 4 %).

In optimum radioeffective doze 40 mg/kg chlorine C by its' effectiveness (80%, the control - 13 %) comes nearer to the widely known radioprotector - mercamine.

Radioprotective activity of chlorine C reduces at an increase of a time of the injection before radiation treatment and at other ways of injection (intramuscularly, subcutaneously, per os).

Studies of medical activity of chlorine C in experiments on mice have shown, that the compound does not possess medical activity. The death of the animals during the experiments did not differ in terms from their death in the control of radiation treatment.

Combined application of chlorine C (before and after radiation treatment) in the experiments on mice did not provide antiray activity. Chlorine C was injected intraperitoneally 30 minutes before radiation treatment in the doze 50 mg/kg and in 1 hour after the radiation treatment in the doze 75 mg/kg.

Thus, as a result of conducted work reasonably high antiray activity of chlorine C is established. At the same time it should be noted, that the compound is effective only at intraperitoneally injection before radiation treatment. In other variants of experience (after radiation treatment, before and after radiation treatment) it is not effective. So, it can be considered to be potential radioprotector.

In the subsequent work we are to evaluate radiodefensive abilities of chlorine C during injection per os and in conditions of radiation treatment in small dozes.

ABSTRACT (See instructions overleaf)

Changes of 5-aminolevulinic acid-induced porphyrines accumulation in thyroid gland cells under irradiation of animals

T.S.LOBANOK, N.A.SHUKANOVA. Institute of Photobiology, Academy of Sciences of Belarus, Minsk, Belarus

The control of proliferate activity of cells under irradiation of organism gives a valuable information about process of cell populations reparation in different organs, danger of pathologic changes development as well as efficiency of radioprotective agents. We studied a changes of velocity of ALA-induced endogenous porphyrins accumulation in rat thyroid gland cells in different terms after acute (up to 3 Gy) and chronic (treatment up to 1400 kBq ^{131}I) irradiation of animals. The control experiments showed a correlation between indicated parameter and proliferate activity of cells. During the first week after acute irradiation it was registered an increase (in 1,2-3,0 times) of ALA-induced velocity of uro-, copro- and protoporphyrin accumulation in gland cells. The similar, but less pronounced changes were been detected during 1,5 month under chronic irradiation of animals. This effect strengthened under increasing of irradiation dose. With using of digital fluorescent microscopy in thyroid gland of irradiated rats after addition of ALA the appearance of cells with bright porphyrin fluorescence has been registered. A relation of observed changes with radiation-induced changes proliferate activity of thyroid gland cells as well as diagnostic value of used parameter are discussed.

GENOME STATE IN SOMATIC CELLS OF ATOMIC ENTERPRISE WORKERS AND THEIR CHILDREN, AND GRANDCHILDREN

N.D. Okladnikova, L.E. Burak, O.B. Musatkova

Branch No. 1 of Russian Federation State Scientific Centre Biophysics Institute
456780, Ozersk (Chelyabinsk-65), Russia

The clinical and experimental investigation evidence that instability of somatic cell genome plays the great role in forming the late consequences of exposure. There are comprehensive data about positive correlation and succession of damages induced in genome of somatic cells, and the consequent tumour development. It is emphasized the possibility to evaluate the genetic danger of exposure by level and character of chromosome changes into somatic cells (1). The purpose of this investigation was to evaluate the genome state in somatic cells of persons exposed to chronic radiation, and their offspring (generations I and II).

MATERIALS AND METHODS

The genome state of lymphocytes in peripheral blood was evaluated in workers of MAYAK PA, first atomic enterprise in Russia, who were exposed to chronic external γ-radiation or joint radiation (external and internal from plutonium-239 incorporated) at first years of building the MAYAK. Total doses of exposure varied from 0.5 to 4.0 Gy, and in some cases they went up to 6.0 Gy for 5-6 years of work. The amount of incorporated plutonium-239 ranged from 0 to 7.4 kBk. Period of 30 years went after end of contacting with exposure. Group of MAYAK workers contains 433 individuals, and control group consists of 150 persons. It was examined 179 children of exposed parents (the gonad dose of father - 1.78±0.11 Gy, of mother - 2.07±0.16 Gy). The age of children during period of chromosome investigation was in range of 30-40 years. It was examined 150 grandchildren (at age 2-6 years) of exposed professionals.

The standard methods of two-day culture of lymphocytes of peripheral blood and the obtaining of chromosome preparations were used. Preparations were stained by Romanovsky-Giesma method. The number of chromosomes in metaphase plate, and the aberrations of the chromatid and chromosome types were analyzed in 100 metaphases for each case.

RESULTS AND DISCUSSION

The frequency of aberrations of the chromosome type varies from 0 to 9 per 100 studied cells at late periods of chronic exposure. The mean values in different dose groups exceed the spontaneous level of aberrations at 4-8 times. The portion of aberration of stable type was 45.0-55.0% of total number of chromosome aberrations. The aberrations of instable type were mainly twin fragments and dicentrics with the accompanying fragments. The frequency of aberrations is higher when there is joint radiation influence, and is determined by correlation with the marrow dose of exposure to radionuclides (Figure). The higher frequency of chromatid aberration did not find out in comparison with control and pathological cell clones.

The frequencies of chromatid and chromosome aberrations in 179 children of exposed parents did not statistically differ from corresponding characters in control (children of town residents who had not occupational contacting with radiation) (Table 1). The portion of stable aberrations was higher in offspring exposed *in utero* (mean

dose of 0.17 Gy) and equal to almost up to 50% of total number of aberrations, than those in offspring not having antenatal exposure.

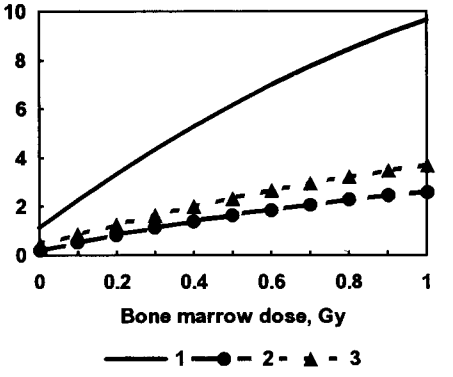

Figure 1. Chromosome aberration frequency (per 100 cells) by external γ-radiation and ^{239}Pu body burden (1 - Cromosome aberrations, 2 - Dicentrics, 3 - Stable aberrations)

Table

Chromosome aberrations (per 100 cells) in children of atomic workers

Groups	Number of patient	Cells scored	Chromatid aberrations	Chromosome aberrations		
				total	dicentrics	stable
Control	92	9200	0.4±0.08	0.37±0.07	0.11±0.04	0.16±0.04
Children of atomic workers	179	17900	0.53±0.06	0.37±0.06	0.11±0.03	0.13±0.08
Father	50	5000	0.52±0.12	0.30±0.08	0.08±0.04	0.10±0.04
Mother and father	37	3700	0.43±0.18	0.38±0.12	0.11±0.05	0.03±0.02
In utero irradiation	92	9200	0.57±0.08	0.40±0.10	0.13±0.04	0.19±0.06

The frequency of chromosome type aberration of examined 158 grandchild (generation II), which grandparents exposed to chronic radiation, corresponded to control (68 children) value (0.47±0.10 and 0.51±0.08 aberrations per 100 cell, respectively).

Thus, the instability of genome is keeping in professionals more than 30 years after chronical external and joint exposures in doses exceeded the maximum permissible dose. This cohort of workers is characterized the higher risk of malignant tumours, especially in those having plutonium-239 incorporation (2). Mutogenic effect of radionuclide was shown earlier (3, 4). In comparison with control, the heightened

instability of genome did not find out in first two generation (F1 and F2) of exposed parents by test of chromosome aberrations.

The cytogenetic effect of antenatal exposure is noteworthy. It is known that exposure *in utero* is the factor of higher risk of leukemia (4). It is necessary the future clinic-cytogenetic observation for seeking the possible prognosticating of exposure consequences by test of chromosome aberrations.

Session 2: Thyroid effects

PERSPECTIVES OF THE USING LOW DOSES OF THYROID HORMONES FOR INCREASING ANTIOXIDANT AND REPAROGENIC POTENTIAL IN PERSONS WITH IRRADIATED THYROID GLAND (approach to the problem)

E.Antipenko, A Cheban, M.Pilinskaya, L.Owsyannikova, A.Antipenko

By the estimation of the postponed consequences of the irradiation by iodine mainly thyroid cancer and hypothyroidism usually had been evaluated. Meanwhile more actual problem there is the development of the symptoms which are typical for hypothyroidism, but not accompanied with decreasing the level of thyroid hormones (TH). In such patients the decreasing of the antioxidant potential and increasing of the level aberrant lymphocytes was marked. This phenomenon probably may be explained by the development of the functional deafness of irradiated cells to TH.

On the other hand the experimental data have shoved that TH increased the genome stability by inhibition of free-radical attack and stimulation repair from injures inflicted in the course of endogenous or induced mutagenesis. Thyroxine acts as antioxidant and reparogen within the physiological concentration range (up to 10^{-12} M), being able to stimulate the repair even after the self-dependent chromosome from injuries has been completed. Potential risks of the chronic overdosage at this situation is absent.

Thus the systematical investigation TH as antioxidant and reparogens and problems their practical treatment on irradiated patients is necessary.

MICROVASCULAR ALTERATIONS AND CYTOGENETIC CHANGES IN MEDICAL PERSONNEL OCCUPATIONALLY EXPOSED TO IONIZING RADIATION SOURCES

Vlatka Brumen, Ivica Prlić, Željko Radalj, Đurđa Horvat, Hrvoje Cerovac

Institute for Medical Research and Occupational Health Zagreb,HR10001

INTRODUCTION

One of the most widespread applications of man-made radiation sources is their medical use. Consequently, numerous radiation-induced biological effects following both iatrogenic and occupational exposure, can be expected, including vascular and genotoxic ones. This study was aimed at detecting both microvascular impairments and changes in the peripheral blood lymphocytes' cell genome among medical personnel occupationally exposed to ionizing radiation sources. In addition, filmdosimetric data on occupational exposure will be reported.

SUBJECTS AND METHODS

The study comprised a total of 54 examinees, divided into two groups. Group 1 consisted of 24 employees of a surgical department of the University hospital Zagreb, performing operations in the X-ray zone. There were 13 men and 11 women in the group, mean age 36,7 years (age range 22-50 years), mean duration of occupational radiation exposure 12,9 years (range 1-29 years). Group 2 consisted of 30 control persons out of the same hospital, who had never worked with radiation sources. Eleven were men and 19 women, mean age 24,7 years (age range 21-38 years).

For each examinee, a detailed questionnaire was fulfilled, comprising data on personal, family and occupational background. By that means, data on counfounders known to affect both peripheral blood flow status and cytogenetic testing outcome, were collected. It was so revealed that 9 persons out of Group 1 and 13 persons out of Group 2 were smokers, none of them smoking more than 20 cigarettes a day. All the interviewed denied alcohol abuse, viral diseases, drug consumption and/or iatrogenic irradiation within one year prior to this study.

Peripheral blood flow status was established via serial application of widefield nailfold capillaroscopy, dermothermometry and digital photoplethysmography, as described already (1). Impairments detected by each method of approach were classified and interpreted according to own previously established criteria (1,2).

Changes in the peripheral blood lymphocytes' cell genome were detected by conventional structural chromosomal aberration analysis. Each examinee was taken a 5 ml venous blood sample. Immediately afterwards, a 48-hours lymphocyte cell culture was carried out according to the standard protocol (3). Coded slides were analyzed microscopically, scoring two hundred well spread first division metaphase cells per subject (4).

All the occupationally exposed examinees constantly wear KODAK personal monitoring film type 2 on their workplaces. Films are regularly read by the experts of the Laboratory for Radiation Protection and Dosimetry of our Institute. Within the framework of this study, radiation doses received in a year prior to it's start are reported. Doses lower than 0.03 mGy are always reported as 0 mGy, since they are bellow the sensitivity of KODAK type 2 personal dosemeter (5).

RESULTS

Overall results of the peripheral blood flow survey are presented in Table I. The data revealed a high incidence of microvascular impairments among surgical staff in comparison to

the controls. It was the method of capillaroscopy and dermothermometry that demonstrated the highest percentage of altered findings in both groups. Photoplethysmographically detectable microvascular changes were the fewest (none in controls). Statistical evaluation of the obtained results by means of t-test proved the increase of microvessel impairments in occupationally exposed subjects to be significant ($p<0.01$). There was also a marked difference in the type of microvascular alterations found in each group. Among the exposed subjects, mostly numerical and morphological changes occured, while in the control group functional changes of capillary blood vessels were predominant.

The results of cytogenetic testing are presented in Table II. Among the exposed examinees, not only significantly higher global frequency of chromosomal aberrations ($p<0.01$), but also a marked difference in aberration types occuring, was verified in comparison to the controls. This goes especially for dicentric and ring chromosomes, which were not found in any of the controls.

Filmdosimetric data on radiation doses received in a year prior to this study (total radiation doses;TRD) are reffered for each occupationally exposed examinee in Table III.

DISCUSSION AND CONCLUDING REMARKS

Ionizing radiation affects human health in a wide variety of ways, including direct endothelial cell damage and genotoxicity. It can be presumed that peripheral blood vessels' impairments underlie skin radiolesions (2). Capillaroscopy is the only noninvasive technique known so far, enabling direct monitoring of microcirculation ***in vivo.*** Despite high sensitivity, it's scope is limited due to the lack of pathognomonic findings (1). Therefore, peripheral blood flow survey should be completed by skin themometry. Findings of those two methods have shown very good correspondence (1). The use of photoplethysmography, however, is limited to the cases where affection of digital arteriolas is to be expected, since capillary alterations are not detectable by this method (1).

Although radiation-induced chromosomal aberrations were studied as early as in 1950's , it was the development of short-term peripheral blood lymphocyte cell culture technique (6) which enabled rapid progress of human radiation cytogenetics and biodosimetry. However, in cases of occupational exposure i.e. chronic exposure to fractionated low-dose radiation, one should be extremely cautious inhealth risk estimations. Namely, at low dose levels, dose response may not necessarily be linear; radiation effects may be immeasurable or undetectable; cellular repair processes and the presence of confounders can either decrease or increase the harmful radiation impact.

The principal aim of this study was to draw attention to some of the less investigated health hazards related to occupational radiation exposure. The results showed that even under regular workplace conditions, certain bioindicators can still reveale changes in the health status of the exposed medical personnel. Therefore, their constant comprehensive dosimetric monitoring and biomonitoring are necessary.

A RECALCULATION OF THE AGE DEPENDENT DOSE-EFFECT-RELATIONSHIP OF THE LIFE SPAN STUDY OF HIROSHIMA AND NAGASAKI

Markus M. Kottbauer, Carl M. Fleck and Helmut Schöllnberger
Atominstitut der Österreichischen Universitäten, A-1020 Wien

Abstract - The basis of the presented model is the multistage process of carcinogenesis as a biological effect. It provides simultaneously the age-dependent mortality of spontaneous and radiation induced solid tumors and dose-effect relationships at any age after exposure. The model has been used to describe the solid cancer mortality rates of the atomic bomb survivors of Hiroshima and Nagasaki. It has characteristics of both relative and absolute risk projections depending on the age of exposure.

INTRODUCTION

Major new insights into carcinogenesis have come from recent advances in cellular and molecular biology. The concept of oncogenes provides a simple explanation how agents as diverses as radiation, chemicals or retroviruses can induce tumors. Today it is known that a neoplasm usually arises from a single cell that has undergone a critical change. Despite its clonal origin, as the cells of a cancer grow and divide, progressive stages can be identified from preneoplasia to malignancy /1/.

To describe the age-dependent tumor incidence rate, we need to know the number of cells of an individual, cells which are able to divide and which are not yet damaged. M_0 is the number of these cells. In each of these cells are several DNA regions which are very sensitive to the induction of cancer. These are for example the proto-oncogenes, normal cellular genes, or tumor-suppressor genes. The mechanisms which convert proto-oncogenes into oncogenes, a process known as oncogene activation, are thought to be the critical genetic events in neoplastic transformation. An oncogene is a gene whose abnormal expression or altered gene product directly determines the production of the malignant phenotyp /2/. The generation of oncogenes from their non-transforming homologs, the proto-oncogenes, can occur in a variety of ways. Among other possibilities they can be generated by mutations within coding regions of oncogenes /3/. Much epidemiological and experimental evidence argues that malignant change is a process which results from multiple genetic alterations. Some of these steps involve oncogenes. The necessary mutations for the origin of cancer are assumed as independent from each other.

THE MODEL

The following differential equation describes the time dependent behaviour of the arising of the first step in the successive process of mutations.

$$\frac{dM_1(t,C,dD/dt)}{dt} = \left(B_0 M_0(t) - B_1 M_1(t)\right) P_u(C,dD/dt) \qquad (1)$$

M_1 (t, C, dD/dt) is the number of cells per individuum at time t which are in the first transformation step, for example: which have one point mutation on a critical, tumor relevant gene locus. The spontaneous cancer incidence rate is mainly dependent of the radicals produced by the natural cell metabolism and by chemical carcinogens. We describe these two damage probabilities with their concentration C. The spontaneous cancer incidence rate is also dependent on the dose rate dD/dt from natural background radiation. B_0 is the number of critical DNA bases (nucleotides) in critical codons of all tumor associated genes per cell. B_1 is the number of critical DNA bases (nucleotides) in critical codons of all tumor associated genes per cell after the first transformation. P_u (C, dD/dt) is the probability for mutations at usual conditions /4/. Equation (1) describes the first step necessary for a complete carcinogenesis. The number of steps necessary for the induction of cancer defines a system of coupled differential equations. Each transformation is represented by one differential equation. We assume that P_u (C, dD/dt) is constant over lifetime. The sink on the right side of equation (1) is due to the fact that cells which have reached the first step of damage are a source term for the second step. M_1 is several orders of magnitude smaller than M_0. Therefore this sink can be neglected and we can set M_0 (t) ≡ M_0 = const. Because of P_u = const. the differential equation (1) can be directly integrated:

$$M_1(t) = B_0 M_0 \; P_u \, t \qquad (2)$$

For M_i (t) we get:

$$M_i(t) = B_0 B_1 \ldots B_{i-1} M_0 P_u{}^i \frac{t^i}{1 \cdot 2 \cdot \ldots \cdot i} \qquad (3)$$

PROLIFERATION ABILITY OF BONE MARROW CELLS OF HUMAN IN LATE PERIODS AFTER CHRONIC RADIATION INFLUENCE

V.S. Pesternikova

Branch No. 1 of Russian Federation State Scientific Centre Biophysics Institute
456780, Ozersk (Chelyabinsk-65), Russia

The ionizing radiation influence on human causes damage of hemopoiesis, that is one of the most radio-sensitive systems. Long-term chronic exposure leads quickly to changing the peripheral blood content, and therefore cytopenia (leucopenia and thrombocytopenia) of different degrees of its expressions depending from the value of exposure doses is being observed(1). The picture of peripheral blood and bone marrow has been fully studied in period of exposure and in period after the radiation influence end, when the gradual recovery of blood indexes was occurring to level that was observed during primary examination (2). The initial thrombocyte level recovered by 5th year of observation, but the leukocyte level recovery occurred later, and approached to the initial indexes in exposed persons by only 10th year. Despite the long-term period after the exposure end (25-30 years), the persons exposed to chronic γ-radiation doses, which exceeded the maximum permissible dose more that at 10 times, had the leukopenia, and in some cases the hypoplastic state of hemopoietic.

There are different interpretations of the leucopenia genesis in the literature for persons exposed, and the number of researchers believes that leucopenia in these patients is the consequence of decreasing the granulocyte production by bone marrow (3, 4). The important significance in changing of production of these cells may be the damage of proliferation processes of granulopoietic elements in bone marrow. There are a few works in literature which indicating to the damage of proliferative ability of hemopoietic cells under chronic exposure. The decreasing of mitotic activity of bone marrow cells occurred in persons who worked during long time period having the contact with the ionizing radiation sources (3). Basing on the experimental data (5, 6), the increase of proliferative ability of bone marrow cells was observed during the processes of the chronic and fractionation exposures, however, for long time exposures (1.5-2 years) it was shown the significant decrease of the proliferation processes with lengthening of cell cycle time by 2-2.5 times (6).

It was conducted the study of morphology and proliferative ability of the bone marrow cells in 46 persons, who were exposed to occupational external γ-radiation, in 25-30 years after end of contact with the ionizing radiation sources. The total doses of external γ-radiation were 2.0 Gy for 12 persons, 2.1-4.0 Gy for 23 persons, and > 4 Gy for 11 persons. The group of the practically healthy persons (9 individuals), who had not contact with ionizing radiation sources, was taken as the control group according to the age-sex content of main group. The proliferative ability of the bone marrow elements was evaluated by mitotic index, and by the degree of incorporation of the specific labeled predecessor of DNA (tritium-thymidine) into nuclei of the bone marrow cell under conditions of the short-term cultivation of bone marrow cells. The bone marrow preparations were made in 0.5, 1, and 2 hours, then they were fixed and treated by autoradiography. Percentage of labeled elements was estimated in preparations for each type of the proliferating cells (the label index). The label intensity was determined by number of silver granules under the nuclei of labeled cells.

The number of erythrocytes and thrombocytes was on the level of norm in the blood of examined patients. For 20 persons, the leucopenia of the different degrees of

expression was found out, and the decrease of number of cells which having nucleus was indicated in punctates of bone marrow because of decreasing of all types of cells or only granulopoietic elements.

The evaluation of proliferative ability of bone marrow elements shown that there is the decreased number of mitoses of both the proliferating granulocytes and erythronormoblasts in persons with hypoplasia. The number of mitoses of proliferating bone marrow elements was on level of norm in patient with normal hemopoiesis.

The values of tritium-thymidine incorporation into nuclei of bone marrow cells differed also in persons with different content of leukocytes in blood. The increase of incorporation of labeled predecessor of DNA into young granulo- and erythro-poietic elements was found for persons with normal content of leukocytes. The significant decrease of index and label intensity of bone marrow cells was in patient with long and stable leucopenia and hypoplasia, this evidences that the proliferation rate of granulopoietic cells decreases when cell cycle and its separate phases have become more long at 1.5-2 times. Apparently, the rate reducing of proliferation of these elements influences greatly on the content of granulopoietic elements in the bone marrow and in production of mature granulocytes as well as its content in peripheral blood. In some cases with expressed hypoplasia of hemopoiesis it was found only single labeled granulopoetic elements. In comparison with granulopoietic elements, the damage of proliferative activity of erythronormoblasts do not significantly influence on the content of erythrocytes in blood, it may be because of the compensatory reactions in the erythropoiesis system: a) the possible change of differentiation direction of the stem pool cells mainly to erythropoietic-sensitive elements (3); b) the significant addition of erythrocyte production may be waited under changing the ratio of elements of early and late generations of erythronormoblasts, i.e., increasing the erythroblast content, pronormoblas and basophilic normoblasts (elements with more high proliferative potential in comparison with polychromatophilic normoblasts); and c) in some cases, it was found out activating of the erythropoiesis (together with the leuco-erythro-blast ratio), that causes the additional erythrocyte production.

Thus, the proliferative process rates in bone marrow elements are significantly lower in persons exposed to chronic γ-radiation and having the hypoplasia of bone marrow, and leucopenia.

ABSTRACT (See instructions overleaf)

Several studies show that small doses of ionising radiation induce an adaptive response to subsequent high doses. As we are doing cytogenetic studies of people working on Portuguese uranium mines for biomonitoring purposes, we use this opportunity to know if that people were more or less adapted to subsequent ionising radiation doses.

For these studies we address the following's questions:

First, can the dose received by miners, function like a prime dose for an adaptive response when they have a subsequent high exposition dose and this equal or different for low or high exposed individuals.

Second, what is the capacity for adaptive response of lymphocytes from miners when they are primed with a low dose of 5 cGy and exposed at a challenge dose of 300 cGy.

Two groups of miners workers were selected on the base of their historical monitoring doses, one as low exposed and another as high exposed and a control group.

Our observations show the ability of peripheral lymphocytes of the two groups of miners to display adaptive response after induction with a small dose of 5 cGy on G1 and a challenge dose of 300 cGy. The group low exposed present more cases with adaptive responses.

We saw also on some miners workers, that the frequency of chromosomal type aberrations after 5 cGy is less than background. If this is confirmed with more cases it means some kind of adaptation to small doses that we do not saw on the control group.

EVALUATION OF FLOW CYTOMETRIC RETICULOCYTE MATURITY INDEX (RMI) AS A DIAGNOSTIC AND PROGNOSTIC INDICATOR IN ACCIDENTAL TOTAL BODY IRRADIATION

INTRODUCTION

In cases of accidental total body overexposures early diagnostic and prognostic methods are recquired. After high doses, bone marrow could be severely damaged. Between peripheral blood cells, reticulocytes could be considered as a useful indicator of erithropoietic activity to evaluate the extension of damage to haematopoietic system and to predict bone marrow recovery.[1]

After an accidental total body irradiation (TBI), their presence in peripheral blood, even in a very low quantity, indicates a remainder bone marrow activity. Their increase after a bone marrow aplasia, may be considered as a sign of functional recovery.

Flow cytometric analysis provide an objective measure of reticulocyte maturity, since fluorescence intensity is directly proportional to ribonucleic acid (RNA) content [2]. It is thus possible to derive a reticulocyte maturity index (RMI) taking into account the fraction of reticulocytes with high fluorescence intensity (HFR) which represents the subset at the earliest maturative stage .

With the purpose of testing the usefulness of flow citometric reticulocyte analysis with determination of a RMI as an early indicator of radioinduced marrow suppresion, this method was assayed in an animal model of TBI.

Considering that therapeutical irradiations could provide useful models of human accidental irradiations,similar studies were performed in fourteen patients undergoing TBI as a conditioning regime for bone marrow transplantantion in order to evaluate the clinical applicability of this method for monitoring bone marrow functional recovery.

MATERIALS AND METHODS

Animal studies: Wistar rats were irradiated with Co 60-gamma radiation, at doses of 2 Gy, 4 Gy and 6 Gy . Blood samples were taken from the tail vein on days 0, 1, 3, 7, 10, 17.and 30 after irradiation (a.i.). Similar sampling was carried out with non-irradiated animals.

*Clinical studies:*fourteen patients undergoing bone marrow transplantation (BMT) (6-54 years) were enrolled for this study. Pretransplant conditioning regimes consisted in chemotherapy (started on day -9) plus radiotherapy (between days -4 and -1). Bone marrow infusion was performed on day 0. TBI was administered at 3 Gy/day in twice daily fractioned doses, at a dose rate of 0.04 Gy/min. Blood samples were obtained daily during conditioning treatment and three times weekly until patient's discharge.

Flow cytometry of reticulocytes: all blood samples using EDTA as anticoagulant were treated in the same way. Whole blood (5uL) was stained for flow cytometric analysis with thiazol orange (TO) Retic Count® (Becton Dickinson) and the corresponding unstained sample was used as autofluorescent control. Both samples were analyzed on a Facstar Plus® cell sorter (Becton Dickinson).

The fluorescence of 50000 red cells was collected. The reticulocyte percentage and the mean fluorescence intensity were calculated using the Lysis I software program.

For RMI defining , data analysis was performed by two different protocols. For the first one, mean channel number of fluorescence was expressed as arbitrary units of fluorescence (UAF/RMI expression) [3]. For the second method, fluorescence intensity of reticulocytes was divided into regions of low (LFR), moderate (MFR) and high fluorescence (HFR) according to Davis [4] [5] and HFR %

was derived by dividing the number of reticulocytes in the high fluorescence area by the total number of reticulocytes.

Engraftment monitoring in BMT patients: a post-transplantation increase in absolute neutrophil count (ANC) to > 500/ml in two consecutive samples was employed to define myeloid engraftment. The second succesive increase of platelets count (PC) to > 25000/ml was considered as indication of trombopoietic recovery. Erithropoietic recovery was defined by three succesive rising counts in RMI following the nadir post-transplantation .

Statistical analysis: satistical analysis of data was performed using the Wilcoxon matched pairs signed rank sum test and one way Anova test.

RESULTS

Animal studies: Considering the whole groups, total reticulocyte percentage fell progressive to a nadir on day 3 a.i. (5.56 % from basal values , $p < 0.01$) A slow recovery was then observed There was a rise on day 17 a.i. This rise was more evident in groups irradiated with the higher doses. In most animals basal values were recovered on day 30 a.i. There was a significant reduction in AFU/RMI on day 3 a. i. (day 0 vs day 3 : 41.1 +/- 5.71 vs 30.83 +/- 1.77 $p < 0.01$) indicating a lower RNA content in reticulocyte population. Recovery was significantly earlier in the group irradiated with 2 Gy ($p < 0.05$). A rise was evident in all groups on day 17 a.i. (figure 1).

Clinical studies: in all patients HFR % decreased more rapidly than reticulocyte count and dropped to zero in most patients. After the aplasic period, the rise in HFR % preceded by several days the rise in total reticulocyte number. Engraftment was detected on day 16.5 +/- 3.2 post-transplantation (p.t.) by HFR % , on day 19.8 +/- 4.6 p.t. by ANC ($p< 0.05$) and on day 26.5 +/- 7.8 p.t. by PC ($p < 0.05$). Figure 2 shows temporal behaviour of total reticulocytes number and HFR % from the beginning of conditioning treatment until patients' discharge.

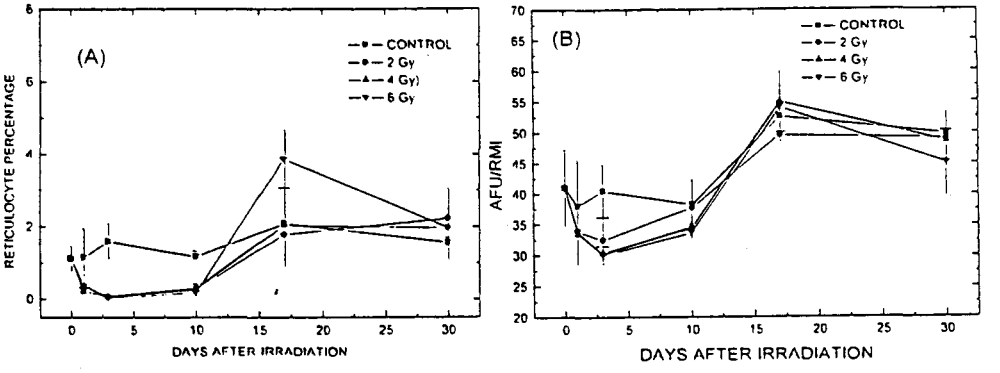

FIGURE 1 : Temporal behaviour of (A) reticulocyte percentage and (B) AFU/ RMI in total body-irradiated rats.

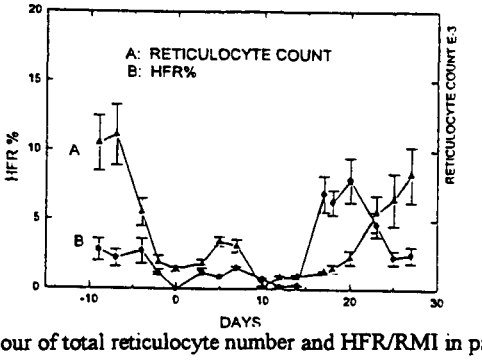

FIGURE 2 : Temporal behaviour of total reticulocyte number and HFR/RMI in patients undergoing bone marrow transplantatation Day 0: bone marrow infusion.

DISCUSSION

Reticulocyte count has been subject of numerous discussions regarding its clinical applicability and the new possibilities offered by flow cytometric methods. Besides the total number of these cells, the mean RNA content may play a role as a parameter of maturation stage , thus providing another useful tool for monitoring erythropoietic function.

Our data from animal studies indicate the sensitivity of this method for evaluating radioinduced damage to haematopoietic system, according to previous results of Tanke et al [6]. Early depletion in peripheral reticulocytes was evident in all irradiated animals but the results didn't reflect dependency to radiation doses . The percentage increased by the third week in all groups, including non-irradiated animals. A regenerative response from bone marrow to periodic blood loss could account for this late rise [7]. Higher values were reached in groups irradiated with higher doses. Thirty days a.i. basal values were recovered. Additional studies with other doses and dose-rates should be done to fully define dose-effect relationship. Considering AFU/RMI it has been possible to detect an earlier recovery in animals exposed to lower doses.

Our study with patients was primarily aimed on the early detection of bone marrow functionally recovery. Temporal relationship between erythroid, myeloid and megakaryocytic engraftment remains unanswered [3]. Although all peripheral blood cells ultimately arise from a totipotential haematopoietic stem cell, early regeneration of cell populations after BMT may be from commited progenitor cells. Hence, the rate of recovery of the three formed elements (red cells, white cells and platelets) could be independent of each other [1] Our results showed that bone marrow function was detected earlier by RMI than by either neutrophils or platelets Rise in HFR % preceded in about 3 days the rise in neutrophil counts This close temporal-relation is in good correlation with previous results of other similar studies [8]

Additional work will be required to standardize RMI and arrive at a common definition and calibration [2] Further experimental and clinical assays could provide more insight regarding the potential clinical utility of this method for monitoring accidentally overexposured patients.

INTRODUCTION

Since the first radiation accidents which resulted into severe health effects into the workforce or the population, progress has been made in the fields of diagnosis, prognosis and treatment of accidentally overexposed victims. Since then, progress has also been made in the medical management of diseases such as aplasia. Because of the relative scarcity of radiation accidents, there is a need for complementary researches, in order to take profit of new techniques and medical approaches.

After whole body overexposure, the key issue is the therapeutic decision, i.e. the choice between bone marrow transplantation and other strategies. The indications of bone marrow transplantation cover only a short range of doses, provided the exposure is distributed uniformly within the body; a rare event in accidental settings. The results of the clinical trials for Granulocyte-Colony Stimulating Factor : G-CSF, Granulocyte/Macrophage-Colony Stimulating Factor : GM-CSF or Interleukin 3 : IL-3, *in vivo* and *in vitro* radiobiology experiments suggest that growth factor therapy could be of use after most accidental overexposures to evidence and to stimulate the remaining haematopoietic stem cells in order to shorten the duration of aplasia, although questions have been raised about growth factor infusion real clinical efficiency (1). The lessons learnt from the management of accidents evidenced that growth factor infusion has been mildly successful. This may be due to ill-defined administration protocols, to the rather narrow spectrum of action of the growth factors available for clinical use, but also to adverse side effects bound to the characteristics of these patients among them combined injuries and radiation induced inflammation (2). Therefore, great efforts should be devoted to researches in this field, exploring possibilities of alternative therapy such as haematopoietic stem cell and progenitor transfusion after their expansion.

Ex vivo expansion of haematopoietic precursor, stem cells and differentiated cells is a new approach of growth factor therapy, which may be of interest for the treatment of patients with accidental radiation-induced aplasia. These studies aim to expand the pool of progenitors and stem cells for transplantation or to expand differentiated cells (mainly granulocytes but also megakaryocytes) for transfusion (3).

This is made possible due to the development of techniques allowing the selection of a population of haematopoietic progenitors and stem cells from the blood (with stimulation by growth factors prior stem cell harvesting) or bone marrow using immature cell positive selection. The next step consisting in their culture with combination of growth factors or additional stroma cells is also under development. Autologous progenitor cells generated *ex vivo* has been recently used with some success for reconstitution of haematopoiesis after high-dose chemotherapy (4).

EXPERIMENTS

Our aim is to investigate the feasibility of expansion of the pool of progenitors and differentiated cells (mainly myeloid) for transfusion purposes.

The first step is the selection of a population of haematopoietic progenitors and stem cells from the blood (PBSC from multiple myeloma patients collected following Endoxan plus G-CSF- mobilisation) or bone marrow using CD 34+ cell positive selection (through immunoaffinity or immunomagnetic bead techniques 70-90% purity of the CD 34+ cell population are achieved).

Depending on the culture conditions, the selected human CD 34+ cell samples are then cultured at various cell densities, with recombinant growth factor combinations to promote expansion and differentiation (liquid cultures 10^3 and up to 50 10^3 cells/ml, G-CSF 10 to 1000ng/ml in conjunction with SCF, Interleukine-1, 3 and 6, 10 to 100 ng/ml) expansion of 88.3 +/- 32 fold could be obtained in one week of cultures for differentiating cells. Committed progenitors which have a longer survival *in vivo* and a high proliferation potential are also expanded 49+/-15 fold (assayed through secondary culture techniques). Expansion of 1625+/-615 fold could be obtained in 2 weeks of cultures (Fig 1,2 and 3). However simultaneous production of mature and progenitor cells was not observed.

High concentration of G-CSF and other growth factor are required to expand maturing cells whereas low G-CSF and high SCF are required to expand myeloid progenitors. Expansion of differentiating cells resulted in the loss of CD 34 expression amongst the cultured cells. The best growth factor combinations assayed allowed a good reproducibility of the experiments. For cultures up to 4 weeks, the harvested cells exhibit a fully-developed granulocyte phenotype.

Our results suggest that, in theory, it is possible to culture from the blood or bone marrow the cells able to proliferate and differentiate, in order to produce a sufficient quantity of cells to cover the transfusion needs of an accidentally irradiated victim through an aplasia episode (5).

The qualitative aspects of *ex vivo* expansion have to be studied in details. To be of therapeutic use the cells produced must retain normal mature cell functions. Our results suggest that the expanded cells have a close to normal chemotactic ability as measured through assay on PVP free polycarbonate filters 48 wells microchemotaxis chamber using fMLP as attractant (43+/-4 vs 68+/-5 for controls). The cells also retain a part of their capacity to generate superoxyde anions after two weeks of culture (measured through chemoluminescence tests). Cytological studies evidenced that *ex vivo* expansion resulted in a combination of cells of various degrees of differentiation in one to two weeks of cultures. For cultures up to 4 weeks, the harvested cells exhibit a fully-developed granulocyte phenotype (6).

DISCUSSION

Important research is necessary to adapt the *ex vivo* expansion of haematopoietic precursor stem cells and differentiated cells for the treatment of radiation-induced aplasia. Some of the growth factors (among which Stem Cell Factor : SCF, interleukine-1 and 6) have restricted use *in vivo* due to their toxic side effects although their effects on haematopoiesis could be useful. *Ex vivo* experiments could allow their use without adverse reaction. Furthermore, while proliferating, *ex vivo* expanded cells are not submitted to the effects of haematopoietic inhibitors (such as Tumor Necrosis Factor TNF alfa) which may be generated in the body following an irradiation. They are also independent from the clinical problems of the patient (such as burns and dehydration) which could delay haematopoietic recovery. It has been suggested after the Brazil accident (where a victim experienced a late hypoplasia) that, when internal exposure is involved, the use of growth factors *in vivo* would stimulate haematopoiesis-induced progenitors or stem cells to progress in the cell cycle, while the cells are irradiated. The combination of haematopoietic growth factors inducing mitosis and simultaneous prolonged radiation exposure might result in the depletion of the stem cell pool. *Ex vivo* expansion may allow the use of haematopoietic growth factors independently of these problems.

This approach could be of interest for the treatment of radiation induced aplasia if the cells necessary for *ex vivo* expansion could be found in the blood or in the marrow and harvested in sufficient quantity and that it is possible to culture them. Such cells could be available in the blood after various types of irradiation as suggested by results on haematopoietic progenitors in the peripheral blood after therapeutic irradiations. Data analysis from the past accidental exposure evidenced also that unhomogenous exposure is very frequent among victims of radiation injury (7), suggesting that in numerous accidents a bone marrow territory may still contain cells which could be used for expansion. Furthermore, preliminary results on *in vitro* irradiated human CD 34+ cells suggest that *ex vivo* expansion remains feasible for cells irradiated up to 2 gy without real loss of expanding ability.

ABSTRACT (See instructions overleaf)

While searching and selecting radioprotectors to protect different groops of specialists under extremal conditions (such as a nuclear power plant accident) the irradiation parameters may be predicted in some cases with the help of a form of the injury distribution depending of the radiation dose.

With such information the preliminary estimation of a radioprotector efficiency is possible to fit these radiation conditions. For this purpose CPC should be used.

CPC is a probabilistic value equal to a share of the protected lives as append to a typic version of radiation injury distribution according to doses. Its value is estimated from the so-called formula of complete probability, and includes a share of biological objects irradiated with different doses as well as a protection probability while using the preparations studied over this dose range.

MAJOR SCIENTIFIC TOPIC NUMBER ..... (see page 7)

ABSTRACT (See instructions overleaf)

For some reasons the current technique of the comparative estimation of antiradiation activity of radioprotectors belonging to different pharmacological groups not always permits to receive adequate and disfortion-free results.

That is why the authors suggest "the integral protection index" (IPI) which is essentially free from the shortcomings, inherent in current methods. Firstly, it belongs to integral criteria, that is characterizes preparation properties over all dose range of interest. Secondly, it may be used for evaluating the preparations with any tipe of action. These peculiarities are evidence of the advantage of such criterion over the rest ones.

IPI is a criterion of radioprotectors efficiency, and its biological essence is to determine a share of "protected" (as to a selected index of injury, as a rule, experimental animals mortality) biological objects with the help of one ore another preparation over the given radiation dose range.

PREVENTIVE TREATMENT OF COMBINED RADIATION INJURIES

R. Boudagov, L. Uljanova, G.Makarov

Medical Radiological Research Centre, 249020 Obninsk, Russia

INTRODUCTION

The risk of sepsis development increases when thermal burns and other trauma occur in conbination with exposure to radiation. Only surgical correction of the life-threatening state recommends within 48 hours after irradiation. All other arrangements have to carry out when hemopoiesis recovery will complete (1). However exposed patients with combined injuries (CI) die during the first two or three weeks mainly due to sepsis. Therefore prophylaxis and preventive therapy of infectious complications are need early. Actual difficulties in choice of valid treatment procedure for acute radiation syndrome (ARS) exhibit additional aggravation under CI. The available facts prove decreasing early therapy efficiency for rather high dose exposure and wound trauma occurrence (2,3). The own results showed that bacterial polysaccharide pyrogenal, glycopin (synthetic analogue of muramil-dipeptide), thymus preparations (thymozin, thymotropin, thymogen), tuftsin, heterologic human and bovine immunoglobulines did not modify the low values of 30-day survival under CI (irradiation + thermal burn). Single injection of prodigiozan, zymozan and some other yeast polysaccharides in 1 hr after CI resulted at moderate increasing of survival (4,5). The main purpose of this study, which bases upon our understanding of CI pathogenesis (6), was search more effective means for preventive treatment of combined radiation injuries. Two groups of remedies were under study. The first group included so called "biological response modifiers" (BRM). These agents may increase host defences to infection, macrophage's activity and hemopoietic growth factor's secretion (7). The second group included antibiotics that should be directed against the potential gram-negative as well as gram-positive pathogens and simultaneously be useful for selective decontamination of gastrointestinal tract (8).

MATERIALS AND METHODS

Experiments performed using CBAxC57BL6 male mice and Wistar rats. Animals irradiated with a ^{60}Co gamma source at 0.45 Gy/min. The midline absorbed dose was 7 Gy for mice and 7.5 Gy for rats. Non-lethal per se full-sickness thermal burn 10% of the total body surface for mice or 15% - for rats inflicted immediately after irradiation by means of powerful lamp's light. Both animal models of CI characterised by sharp decrease of 30-day survival in compare with only irradiated mice and rats. The main increment of lethality observed during the second week after irradiation.

Human recombinant IL-1-β was kindly supplied by Dr S. Ketlinski (Institute of High-Purity Biopreparation, St.-Petersburg, Russia). IL-2 (Biotech, St.-Petersburg, Russia) was a generous gift from Dr J. Jurkevich. Extra-cellular yeast polysaccharides of Bullera alba (B-678), Sporobolomyces albo-rubescens (Sp-50) and Ronasan (sulphated mannan) prepared by Prof. N.Elinov et al. (Chemical and Pharmaceutical Institute, St.-Petersburg, Russia). Heat-killed Lactobacillus acidophilus have prepared in collaboration with Dr V.Pospelova et al. (Institute of Microbiology and Epidemiology, Moscow, Russia). Increase of survival during 30 days after CI and beneficial effects on blood system state used as indexes of BRM's efficiency.

The next broad-spectrum antibiotics were under study: ampicillin, doxiciclin, rifampicin, rifametoprim, sulacillin, ciprofloxacin and pefloxacin. We thank Prof. I.Fomina and Dr M.Vyadro, Russian National Research Institute of Antibiotics, who provided us with medicines for this experimental study. Increase of survival, absence of side effects to hematopoietic system and lymphoid organs, correction of intestine microbiocenosis, increase of host resistance to exogenous infection used as indexes of antibacterial therapy efficacy.

THERAPEUTIC PROPERTIES OF BIOLOGICAL RESPONSE MODIFIERS

Single i.p. injection of B-678, Sp-50 and Ronasan (20 mg/kg) in 1 hr after CI increased 30-day survival from 3% (untreated mice) accordingly to 23%, 20% and 34%. Intraperitoneal two or four injection of rIL-2 within the first or second days after CI (single dose was equal to 5000 U/mouse) provided statistically significant increase of survival up to 42-49% as compare with untreated mice. The best results obtained when mixture of heat-inactivated L.acidophilus used (base concentration 10^8 microbes per 1 ml growth media). Single s.c injection of this remedy in 15 min after CI (0.1 ml/mouse) provided survival increasing from 27% (untreated mice) to 80%. The own results are according to early published data (9) that single subcutaneous injection of heat-killed L.casei in 10 min after irradiation may increase survival.

The opposite data revealed when therapeutic properties of hrIL-1-β investigated in the murine model of CI. This multy-functional cytokine did not improve 30-days survival. Moreover, when given once in 4 hr after CI (100 micrograms/kg, s.c., dose recommended for ARS treatment) IL-1 caused a higher rate of mortality in early stage of CI. In particular, 28 from 40 "treated" mice died in 2-3 days instead of 100% survival untreated animals during the first 5 day after CI. Analogous results obtained when IL-1 dose reduced to 150 ng/mouse (40% of "treated" mice died at early phase of CI). Single s.c injection 150 ng IL-1 even followed 24 hr after CI accelerated lethal outcomes. It should be stressed that single administration of "high" dose IL-1 (100 micrograms/kg) to only irradiated mice did not modify the early phase of ARS in our experiments. Moreover, slightly therapeutic effect took place and survival rate in 30-day period increased up to 15 or 30%. Effects of repeated i.p. injections of smaller dose IL-1 (100 pg/mouse in 2, 4 and 6 days after irradiation and CI) studied too. Such therapeutic scheme slightly increased 30-day survival of irradiated mice. IL-1 repeatedly injected after CI did not improve survival rate during observation period. The influence of the most effective two BRMs (IL-2 and L.acidophilus) on blood system state studied in 8 days after CI. Results showed that number of bone marrow nucleated cells, white blood cells, neutrophyls end erythrocytes in peripheral blood did not differ in treated and non-treated groups. Statistically significant differences revealed only in platelet's number. However the most effective remedy (L.acidophilus) decreased blood platelet's number as compare to control group. Thus, revealed increase of 30-days survival did not accompany by corresponding correction of cytopenia under CI.

Increase survival rate of irradiated mice receiving BRMs may be connect with enhanced antimicrobial activity of relatively radioresistant macrophages, because protective effect has been seen before significant bone marrow regeneration could occur (10). Probably, BRM-induced increase of macrophages' activity has some "limits of possibility" to enhance antimicrobial host resistance under CI. Because in this situation microbial burden increases due to radioinduced translocation of microorganisms from gastroenteric tract and bacterial invasion from the contaminated burned wound. Macrophage's activation as affected by BRMs may prove to be insufficient for overcoming the infection under CI. An additional need appears in supportive therapy with antibiotics and replacement therapy with selective hemopoiesis regulatory cytokines.

THERAPEUTIC PROPERTIES OF ANTIBIOTICS

Selection of optimal antibiotics for preventive therapy made in rats and murine models of CI. According to obtained results beta-lactams, rifampicin, rifametoprim (rifampicin + trimetoprim) and ciprofloxacin did not modify the low value of survival as compare with non-treated animals. Moreover, ciprofloxacin's administration (the daily dose 20 mg/kg) aggravated bone marrow and thymus devastation, increased level of leukopenia and thrombocytopenia. New combined antibiotic sulacillin (ampicillin+β-lactamase inhibitor sulbactam) and pefloxacin has rendered strong prophylactic action during the first 8-10 days after CI but did not increase 30-day survival rate when given as single agent therapy. Results of the preventive therapy was the best when animals treated during 7-10 days simultaneously using sulacillin (the daily dose 500 mg/kg) and pefloxacin (the daily dose 50 mg/kg). Treatment course started from the first day after CI. Percentage of survival following such antimicrobial therapy increased from 7% (untreated group) to 53%. Selective decontamination effect occurred. There were not find side aggravating effects of sulacillin and pefloxacin to the radiosensitive haemopoietic system and lymphoid organ's state. Selected antibiotics increased host resistance to exogenously inoculated Ps.aeruginosa under CI.

Presented data indicate that some medicines recommended for ARS treatment provide rather insufficient effects under CI or completely fail to improve survival rate. Moreover, single injection of rIL-1-β within the first 4-24 hs after CI is very dangerous and increases death rate. Biological response modifiers such as IL-2 and heat-killed L.acidophilus as well as antibiotics sulacillin and pefloxacin may be recommend for CI preventive treatment.

This work supported in part by Commission of the European Communities according to "EC/CIS Agreement for International Collaboration on the consequences of the Chernobyl Accident" (Joint Study Programme JSP3).

EXPERIENCE ON THE STUDIES OF MEDICAL-BIOLOGICAL EFFECTS OF RADIATION INCIDENTS IN THE URALS

A.V. Akleyev, V.L. Shvedov, N.V.Startsev

Urals Research Center for Radiation Medicine, Chelyabinsk, Russia

INTRODUCTION

In 1948 a facility for production of plutonium for atomic weapon (Mayak industrial complex) was put on line in the Southern Urals near the city of Chelyabinsk. In the early years the operation of the plant brought about several accidental situations. Of these incidents the most heavy ones, with respect to the impacts on the population of the nearby communities, were connected with large amounts of radioactive wastes resulting from plutonium separation. Inadequacy of the methods used for waste storage and lack of experience in radioactive waste management were the key factos which led to radioactive contamination of some territories in the Urals region and radiation exposures of the residents.

From 1949 through 1956 medium- and high-level wastes (about 3 million Ci) were discharged into the Techa-Iset-Tobol river-system. On September 29, 1957, a thermo-chemical blast occurred in one of the storage tanks containing 20 million Ci of high-level wastes. The radioactive plume with total activity of 2 million Ci passed over Chelyabinsk, Sverdlovsk and Tyumen Regions and formed the so-called East-Urals Radiation Trace (EURT). The third major radiation situation developed in the spring of 1967 due to a downwind transfer of radioactive silt deposits (total activity amounted to 600 Ci) from the dried up shoreline of the lake Karachay, an open depot of liquid radioactive wastes.

The population of the contaminated territory was exposed to a combined (internal and external) irradiation. The external exposure was due to an elevated gamma-background level on the Techa floodlands and on the territories of the villages, while internal exposure resulted from Sr-90 and Cs-137 body intakes with water and foodstuffs produced in the contaminated area (1, 2).

The critical organs in cases of population exposures were the skeleton and red bone marrow (RBM). The maximum values of the equivalent dose to RBM amounted to 4-5 Sv for the Techa riverside residents and 0.9 Sv for the EURT residents. The majority of the population in the Techa villages (74%) received doses below 0.5 Gy, 8% received doses to RBM of over 1.0 Gy and about 1% received doses to RBM in excess of 2.0 Gy (3).

ORGANIZATION OF MEDICAL FOLLOW-UP AND DOSIMETRIC STUDIES

Regular medical examinations and dosimetric measurements for the Techa riverside residents were started in the summer of 1951. They were conducted by the specialists of the Central Research Laboratory of the Mayak combine and Biophysics Institute, Health Ministry, USSR. Beginning from 1955 medical follow-up of the exposed population was carried out by the staff of the specialized dispensaries No 1 (Chelyabinsk city) and No 2 (Shadrinsk city). Radiation-hygienic and dosimetric studies were conducted beginning from 1958 by Chelyabinsk Branch of the Leningrad Research Institute for radiation hygiene and Agricultural Research Laboratory which were re-organized into Branch No 4 of Biophysics Institute, currently the Urals Research Center for Radiation Medicine (URCRM).

Medical examinations of the population after the accident of 1957 and incident of 1967 were started within the first weeks of the exposure by the staff of the Central Hospital of the Mayak combine and later were carried on by the specialists of the URCRM. Dosimetric studies of the

environment included radiometric and radiochemical analysis for contents of Sr-90, Cs-137 and Pu in water, bottom deposits, soil, as well as estimation of dose rates of gamma-radiation. Individual measurements conducted for exposed people included studies of autopsy material for Sr-90 and Pu, analysis biological discharges (urine, stools) for Sr-90, beta-metry of front teeth and frontal bone, analysis of Sr-90 content in the whole body using a whole body counter, measuring the absorbed dose in the tooth enamel using the EPR, etc.

REGISTRY AND MEDICAL-DOSIMETRIC DATA BASE

In 1967 the staff of the URCRM started to create a registry of exposed people and the medical-dosimetric data base to facilitate a medical follow-up of the exposed population. Currently, the computer-based data base contains individualized data on 90158 people exposed to radiation, their offspring, subjects exposed in utero and a comparison group.

The structure of the Data Base is composed of the following 5 registries: registry of the followed-up people, death registry, diagnosis registry, registry of family histories and dosimetry registry.

The sources of the information included in the medical-dosimetric data base are the results of medical examinations, data derived from the Civil Registrar's Office, Address Bureau, records of specialized medical institutions (oncology clinics, endocrinology dispensaries, etc).

EXPERIMENTAL STUDIES

For the purpose of predicting possible health effects for people exposed in the Urals region the URCRM staff conducted a large-scale experiments using chronic (including for life time) intakes of Sr-90 within a wide range of doses (including combinations with gamma-radiation) in the organism of laboratory animals (rats, mice). It became possible to determine the dynamics of Sr-90 accumulation in the skeleton and tissue dose formation in experimental animals and their offspring, effects of Sr-90 on the bone and hemopoietic tissue, immune system and reproductive function, dependences governing changes in life span, and optimum conditions for blastomogenic effect of Sr-90.

Among the long-term post-exposure effects of Sr-90 in animals osteosarcomogenic effect presented the highest interest. As a result of the investigations the minimum osteosarcomogenic dose was estimated (50 Gy) and the optimum Sr-90 exposure modes for sarcoma induction were defined:

- dose absorbed by bone tissue (70-90 Gy given by a single injection, 150-180 Gy for chronic irradiation)
- average dose rate (25-35 cGy/day for a single dose irradiation, 50-70 cGy/day for chronic exposure).

Extrapolation of the experimental findings to humans has shown that the daily Sr-90 concentrations which do not induce pathological conditions in cases of daily Sr-90 intakes throughout life in humans, account for 0.0185 kBq/kg, with dose rates to RBM being 0.06 cGy/day.

It has been established that under the conditions of a combined radiation exposure using osteosarcomogenic doses of Sr-90, gamma-irradiation does not exert a considerable influence on osteosarcoma induction. The effect of the combined exposure on the life span was estimated as additive at relatively high doses of Sr-90, and more additive at medium doses.

HEALTH EFFECTS OF POPULATION EXPOSURES

Medical follow-up of the population exposed in the Urals region allowed to observe the occurrence of deterministic and somatic-stochastic effects mainly in the residents of the Techa riverside area. The first medical examinations conducted 2 years after the discharges of radioactive wastes into the Techa started, gave an opportunity to detect the signs of chronic

radiation affection syndrome manifested by hemopoiesis and immunity inhibition, changes in the nervous system (asthenia, vegetative disorders, etc) and occurrence of ostealgic syndrome.
A proportion of the Techa and EURT populations developed post-exposure reactions of some of the body systems (leukopenia, granulocytopenia, immunodeficiency, asthenic conditions, vegetative disorders, microorganic affections of the nervous system, etc) at dose rates to RBM of 30-50 cSv/yr and higher (1, 2). Long-term radiation effects (cancer, leukemia) were only noted among the residents of the Techa riverside villages, those who received the highest doses (4).
Birth and fertility characteristics of the Techa residents (average equivalent dose to gonads for this population made up 16 cSv) witnessed to the normal status of their reproductive function. The incidence of spontaneous abortions and stillbirths correlated with the respective characteristics for unexposed women. The health status of the offspring of children and grandchildren of exposed people did not differ from the offspring of unexposed people with respect to certain parameters (mortality, morbidity, etc) (1).

PROGNOSTICATING AND PHARMACOLOGICAL PROPHYLAXIS OF RADIOGENIC MALIGNANT TUMOURS

K.N. Muksinova, E.N. Kirillova, E.I. Rabinovich,
G.S. Mushkacheva, E.S. Revina, V.K. Lemberg

Branch No. 1 of Russian Federation State Scientific Centre Biophysics Institute
456780, Ozersk (Chelyabinsk-65), Russia

Cancerogenic effect risks due to ionizing radiation, that impacted on large population groups because of Chernobyl and other accidents, cause the actuality of early diagnosis problems and of radiogenic tumour prevention. Since cancero-embryonic antigen and α-fetoprotein had been found, the tumour markers began to be frequently used by oncologists. However, attempt to use onco-markers, as test for earlier pre-clinic determination, have been unsuccessful. The secondary messengers of hormonal signal, cyclic nucleotides, that take the leading place in system of organism self-regulation, had attracted our attention. As known, the increase of cell division number and suppression of morphological and biochemical developments of differentiation are the fundamental characteristics of tumour growth and are proceeding together with participating of cyclic nucleotide system. The including of both nucleotides in neoplastic transformation and at the same time their constant presence in extracellular fluid (blood serum, urine) makes the perspective use of these compounds as indicators of tumour growth before the appearance of clinic signs of diseases. This coincides with the modern viewpoints on the developments of optimum programs for pre-clinic diagnosing of tumours, that needs to base on the change in homeostasis preceded the malignant tumour development (1).

The check of ability of nucleotide ratio test to give the information for prognosis of onco-diseases has been conducted in experiments on the *Wistar* rats, and allow to observe the cancerogenesis process from tumour growth induction through its outcomes during a cohort lifetime that was maximum short period - 650-700 days. Animals were exposed to γ-radiation at accumulated doses of 10 and 20 Gy, under which the malignant tumour frequency increased up to 65% (in control group up to 25%). The contents of cyclic AMP and cyclic GMP in urine were determined in each rat in 10 months after exposure (time of tumour outcome) and further in each 2 month up to natural death by using *Amersham* Kits. The postmortem diagnoses were determined by histologic methods. Results of retrospective analysis evidence that the increasing of cAMP/cGMP ratio was being observed in urine of animals, that had tumours, long before their deaths and independently from tumour localization. This period may be formally recognized as pre-clinic, and it includes different stages of tumour growth. The increase of the ratio was being due to both the reinforcement of cAMP excretion and decreasing of cGMP excretion. The data base on rats, that had the tumour, was processed statistically for obtaining the objective evaluation of possibility to use this test for pre-clinic tumour growth diagnoses. It was shown that test has the high diagnostic sensitivity (85%) and the high ability of prognosticating positive result (73%) as well as the satisfactory diagnostic effectiveness (68%). In special experiment, we have applied the prospective approach to data analysis. We assumed that the positive tumour diagnosis is recognized *a priori* during lifetime on the base of the registered increasing of cAMP/cGMP ratio. Diagnoses have been verified after animal death by histologic methods. The results of comparison between the biochemical prognosis and histologic diagnosis indicated that the coincidence was in 87% of cases. We think that the increase of cAMP/cGMP ratio, observed in urine of rats with tumour, evidence

there is the "accident regulation" start, which is used for preservation of homeostasis on new level and for control of differentiation in spite of tumour growth (2).

Basing on our conducted studies, we took out the patent for the method to find out the tumoural process in experimental animals (3). The similarity of molecular and cellular mechanisms of malignant transformation in animals and persons, and the same tissue response following the genotoxic factor influence have allowed us to begin the clinic test of this method. For this purpose, the group of high risk of malignant disease development have been selected in "Mayak" PA personnel, the first atomic complex in our country. Part of the group had been exposed to radiation at doses exceeded the maximum permissible dose at early stages of production organization, and now these individuals are at age of realization of malignant tumours.

At the same time we are conducting the studies of prevention of induced tumour diseases. The effectiveness of the medicinal preparation to prevent or to decrease the frequency of spontaneous and chemical cancerogens-induced tumours have been shown in the experimental and epidemiological studies (4,5). However, the scientific developments of the radiation cancerogenesis prophylaxis are not numerous.

We are developing the methodology to conduct the pharmacological prophylaxis of radiation cancerogenesis basing on the experimental models of chronic influence of different kinds of ionizing radiation. These models if taking into consideration the dose characteristics, were approached to conditions of occupational exposures and radionuclide influence on the contamination territories following the radiaiton accidents. The developing methodology allows for peculiarities of radiation cancerogenesis under the influence of incorporated α- and β-emitters (transuranium nuclides, tritium). These include the forming of tumour process under conditions of increased burden for antioxidant system and the corresponding increase of organism necessity of antioxidant substances. Further, the cancerogenic metabolite contents are increased because of damage of monooxygenase system P-450 of liver following the organism exposure and especially the incorporation of transuranium nuclides. In addition, the radiogenic tumour development goes frequently on the background of damage of the general and/or local immunity. The insufficiency of this system, as known, is the strong promoter of oncogenesis. Basing on the traits of radiation cancerogenesis, the medicinal preparations are selected, and their application regimen is determined (time period, pattern, and duration) for purpose of prophylaxis of tumour growth.

The approbation of the developing methodology was conducted in experiments with *Wistar* heterozygous rats and *CBA* inbred mice. The prophylactic effectiveness of medicinal preparations with different mechanisms of action (antioxidants, immunomodulators) was studied under different ways of one-time intake of plutonium-239 and under long-time (during 1/3 of lifetime) injection of tritium oxide. The preliminary findings in experiment with 391 rats indicated that the ration enrichment by β-carotin (2 mg per day) or by its complex with α-tocopherol (1 mg per day) did not modify the spontaneous cancerogenesis during all period of observation. At the same time, the using of β-carotin in 750 animals exposed to α-radiation of incorporated plutonium-239 after inhalation intake (plutonium-239 citrate, the lung absorbed doses of 240- 404 cGy) decreased the general frequency of malignant tumours in rat males at 1.5 times (48%; in control group - 72.3%) due to mainly the decreasing of lung cancer frequency. The frequency modification of osteosarcomas induced by α-exposure of bone tissue to incorporated plutonium-239 was also found only in rat males that had β-carotin and α-tocopherol in ration during all lifetime after inhalation, decreases were for standard ration - up to 30%, and for ration with vitamins - up to

5%. The β-carotin and its complex with α-tocopherol did not influence on plutonium-239-induced oncogenesis of rat females. The dependence of this preparations' modification effect from sex has been shown in other papers (6).

The distinct onco-prophylactic effect of β-carotin was also revealed on the basis of experimental model of even β-exposure of 250 *CBA* mice to incorporated tritium. The receiving of this preparation with feed (1 mg per mouse 3 times per week) during all period of radionuclide influence (6.5 months, the absorbed dose of 8.7 Gy) decreased the induced malignant tumour frequency at 1.5 times in comparison with exposure control (38.3% and 58.6%, respectively). Most demonstrative decrease was for lung cancer - 1.6% and 13.3%, respectively.

The immunomodulating preparations modified the radiogenic tumour frequencies when they were used at period of radiation damages in immune system (1350 *CBA* mice, and 800 *Wistar* rats). Myelopid (MP), produced at the Immunology Institute, Moscow, was being received by *CBA* mice exposed to β-radiation (the absorbed dose of 8.7 Gy) weekly during 3.5 months (0.5 mo. - the end of HTO intake, and 3 mo. - period after the intake end) in summary amount 700 μg per mouse ; and decreased the frequency of induced myeloleukemias at 3.6 times (up to 4.4% vs 16% in exposed control), and of lung cancer at 1.7 times (7.3% and 13.3%, respectively). However, the decreasings of the MP intake up to one-time per month and summary amount up to 300 μg per mouse during 3 months led to the decrease of MP effectiveness. The dependence of onco-prophylactic effect of MP from the pattern of intake and from received preparation amount has been also shown for α-exposure to incorporated plutonium-239 intake into blood flow. The decreasing of induced tumour frequency in organs of main deposition of radionuclide (liver, skeleton) has been only in case of using the first scheme of the MP receiving.

ABSTRACT (See instructions overleaf)

The estimation of consequences of chronical exposure was made in workers of atomic enterprise "Mayak" on the basis of studies for 40-45 years. The doses ranged from the permissible one for professionals to 10.0 Gy. The summary doses of gamma-exposure more than 2 Gy (more 1 Gy per year) caused the development of syndrome complex of the chronic radiation sickness. The early consequences were acute leukemia and bone marrow hypoplasia. At later period, the number of cases had the incomplete recovery in hematopoiesis, immune dysbalance, unstability of somatic cells' genome, and early atherosclerosis. The main cause of death was the malignant tumour, mainly pulmonary cancer in persons with plutonium-239. The multifactorial analysis enabled to reveal the significant influence of smoking on lung cancer outcome, stomach-gastritis outcome with secretory insufficiency. It was estimated the effects of internal exposure due to incorporated plutonium-239 (pneumosclerosis, liver and skeleton tumours, osteodysplasia, ostalgic syndrome, changes in lymphocytopoiesis, cytogenetic effects). It was found the reproduction function in families of person exposed, and the first generation health was evaluated. The consequences of expogure in utero were the high morbidity, immune dysbalance, unstability of genome. The study on 1577 grandchilren (at age 10-15) of exposed persons did not found deviation in physical development, biological maturation, morbidity and etc. in comparison with the control.

ABSTRACT (See instructions overleaf)

ESTIMATION OF THE HEALTH EFFECTS IN PERSONS WHO PARTICIPATED IN THE LIQUIDATION OF THE CONSEQUENCES OF CHERNOBYL NPP ACCIDENT

Anatoly Romanenko, Vladimir Bebeshko, Andrew Noshchenko, Anatoly Nosovsky (Research Centre of Radiation Medicine, Kiev, Ukraine)

At present the most striking consequences in the health status are detected in persons who had suuffered from acute radiation syndrome and those who had worked for a long period in the 30-km zone of the Chernobyl NPP. Chronic inflammatory pathology, ulcerous and erosive changes of gastro-intestinal tract, circulation consequences and arterial hypertension, diseases of the nervous system, atypical anemias, lymphoadenopathias and fibrous changes of thyroid gland are characteristic.
Peculiarities of diseases are registered in the different organic pathology combinations, chronic progredient course, low effectiveness of usual treatment methods. It's supposed that genome instability induced by the complex of accident negative factors are the basis of these consequences as well as changes of cellular methabolism and autointoxication syndrome formation. Discirculatory, methabolic and immunity changes seemed to be of secondary origin.
Analysis of the existing pathology allowed to make the prognosis of the elevation of vascular and oncologic pathology frequency.

ESTIMATION OF CYTOGENETIC AFTER-EFFECTS OF THE CHERNOBYL EXPLOSION IN BELARUS

INTRODUCTION

Investigation of mutation process in cells of human beings and animals from radiocontaminated areas of Belarus is a very important problem for understanding of Chernobyl accident consequences related with damages of genetic material in somatic and germ cells.

RESULTS AND DISCUSSION

Just after the Chernobyl accident we began cytogenetic studying of rodent, amphibian and children from radiocontaminated regions. Most of our investigations are carried out using a chromosome aberration analysis (metaphase and micronucleus methods) in different tissues: in mourine rodent - bone marrow cells, alveolar macrophages, intestinal epithelium; in frogs - bone marrow cells, intestinal epithelium; in children - peripheral blood lymphocytes. For slide preparation were used conventional methods (1-4). Berezinsky biosphere reserve, Minsk environs, Braslav District of Vitebsk Region were used as the control area. The data obtained in first years after the Chernobyl accident have shown a high level of cytogenetic damages in all objects examined: a) percentage of aberrant cells was much higher in cells of species from radiocontaminated areas than that in the control; b) aberration number in the damaged cells was higher in all objects from radiocontaminated areas. Multiple aberrations were found in cells of all the species studied; c) chromatide-type aberrations, chromosome type aberrations including markers of radiation (dicentrics and rings), were detected too.

A part of our investigations results in inhabitants of Gomel Region is presented in Table 1. Percentage of chromosome-type aberration is higher in peripheral blood lymphocytes of children than in bone marrow cells of animals because lymphocytes are out of cycle (Go) but bone marrow cells are proliferative, therefore during exposure they occur at different stages of the cell cycle. In view of this, aberrations of both chromosome and chromatide types arise naturally which corresponds to irradiation at stages G1 and G2. Increased level of cytogenetic damages in intestinal epithelium of frogs and rodent and in alveolar macrophages was found too.

For the last years a statistically significant reduction of the chromosome aberration frequency in bone marrow cells and in peripheral blood micronuclei of frogs from some areas was observed. In some areas we could not see aberration of chromosome type.

The results of 10-year examination of children from Gomel, Mogilev and Brest regions of Belarus either in dynamics or in statics have shown the necessity of evaluation a complete spectrum of genetic damages in peripheral blood lymphocytes (3-5).

Table 1. Level of chromosome aberrations in different objects from radiocontaminated regions of Belarus

Object of investigation, type of cells	Area	Density of contamination (kBq/m2)		Year	% aberrant cells in contaminated area / % aberrant cells in the control	Ratio chromosome and chromatide type of aberrations
		^{137}Cs	^{90}Sr			
Human (Children, peripheral blood lymphocytes)	v.Nudichi	680	118	1986	3.2	1.9 : 1
	v.Ilichi	815	127	1986	2.6	2.1 : 1
	v.Gluhovichi	490	67	1986	3.7	2.4 : 1
Bank vole (Cl.glareolus), bone marrow cells	v.Maisk	90	70	1986	4.5	1 : 2
				1991	4.5	1 : 10
	v.Babchin	1524	70	1986	3.3	1 : 25
				1991	4.0	1 : 7
	v.Lomachi	2331	284	1990-1993	4.4	1 : 2
Rana arvalis, bone marrow cells	v.Savichi	740	55	1986-1989	5.4	1 : 1.3
				1992	3.5	1 : 7,5
	v.Babchin	1110	77	1986-1989	4.6	1 : 5.5
				1990-1992	3.7	1 : 3
				1995	4.1	0 : 1
	v.Lomachi	2331	284	1986-1989	4.2	1 : 2.5
				1995	2.6	0 : 1

Biodosimetry carried out on the basis of our findings by using different standard curves (6-8) for evaluation of the absorbed dose has shown that the registered level of chromosome aberrations in children from the 30-km zone of Bragin District and the town of Bragin corresponds to the dose of 300-500 mSv.

A high level of mutant cells in HPRT locus ($1.4\text{-}2.9 \cdot 10^{-4}$ in comparison with the Minsk control group $3.5 \cdot 10^{-5}$ in 1991 and $3.0 \cdot 10^{-5}$ in 1993-1995) against the background of a relatively low level of chromosome aberrations as compared to 1986-1990 was revealed. However, quantitative values of chromosome aberrations exceeded appropriate frequences in the control groups and depended on the factors of the radioecological situation as well as on duration of residence in radiocontaminated region (9).

The role of cell death in forming the genetic effect of chronic irradiation of lymphocyte populations in peripheral blood of the examined children was revealed.

Complex interactions between mutation pressure and the selection effect of eliminating cells bearing chromosome aberrations and gene mutations take place in lymphocyte populations of children in radiocontaminated areas under chronic ionizing radiation. The cells with gene mutations compatible with their vital functions seem to be less subjected to the selection effect in minus-direction. Owing to this fact over the past years we observe a high level of cells with gene mutations against a background of a relatively low level of chromosome aberrations (in comparison with the level registered in the first years after the Chernobyl catastrophe).

Investigations demonstrate that chronic influence of the radiocontamination factors induces genome destabilization, increases genetic load at the level of somatic cell populations that results in reduction of their viability.

The increased radiosensitivity of a genetic apparatus of cultivated cells in children from contaminated areas was revealed (10). A chromosome aberration yield under additional X-irradiation of lymphocytes in children from radiocontaminated regions at the dose of 0.3 Gy is the same as the control children at the dose of 1.0 Gy. So far as there is relations between mutation emergence and carcinogenesis risk, the revealed children's populations with high genetic radiosensitivity should be classified as a risk group with high predisposition to tumoral diseases.

ABSTRACT (See instructions overleaf)

SUM OF 10-YEARS MONITORING OF HEALTH STATE IN PATIENTS WHO SUFFERED FROM ACUTE RADIATION SYNDROME AS THE RESULT OF CHERNOBYL ACCIDENT.

Bebeshko V.G., Kovalenko A.N., Belyi D.A.

Scientific Center of Radiation Medicine, Kiev, Ukraine

At present time 180 patients, to whom the diagnosis of acute radiation syndrome (ARS) as the result of Chernobyl accident was established in 1986, are living in Ukraine. 13 patients died in postaccidental period from different diseases.

In 40 % of patients there were determined pathological changes in haematopoiesis. It consists of transitory or steady leukopenia and leukocytosis. One patient after ARS III died from erythromyelodysplastic syndrome.

In erythrocytes were revealed changes of enzyme activity of antioxidant defence system, an activation of processes of lipid perosyde oxidation, weakening of mechanism of antiradical defence, increase of membranes destruction and activity of lizosomal enzymes (hydrolysis).

In 1/3 of patients the qualitative and quantitative changes of immunity were revealed.

In hormonal sphere there were observed an increase of basal plasma cortisol level and essential decrease of corticotropin concentration. Long hypotestosteronemia was accompanied by low hypophisis honadotropic activity and hyperprolactinemia. 5-6 years after radiation trauma tendency to increase of basal testosterone secretion was appeared. It was less in patients after ARS II and III degree of severity.

Chronic diseases of visceral organs characterise the somatic status of organism. The tendency to increase the digestive tract diseases, cardiovascular pathology, steady psychoneurological disorders, decrease mental and physical working capacity were revealed. The lost of ability to do their professional work was in 90% of patients.

The six cases of thyroid gland hypofunction were found. In others the deviation in hormones that determined thyroid gland function was not statistically reliable.

In half number of patients atherogenic changes in lipid metabolism were revealed. Their frequency and severity didn't depend from severity of irradiation.

ABSTRACT (See instructions overleaf)

PRINCIPLES OF STAGE BY STAGE REHABILITATION IN PATIENTS WHO SUFFERED FROM ACUTE RADIATION SYNDROME. Bebeshko V.G., Kovalenko A.N., Khalavka I.G., Belyi D.A.

Scientific Center of Radiation Medicine, Kiev, Ukraine

The problem of rehabilitation of patients, who suffered from acute radiation syndrome (ARS), doesn't end at the end of acute period of this disease. After bone marrow syndrome nonspecific remote radiation pathology forms. It connects with destruction in low proliferative and nonproliferative cell systems and with specific type of their reparation that consists in compensation hypertrophy.

Inside this group of patients rehabilitation measures are based on some principles:
1) to weak of lipid peroxide oxidation; 2) to increase the activity of organism antioxidant system; 3) correction of vitamin and microelements balance; 4) to reduce the immunological insufficiency; 5) to stabilise the vegetative status; 6) to normalise the lipid metabolism (dislipidemia correction); 7) to treat and prevent chronic disease of different organs and systems; 8) to increase the physical and mental capacity; 9) to propagandise the health way of life and refuse from bad habits and professional harmfulness; 10) to have rational and balance nutrition; 11) to treat in sanatoriums; 12) to make succession in hospital, out-patient and sanatorium treatment.

For this purpose the individual combinations of antioxidants, vitamins, adaptogenes, polyvitanime-microelements complexes, immunomodulators, nootropics, adrenoblockators, sedatives, vasoactive drugs, hepatotropics and other drugs, physical training, reflex- and psychotherapy, massage and diet are used.

An introduction of elaborated rehabilitation system directed to reduce promote radiation pathology in patients after ARS has some difficulties. It is connected with deformation of mental, psychological and social status of these patients. So rehabilitation includes permanent explanatory and sanitary education.

IMMUNOBIOLOGY AND HEMATOLOGICAL ASPECTS OF HEALTH - 10 YEARS AFTER CHERNOBYL DISASTER

INTRODUCTION

The Chernobyl Accident led to special situation when some people taking part in elimination of its onsequences of Chernobyl accident were irradiated in high doses. 145 men had suffered from acute radiation syndrome of different degree, and 105 of them lived in Ukraine. Millions ofUkrainians were also suffered from other accident consequnces as a clean-up workers, inhabitants of highly contaminated territories etc. Immune and hematologic disturbancies played the important role in early reactionsto irradiation and other factors [1 - 3]. They are veryimportant still in predicting late health effects 10 yearsafter the Chernobyl accident.

PATIENTS AND METHODS

Forty two thousand of patients who belonged variouscategories of irradiated population were studied during 10years after the accident. Chernobyl acute radiation syndromepatients, clean-up workers who were exposed to the dosesunder 1 Gy limit in 1986 and subsequent years, children andadults evacuated Prypjat, 30-km zone and contaminatedterritories population were the groups of first-lineinterest.

Immunologic studies included flow cytometric determinationof immunologic phenotype with Leu IMK , IMK Plus, Simulsetmonoclonal antibodies (MoAbs) kits (Becton Dickinson, CA, USA) in two-color assay, DNA cytometry and cell cycle analysis, activation studies (tetracycline incorporation, IL-2R, TrR expression, BRDU-, 3HTdR-uptake) in perturbed and non-perturbed cell populations, also serum Ig content, anti-RBC, anti-WBC and anti-platelet agglutinins and lysins. Radiation induced variant cells content was investigated inRBC GPA-expression assay from 1990, TCR-mutations assay from1992. Search of genetic basis of radiosensitivity was performed in HLA-A, B, C, Dr distribution (Dr.J.Minchenko).Patients evaluation was supported by IPHECA WHO project from1993. HbsAg and HbC prevalence studies in irradiated population were conducted with the help of Dept. ofEpidemiology, Hiroshima Univ.(prof.H.Yoshizawa). 'Comet'DNA assay was introduced in 1995. Hematological studiesincluded peripheral blood, bone marrow cells morphologic and cytochemical examination by means of light and electronmicroscopy, studies of microenvironment, progenitor cells and fibroblast cultivation, electron-paramagnetic resonance, infra-red spectrascopy etc. Dose dependent estimation was available with the help of dosimetric departments of Chernobyl NPP, Instituts of Experimental Radiology andEpidemiology of RCRM. Cytogenetic studies of acute radiationsyndrome patients in 1986 were performed in Medical Radiology Centre in Obninsk. Clinical investigation and laboratory data analysis were performed with the help of standartized criteria.

RESULTS AND DISCUSSION

A three stage process of the immune system recovery was seen in persons who suffered from external acute irradiation.Dynamic investigations of immune state revealed apostradiation defficiency. The cellular or/and humoralimmunity disturbances included surface phenotype changes,especially in mitogen-associated populations of CD3+, CD4+ and NK- cells (CD57+,CD11+16+) . It was worth to mention the mozaic of injury and reparation of surface membranes of immunocompetent cells. B-cells exhibited the short-time decrease of C3+ and pan-B-antigen bearing cells. Membrane changes also evoked the difficulties in locus A,B,C HLA-typing. A study of T-cell receptor stable alterations was performed among the population of contaminated territories and personnel of the Chernobyl station in 1990 -1992. A two-fold (0.4 - 0.6 per cent of the PMNC) increase of aberrant cells with decreased TCR expression was found in investigated contingents. It was accompanied by the 2 -3fold increase of GPA aberrant RBC. The duration of first stage was from 6 to 24 mnths, the absorbed dose and theduration of irradiation, the presence of somatic andpsychosomatic

pathology, age at the moment of irradiation have influenced greatly.At the second stage was the restitution of the radiation injury the increase of subpopulation of CD3+DR+ lymphocytes was seen ,accompanied by stable tendencies of finding in the peripheral blood of lymphocytes with phenotype CD4+8+ ànd CD1+, which normally were characteristic only for intrathymic stages of differentiation. The increase of B-lymphocyte count, which had pan-B-markers as CD21, C3, late differentiation markers such as surface IgG and early antigens as CD10. HLA-typing revealed the prevalence of HLA A1, 28; B 5,38; B 6, 17; B17, 18; B8,22; B 8, 27; B 27, 35; A1, B16; A1, B27; A2, B38; A10, B38; A 28, B 8 in patients who had suffered from acute radiation sickness. These data are very important for the estimation of the radiosensitivity in individuals exposed to the lesser doses and for professional selection. HLA-A1,9; B8,12; B12,13; B15,35 antigens were associated with thyroid pathology both in contaminated and clear regions of Ukraine but no differences depended on radiation. Five-six years after the irradiation a heterogenity of types of immunologic response of acute radiation sickness reconvalescents was detected. A group of patients demonstrated normalisation of CD3+, CD4+, CD11+ cell count and serum IgG and IgA content, while the others revealed immunologic defficiency of the mixed type.Subset cell cycle analysis with PJ showed the decreased response to Con A in 18 hour cultures as well as 3H-Tdr uptake in 72 hourscultures. Dose-dependent changes of enkephaline receptor on PMNC and sensibilisation to brain antigens accompanied by changes of TrR, RIL-2, CD10, CD23 activation antigens expression in healthy irradiated persons as well. Late radiation subset and functional effects could be explained by neuro-humoral regulatory changes.Late effects included compensation of radiation injury in 32% of patients. High CD3+19-, CD4+8-, CD16+56+ cells counts were accompanied by low proportion of CD8+4- cells. Non- specific activation of T-link was revealed with high contens of CD3+ and CD4+ cells, exhibiting HLADR antigens and high IL-2 and Transferrine receptors expression. Non-specific activation, especially of B-cells could be the basis of immunopatologic processes in the future. Compensatory changes were associated with the low mutation rates in T-cell receptor complex.

Dysregulatory changes were detected in 37% of patients. Individualisation of immune disorders, changed response to neuro-humoral stimuli and wavy variations of immune parameters were accompanied by the low variant CD3-4+ cells incidence - less than 5 cells/10000. Depression of cellular immunity developed as the decrease of compensation abilities especially in T-cells.

During the investigations of the mechanisms of radiation-induced pathology of haemopoietic system and role of haemopoietic cells and its microenviroment in creation of the distant irradiation consequences among reconvalescents of ARS different qualitative modifications of peripheral blood and bone marrow cells were found. Hypersegmentation, fragmentation of nucleas, the toxical granulation, fringe and basophilia of the lymphocyte's cytoplasma, the vacuolisation of cytoplasma and nuclea were found. The increase of bone marrow cellularity about 10,0 - 13,0 x 10^9 /l in 8 patients of examined group was determined. For the other 14 people the number of myelocaryocytes was normal and the hypercellularity was found in 7 patients. The number of megacaryocytes fluctuated , as a rule , on the level of physiological standart, but the increase of the number of megacaryocytes with less size of nuclear and its shape modification was found. The number of cells with active production of platelets was decreased.

The correlation between the hematopoietic lineages was normal in the most cases in spite of the number of myelocaryocytes have decreased. Four of the patients had the narrowing of erythroid lineage from 5,5 to 10,5 %. For only one patient with myelodysplastic syndrom the irritation of erythroid lineage about 42% was observed. Three of the patients had lymphocytosis in the bone marrow about 33-34%, two of them had eosinophylia about 5%.

The membrane permeability of blood erythrocytes was increased in the investigating group according to the data of osmotic and mechanical resistanse of erythrocytes. The results of studying of surface membran adsorbtion ability and its volume showed the considerable modifications of these indices. The thorning and spherical shapes of erythrocytes were found in the peripheral blood of 40 % observed patients.
Bone marrow paramagnetic centres studies showed that intensity of index of bone marrow paramanetic centres differented from one in blood in persons with steadfast deviations of peripheral blood. These results testify to significant modifications in function of important metalloproteides - transferrine and ceruloplasmine, which carry out iron transport in bone marrow, in each specific case.

The restitution of the homeostatic characteristics of hemopoetic and immune systems occured at the deviated level of regulation especially in patients with high absorbed doses; individual radiosensitivity could be revealed in the low dose limit as well as in radiation pathology. Comprehencive investigation of various exposed groups led to the opinion that the control of cell differentiation could be the key point in late effects of irradiation. Still the quantity of questions is overwhelming.

ABSTRACT (See instructions overleaf)

HORMONAL HOMEOSTASIS IN LIQUIDATORS OF CHERNOBYL ACCIDENT WHO HAVE DOSES OF IRRADIATION LESS THEN 1 GY Kovalenko A.N

Scientific Center of Radiation Medicine, Kiev, Ukraine

In liquidators of 1986 year basal levels of some hormones were investigated by radioimmunological method 2-6 years after they left 30 km zone around Chernobyl power plant. There was revealed an increase of hypophisis function that takes part in reactions of non-specific adaptation (corticotropine, somatotropine) but not others (follitropine, lutropine, prolactine, vasopressine). Spontaneous secretion of peripheral glands was increased in common (cortisol, insulin, C-peptide, angiotensine-II, estradiol). Glucohone, renine, aldosterone secretion was not change but testosterone was reduced.

The reaction of hormonal functions on radiation trauma has prolonged character because changes were observed during some years. A part of indexes returned to optimal levels or had a tendency to normalisation.

A concentration of cyclic nucleotides in plasma was essentially high and their dynamic shows an increase of total pules during years of observation.

According to conclusion that polyfactorial changes of hormonal status connected with consequences of radiation exposure are systemic and non-specific it may be characterised as postradiation endocrinopathy.

ABSTRACT (See instructions overleaf)

The autoantibody content of neurospecific proteins (NSP): MBP, S-100, NSE was studied in the blood serum from 70 patients with cerebrasthenic syndrome who were exposed to low dose of radiation after Chernobyl disaster in 1986 - 1987. All these patients worked on liquidating of consequences of Chernobyl catastrophe. Their syndrome is characterized by asthenia, fatigue or chronic tiredness, headaches, dizziness, poor concentration, and attention, poor memory, irritability, mood liability, expressiveness, exhaustion of physical and mental activity, high blood pressure, vegetative and vascular symptoms, feelings of hopelessness, worthlessness, lack of libido. They had a high sensitivity to loud sounds, light and temperature. The overall symtoms of these syndrome were so alike that we called it as postchernobyl cerebrasthenic syndrome.

The autoantibody levels to NSP were determined after Voller et al.,1979, the NSP being isolated from the bull brain (Berezhnoy, 1986). Increased autoantibody level to NSH was found among our patients more friequently (30- 50%) than in healthy subjects (14-20%).Despite diagnosed disease no antibodies were identified in 20% of patients. The patients revealed autoimmune responses to various brain structures-myelin-MBP, glia -S-100 and neuron - NSE proteins thereby testifying to the involvement of both glia and neurons in the brain pathology. The highest level of autoantibodies was found to MBP.

ABSTRACT (See instructions overleaf)

The revealing of clinico-biochemical and haematological infringements at patients as a result of effect of small doses ionizing radiation can promote to understanding the gears of formation the postradiation encephalopathy. Was investigated the 300 patients, damaged at liquidation of Chernobyl accident. Were studied the parameters of protein metabolism, acid- main condition, waterionic exchange, mediomolecular peptides, adaptation parameters (index Garkavi).The clinical and laboratory parameters are processed mathematically, on basis that the mathematical models of gravity condition of patients and gravity of metabolic infringements are created.The models were compared among themselves. The significant infringements of metabolic homeostasis in form the change of parity of protein fractions, activity of sulfhydryl groups, free and connected water, increase of hamatocrit, medium molecules, activity of transaminases, hypoosmoliarity are found out. Was detected the heterogenesis and undulation of biochemical deviations in dynamics of disease and intensification in time (in researches 1991 - 1994 years), with drawing into the increasing number of vital significant metabolic links, that is connected with various degree of exertion of adaptation and compensational reactions. Was established the correlation between the level of erythrocyties and haemoglobin, reduction pO2 and increasing pCO2. That all correlated with level of reduction of active blood reaction, changing of unprotein sulfhydryl groups and transaminases and testified about availability in patients the phenomena of endogenous intoxication and about stress of compenssational organism reactions. Was established statistically authentic correlation of clinical and biochemical parameters at majorities of patients.

Thus, revealed infringements on party of metabolitical homeostatis testified about formation at damaged steady pathological confition and can promote to development the postradiation encephalopathy.

FEATURES OF INFRINGEMENT OF RESPIRATORY BLOOD FUNCTION AT PERSONS, DAMAGED AFTER CHERNOBYL ACCIDENT.

The study of gears of infringement of biochemical parameters, connected with maintenance of main function of respiratory system- delivery of to metabolic tissues and conclusions forming in constitution carbonic-acid at ills with postradiation encephalopathy is interesting and little-learning task in connection with complexity of metabolic changes at effects of ionizing radiation, availability of neurochemical conversions as a result of such effect, infringement of regulatory gears of constitution.

Actuality of given task is caused by necessity of dinamical check condition and execution duly correcting measures to persons, damaged at liquidation of consequences of Chernobyl failure.

The infringements physiological processes in organism are especially dangerous for the brain tissue, sensitive to effect of ionizing radiation. The influence of radiation, hypocsia entail the infringement of processes of synthesis of structural components of plasmatic membranes, resulting in changing in structure of membrane layers, prescription properties of membranes, processes inside and inter-cellular transport [1].

With the purpose of study of influence of infringements some biochemical parameters on maintenance respiratory the processing was conducted of function of blood at ills with postradiation encephalopathy the biochemical analyses 110 patients, damaged at liquidation of Chernobyl accident. The change of biochemical parameters at va - rious expressing of infringements of pressure of oxygen and carbon dioxide in veinus blood was evaluated. The received data on changes, potassium and sodium in plasma of blood, acid of environment- pH, sulphgidril groups, average molecules and etc. are adduced in tab. 1, 2.

Табл. 1 SOME BIOCHEMICAL PARAMETERS AT VARIOUS EXPRESSION OF INFRINGEMENTS OF OXYGEN PRESSURE IN VEINUS BLOOD

Parameters	pO2 < 35	pO2 35-45	pO2 > 45

- protein	214.54+12.08	268.9 +34.76	359.45+21.02

Табл. 2 SOME BIOCHEMICAL PARAMETERS OF VARIOUS EXPRESSION OF CARBON DIOXIDE PRESSURE IN VENOUS BLOOD

Parameters	pCO2 < 35	pCO2 35-45	pCO2 > 45
Potassium, plasma	4.06 +0.069	4.24 + 0.09	4.14 + 0.078
Sodium, plasma	141.6 + 0.79	153.1 + 9.01	142.9 +0.65
pH	7.3 + 0.075	7.34 +0.007	7.29 +0.005
Middle molecules	0.39+ 0.015	0.31 + 0.012	0.32 + 0.016
AlAt	0.54+ 0.036	0.43 + 0.04	0.45 + 0.03
AcAt	0.44+ 0.031	0.38 +0.024	0.39 + 0.02
Sulfgid. groups			
- general	358.26+17.66	319.26 +24.9	318.54+21.94
-without-protein	94.64+ 7.59	81.29 +3.76	86.75+ 5.69
- protein	263.77+18.02	238.98+22.05	231.13+21.64

Is received, that at oxygen deficit the processes endogene intoxication, acidosis and deficits of potassium are aggravated.

The low pressure of carbonic acid in blood is possible to be regarded as the certificate of unsufficient activity of metabobo-

lic processes with accumulation in blood underoxidizing products.

The marked normalization of parameter of concentration of hydrogen ions (pH) for significances of pressure of oxygen and carbon dioxide in venous blood within the limits of norm speaks about importance of given parameter for valuation of processes of transport of carbon dioxide and in organism.

For postradiation encephalopathy the tendency to decrease the parameter of acid environment- pH was marked. The parameters, informative for infringement the correlative communications with changes of acid of environment, are adduced in tab. 3.

Tab. 3 CHANGE SOME BIOCHEMICAL PARAMETERS AT INFRINGEMENTS of PARAMETER OF ACID OF ENVIRONMENT - pH

Parameters	pH < 7.35	pH >=7.35
Protein gener.	65.002 +0.69	67.78 + 0.986
Middle molec.	0.391 + 0.02	0.32 + 0.011
AmAT	0.54 + 0.03	0.442 + 0.024
AcAT	0.45 + 0.03	0.39 + 0.016

The increase of average molecules at decrease of parameter pH speaks about importance of this parameter for judgement about expression of processes endogenous intoxycation.

Connection with the above-mentioned constructs the mathematical model of dynamics the pressure of oxygen in various tissues of organisms and the regimes of regulation in dependence on kind external and internal indignations are investigated.

The conducted mathematical simulation permits to receive the additional criteria of character of clinical course of postradiation encephalopathy in dynamics of treatment.

ABSTRACT (See instructions overleaf)

CHANGES OF ERYTHROCYTIC SYSTEM IN IRON DEFICIENCY ANEMIA (IDA) IN CHILDREN ON THE BACKGROUND OF COMBINED EFFECT OF RADIATION AND OTHER UNFAVORABLE FACTORS IN THE REPUBLIC OF BELARUS.

SLOBOZHANINA E.I., KOZARESOVA T.I., GRES N.A., KOZLOVA N.M., Institute of Photobiology, Academy of Sciences of Belarus, Belorussian Institute of Advanced Training Doctors, Minsk, Republic of Belarus

The morphological characteristics and physico-chemical properties of erythrocytes, erythrokinetics, activity of enzyme protection antioxidant (superoxide dismutase, catalase, glutathione reductase in 668 children from the region of the Republic of Belarus with different level of contamination with radionuclides, lead, mercury and nitrates have been examined.

It was shown that the children with the 3-rd degree of IDA develop the impairment of erythrocyte morphology, a decrease of their life duration at the expense of intensified hemolysis, change of erythrocyte membrane stability to some physico-chemical factors and decrease of the enzyme activity of antioxidant system. The direct dependence on the heavy metal and nitrate concentration in blood and urine, degree of the impairment of structural-functional indices of erythrocytes and a marked anemic syndrome in children has been determined. It has been established that in IDA genesis a combined effect of unfavorable ecological factors plays a considerable role and chronic effect of low doses of radiation.

MORPHOLOGICAL PECULIARITIES OF CHRONIC GASTRITIS IN CHILDREN AND ADOLESCENTS OF BELARUS UNDER CONDITIONS OF LOW DOSE RADIATION-CHEMICAL EXPOSURE

Following the accident at the Chernobyl nuclear power station, the unfavourable ecological situation due to chemical contamination of the environment was aggravated by the radiation effect. At present, radionuclides of caesium and lead, as well as the nitrates, are the most widely distributed ecotoxicants.

Under conditions of the negative ecological effect as the result of per os penetration of the majority of xenobiotics, the gastro-intestinal tract is at particular risk. During 1990-1994, 442 children and adolescents aged 10-17 residing at the ecologically different regions of the Republic have been examined. The program of examination included morphological investigation of bioptates of the stomach mucous membrane, determination of the radiocaesium specific activity in the body and the evaluation of lead content in blood and nitrates content in urine.

Depending on the level of radionuclides and xenobiotics accumulated in the body, all the children were divided into two groups. The main group (n=289) was represented by the schoolchildren residing at the contaminated with radionuclides territories of the Gomel and Brest Regions. Average annual effective dose equivalent in these children exceeded 3-5 times relatively permissible level (1 mSv). In 2/3 of the examined children, due to the Cs-137 accumulation in the body, the contribution from the internal exposure to the total dose formation made 63-96%. Besides, an excess of the permissible level of lead in blood was marked in 53.3% of children from this group (average index in the group- (0.117 ± 0.008 mg/l) and an excess of nitrates in urine - in 24.4% of children (71.8 ± 3.5 mg/l).

The control group (n=153) was represented by the schoolchildren residing under similar socio-economical conditions of the Vitebsk Region at the territory with natural background radiation. Nitrates loads in these children were identical with those of the main group (average index - 72.0 ± 5.2 mg/l) with the permissible lead indices in blood (0.053±0.009 mg/l).

It has been ascertained that the occurence of chronic gastritis is high in the first and second group with no statistically significant differences between them and equals, accordingly, to 70.9 ± 2.7% and 71.2 ± 3.7%. The majority of chronic gastritis are helicobacter (HP)-assOciated (Table 1).

The occurence of HP infection with the unchanged stomach mucous membrane was considerably higher in schoolchildren residing under conditions of ionizing exposure.

Table 1

Distribution of the examined children (%) with respect to the revealed HP-infection in the stomach mucous membrane

Analysed index	Main group	Control group
Chronic gastritis associated with HP	88.8 ± 2.2	78.0 ± 4.0

Table 1 (continuation)

Analysed index	Main group	Control group
HP presence on the stomach mucous membrane in healthy children	44.0 ± 5.4 *	18.2 ± 5.8 *

Note: * - differences are statistically significant ($p < 0.001$).

According to literature reports, statistically significant relationship between the HP infection of the stomach mucous membrane and the morbidity and mortality from stomach cancer has been ascertained [1,2,3], the possibility of procancerogenous effect from the HP infection being increased when combined with the effect of toxic factors of the environment.

It is known that chronic gastritis caused by HP infection is developing, as a rule, until atrophyc changes in the stomach mucous membrane occur [3]. The conducted by us analysis revealed statistically significant differences ($p < 0.001$) in the frequency of atrophy of the stomach mucous membrane in schoolchildren from the first and second groups (Table 2).Intestinal metaplasia of the mucous membrane epithelium and a combination of metaplasia with the atrophyc changes on the background of chronic gastritis were also observed more frequently in children residing at the contaminated with radionuclides territories.

Table 2

Occurence (%) of atrophy and intestinal metaplasia in stomach mucous membrane in children and adolescents with chronic gastritis

Analysed index	Main group	Control group
Atrophy	16.1 ± 2.6 *	2.7 ± 1.6 *
Intestinal metaplasia	5.4 ± 1.6	2.7 ± 1.6
Atrophy + intest. metaplasia	2.9 ± 1.2	0.9 ± 0.9

Note: * - differences are statistically significant ($p<0.001$).

It's important to note that the frequency of the mucous membrane atrophy was growing with the increase of a number of toxicants in the body.In schoolchildren residing under conditions of high radiation levels, the occurence of atrophyc gastritis made 4.1% with the permissible concentrations of lead and nitrates in the body. In children of the same group with the elevated concentration of nitrates in urine (more than 100 mg/l), the occurence of the stomach mucous membrane atrophy was increasing and reached 9.4%. With the elevated lead concenrations in blood (more than 0.10 mg/l),it made 11.7%. With the elevated level of three toxicants in the bodsy (caesium-137, lead, nitrates), the frequency of atrophyc gastritis made 36.8%.

Thus, in a considerable number of children and adolescents residing at the contaminated with radionuclides territories of Belarus, an increased content of caesium radionuclides in the body was revealed, as well as increased concenrations of lead and nitrates which present a potential health hazard.

From our point of view, these factors contribute to the appearence, already in the childhood, of chronic stomach pathology, to its rapid growth with the development of atrophy and intestinal,metaplasia of the mucous membrane. Taking into account high occurence of the HP stomach infection not only in patients with chronic gastritis, but also in healthy children, we face the situation which is not typical for children's age and prognostically dangerous, since it suggests high pre-cancerous potential for chronic gastritis.

New IAEA recommendations on the calibration of radiation protection monitoring instruments

J. Böhm [1], I.M.G. Thompson [2], R. Griffith [2]

[1] Phys.-Techn. Bundesanstalt, Bundesallee 100, D-38116 Braunschweig, Germany
[2] International Atomic Energy Agency, Wagramerstrasse 5, A-1400 Vienna, Austria

Introduction

In 1971, the IAEA provided the Technical Report Series No. 133 (1) as a guide for those establishing or operating calibration facilities for radiation monitoring instruments. The sources of radiation and associated apparatus and calibration techniques presented in the report are examples of what established calibration laboratories deemed adequate. Because of the multitude of applications for radiation monitoring instrumentation, e.g. in medicine, radiography, agriculture, it is impossible in one report to describe the complete calibration of all instruments. However, the principles described serve as a basis for calibrating radiation protection instruments.

The calibration report had to be updated for various reasons:

- Considerable progress has been made in standardizing reference radiation fields and calibration procedures by the International Organization for Standardization, ISO.
- The International Electrotechnical Comission, IEC, has produced many standards on the performance specifications and type testing of radiation protection monitoring instruments.
- New quantities and units were introduced by the International Commission on Radiation Units and Measurements, ICRU, in Report No. 39, 43, 47, 51 (2, 3, 4, 5).
- The International Commission on Radiological Protection, ICRP, has recommended a revised system of dose limitation, including specification of primary limiting quantities for radiation protection purposes (6).
- A new method has been recommended by ISO for the expression of uncertainty in measurement (7).
- A network of secondary calibration laboratories has been set up by WHO/IAEA in many countries. Although these laboratories were primarily concerned with therapy standards they are increasingly becoming more involved with calibrating radiation protection instruments.

The contents of the individual chapters of the report (1) have been considerably revised and extended. After explaining the purpose of calibration, this paper describes some general concepts applied in the revised report which is expected to be published in 1996.

Purpose of calibration

The primary objectives of a calibration are defined as follows:

- To ensure that an instrument is working properly and hence will be suitable for its intended monitoring purpose.

- To determine, under a controlled set of standard conditions, the indication of an instrument as a function of the value of the quantity intended to be measured. This shall be done over the complete range of indication of the instrument.
- To adjust the instrument calibration, if possible, so that the overall measurement accuracy of the instrument is optimized.

The revised report describes a comprehensive range of calibration equipment and techniques. However, the scope of tasks performed by any one particular facility will depend upon the types of instruments that must be calibrated, as well as upon the conditions under which the instruments are likely to be used. The facilities may range from those which perform routine calibration or checks using simple assemblies to highly sophisticated laboratories where detailed energy response characteristics can be determined. The more sophisticated of these facilities will have a range of reference instruments and reference sources which, in general, will be compared to national primary standards which are themselves probably subject to international intercomparison.

General concepts

Calibrations of dosimeters are only considered in terms of the operational quantities for area monitoring ambient dose equivalent $H^*(10)$ and directional dose equivalent $H'(0.07, \Omega)$, and for individual monitoring personal dose equivalent $H_p(10)$ and $H_p(0.07)$. The quantities $H'(3, \Omega)$ and $H_p(3)$ are used very rarely and are often conservatively estimated by $H'(0.07, \Omega)$ and $H_p(0.07)$. Therefore they are not dealt with in the revised report.

One has to be aware of the relationship between reference radiation fields, physical quantities that characterize the dosimetric properties of the reference radiation fields, and quantities used for calibrations and type tests. Reference fields recommended by ISO are established in the calibration laboratory. Physical quantities like fluence for neutron radiation and air kerma for photon radiation characterize the reference radiation field and are measured with reference instruments. Quantities related to calibrations and type tests are derived from the physical quantities by appropriate conversion coefficients. Tables of conversion coefficients for ISO reference radiations of normal incidence are given in the revised report.

Personal dosemeters should, in principle, be irradiated on standardized phantoms. The water slab phantom, water pillar phantom and PMMA rod phantom of ISO have been selected for calibrations and type tests. When these phantoms are used no corrections shall be applied to correct for any differences in backscatter relative to ICRU tissue.

Routine calibrations of personal dosimeters may be done, sometimes more simply, free in air or on a PMMA phantom, and even with a type of radiation other than that which the instrument is intended to measure. Such simplifications can be justified provided the calibration procedure is checked during the type test so that the difference in the responses of the dosimeter under both irradiation conditions is the same for each dosimeter of the same type. Calibration on a phantom should be done if the dosemeter is very sensitive to the radiation backscattered from the phantom, such as the neutron albedo dosimeter, for example.

A distinction is made between four methods of calibration

- calibration by successive irradiations of a reference instrument and the dosimeter without using any monitor detector

- calibration by successive irradiations of a reference instrument and the dosimeter with the aid of a monitor detector
- calibration by simultaneous irradiations of a reference instrument and the dosimeter
- calibration in a known radiation field (without any reference instrument)

The second method is illustrated in figure 1.

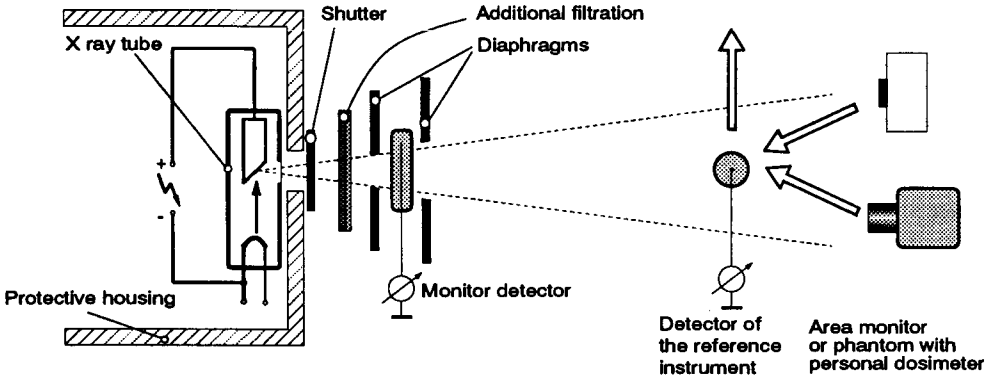

***Figure 1:** Calibration set-up for reference filtered X radiations consisting of an X ray tube with protective housing, beam limiting and shielding diaphragms, shutter, filter, monitor detector, detector of the reference instrument, and area monitor or phantom with personal dosimeter to be calibrated.*

Detailed numerical examples are given including the estimate of the uncertainty of the calibration factor and how to state this uncertainty in calibration certificates.

Concluding remarks

In assesssing whether a particular radiation monitoring instrument is adequate for its intended use and before it is used for the first time, it is important to have access to reliable type test data on that instrument. Often the instrument manufacturer does not possess facilities for the complete type-testing, and even sometimes cannot calibrate the instrument over the complete dose equivalent range with a reference radiation. There is a tendency for new users of radiation monitoring instrumentation to overestimate the facilities of the manufacturers. Each individual instrument should be calibrated before its first use and then recalibrated periodically. There are examples where inadequate calibration procedures have in the past caused large errors in some dose estimates.

THE RUSSIAN STATE SYSTEM FOR QUALITY ASSURANCE OF RADIATION MEASUREMENTS

Prof. Yu.V.Tarbeyev, Dr. V.I.Fominykh, Dr. I.A.Kharitonov

The D.I.Mendeleyev Institute for Metrology, St.Petersburg, Russia

The State system for ensuring quality of radiation measurements (hereinafter referred to as "System") has been establishing in Russia throughout a long period of time. When arranging the System, any measurements of physical quantities and parameters, which characterize sources and fields of ionizing radiations, were considered as the radiation measurements (RM).

The System has some distinguishing features caused by the factors which are basically characteristic for this field of measurements made in Russia.

The first factor resides in the fact that in Russia, the RM are currently central problems because of a great number of installations where the ionizing radiations exhibit activity. Among them there are radiochemical enterprises, atomic power plants, research reactors, Navy and Civil fleet with atomic engines, radionuclide diagnosis, radiation therapy etc.

The second factor is a great variety of the RM types, stemming from a large number of physical quantities and parameters: specific activity - with numerous radionuclides being measured, the flux and flux density of the charged particles and neutrons - within a wide range of energy, power of the absorbed and equivalent doses - within a wide power range for different types of radiations etc., as well as from a number of problems, the solution of which require such measurements as: technological (at the enterprises and plants), diagnostic (in medicine and manufacture), radioecological (at monitoring laboratories) and so on.

The third factor consists in the necessity to conduct quite often the RM for economic subjects such as atomic power plants or ecology organizations which have the same interests and should come to some responsible conclusions related to the fate both of manufacture and of population.

To satisfy the above requirements, the System should be arranged in such a manner that it could be used as an objective basis for solution of any problems including the disputable ones which refer to the RM.

Thus, from the very beginning, the System has been created with the aim to provide the metrological assurance of all economy branches of Russia in the field of the RM, using as a basis the centralized principle which means:

- reproduction of measurement units which are the main ones for a given field of measurements with the help of state standards;
- the legalized hierarchy chart for calibration of measuring means with an approved list of secondary and working standards and definite intercalibration intervals;
- availability of specifications regulating methods and accuracy limits of measurements for the whole park of the working measuring means being in usage.

At present the System is based on 11 state primary and special standards which provide to reproduce the main measurement units for the activity of radionuclides in sources, gases, aerosols, flux and flux density of the charged particles and neutrons, power of the absorbed dose of photon, neutron and beta-radiation as well as some other measurement units.

The size of the units reproduced by the standards is transferred to the working measuring means according to the hierarchy calibration charts including more than 50 working standards operating in the form of suitably designed dosimetry and radiometry set-ups installed at the leading enterprises or at the main metrological laboratories. As the certified radiation sources, they use radionuclide sources, x-ray apparatus, reactor channels, output accelerator beams. All measuring means including working standards, are tested every 3-5 years, the same interval being used for metrological certification of the measurement methods.

The System described, which to some extent appears to be bulky, has demonstrated its efficacy in carrying out the works on liquidation of consequences of the accident at the Chernobyl Atomic Power Plant.

First of all, it was found to be very important that all radiometers and dosimeters being used at the accident site, had been calibrated in the established units and that the measurements were performed according to the specified procedures. This enabled to assess the accident scale correctly, to bring out the major seats of origin of the damage and to forecast the development of radiation conditions. Thus, it was possible to organize and monitor the radiation dose of individuals promptly and on a large scale.

At the same time with the liquidation of the direct accident consequences, a demand arose for a radiation inspection of population, food, soil, water. This problem was promptly solved at a high level of reliability by means of manufacturing the standard specified measures of activity serving as full-scale models (imitators) of the tested samples taken at the contaminated locality to calibrate scales of radiometers and spectrometers, as well as whole body counters at the laboratories of sanitary and epidemiology services including those situated in the regions of the radiation contamination. At the same time, to certify the radiometer set-ups and to measure the radionuclide activity in the samples, some methods and corresponding procedures were developed. Thanks to the System, they were brought up to their direct executors.

Thus, thanks to the existence of the System, it was possible to solve the problem of carrying out reliable radiation measurements under the conditions of liquidation of the large-scale accident consequences. This in itself is a good evidence that the choice of a centralized system for metrological assurance within this field of measurements in Russia has been chosen correctly.

In 1981 at the IMEKO international symposium in Leningrad we underlined that the most rational method to provide the metrological assurance of devices measuring the specific activity of low activity media involves a wide use of standard solutions of radionuclides, whose application provides a high accuracy of instrument calibration over the whole range of specific activity values.

Numerous international comparisons of national standards of the radionuclide activity with the help of radionuclide solutions eliminate the possibility of rough systematic errors for widely used and well studied radionuclides.

The question of mutual acceptance of certification results of these solutions in different countries refers rather to the category of legislative than to technical problems. Hence the application of the SSR for the metrological assurance of measuring devices solves the problems of accuracy and traceability of the specific activity measurements.

For example, in Russia more than 60 certified standard solutions of radionuclides are manufactured in large quantities. The specific activity of main solutions is 10^5 Bq/g (for separate radionuclides 10^2-10^5 Bq/g); that is they are convenient both for measurement with the help of standard set-ups and for practical use.

The uncertainty of the most radionuclide solutions manufactured commercially is usual $\pm$ 2% at a confidence level P=0.99.

For environmental monitoring part of these solutions is used directly, the other part, used for the manufacture of imitators of soils and food is diluted by a factor of 100-1000 using precision methods of dilution as a result of which an additional uncertainty of 0.1-0.5% is introduced.

If at all stages the rules to avoid sorption are followed strictly (special vessels glassware, disposable pycnometers, nonradioactive carriers, etc are used) when applying a step-by-step dilution (by two-three stages), then it is a relatively simple matter to manufacture standard measures (simulators) with the uncertainty of 3-5% (P=0.99) at the level corresponding to the natural activity.

To provide precise laboratory measurement methods simulators with radionuclides existing in real samples are manufactured from solutions: ^{137}Cs, ^{134}Cs, ^{90}Sr, ^{90}Y or with other long-lived radionuclides, with close energies of particles. In addition ^{40}K from natural chemical agents is used. Volume standard measures of radioactivity based on natural disperse materials of various densities (quartz sand, resins, grain cultures, sawdust etc) containing one or several radionuclides are of considerable current use. For a short period of time low activity water solutions are suitable for use as well.

The volume measures of radionuclide activity imitate well real samples, they can be contained in any vessels, cups and dishes. Some of them are manufactured as a set with a nonradioactive carrier to measure background accurately. The importance of express methods for a bulk inspection of foodstuffs should be noted. We take the word "an express method" to mean radiation monitoring without taking a sample for an analysis, that is, we measure activity directly in commercial containers, boxes, cans, barrels etc. Devices with scintillation gamma-detectors are used to conduct such inspection. It is necessary to separate products known to be "noncontaminated " from products

whose radiation contamination is significantly below permissible limits, and to detect "contaminated" products to be tested accurately. The metrological assurance of such express methods of measurements involves manufacture of special volume measures of specific activity large in size (e.g. cans or boxes). In this case the usual volume measures of radioactivity is mixed with nonradioactive carrier in two or three steps. The uncertainty of such a measure is within 5%.

The above mentioned examples show the convenience, effectiveness, reliability, versatility of the metrological assurance of measuring means based on measures manufactured on the base of certified standard solutions of radionuclides.

In connection with the accident at the Chernobyl Atomic Power Plant the problem of the metrological assurance of measurements of the radionuclide activity of the personnel operating and maintaining nuclear installations and of the population living in regions exposed to radioactive contamination has become urgent. To check the content of radionuclides in human body direct measurements of γ-radiating radionuclides activity are carried out. The most authentic data on the radionuclide content in the human body are obtained using body radiation counters that have been previously calibrated against standard special-purpose sources. Semiconductor detectors based on Ge and scintillation detectors based on NaI(Tl) are employed as gamma-ray detectors in most commonly used counters. Before usage these counters must be certified taking into account age anthropometric distinctions of a person. To this end special phantoms imitating an adult, teenager and child have been developed and are used. Built-up phantoms consisting of standard special-purpose volume radionuclide sources are used; wherein 35 standard sources imitate an adult's body and 6 standard sources -that of a child.

The system developed by now for the metrological assurance of radionuclide activity measurements in the human body includes:

- development and investigation of phantom sources imitating an adult, teenager and child;
- certification of these sources as standard measures of gamma-ray radionuclide activity;
- development of procedures for counter certification;
- metrological certification of these spectrometers on a periodic scheduled basis.

As a rule counters are certified against the activity values of ^{137}Cs gamma-ray radiation. Counters certified as standard activity measures of ^{60}Co, ^{241}Am etc are used as well.

The activity of radionuclides found in the human body is measured by the relative method, comparing the pulse count rate of gamma-rays from the person with the pulse count rate of gamma-rays of the same energy from the phantom which serves as the standard activity measure of the radionuclide present in the human body. The radionuclide activity values obtained in such a way are used to calculate the absorbed (equivalent) dose a person takes due to the internal irradiation.

In addition to the above-listed programs the Government of Russia is currently funding a number of others within which a system for ecological monitoring of the country is being created including radiation monitoring. A network of testing laboratories is being created. These laboratories are accredited for the right to carry out radiation measurements for mapping territories, the hydrosphere, the atmosphere, for certification of building materials, food, wood etc. This allows not only to define localities contaminated with radionuclides of the technical origin but to forecast correlations between health of the people living in this locality and characteristics of the locality, given in the certificate.

Once the System has been created, it is being continuously developed and improved. One of the most urgent problems which it faces now is the creation of a network of laboratories for monitoring the radiation. These laboratories will be accredited for the right to carry out the radiation measurements according to the rules regulated by ISO/IEC standards for the testing laboratories included in the system of radionuclide product certification.

The System is being continuously developed and improved. Radiation measurements performed in the certified testing laboratories in compliance with the ISO/IEC standards will make it possible to harmonize the Russian System with the international one.

NEW IAEA COMPENDIUM OF NEUTRON DOSE CONVERSION COEFFICIENTS, SPECTRA AND DETECTOR RESPONSES FOR RADIATION PROTECTION.

R.V.Griffith[1],J.Palfalvi[2] and B.R.L. Siebert[3]

INTRODUCTION

The recommendations made by the International Commission on Radiological Protection (ICRP) in their Publication 60[(1)] mean some major changes in concepts of radiation quantities. The protection quantity effective dose equivalent (DE), H_E, has been replaced by the effective dose, E, radiation weighting factors, w_R, have been introduced for protection quantities and the $Q(L)$ relation used with operational quantities has been modified. These recommendations have also been discussed by the International Commission on Radiation Units and Measurements (ICRU) in their Report 51[(2)]. A joint ICRP-ICRU task group has collected the fluence to dose conversion coefficients for the new quantities.

These recommendations brought a renewed focus on the importance of neutron spectra in occupational radiation protection. Indeed, in recent years there was considerable progress made in developing new and improving existing spectrometers and dosemeters and in the determination of spectra at work places[(3)].

The availability of this data has prompted the International Atomic Energy Agency (IAEA) to prepare a supplement to TRS 318[(4)]. In addition to the presentation of the new data, the supplement will include spectrum weighted values of the protection and operational quantities for the original spectra. As with the prior publication the data will be available on diskette. A feature of the new work is software that will allow the user to perform spectral weighting with other data that are not available in either publication.

The aim of this paper is to give a sneak preview. In the following, the formalism used in the new publication is summarized. Some examples are given to illustrate the data contained, i.e. conversion coefficients, spectra and responses. Finally, the use of the supplement is discussed.

FORMALISM

The primary physical quantity for the assessment of derived radiation protection quantities for neutrons is the neutron fluence, Φ, and its distribution density in neutron energy, E, i.e. the neutron spectrum, $\Phi_E(E)$.

The instruments used are described by their neutron fluence response, $R_\Phi(E)$, and the reading of an instrument exposed to a neutron spectrum, M, is computed as the energy integral over the product of $\Phi_E(E)$ and $R_\Phi(E)$. Possible influences due to dead time, fading or background are not discussed.

The quantity to be determined is a specific dose equivalent (DE), H, which is computed as the energy integral over the product of $\Phi_E(E)$ and the fluence-to-DE conversion factors, $h_\Phi(E)$.

In the context of this compendium only ratios of fluence weighted quantities are of interest and it is sufficient to restrict the discussion to *normalized* fluences and to assume that the fluence is

uniform throughout space. The neutron fluence is in practice also distributed in the angle and the fluence response function of an instrument and the DE quantity considered may depend on the angular distribution of the neutron fluence. However, for the sake of clarity, this compendium is restricted to the consideration of broad parallel beams and few idealized irradiation geometries. Measured or computed neutron spectra are in most cases originally obtained as group fluences, φ_i, in energy bins, (E_i, E_{i+1}). A fixed energy grid is used in the compendium. Any bin is described by its lower and upper boundaries. Sixty energy bins are used from E_1 = 1 meV to E_{61} = 0.5 GeV. It is understood that the fluences are normalized: the value of $\Phi = \varphi_1 + ... + \varphi_{60}$ is by definition 1 cm^{-2}. The mean energy of a bin is defined as the geometric mean of its lower and upper boundary, i.e. $\overline{E}_i = \sqrt{E_i \cdot E_{i+1}}$.

The fluence response function of instruments and the fluence-to-DE conversion coefficients are in general continuous functions of neutron energy. In order to avoid any ambiguity the integrals needed for the calculation of spectrum averaged quantities are replaced by sums and as discrete representation it is defined:

$$M = \sum_{i=1}^{i=60} \varphi_i \, r_i \qquad \text{and} \qquad H = \sum_{i=1}^{i=60} \varphi_i \cdot h_i \qquad (1)$$

where $r_i = R_\varphi(\overline{E}_i)$ and $h_i = h_\varphi(\overline{E}_i)$. Depending on the width of an energy bin and the energy dependence of the fluence response function or the conversion factor this procedure may lead to slight deviations as compared to the results obtained from correct integration. In general, these deviations are irrelevant within the scope of this compendium and within its main purpose to study ratios of spectrum averaged quantities. However, as far as the calibration spectra are concerned, it is felt to be perturbing, if the values provided differ from the recommend ones. Therefore a table with recommended mean fluence-to-dose equivalent conversion factors is given in the supplement.

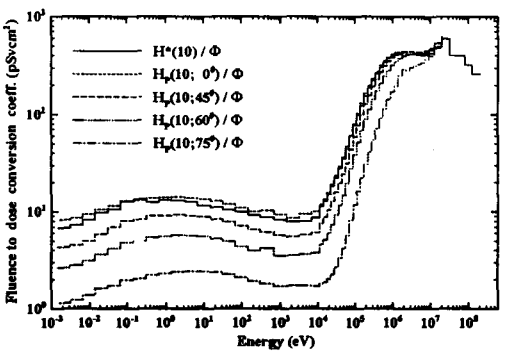

Figure 1. *Neutron fluence to dose equivalent conversion coefficients*[5] *as a function of incident neutron energy.*

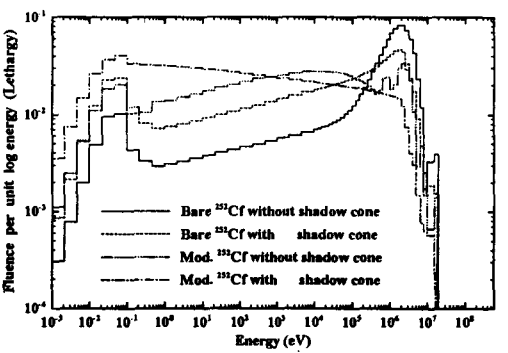

Figure 2. *Calibration spectra in a bunker room*[6] *as a function of incident neutron energy.*

QUANTITIES, SPECTRA AND RESPONSE FUNCTIONS

The *operational* quantities for area monitoring, i.e. the ambient DE[1,2], $H^*(10)$, and for personal monitoring, i.e., the personal DE[2], $H_p(10,\alpha)$, are shown in Figure 1. The *protection* quantity effective dose[1], E, -not shown here- will be given for the standard irradiation geometries, i.e. AP, PA, LAT, ROT and ISO.

Examples of new calibration spectra determined by Bonner spheres spectrometry and calculations[6] are shown in Figure 2. It is interesting to know, that a sequential irradiation in these spectra allows to realize virtual spectra with interesting dosimetric properties.

Responses of some new survey instruments[7,8] and etched track detectors[9-11] are shown in Figures 3 and 4, respectively. The supplement will also feature new response functions for Bonner spheres and Bubble detectors.

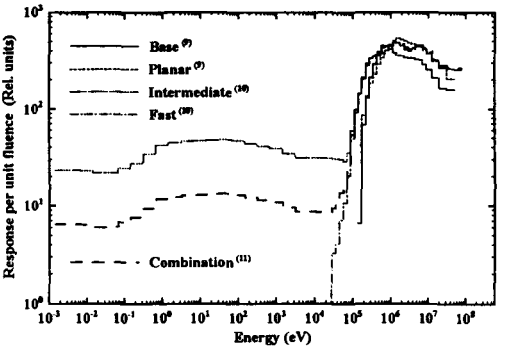

Figure 4. *Etched track dosemeter responses*[9,10,11] *as a function of incident neutron energy.*

THE USE OF THE CATALOGUE

Printed tables and the data and the software that will be supplied on diskette will assist in practical neutron radiation protection in several ways.

- The data on fluence conversion coefficients to the new protection and operational quantities to be included provide a complete set of data for routine neutron radiation protection.
- Many new spectra usable for calibration and found in work places provide valuable assistance in deciding where and how to calibrate instruments and to judge the dosimetric properties of actual work places of interest.
- The influence of the change of DE quantities for actual work places and for particular instruments can be studied. This is of great importance for the decision whether existing instrumentation is still adequate with the new DE quantities.
- Finally, valuable support is given in selecting new appropriate instrumentation if necessary or provide correction factors if the old instrumentation must be used.

In summary, the supplement will assist in assuring continued high quality in neutron radiation protection practice.

POSTER: RADIATION PROTECTION OPTIMIZATION AT DIFFERENT WORKING POSTS

M. Guelin, D. Delacroix and C.Lyron
CEA Saclay. UGSP/SPR Service de Protection contre les Rayonnements
91191 Gif-sur-Yvette

Increasingly sophisticated elecronic dosemeters have been introduced into the market over the past few years. The use of electronic dosemeters is becoming more and more widespread as a result of demands being made for dosimetry management on both the national and international level.

The dosicard system involving the use of credit-card sized dosemeters and a data acquisition and processing environment is well suited to satisfy demands in this field. It should be noted, that in addition to assuring the traditional functions of dose and dose rate equivalent measurements, these dosemeters also provide an autonomous management of cumulated doses (on a daily, weekly, three-monthly or annual basis), which can be consultated in real time by the wearer.

This system also allows the restitution of the previous hundred measurements (through variable increments) together with time, date and duration information for events involving the exceeding of predetermined thresholds (defined in terms of dose and dose rate equivalents). These characteristics have incited studies on the use of such dosemeters to determine the characteristics of working posts. Experimental studies have been conducted over a period of several months in a radioelement production laboratory and in a hospital service specialized in radiochemistry and medical imagery.

The main characteristics of the Dosicard system are recalled. The results of these two series of studies are then examined. A demonstration is then provided on the way in which this sort of approach influences the behaviour of the wearer relative to radioprotection specialists.

PERSONNEL MONITORING AT JINR

Yu.V.Mokrov

Joint Institute for Nuclear Research ,Dubna

1. INTRODUCTION

For more than 40 years the Division of Radiation Protection (DRP) has provided personnel monitoring (PM) at the Joint Institute for Nuclear Research (JINR). The JINR have a set of basic nuclear fasilities, such as: 10 GeV proton and light nuclei Synchrophasotron and superconducting accelerator of relativistic nuclei "NUCLOTRON", the U-400, U-400M, U-200 heavy ion cyclotrons, the 680 MeV proton phasotron, the fast neutron pulsed reactors IBR-2 and IBR-30. These facilities are a powerful sources of ionization radiation filds with wide energy range and complex composition. The DRP carries out a sistematic personnel monitoring service of gamma, beta, X-ray and neutron exposures at the JINR. The number of persons monitored has not changed considerably for the last years and at present it amounts to about 2100 persons, including visiting scientists and outside contractors(120). The PM for external exposure is still based on film badge IFK-2,3 with TLD cards for gamma dosimetry, the double film ORWO RD-3,4 for X-ray and beta and nuclear emulsion MK-20 for neutron. The film badge IFK-2,3 contains the different filters combination and open window.

2. METHOD AND MEANS

For gamma dosimetry are used cards containing two natural LiF chips (G1) of identical dimensions (3x3x1mm) mounted between Teflon foils. A hope code is used for identication of the dosimeter cards. One TL-detector is placed behind a filter of 850 mg/cm^2 Pb and another one behind open window. The dose equivalent randges are 0,1 - 1000 Sv. For photon the energy randges 100 keV - 3 MeV the error is not more than 40%, at low energy the error is increasis. The system consists HARSHAW 2271, containing an automated reader and autoranging picoammeter. The absorbed dose beta radiation above 0,12 MeV are indicated by means of film by comparing the optical densities behind the three filters and open window. The absorbed dose randge are 0,2 mGy - 0,15 Gy. The TL-detectors of $CaSO_4$ thickness 0,1mm are used in finger ring dosimeters ters for beta and X-ray. The neutron dosimeter are based on nuclear emulsion MK-20 thickness 20 μm supported on a 140 μm cellulose triacetate base. The MK-20 are packed into the correction packet to correcte the energy dependence. The correction packet with MK-20 are placed behind a TLD card in film badge - IFKn-method /1/. Remresponse of the MK-20 are determined for energe randges from thermal neutron to 20 MeV /2/. The dose equivalent for high-energy hadron (above 20 MeV) are determined by the star prodaction in the nuclear emulsion (three and more rays). Most of neutron dose mesurements (without high-energy hadrons) made by film are within the error randge 50%. For high-energy stray filds IFKn-method is overestimates the dose equivalent by a factor of two. In these cases are used corretion method for reading of film dosimeters /1/.

Latent image fading of track density from high-energy hadrons is not more than 30% and from Cf-252 source neutrons is not more than 10% for three months. A data bank realises storing, updating, retrieval, statistics processing and output of the personal and dose information for over 2100 persons, controlled quarterly for external radiation /3/. The basic compontnts of the data bank are a data base (personal and dose files as current as archival) and a package of application programs for the work with the data base in the dialog mode by means of menus. The data bank was organized on the basis PC AT-386 with assistance of the relational DBMS dBASEIII PLUS and the Clipper compiler for the interpretive dBASEIII programming language, working under the control MS DOS, version 6.10.

3. CALIBRATION PROCEDURES

The gamma dosimeters are calibrated free in air of Co-60 radiation. The calibration irradiation are in terms of exposure. The exposure values are converted to dose equivalent with conversion 0,97 cSv/R. The area of the open window of the film badge with ORWO is calibrated in additional to dose equivalent of beta-rays of Sr-90+Y-90. In routine the neutron dosimeters are calibrated free in are of Cf-252 (for dosimeters are used in Laboratories of Neutron Physics and of Nuclear Reactions) and Pu-Be (for anothes laboratories). For calibration are used the fluens-to-dose equivalent conversion factor ($3{,}3{*}10^{-10}$ Sv$*cm^2$ for Cf-252 and $3{,}6{*}10^{-10} Sv * \mathrm{cm}^2$ for Pu-Be), factor on-phantom and free -in-air calibration and factor normal and rotatory irradiation for calibration /4/.

4. PERSONNEL DOSES

About 2100 radiation workers are subject to individual monitoring of external radiation in the JINR. This number includes 1500 persons monitored for neutron exposures. About 60 persons wear additionally film ORWO. Dosimeters are issued normally for a period of 3 months. Each monitored person has a personal card, where the values of all doses recieved and recorded. The individual dose values besides being stored in an electronic data bank also recorded in the personal radiation pasport of each radiation worker. The results of dose measurement for whole body are summed each year. The mean annual dose equivalent for person has not changed considerably for last 15 years and amounts about 2 mSv. Annual reference dose for radiation worers is 50 mSv in Russia. The mean annual dose ($\bar{H}$) and collective dose (H_Σ) is shown in fig.1. As an illustration fig.2 show the annual dose distribution for 1994. About 40% persons have annual dose below the detection limit (about 1 mSv). The exposures registered are very low, for exsample, in 1994 about 99,8% less than 15 mSv and 0,2% between 15 and 50 mSv per year. Maximum value was 20 mSv.

THE CURRENT STATUS OF NATIONAL RADIATION METROLOGY LABORATORY IN TAIWAN

M. F. Su and S. J. Su

Institute of Nuclear Energy Research, Lung Tan, Taiwan, R.O.C.

INTRODUCTION

The Institute of Nuclear Energy Research (INER) has been entrusted by the National Bureau of Standards (NBS) , Taiwan to establish the national radiation metrology laboratory (1-4) since 1991. Three major radiation fields such as photons and betas, neutrons and radioactivity measurement, have been studied by the INER. The established standards and techniques are applied in personnel dosimetry proficiency test in addition to instrument calibration. Whenever possible INER also actively takes part in international intercomparison programs to ensure the uniformity of the established standards and techniques with the international community.

PHOTONS(1)AND BETAS(2)

High energy photons are produced by radionuclides ^{60}Co and ^{137}Cs with average mono-energies 1.25 MeV and 0.662MeV, respectively. Since there have no radionuclide emitting photon energy below 300 keV with suitable half-life, X-ray machines are used to generate photons with energies from 10keV to 300 keV. Self-made graphite ionization chambers are used to measure the exposure from high energy photons. For low energy photons free-air ionization chambers are used. Transfer ionization chambers are used for intercomparison with Electrotechnical Laboratory (ETL, Japan) and National Institute of Standards and Technology (NIST, USA). The results show about 1-2% deviation. For beta fields, three sets of radionuclides $^{90}Sr+^{90}Y$, ^{204}Tl, and ^{147}Pm are used to create beta irradiation fields which are determined directly by an extrapolation ionization chamber. The results of intercomparison with PTB (Germany) show about 3% deviation.

NEUTRONS(3)

A room with dimension 5×6×9m is used for neutron irradiation. The four walls and the ceiling are made of aluminum in order to minimize neutron backscattering. Neutron sources can be hanged about 5m above the ground which is made of concrete. The neutron scattering effect is studied thoroughly. Radionuclide neutron sources such as ^{252}Cf situated at the center of a D_2O sphere with radius of 0.15m is used to simulate the neutron field outside the containment of a nuclear power plant. Neutron detectors are calibrated with bare and D_2O moderated ^{252}Cf respectively. The neutron emission rate of a radionuclide neutron source is determined directly by a manganese sulfate bath system.

Mono-energetic neutron fields produced by accelerating protons with a 7MV van de Graaff accelerator hitting lithium target are measured by various suitable techniques such as associated particles, proton recoil telescope and proportional counter.

Neutron spectrums are determined by bubble detectors, activation foils, Bonner spheres and NE-213 detector whenever is appropriated. Various computational techniques are applied to calculate the neutron spectrum of a D_2O moderated ^{252}Cf. The results are in good agreement with that of experiment.

RADIOACTIVITY MEASUREMENT(4)

The activity of radionuclide is determined directly by conventional $4\pi\beta-\gamma$ coincidence method which is good for simply decaying radionuclides such as ^{60}Co. For complex decaying radionuclide such as ^{133}Ba, $4\pi\beta-\gamma$ coincidence method coupled with two dimensional extrapolation method is used. Radionuclides distributed by ETL are used for intercomparison. Good agreement shows about 1% deviation but, in some cases, 7% deviation can be achieved which need some more careful studies. A system of $4\pi\gamma$ ionization chamber is used as the secondary standard to determine the activity of a radionuclide because of its long term stability and easy calibration. Other secondary standards for radioactivity measurement are high purity germanium system and $2\pi\alpha-\beta$ system.

PERSONNEL DOSIMETRY PROFICIENCY TEST(5)

INER is also entrusted by the Chinese National Laboratory Accreditation (CNLA) as the testing laboratory to carry out the proficiency test of personnel dosimetry service. Six personnel dosimetry service laboratories participated the performance tests in 1991 and 1993. In these two tests only gamma and X-ray were carried out. All of the laboratories passed the tests. Recently a full span of the test including beta and neutron dosimetry in addition to photon dosimetry was carried out. About nine personnel dosimetry service laboratories took part in the test.

SUMMARY

INER has paid much effort to establish the primary radiation standard in this country since 1991. The radiation fields include photons, betas and neutrons. In addition to instrument calibration, these fields are also applied to the personnel dosimetry proficiency test.

SEVEN YEARS OF INDIVIDUAL MONITORING SERVICE IN CUBA

R. Cruz Suárez , E. D. Díaz Bernal , G. M. López Bejerano,
and L. A. Jova Sed

Center for Radiation Protection and Hygiene, Havana, Cuba

ABSTRACT

The Center for Radiation Protection and Hygiene (CPHR) has been carrying out from 1987 the individual monitoring of workers occupationally exposed to the ionizing radiations in the Republic of Cuba, excepting those that employ X rays in diagnostic radiology. In this paper the results of the individual monitoring services during the period 1987-1993 are discussed. For all occupational practices the current system of dose limitation established in the country with 50 mSv as limit of annual dose is satisfied. The distribution in all occupational practices other than Nuclear Medicine and Gammatherapy is characterized by having more than 95% of the controlled personnel with an effective dose lower than 5 mSv. In the case of Nuclear Medicine and Gammatherapy, more than 80% of the workers were below that dose value. For the practices evaluated in this paper the possibility of assuming the system of dose limitation recommended by ICRP is evident. The evaluations carried out for the introduction of operational quantities Hp(0.07) and Hp(10) in dose assessment procedure are presented. The expressions obtained during the characterization of the film badge dosimeter, in terms of operational quantities guarantees a deviation of response of the dosimeter with depending upon energies, lower than 20 %.

INTRODUCTION

The Center for Radiation Protection and Hygiene (CPHR) has been carrying out from 1987 the individual monitoring of workers occupationally exposed to the ionizing radiations in the Republic of Cuba, excepting those that employ X rays in diagnostic radiology. The services offered refer to the control of external exposure by employment of film badge dosimeters for whole-body irradiation and TLD rings for the control of the dose in hands. "In vivo" and "in vitro" internal contamination monitoring for different radionuclides (^{131}I, ^{125}I, ^{32}P, ^{3}H, ^{14}C, ^{35}S) is also included.

MATERIALS AND METHODS

The individual monitoring of external exposure was carried out by using film badge dosimeters. The characteristics of the commercial "whole-body" dosimeters utilized, such as the procedures of calibration and methods for dose assessment are presented in [1]. Until 1991 the radiation monitoring film used in the service was the ORWO RD3-4 made in German Democratic Republic. That model was substituted by the AGFA-GEVAERT film "Personal Monitoring". The Service included individuals occupationally exposed to external radiation , who worked in following practices : Nuclear Medicine, Gammatherapy, Roentgentherapy, Research with ray X, Customs Control, Unsealed Sources, High Activity Sources, Geological Prospection, Industrial Radiography with ray X and gamma radiation. The monitoring period was for one month until 1990. Starting from 1991 the monitoring period was extended to three months.

In 1990 the individual monitoring of exposure in hands with TLD (LiF) given by the IAEA was established. That Service was limited to 50 users. For selection of workers to be controlled was kept in mind the dose received for the whole body in practices Nuclear Medicine and Unsealed Sources.

For the internal contamination monitoring, the effective dose calculation was carried out by applying the metabolic models, recommended by the ICRP in their publications [2]. The procedures of calibration and methods for dose assessment are presented in [1].

As a consequence of the recommendations of the ICRP [3], the response of the film badge dosimeter was characterized per unit of personal dose equivalent at both depths of 10 mm and 0.07 mm, (Hp(10) and Hp(0.07) respectively) [4]. Two reference methods for determination of the dose were applied, one in which dosimeters for calibration, irradiated with ^{137}Cs are used, and another in which two sets of dosimeters were employed for

calibration, one irradiated with a ^{137}Cs source and the other one with a ^{241}Am source. As a procedure for dose assessment the linear combination of the dose calculated for the different sectors of the dosimeter are analyzed.

RESULTS AND DISCUSSION

In the Film Dosimetry Service, values of mean annual effective dose per occupational practice (Table 1) evidence that practices with largest mean doses for external irradiation are those of Nuclear Medicine and Gammatherapy. The total mean dose in these years oscillates from 1.2 to 2.6 mSv (Table 2). Only 42 workers had exceeded the 15 mSv (three tenths of permissible limits of annual dose). Practices of Nuclear Medicine (17) and Gammatherapy (16) had the major number of workers involved.

Table 1: Mean annual doses for practices. Period 1987-1993. Film dosimetry service.

Occupational practices	Mean Annual Effective Doses [mSv]						
	1987	1988	1989	1990	1991	1992	1993
Nuclear Medicine	3.21	3.16	4.33	3.89	2.44	3.25	2.71
Gammatherapy	3.19	3.60	3.59	4.06	2.39	1.94	1.65
Roentgentherapy	2.49	1.28	1.42	0.72	2.55	1.34	1.15
Research with rays X	0.74	0.74	0.73	0.76	0.57	0.54	0.43
Customs Control	1.29	0.80	0.72	0.80	0.30	0.19	0.36
Unsealed Sources	2.51	2.44	2.58	2.71	1.07	1.21	0.84
High Activity Sources	2.40	2.41	2.56	2.41	1.00	0.82	0.57
Geological .Prospection	2.40	2.40	2.50	2.41	1.25	1.03	0.33
Industrial Radiography with rays X	0.82	0.73	0.98	0.75	0.26	0.36	0.48
Industrial Radiography with gamma radiation	2.80	2.60	2.80	2.81	1.14	0.75	0.67

Table 2: Results of the individual monitoring with film badge dosimeters

Year	Number of controlled workers	Mean effective dose [mSv]	Workers with doses above 15 mSv	Maximum Dose [mSv]
1987	1263	2.47	2	16.8
1988	1475	2.38	2	16.1
1989	1714	2.48	9	24.2
1990	1542	2.55	11	42.7
1991	1459	1.28	4	44.2
1992	1079	1.53	8	34.8
1993	1002	1.16	6	22.8

The variation of annual mean effective dose for different occupational practices, shows that in no case it exceeds the 5 mSv. The percentage of workers which received doses lower than that value, is in all practices over 95%. Practices of Nuclear Medicine and Gammatherapy where the accumulative frequency is over 80% are exceptions. No worker had exceeded the permissible dose limit of 50 mSv established for one year.

In the Individual Monitoring Service of exposure in hands, the maximum number of workers controlled during a year was 34. No worker had exceeded the annual limit of dose equivalent for a specific organ. The higher annual doses registered were: during 1990- 151 mSv, in the practice of Unsealed Sources in 1991- 86 mSv and in 1992- 96 mSv both in Nuclear Medicine.

In the Internal Contamination Monitoring Service the higher number of detected incorporations was found for radionuclides ^{131}I, ^{125}I and ^{32}P. In the case of Nuclear Medicine for the ^{131}I, values of committed dose equivalent oscillated between 2.50 - 28.76 mSv, the last being the largest committed dose equivalent detected throughout the control periods. The values of the mean committed effective dose for each occupational practice did not reach the level of 5 mSv.

During the last three years the lowest values of annual effective dose was registered for all practices. This situation could reflect the effectiveness of the radiation protection measures implemented in each practice and of the complete supervision system in Cuba.

As a result of the characterization of the film badge dosimeter in terms of operational quantities it was verified that the lowest deviation of the response of the dosimeter with the energy occurs when the 5 sectors of film badge dosimeter observed are combined [4]. Expressions that guarantee a deviation of the dosimeter response with depending upon energies lower than 20 % were gotten. Both methods of reference dose showed a comparable effect in the smoothing of the energetic dependence. It is observed that only for energies near 20 keV differentiated calculations of Hp(0.07) and Hp(10) make sense.

In order to evaluate the practical implications that the reduction of the dose limit to value lower than 50 mSv could have, the following analysis was performed. The frequency of cases above 20 mSv oscillate between 2 - 3 workers per year. This number represents a 0.2% of the total of the personnel controlled and it could be possible to reduce it with a more specific control of the practice where that is manifested [1]. Taking into account these aspects, it could be affirmed that is possible, in a practical situation, to reduce the current dose limit without great investments in order to guarantee compliance with the new dose limitation system, at least in those practices controlled by the CPHR.

CONCLUSIONS

For all occupational practices the current system of dose limitation established in the country with 50 mSv as limit of annual dose is satisfied. The workers receive annual mean effective dose that does not exceed three tenths of this limit. The distribution in all occupational practices except Nuclear Medicine and Gammatherapy is characterized by having more than 95% of the controlled personnel with an effective dose lower than 5 mSv. In the case of Nuclear Medicine and Gammatherapy, more than 80% of the workers were below that dose value.

The low value of mean effective dose evidences that the radiological protection requirements in our country guarantee the avoidance of significant doses for external and internal exposure. For the practices evaluated in this paper, the possibility of assuming the system of dose limitation recommended by ICRP is evident.

The expressions obtained during the characterization of the film badge dosimeter, in terms of operational quantities guarantees a deviation of response of the dosimeter with depending upon energies, lower than 20 %. Only for energies near 20 keV differentiated calculations of Hp(0.07) and Hp(10) make sense.

ABSTRACT (See instructions overleaf)

The RRPPS provides a service for calibration of external x-ray, beta and gamma dose and dose-rate meters and alpha, beta and gamma contamination monitors. An upgrading of the RRPPS testing and calibration facility is described. In this exercise latest UK HSE, ISO & NAMAS guidelines have been considered. Results are presented of tests of the ^{137}Cs irradiation jig for calibration of gamma dose-rate meters. Spectral measurements and Monte Carlo simulations have been performed at the defined calibration points; the applicability of the standard air kerma to ambient dose equivalent conversion factor is examined.

Calibration conditions are not intended to reflect field conditions. However in order to also fulfil the RRPPS role as an RPA, quantitative estimates of the differences between calibration and field conditions have been made for a limited number of cases. Typical working surfaces were uniformly contaminated with known activities of ^{99m}Tc, ^{125}I and ^{32}P and measurements were made using commonly encountered instruments.

MONITORING SURVEY INSTRUMENTS BEHAVIOUR IN STANDARD LOW ENERGY X-RAYS

São Paulo - Brazil

INTRODUCTION

The Calibration Laboratory of São Paulo offers calibration services for monitoring survey meters with gamma, beta, alpha and X radiation. For the calibration of these instruments with X-rays, at Radioprotection level, seven standard low energy X-rays fields were established. Five of them are used at the National Physical Laboratory (NPL) (1), with energies between 16 and 38 keV, and two are recommended by the International Standard Organization (ISO) (2), with energies of 33 and 48 keV.

Different survey meters such as ionization chambers and Geiger-Müller detectors were studied on relation to their energy dependence. These instruments are used for area monitoring of gamma radiation, but some of them detect low energy X-rays too. The energy spectra in area monitoring are usually large because of the scattered radiation. Therefore it is important to know the behaviour of these instruments in a wide energy range.

MATERIALS AND METHODS

The low energy X-rays calibration system consist of a Rigaku-Denki Generator, model Geigerflex, with a Philips tube model PW/2184/00 (Tungsten target and Beryllium window). The voltage and the current can be varied between 20 and 60 kV and 2 and 80 mA, respectively. Table 1 shows the characteristics of the low energy X-rays qualities established at the Calibration Laboratory. The measurements were taken at 200 cm distance from the target, in a field of 25 cm diameter. Six ionization chambers and four Geiger-Müller detectors of different models and manufacturers were tested (Table 2).

Table 1-Characteristics of low energy X-rays qualities

Voltage kV	Additional Filtration mmAl	mmCu	Effective Energy keV	1st. HVL mmAl	mmCu

Nardeux	Babyline 81	Nortron	NMR-1000
Victoreen	450	Victoreen	Minimonitor II
Victoreen	470A		
Victoreen	471		

RESULTS

Several monitoring survey instruments were tested, but the results of only the most representative of them are shown in this work. In the Figures 1 and 2 the results obtained with some ionization chambers can be observed; they presents an energy dependence between 7 and 33 % in the 16-48 keV range. The most suitable of these radiation detectors is the Victoreen 470A, although all of them can be used in this energy range.

In the case of the Geiger-Müller detectors, they presents a very high energy dependence, as can be seen in the Figures 3 and 4.

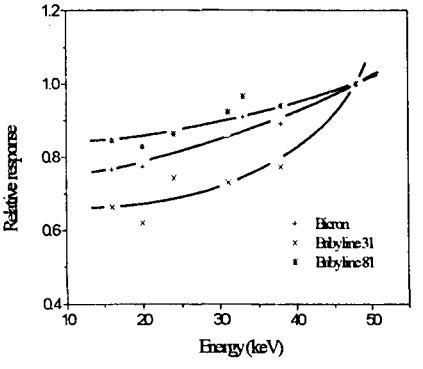

Figura 1 - Energy dependence of ionization chambers

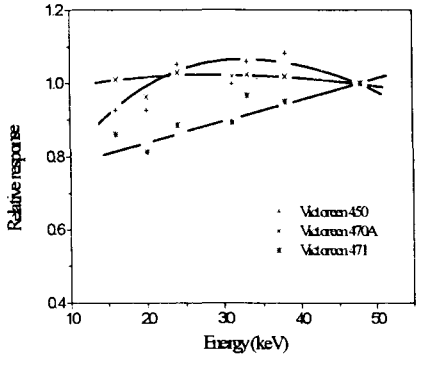

Figura 2 - Energy dependence of ionization chambers

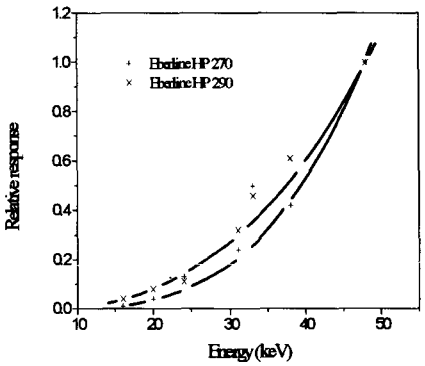

Figura 3 - Energy dependence of Geiger-Müller detectors

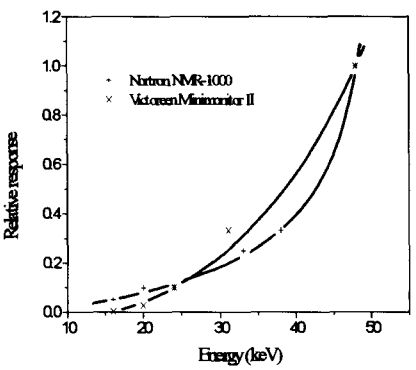

Figura 4 - Energy dependence of Geiger-Müller detectors

CONCLUSIONS

All tested instruments, ionization chambers and Geiger-Müller detectors, can be used for low energy X-rays detection, but the results show the importance of knowing their energy dependence in order to allow the application of correction factors on the measured values of exposure rates.

ABSTRACT (See instructions overleaf)

A sequential Tandem system of plane parallel ionization chambers developed at IPEN was used to determine the radiation qualities of an X-rays system (300 kV) for instruments calibration purposes at radiotherapy level. The Tandem arrangement is formed by chambers with different energy dependences. The results were compared with those obtained through the conventional method of HVL determinations using thimble chambers and absorbers with different thicknesses.

Ivana Avramović and Olivera Čuknić

Institute of Nuclear Sciences "VINČA", Belgrade, Yugoslavia

ABSTRACT

The dose rate distributions of photon fields for calibrating personal dosimeters are measured free-in-air and in front of the PMMA and water phantoms. The backscatter factors and relative inhomogeneity of photon fields at both of phantoms are compared. From radiation protection aspect, for the hospital staff at Rö diagnostics, we have discussed the preferences and defects on the occasion of use for everyone of phantoms separately. It turned out that in to give the objective opinion for occupational health, we have to consider to the positioning of the personnel dosimeter during their calibration in photon fields X ray apparatus of the Standard Dosimetry Laboratory.

INTRODUCTION

In the many investigations, it were appearing that the staff at Ro diagnostics and radiotherapeutics division have been greatly depending of coordinates extent in ionization irradiation fields. On another side, the individual dosimeters have calibrated on the conventional phantoms and in defined reference radiation fields. Instantaneously, the ICRU recommendations have referred one to the phantoms, like a sphere or a slab with tissuequivalent matter or simply Plexiglas (PMMA,polymethyl methacrylate) (1,2). The slab phantom is better for perceive the extent inhomogeneity fields. In as much it's envisaging angular and energy distributions of the photon flux in a longitudinal direction parallel to primary radiation beam, a buildup factor is significant. In a lateral direction, perpendicular to primary beam, a backscatter factor is representative (4,5). In both cases, it's adopting that the photon backscatter is minor from room's wall. Finally, should be establish influence of anisotropy angular distribution of emitted photons from the target X ray tube and contribution of the photon backscatter at the total field profile on the front phantom, on account of the primary radial beam. At the same time, should be see and the good reason for the water phantom utilization.

EXPERIMENTAL MEASUREMENTS

Firstly, all measurement results have concerned at exposure dose rate. The measurements are performed by X ray apparatus with conditions for maximal exposure dose rate at all mean energy photon spectra (6). We have used ionization chambers made by PTW-FREIBURG, volume 0,2 cm^3 , 1 cm^3 and 30 cm^3, uncertainty in measurement ± 2%. Constant potential X ray system MG 320 Philips with metal-ceramic tube MCN321, can generate direct voltage in the range from 30 kV to 320 kV. Other technical data are: anode angle 22^0 , inherent filtration 2,2 mmBe and standard focus 4mm x 4mm. It is existing possibility that conventional mean energy X ray spectra are reproduced by the beam passes through selective filters disc. The beam quality have been accord with the requirements of international standards (3,6). Dimensions water and PMMA (density 1200 kg/cm^3) phantoms were 20 cm x 20 cm x 15 cm. On the occasion of those measurements exposure dose rate at focus-phantom distance 1,5 m , beam diameter was 25 cm. However, measurement results at an edge of the phantom exist insecure for real conclusions because the border effects change backscatter factor for different mediums.

RESULTS AND DISCUSSION

Maximum lateral distribution free-in-air, perpendicular to the beam axis and parallel to the tube axis (PLD), with increasing voltage (60kV-300kV) shifts to the "anode side" (fig.1). For fixed voltage of 300 kV , (fig.2), an alteration lateral profile for different filtration are demonstrated /A30(4 mmAl + 2,2 mmBe, A0(2,2 mmBe)/. The most unfavorable field profile exist for very heavy filtration and high tube

voltage (HFHV conditions as A300 and B300). Lateral distribution in the direction perpendicular to the tube axis (NLD) is smooth, but asymmetrical to the center field because there are the photon scatter from the bench measuring (fig.7).

(#) Inherent filtration 2,2 mm Be.

In front of the water and PMMA phantom, on account of divergence beam, values backscatter factor are smaller than for "ideal" parallel beam. It's very significant fact since exposure dose rate profiles are created by local distribution of the photon backscatter. Maximum backscatter yield is for 82 keV (narrow spectra) and for 78 keV (broad spectra) , Table 1. It's finding out the most steep slope at the field profile for B110 (fig. 3 and 5). The symmetry PLD is loosed at extreme irradiation HFHV conditions on account of photon anisotropy emission by X ray apparatus (fig. 4 and 6). Then profile is spreaded evenly to the "anode side", because local diminution photon backscatter is compensated by yield of angular anisotropy emission. There are recommendations (2,3) that permissible inhomogeneity is less than 5%. For all energies in Table 1, at the front slab water phantom those express request have accomplished from 5 to 12,5 cm, until for slab PMMA phantom from 3,75 to 13,75 cm. As for NLD, the symmetry is peculiar and influence of photon scatter from bench measuring is slight. Inhomogeneity within 5% is tolerated from 2,5 to 15 cm above bench (fig.7).

CONCLUSIONS

Prior to employment modern X ray apparatus in the Standard Dosimetry Laboratory should be acquainted the profiles of photon fields for calibrating. At the base well known dimensions of the individual dosimeters (TLD, RPL, film and pMOS solid state) it can project and execute the conventional calibration. One fact is worth putting forward, that the region of high homogeneity (greater than 95%) at front PMMA is greater than for front water phantom.

INTRODUCTION

On the occasion of installing the γ-ray irradiation system for animal experiments at the Radioisotope Research Center of Osaka University both lead collimators and shield screen have been supplemented to the system in order to satisfy the Japanese legal regulation that the dose equivalent rate outside the controlled area should be less than 300 μSv/w because the experimental room has not been so designed as to install such an apparatus.

The original use of the system is to study the internal β-ray exposure of a small animal on a dosage of tritium water, which will be eliminated from a body with a biological half-life. Accordingly, the dose rate of internal exposure due to β-rays will change with time, and hence such a situation could be simulated with an external exposure due to γ-rays by changing the dose rate spatially, that is, the distance between the γ-ray source and a sample.

It is, however, anticipated that improvement of the system would bring increase in the scattered γ-rays at an irradiation point and hence it becomes the purpose of the present paper to obtain precise exposures including scattered γ-rays at each irradiation point for animal experiments and also to find an optimum point for standard calibration where no scattered γ-rays are observed. For that purpose the effect of them will be evaluated with both calculations due to the Monte Carlo code for neutron photon transport (MCNP) and experiments due to the ionization chamber calibrated at the National Bureau of Standard in Japan.

EXPERIMENTAL APPARATUS

The γ-ray irradiation system is composed of fixed γ-ray source part and an exposure deck movable along the rail. The latter is so controllable remotely with a computer that the dose rate could continuously be changed from 0.0668 mSv/h to 10.7 mSv/h by adjusting the distance between the source and the measuring point. In the source part are contained three kinds of radioisotopes, ^{137}Cs's of 111GBq and 11.1GBq, and ^{60}Co of 3.7GBq (nominal activity).

The irradiation system has been improved to clear the legal regulation for the radiation safety in the following two items. One is that the exposure deck has been mounted with a lead shield screen (1200w × 1200h × 30t) covered with iron plates (20t) at the back edge side as shown in Fig. 1. The other is that a lead ring collimator system has been supplemented to the source part. It is composed of three kinds of square collimators whose angular apertures are 6.03°, 9.27° and 20.02°, respectively. They can

selected automatically by rotating the ring collimator system as shown in Fig. 2 in response to the distance between the source and the deck, which enables the irradiation field to be confined within the added screen.

The collimator system can smoothly rotate round the RI sources owing to the compact structure though it weighs to be about 280 kg, which assures high stability and reliability in operation.

CALCULATED AND EXPERIMENTAL RESULTS AND DISCUSSIONS

The Monte Carlo code for neutron and photon transport (MCNP) has been used to evaluate the effect of the scattered γ-rays on the energy spectrum of the irradiation field. In Fig. 3 are shown the calculated results of normalized energy spectra including the scattered γ-rays for three different aperture sizes of the collimators. In the calculation a point source of ^{137}Cs has been set on the axis of the cylindrical irradiation part at a height of 1.2 m from the floor, and three right pyramid holes have been excavated through the lead cylinder perpendicularly to the axis as collimators, whose outlet areas are $3\times5cm^2$, $6\times8cm^2$ and $9\times11cm^2$, respectively.

The calculation has been carried out assuming that a detector with a known energy resolution is set at a point of 1m from the source. It is obvious from the figure that adopting a collimator of the smaller aperture would cause decrease in the effect of scattered γ-rays, that is, the total energy peak becomes more remarkable.

In Fig. 4 are shown the calculated results of dependence of the absorbed dose rate on the distance from the source in order to clarify the effect of the added shield screen on the spectra which would be a little modified by scattered γ-rays. In the calculation the absorbed dose rates of 10 different points located between two reference points, distances of 0.5mand 2.2m from the source point, have been obtained with a collimator of $9\times11cm^2$ and with the shield screen at 2.2m from the source.

In the same figure the absorbed doses measured with an ionization chamber are also shown together with the $1/r^2$-dependence curve. The chamber has been calibrated at the Electrotechnical Laboratory(National Bureau of Standard in Japan). It can be seen from the figure that the effect of scattered γ-rays on the absorbed dose is remarkable in the neighborhood of both collimator and screen. The difference between calculated and measured results is mainly attributed to the fact that the collimator size adopted in the calculation was different from the real collimator one. It is, however, found that there exist several points near the middle region where both numerical and experimental results obey the inverse square law. In other words the absorbed dose rates observed there include no scattered component of the irradiated γ-rays.

CONCLUSION

A well-controlled γ-ray field has been established with the improved commercial γ-ray irradiator system. It is ascertained that in some limited region the observed dose rate coincides with the calculated results and also satisfies the inverse square law, which means that the γ-ray field could be a standard one for calibration of both survey meters and all kinds of dosimeters prevailing in Osaka University.

ABSTRACT

A study was made on the energy spectrum of gamma radiation field used for calibration of radiation survey instruments. Energy spectra were measured with a NaI(Tl) detector and compared with those by Monte Carlo calculations. A good agreement was obtained between the measurement and the calculation. It was found that the use of collimator gives a different energy specification.

INTRODUCTION

A high-quality calibration of photon survey instruments requires information of energy spectrum in the calibration field, because the response of the instruments depends significantly on photon energy. Thus, it is important to estimate the mixture of scattered radiations in the calibration field.

Origins of the scattered radiations are the collimator, the room wall, the room floor, the table of instrument for calibration and the surrounding air. The scattering feature depends on the distance between source and instrument, the size of irradiation room, the type of gamma-ray source and the collimator. Then, the energy spectrum of radiations should be estimated at each calibration point in the field.

In the present work, gamma-ray spectrometry was carried out in some different calibration fields. Monte Carlo calculations were performed using the EGS4 code[1] to verify the experimental results.

METHODS

(1) Gamma-ray spectrometry

The Japan Atomic Energy Research Institute possesses two gamma-ray calibration rooms: a small room and a large one. The small room measures 6.5m x 5m x 4m high and the large one 6.5m x 12m x 6m high. Two calibration sources of ^{137}Cs and ^{60}Co are used extensively in each room. Gamma-ray spectrometry was performed with a 3 inch-diameter spherical NaI (Tl) scintillation detector. The distance between the source and the detector ranged from 1.5m to 2.0m in the small room and from 1.5m to 3.0m in the large one. The source was contained in an irradiation apparatus with a lead collimator and placed on an open field at a height of 1.2m above the floor. A lead shadow shield was placed between the source and the detector to absorb the primary gamma radiation. Four types of irradiation were selected considering the combination of the collimator and the shadow shield as shown in Table 1 ((a), (b), (c) and (d)).

(2) Separation of pulse height spectrum and unfolding

Scattered radiations were divided into three components by their origins. The first is radiations scattered by the collimator (collimator-scattered radiation), the second by the room wall, floor and the table (room-scattered radiation), and the last by air (air-scattered radiation). Table 1 gives these components on the pulse height spectrum for each type of irradiation.

The pulse height spectrum of the room-scattered radiation was obtained by subtracting (c) from (d) and that from the primary radiation by subtracting (d) from (b). Subtracting the primary radiation and (c) from (a) gives the pulse height spectrum from the collimator-scattered radiation. The measured and

divided pulse height spectra were converted to energy spectra by unfolding procedures. The energy distribution of exposure was calculated by multiplying the energy spectra by the corresponding conversion coefficients.

(3) Monte Carlo calculation

Monte Carlo calculations of energy distribution were carried out to verify the experimental results using the EGS4 code[1]. The calculation conditions were modeled as being close to the experimental conditions.

RESULTS AND DISCUSSION

Figure 1 shows the spectral distributions of exposure for the two irradiation types of (a) and (b) in the small room with the ^{137}Cs source. A significant difference can be observed in the energy spectrum between the two irradiation types in the low energy region below 300keV. The result by the Monte Carlo simulation is also depicted for the irradiation type of (a). A good agreement is seen between the measurement and the calculation for energies below 600keV.

Figure 2 shows the collimator-scattered and the room-scattered components in the spectral distributions of exposure in the small room with the ^{137}Cs source. The photon energy of the collimator-scattered radiation is distributed near 662keV and that of the room-scattered is distributed over the energy range from 50keV to 350keV. The former component consists of radiations scattered at the collimator with small angles, and the latter component consists of radiations scattered at the room wall, floor and the table of instrument with large angles. The energy spectrum of each component closely relates with the scattering angle. The two scattered components resulted in a difference in the spectrum between two irradiation types of (a) and (b) in Fig.1.

Table 1 gives the ratio of exposure by scattered radiation to that by primary radiation in the small room for the two irradiation types of (a) and (b) with the two calibration sources. In the results of the ^{137}Cs source, the effect of scattered radiation was larger in (b) than in (a), whereas the inverse results are seen for the ^{60}Co source. It should therefore be noted that the use of collimator can give different characteristics in the effect of scattering between the ^{137}Cs source and the ^{60}Co source.

It is recommended that radiation survey instruments should be calibrated in terms of the ambient dose equivalent, $H^*(10)$, for strongly penetrating radiation[2]. $H^*(10)$ is usually calculated with multiplying the exposure by the conversion coefficient corresponding to the energy of the primary radiation. A more accurate $H^*(10)$ can be calculated with the spectral distribution of exposure in Fig.1. $H^*(10)$ values obtained from Fig. 1 are larger by 1.9% for the irradiation type of (a) and by 3.0% for the irradiation type of (b) than the value conventionally calculated.

CONCLUSION

The feature of energy spectra in the gamma-ray calibration fields was clarified by the measurement and the Monte Carlo simulation. The scattering feature depends significantly on the use of collimator. $H^*(10)$ values obtained in consideration of the energy spectrum are a little larger than the value conventionally calculated.

INTRODUCTION

Radiation streaming is one of the difficult problem in the radiation shielding. For photons, several works on the attenuation of photon dose through the streaming pass exists and the discussions were done by mainly considering geometrical effects. As a recent movement, connecting to the radioactive waste handling facilities and the reprocessing plants, the precise handling of gamma streaming has been required(1-3). In this paper, as a purpose of providing a benchmark data, the experiment and calculation for photon streaming of three bent labyrinth was performed.

EXPERIMENT

The experiment was done in the Cobalt-60 Irradiation Facility Room of the University of Tokyo(4). The irradiation room and labyrinth structure are shown in Fig.1. Gamma dose were measured by ionization chambers, which were used as a monitor and an absolute detector. Thermoluminescent dose meters (TLD) were also used as a dosimeters for maping of spatial gamma dose distribution. For several typical positions, a photon spectrometer of NaI(Tl) scintillator was used to get gamma spectra by doing spectral unfolding.

CALCULATION

The calculational method was a Monte Carlo method and MCNP4a code was applied. The photon cross section was Hubbell's one(5). The variation reduction techniques were used based on the discussion of scattering importance and the determinations of scattering region and angular selection. The used calculational geometry is shown in Fig.2. The detailed structure of concrete and iron lining of room wall etc. were included in the calculation.

RESULTS AND DISCUSSIONS

Some of the measured and calculated results are shown in Fig.3 and 4. The comparison between experiment and calculation was done. On the spatial dose attenuation along the axis of labyrinth, a completely good result of C/E was obtained in Fig.3, in spite of seven decades decrease of gamma dose. From the detailed discussions of dose distribution in the labyrinth, the followings were found. The first scattering wall has an important roll of streaming estimation, which is, for instance, a kind of shining source to the labyrinth.

For photon spectra, typical results are shown in Fig.4. In this figure, Co-60 high gamma was suddenly degraded in energy, and Compton and multiple scattered gamma made a soft spectrum. This procedure was excellently reproduced by the calculation. The uniform spectral field was fabricated after second bent. This means the conversion factors of the measured TLD to radiation dose should be differently used, depending on the position, for the reasons of sudden spectral change.

CONCLUSIONS

Co-60 photon streaming experiment through triple bent labyrinth was done and dose attenuation along the central axis and gamma spectral change were obtained. The analysis of the Monte Carlo calculation was followed and the important scattering region and angular section was clarified. This good estimation of C/E contributed to the establishment of the photon streaming analysis.

ON DETERMINATION OF THE OPTIMAL SAMPLE SIZE IN RADIATION CONTROL

INTRODUCTION

Among various statistical models used for fitting occupational and environmental radiation data the lognormal distribution is the most common one. Its application became especially wide after this model has been adopted by International Commission on Radiological Protection (1, 2). Natural and occupational gamma- radon- and ultraviolet exposure, rate of global radioactive fallout, radiation contamination of the atmosphere are very often distributed lognormally (3,4). Typical problems arising when using the lognormal distribution model for purposes of radiation control are: how to estimate the average level of radiation with a given accuracy (the problem of estimation of unknown true mean of the distribution) and how to determine the minimum number of measurements by which the calculated average contamination differs from the true mean value no more than a given value of error (the problem of the number of sampling which is enough for estimating the unknown true mean with a given accuracy). The method universally practised of estimating the mean value consist of finding the arithmetic mean of the set of N measured values. Although the arithmetic mean as a statistical estimator is unbiased, it not always provides minimum variance of the estimation. Naturally arithmetic mean often differs from the true mean if the statistical distribution differs from Gaussian normal distribution. Therefore, it is necessary to know the distribution of sample mean from a lognormal population, but unfortunately this distribution is not known. All that can be said is that for a large number of samples it has an asymptotically normal distribution behaviour (5). Early, an attempt was made to obtain this distribution using some simplifications (6, 7), but uncertainty of the results caused by these simplifications, is too difficult to assess. In the present paper the sampling distribution of the lognormal population was found without any simplification.

GENERAL CONSIDERATIONS

As shown by Finney (8) the best estimation x_{EST} of the true mean value $\bar{x}$ (unbiased and given minimum variance of the differences from the true mean) is given for lognormal distribution by the formula:

$$x_{EST} = \exp(\mu)\,\psi_N(S^2) \qquad (1)$$

where μ and S^2 are the sample mean and variance, respectively, and $\psi_N(S^2)$ is a correction function depending on the sample variance S^2 and on the sampling number N. In (9) was shown that the variable L, defined as the ratio of sample mean calculated using expression (1), to its true mean value

$$L = x_{EST} / \bar{x} \qquad (2)$$

can be considered as a function of two random independent variables ξ and U, where the first is distributed normally and the second has a χ^2 distribution. Taking this into account we can express the distribution of L by multiplication of the distributions of ξ and U. Therefore the probability of fulfilling the condition $L \leq L'$ can be expressed by the integral of this product in that region of ξ and U, where this condition is fulfilled:

$$P(L \le L') \sim \iint_{L \le L'} \varphi(\xi)\, \chi^2(U)\, d\xi\, dU \qquad (3)$$

CALCULATION OF THE DISTRIBUTION

In the paper (9) the distribution of L was calculated by method of statistical testing (Monte Carlo method). But this technique is not an appropriate method if it necessary to get the results with a high precision. That is why in this investigation analytical and numerical methods were used. It gave the possibility to improves considerably the accuracy of calculations.

We have determined the distribution of L by numerical calculation of the integral (3) using Gauss' method with 64 nodes and their corresponding weight coefficients. For each combination of the sample size N (varied from 2 to 200) and sample standard deviation S (varied from 0.1 to 2.0) values for the cumulative probability, corresponding to different relative deviation D, between the true mean value and its best estimation, given by

$$D = (x_{EST} - \bar{x}) / \bar{x} \qquad (4)$$

were calculated. The D values for which calculations were made varied from 0.1 to 1.0 with a step equal to 0.1. The probability F_- and F_+ for negative and positive deviations of x_{EST} from the true mean $\bar{x}$ was calculated separately. Thus, the obtained data give a possibility to determine the probability of underestimation as well as overestimation by using x_{EST} as estimator of the true mean $\bar{x}$. Also their sum $F = F_- + F_+$ were calculated.

RESULTS AND THEIR APPLICATION

The distribution of the sampling mean were calculated and then used for the determination of the number of the sample size N that is enough for the estimation of the unknown true mean with a given accuracy. A part of the results obtained are presented in Table 1. The required number of sampling N are given in the Table as a function of the empirical variance S^2 and the confidence level P. For estimation of N it is necessary first to calculate μ and S^2. Then for a given value of error D and for a desirable confidence level P in Table 1 the number of N can be found.

NEW DOSIMETRIC INSTRUMENTS BASED ON A RECOMBINATION CHAMBER

N. Golnik, M. Zielczyński and Z. Rusinowski

Institute of Atomic Energy, Świerk, Poland

INTRODUCTION

Three prototypes of new dosimetric devices were recently developed for different purposes of radiation protection in mixed radiation fields. The REM-2 high pressure tissue equivalent ionization chamber serves as the detector in all the systems described. The operation of the chamber under conditions of initial recombination of ions enables evaluation of radiation quality in radiation fields of unknown composition.

RECOMBINATION CHAMBER

The REM-2 chamber contains 25 tissue-equivalent electrodes, which form 12 parallel sections (1). The electrodes are 12 cm in diameter and 3 mm thick. The distance between electrodes is 7 mm. Total mass is equal to 6.5 kg. The effective wall thickness of the chamber is equivalent to about 1.8 cm of tissue and the gas cavity volume is of about 2000 cm^3. The chamber is usually filled, up to about 1 MPa, with a gas mixture consisting of methane and 5% of nitrogen. The central rod connects 12 collecting electrodes. The polarizing electrodes are connected alternately to one of two side rods and thus form two sets of electrodes. The chamber can be used in different operating modes. Two of them are important for the devices considered:

1) The *saturation* mode, when the voltage ensuring near saturation conditions (1200 V) is applied to both sets of the polarizing electrodes. This mode is used for determination of the ambient absorbed dose, $D^*(10)$ of mixed radiation. The sensitivity of the chamber in this mode is equal to 100 $fA/\mu Gy \cdot h^{-1}$.

2) The *differential* mode, when the saturation voltage is applied to one set of the polarizing electrodes and the recombination voltage of opposite polarity is applied to the another one. This mode ensures direct proportionality of the charge collected on the measuring electrodes to the ambient dose equivalent of mixed radiation of any composition. The sensitivity of the chamber operated in this mode equals to 2 $fA/\mu Sv \cdot h^{-1}$.

MICROCOMPUTER CONTROLLED DOSE EQUIVALENT RATE METER

It was shown earlier (1-3) that the ionization chamber of REM-2 type may serve as a good detector of $H^*(10)$, with weak dependence on neutron energy (see Fig. 1).

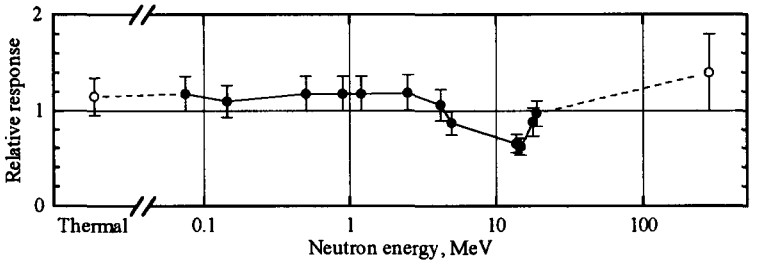

Figure 1. Relative response of the REM-2 recombination chamber to H*(10) versus neutron energy (1)

Now a laboratory set-up was designed (1), which can be considered as a prototype of a microcomputer controlled dose equivalent rate meter, based on a recombination principle and intended for routine use in radiation protection. The device consists of: a recombination chamber REM-2, a monitoring chamber, and an electronic circuit connected to a personal computer and controlled by special software for the measurement control, data collecting and on line processing.

The basic circuit of the device is shown in Fig. 2. Additionally to the main measuring channel with the REM-2 chamber it contains also the monitoring channel with the second chamber M. The monitoring is necessary if the radiation field is unsteady i.e. when the mean dose rate changes more than 1% during the time of measurements, which is of order of minutes.

The dose equivalent is proportional to the amount of recombination, so it can be determined by comparison the ionization currents collected at two different collecting voltages applied to the chamber. In our device the sequential application of the voltages to the chamber is controlled by the computer. The high-stability voltage unit U_{CTRL} is used as the voltage source. Its output voltage is exactly 200 times higher than the control voltage given by the analog output of the DAC computer card.

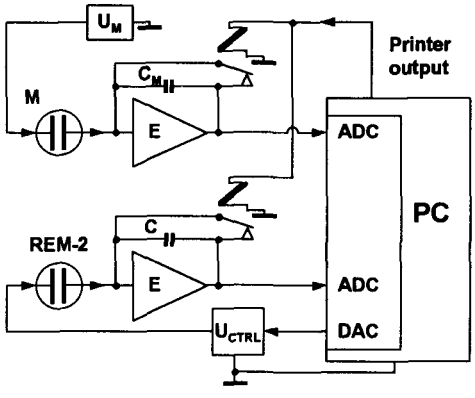

Figure 2. Principle circuit of the ambient dose equivalent meter (1).
REM-2 - recombination chamber, U_{CTRL} - externally controlled high voltage supply unit, E - electrometer, PC - personal computer with ADC/DAC card, M - monitor chamber, U_M - steady voltage unit.

Ionization current is measured by the electrometer E operated in an integrating mode. Ions collected on the electrodes of the chamber charge the integrating capacitor C during an appropriate time interval. The output voltages are measured using the analog input of the computer card (ADC). The 5 V signal from the printer output of the computer is used for discharging of the capacitor C and for shortening of the electrometer at the time of the voltage change-over.

The basic measuring range of the dose rate is from $\dot{D}^*(10) = 25$ μGy/h up to 250 μGy/h, and the whole range - from 1 μGy/h to 0.25 Gy/h, which corresponds to the values of $\dot{H}^*(10)$ from 1 μSv/h up to about 1 Sv/h. The accuracy of measured values of $\dot{D}^*(10)$ and of $\dot{H}^*(10)$ depends primarily on energy characteristic of recombination chamber and on dose rate. Usually, it is better than 10% for $\dot{D}^*(10)$ and better than 20% for $\dot{H}^*(10)$, in the basic range of dose rates. Accuracy of $\dot{H}^*(10)$ in the whole range of dose rates and energy covered by the device is within a factor of two.

SYSTEM FOR IN-FLIGHT AND LOW-LEVEL DOSIMETRY

The minimum detection level, stated in the technical manual of the REM-2 chamber is 10 μGy/h for the saturation mode and 500 μSv/h for the differential mode. These values do not satisfy the requirements of in-flight dosimetry. The problem can be solved by use of the self-contained measuring system (4), shortly described below (see Fig. 3).

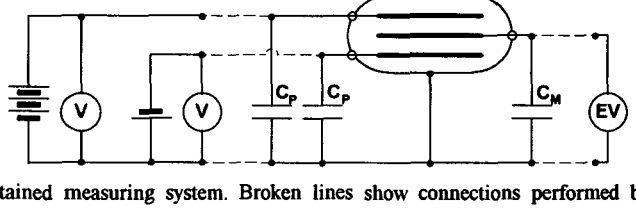

Figure 3. Self-contained measuring system. Broken lines show connections performed before and after irradiation.

The system consists of recombination chamber with three capacitors. The distortion charge is compensated by use of a special procedure for charging the supplying capacitors and for reading the voltage on the measuring capacitors. The signal measured by the system is proportional to $H^*(10)$.

Before the flight the capacitors C_P should be charged to the voltage U_{P0} at known temperature T_0. It was shown that the charge collected on the measuring capacity C_M does not depend on course of changes of the polarizing voltage and temperature and is proportional to the absorbed dose if the temperature of the chamber at the time of read out of the voltage on the measuring capacity is equal to T_0 and the voltage between the chamber electrodes is equal to U_{P0}. Therefore, after the flight the irradiated measuring system should be placed in laboratory conditions at the temperature T_0 for sufficiently long time. Then the polarizing capacity should be connected to a source of voltage, exactly equal to the initial voltage U_{P0}.

Provisional results indicate that our system gives possibility to measure the $H^*(10)$ of order of some μSv with uncertainty ca. 25% in any field of penetration radiation, with an integration time up to some days. Investigations of the performance characteristics of the system are under progress.

ANALOG METER OF QUALITY FACTOR

In this device (5), the modified recombination chamber, denoted REM-2Q, serves as a detector. The modification lies in the change of the interelectrode spacing such that two parts of the differential recombination chamber are not equal: the ratio of their volumes equals to about 0.9. The device enables direct determination of the radiation quality factor (QF) in mixed radiation fields.

The operational principle of the QF-meter is shown in Fig. 4.

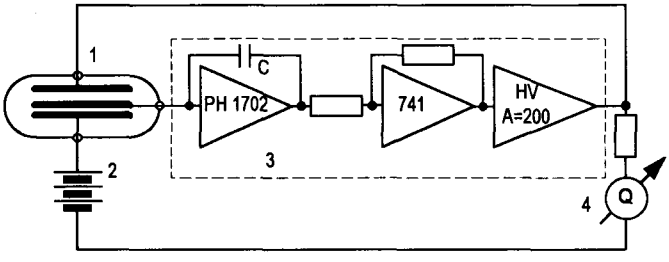

Figure 4. Functional circuit of the QF-meter: 1 - recombination chamber; 2 - high voltage source; 3 - high voltage electrometrical amplifier; 4 - voltmeter calibrated in units of quality factor.

When the chamber is placed in a radiation field, almost all the positive ions created in the smaller volume of the chamber, are collected to the middle electrode and charge the capacity C. This causes an increase of the negative voltage at the output of the high voltage amplifier. This voltage is applied to the electrode supplying the larger volume of the chamber. Therefore some negative ions from the larger volume can also reach the collecting electrode, reducing the effective current charging capacity C. An equilibrium voltage of the upper electrode is established when the resulting ionization current through the collecting electrode is equal to zero, i.e. when the ratio of the ion collection efficiencies in the larger and smaller parts of the chamber is equal to the volume ratio of the chamber. The recombination chamber works under conditions of local recombination of ions, so the value of the equilibrium voltage depends on LET and is approximately proportional to the radiation quality factor, as defined in ICRP Report 21.

ABSTRACT

The characteristics of four extrapolation chambers designed and constructed at the Calibration Laboratory of São Paulo were studied in this work. The relationship between the collecting electrode size and the entrance window density with the estimated absorbed dose-rate was investigated. Comparison with the Amersham calibration certificate indicate surface dose-rates agreement within 5%.

INTRODUCTION

^{90}Sr applicators have been successfully used for the treatment of superficial lesions. Different calibration techniques such as TLD, radiochromic dye films, fixed volume ionization chambers and scintillators have been reported (1,2). Nevertheless, significant discrepancies in the calibration of this sources are still observed (3).

At the Calibration Laboratory of São Paulo, four extrapolation chambers were projected and constructed with the aim of calibrate dermatological applicators. In this work, the influence of several parameters including the choice of the collecting electrode diameter and the entrance window density in the measurements of absorbed dose-rate was investigated. The absorbed dose rate of a $^{90}Sr + ^{90}Y$ beta radiation applicator was obtained using the different chambers, and the results were compared.

MATERIAL AND METHODS

The developed extrapolation chambers have a collecting electrode and a guard-ring of graphite. The chamber bodies are of Lucite and the entrance window of aluminized Mylar. Lucite was also used as insulating material between the electrode collector and the guard-ring . The main characteristics of the chambers are presented in Table1.

Table 1 Characteristics of the IPEN Extrapolation Chambers

Chamber	Collecting Electrode Diameter (mm)	Entrance Window Superficial Density ($mg.cm^{-2}$)	Effective Area (mm)
C1	10	0.84	78.5
C2	10	6.42	78.5
C3	3	6.42	8.30
C4	3	0.84	8.30

A Keithley 617 electrometer was used as measurement assembly. The applicator of the present study was from Amersham, Model SIQ, containing 1480MBq (1968) of $^{90}Sr + ^{90}Y$. The absorbed dose-rate in tissue ($7mg.cm^{-2}$) quoted by the manufacturer on 8.11.68 and corrected for the decay time to the measurement day and for the recent values of $\overline{W}/e$ and S_{air}^{tissue} is 31.01 $mGy.s^{-1}$.

RESULTS

a. Transmission Factors

The transmission factors were obtained covering the chambers with the polyethylene therephthalate (Hostaphan) foils and Plexigles plates with different thicknesses. The measurements were realized with the $^{90}Sr + ^{90}Y$ applicator placed as near as possible of the chambers and also at a distance of 1,0cm. The maximum relative standard deviation in these measurements was 1%.

The transmission factors determined for typical values of the tissue equivalent material with the chamber C4 are presented in Table 2. Similar results were verified with the other chambers; a comparison between the obtained transmission factors showed a difference lower than 1%. The results of Table 2 also indicate that, for a null source-detector distance (a=0), the effect of adding 7mg.cm^{-2} of plastic to the extrapolation chambers has been found to lower the measured dose rate by about 5%.

Table 2. Transmission factors for beta radiation $^{90}Sr + ^{90}Y$
a: Chamber C4-source distance

Tissue Thickness mm	Superficial Density mg.cm^{-2}	a = 0	a = 1cm
0	0	1.000	1.000
0,02	2	0.984	1.002
0,04	4	0.972	1.008
0,05	5	0.968	1.010
0,07	7	0.956	1.012
0,10	10	0.936	1.016
0,20	20	0.888	1.020
0,50	50	0.748	0.992
1,00	100	0.554	0.816

b. Absorbed Dose-Rates to Tissue

The absorbed dose rates to tissue were determined from current measurements at air gaps from 0.10 to 0.30mm. The measurements were realized with the applicator positioned as near as possible from the chambers. The extrapolation curves were obtained measuring the ionization current for both potential polarities applied to the chambers and plotting the average of this values as a function of the chamber depth. A linear function was fitted to the current-versus-air-gap data and the slope was used to determine the average surface-absorbed-dose-rate over the central area of the source. A constant potential gradient of 100V/mm was employed for all air gaps.

The absorbed dose rate to tissue in Gy/s is given by (3):

$$\dot{D}_z = \frac{(\overline{W}/e).S_{air}^{tissue}}{\rho_0 . A}\left(\frac{\Delta I_c}{\Delta d}\right) \qquad (1)$$

where $\dot{D}_z$ is the absorbed-dose rate to tissue at depth z, $\overline{W}/e$ is the average energy required to produce an ion pair in dry air (33.97 J/C), S_{air}^{tissue} is the ratio of the average mass stopping power of tissue to air (1.12), ρ_o is the density of dry air at reference conditions of 22 °C and 101.3kPa, A is the area of the collecting electrode and $\left(\frac{\Delta I_c}{\Delta d}\right)$ is the fitted slope of the corrected current versus air gap function. The transmission factors were applied in the determination of the absorbed-dose rate at 7mg.cm^{-2}.

The uncertainties in this procedure include the measured $(\frac{\Delta I_c}{\Delta d})$ ratio as well as the uncertainties in the chosen values for the average energy per ion pair, the stopping power ratios and other correction factors. The overall uncertainties of the absorbed dose rates were estimated to be approximately 13%. Table 3 presents the obtained results of the four chambers.

Table 3. Absorbed dose rate to tissue at 7mg.cm^{-2}

Chamber	$\dot{D}_m$ (mGy.s^{-1})	Δ (%)
C1	30.91	0.3
C2	30.85	0.5
C3	30.18	2.7
C4	30.98	0.1

where:

$\dot{D}_m$: absorbed dose rate to tissue at 7mg.cm^{-2} obtained experimentally;

Δ: percentual difference between $\dot{D}_m$ and $\dot{D}_0$ for the null distance.

Comparing the absorbed dose rates to tissue, determined using the four chambers with those of the source calibration certificate, corrected for the more recent values of $\overline{W}/e$ and S_{air}^{tissue}, a maximum percentual difference of approximately 2.7 % was verified.

CONCLUSION

The results show that the dose-rate determination using the developed extrapolation chambers are in agreement with the Amersham evaluations (corrected for the recent constants) with the overall uncertainties. In this study, the influence of the collecting electrode size of the chambers was negligible. However, in this case all chambers used an electrode smaller than the source size. The comparison between the results obtained with the four chambers indicate a percentual difference lower than 3%, showing a good agreement. From the experiments, it was also verified that the dose rate for tissue irradiation falls off by approximately 5% between the surface and a depth of 7mg.cm^{-2}.

ABSTRACT (See instructions overleaf)

For the purpose of solving electron transport problems by Monte Carlo simulation, a computer codes package was develloped (ELSIM). ELSIM is based on condensed history Monte Carlo algorithm. In order to get reliable results over a wide range of electrons energies, a variety of electron transport techniques was implemented like: Molière and Goudsmit-Saunderson multiscatter angle distributions, Blunk-Leisegang multiscatter energy distribution, sampling of electron-electron and bremsstrahlung individual interactions. Also are included path-length and lateral displacement corrections algorithms and a module for computing collision, radiative and total restricted stopping powers and ranges of electrons. Each component was tested and rezults obtained with different techniques was compared. Also is presented the solving of some typical electron transport problems which apear in radioprotection and dosimetry.

A MICRODOSIMETRIC INTERPRETATION OF LET-DEPENDENT RADIATION EFFECTS *

W. Schöner, N. Vana, M. Fugger and E. Pohn
Atominstitute of the Austrian Universities,
A-1020 Wien, Schüttelstraße 115

ABSTRACT

LET dependent effects in LiF TL-dosemeters seem to be similar to effects observed in biological systems. Analyses of the glowcurves of LiF- TLDs reveal a significant dependence of the peak hight ratios on the linear energy transfer (LET) of absorbed radiation. Several types of thermoluminescence dosemeters (TLDs) were calibrated in beams of heavy charged particles with various energies. In order to simulate the high energy densities around high LET particle tracks the dose response of the TLDs was recorded up to 40 kGy using Sr-90/Y-90 beta irradiation. A track structure model was applied in order to calculate the radial energy density gradients for the heavy charged particles. The energy density distribution around particle tracks was foulded with the dose characteristics of the dominant peak (200°C) as well as with the dose characteristics of the high temperature peaks (230-350°C). The applied model describes the decreasing TL-efficiency as well as the increasing peak ratios with increasing LET of absorbed radiation. The peak height ratios of LiF-dosemeter material is determined by the microdosimetric energy density distribution and may be used for determination of average LET respectively the mean specific energy density in mixed radiation fields. The biological relevance of these effects will be discussed.

INTRODUCTION

In former investigations a method of LET determination with TLDs was developed. This method was approached to measure the average LET in complex mixed radiation fields like in spacecrafts and aircrafts. The method utilizes the change of the peak height ratios in glowcurves from LiF thermoluminescent dosemeters. Irradiations of different types of TLDs were carried out in fields of different high energetic heavy ions as well as with alpha particles, neutrons, beta and gamma radiation and in mixed fields. It was found, that the ratio of the high temperature peaks (peak 6, 7) to peak 5 increases steady with increasing LET of absorbed radiation. This effect was calibrated and used for determination of the average LET of space radiation (1). It is common known, that the LET is not the optimal parameter to describe the biological effectiveness of radiation. For this reason in microdosimetry the LET is replaced by statistical parameters like the lineal energy or the distributions of energy density or the specific energy. Of course, from the point of view of microdosimetry, „LET"-dependent effects in TLDs are also a result of the microdosimetric distribution of energy density. For a better undestanding of these effects and in order to use TLDs as micro-dosemeters we started to investigate the microdosimetric properties of TLDs. For this purpose we applied a model of track structure theory.

SCIENTIFIC METHODS

Track Structure Theory was developed in order to understand the behaviour of different detectors as well as the sensitivity of biological material in connection with the absorption of radiation with high LET (2). This theory is based on the assumption, that the macroscopic parameters of detectors (efficiency, dose response etc.) or the damage in biological material is determined by the microdosimetric distribution of energy density within the tracks of heavy charged particles (HCP). In contradiction to the concept of LET this theory takes the radial distribution of energy density around the track of a charged particle into account. Several authors have applied this theory on thermoluminescent dosemeters in order to calculate their efficiency against HCP (3).

Zimmerman suggested a model to calculate the alpha efficiency of TL-materials (4). He foulded the dose dependent efficiency, measured after absorption of sparely ionizing beta radiation of several TL-materials, with the calculated energy density distribution around the tracks of alpha particles and integrated over the radius of the track. This integral gives the TL-response per unit track length. This has to be compared with the TL-response for the equal absorbed energy caused by a low dose of beta radiation. The ratio of these two responses is the relative efficiency of the material against alpha radiation. With this model Zimmerman obtained good theoretical results for the alpha efficiency of various TL-phosphors. We followed the suggestions from Zimmerman but used a more sophisticated track structure model introduced by Zhang (5). The energy density around particle tracks, calculated using this algorithm, was numerically integrated under consideration of sensitive site diameters to get the average grain dose suggested by Hansen (6). A computer code was developed for the calculation of the average grain dose distribution and foulding with the measured, dose-dependent beta efficiencies of TL-crystals, for various projectile ions. With this computer code it is possible, to do calculations for various diameters of the sensitive sites.

EXPERIMENTAL

Irradiation of various types of dosemeters with high energetic heavy ions (HCPs) were carried out at the accelerator center in Dubna. For irradiation beams of 5.12 GeV oxygen ions, 5.95 GeV and 5.23 GeV fluorine-19 ions were used.

* Work supported by the Austrian Society for Aerospace Medicine (ASM)

The LET-spectrum in the fluorine ion beams was changed by using different absorber thicknesses varying from 0 to 9.53 g/cm^2 and the LET of fluorine ions was shifted from 30 to 80 keV/µm in tissue. The LET spectrum during irradiation was recorded by a semiconducter detector. To get additional calibration points in a lower LET region, carbon-12 ions with different energies (150, 300 and 600 MeV/nuc) were used with a LET of 9.1, 12.5 and 19.4 keV/µm. The results of irradiation with different LET-radiation are shown in fig. 1. The dosemeters were irradiated with low doses in the linear range far below 10 Gy. To line out the differences in the high temperature range, the glow curves were normalized to peak 5 at 200 °C. In order to measure the dose response with sparely ionizing radiation the dosemeters were irradiated with a Sr-90/Y-90 beta source. The dose characteristic of peak 5, 6 and 7 were recorded up to 40 kGy. Some glowcurves after high dose beta irradiation are shown in fig.2. Glowcurves were normalized to peak 5.

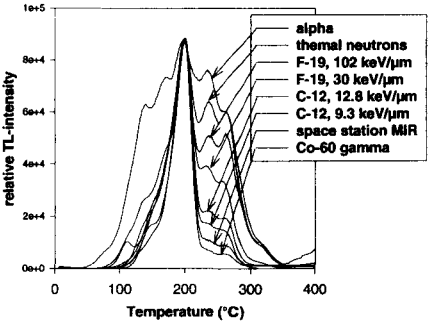

Fig.1: Glowcurves from TLD-600 after absorption of radiation with different LET (low dose)

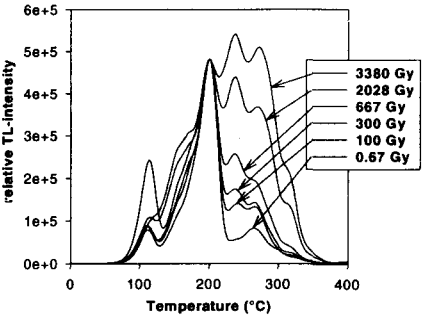

Fig.2: Glowkurves from TLD-600 after absorption of high dose beta radiation

RESULTS

A comparison of fig.2 with fig.1 lines out how similar the glow curves look in the high temperature region, measured after absorption of low dose high LET radiation and high dose beta irradiation respectively. This fact leads to the assumption, that the microdosimetric distribution of energy density determines the shape of the glowcurve and it is possible to use this information in order to obtain important microdosimetric parameters.

Therfore we started to check the assumption, that only the energy density distribution determines the efficiency of the peaks in the glow curve, with track structure calculations. For this reason the dose dependent efficiency of the crystals was fitted in order to get a function for calculation. The plot of the measured relative efficiencies of the peaks 5, 6 and 7 of TLD-600 against dose (fig.3) shows, that after reaching the maximum of supralinearity at about 300 Gy the efficiency decreases rapidly.

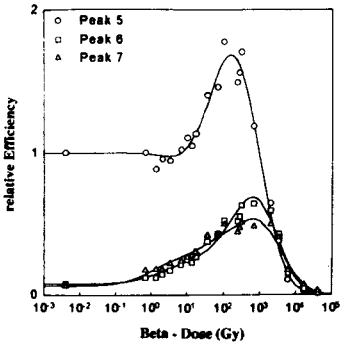

Fig.3: Measured dose dependent efficiencies for peak 5, 6, and 7 after beta irradiation. The least square fit was used for calculation.

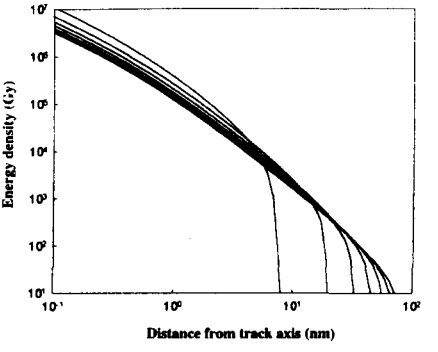

Fig 4: Calculated radial energy density in an alpha track. The distribution of energy density was calculated in 7 layers from the surface to the end of the range.

The efficiencies of the peaks 6 and 7 increase up to 1000 Gy and start to decrease above about 3000 Gy. The efficiency of peak 6 decreases more rapidly than the efficiency of peak 7. Because the peaks are strongly overlapping and deconvolution is not very reproducible, peak maximum was choosen as parameter. The next step was to calculate the energy density around particle tracks. We started to test our model with Am-241 alpha irradiated chips. Because the LET of 4.5 MeV alpha particles increases within the range, calculation was carried out for 7 layers within the range. Fig. 4 shows the change of calculated track structure. The track diameter is decreasing from about 120 nm in the first

layer to 14 nm in layer 7. The energy density in the center of the track is increasing towards Bragg-peak. Grain dose distribution was calculated in each layer and foulded with the beta efficiency. Target radius a_0 was varied in the calculation from 5 to 30 nm. The best correspondence between observed and calculated values was found for target radii of 15 nm (peak 5 and peak 6) and 11 nm for peak 7. Table 1 shows the excellent agreement between measured and calculated peak efficiencies.

Table 1: Measured and calculated peak efficiencies of TLD-600 after alpha irradiation:

Dosemeter	Peak number	Measured efficiency	Taget radius a_0 (nm)	Calculated efficiency
TLD-600	5	0.125	15	0.124
TLD-600	6	0.093	15	0.094
TLD-600	7	0.070	11	0.070

The target radii (radius of the sensitive site) obtained from this experiment were used for further calculations. Table 2 shows the relative peak efficiencies measured after irradiation with different high energetic heavy charged particles (HCP) in comparison with the results from track structure calculations.

Table 2: Measured and calculated relative peak ratios after HCP irradiation:

Irradiation			Peak - ratios, TLD-600			
Particle	Energy	LET	Peak 6/Peak5		Peak 7/Peak5	
	(MeV)	(keV/µm tiss)	measured	calculated	measured	calculated
C-12	1800	19.4	0.42	0.25	0.42	0.21
C-12	3600	12.5	0.25	0.21	0.22	0.18
C-12	7200	9.1	0.19	0.18	0.16	0.17
F-19	1235	80	0.46	0.30	0.46	0.24
F-19	2280	50	0.43	0.28	0.40	0.23
F-19	5225	30	0.39	0.25	0.36	0.21

Although our calculations for the alpha efficiencies of single peaks lead to very good results in agreement with measured and reported values of $\eta_{\alpha\beta}$, the model is underestimating the efficiencies after absorption of high energetic ions. Nevertheless the model describes the relative increase of the high temperature peaks (peak 6 and 7) with increasing LET of absorbed radiation.

DISCUSSION

The excellent agreement of experimental results and results of the applied track structure model confirm, that the peak ratios in glowcurves from LiF-TLDs are determined by the microdosimetric distribution of the energy density. For high energetic ions the model does not describe the absolute values of peak efficiencies sufficiently, but qualitatively the increase of peak ratios with increasing local energy density is described. The deviation of the calculated results from the experiments with high energetic ions is caused by at least two reasons:

1. The model used for the calculation of energy density in the particle tracks is neglecting the angel distribution of delta electrons and is assuming that all electrons leave the track normal to the track axis. This leads to greater track diameters in the model. This error is especially high for high energetic particles.
2. The model is assuming homogeneous tracks. This is more or less true for low energy alpha tracks. For high energetic particles the statistical nature of energy deposition has to be taken into account. High energetic delta electrons generate tracks itselves causing an energy deposition with a treelike shape. For this reason the homogeneous discription causes considerable errors.

Therefore improvements of the model are intended by the intoduction of statistical models for particle tracks. Furthermore a better understanding of the microdosimetric properties of TLDs and a consequent substitution of macroscopic parameters (like LET) by microdosimetric values (like specific energy) opens the opportunity to use TLDs as micro-dosemeters in order to get important information for a better understanding of biological effects after absorption of different kinds of radiation.

ABSTRACT (See instructions overleaf)

Monte Carlo code AVALAN was developed to simulate an electron avalanche development under different operating conditions namely different counter geometries, gas pressures and electric fields. The first simulations were performed in low pressure proportional counters filled with methane gas. They allowed us to study all temporal and space aspects of the electron avalanche development. The dependence of gas gain, radial and time extend of the avalanche on gas pressure are described. We explain our results by the existence of *seeding* region in the avalanche where a relatively small number of electrons is created. Each of these electrons gives subsequently rise to a *partial* avalanche in the proper avalanche region. Results of the simulations are compared to measured data and to Boltzman equation results. The effects of the electron-molecule cross-sections uncertainties on the final results are discussed.

CALCULATION OF PHOTON DOSE FROM POSITRON SOURCES

Khamis A. Nahdi [1,2], Manfred Tschurlovits[1]
[1]Atominstitute of Austrian Universities, A-1020 Vienna, Austria
[2]present address: Jeddah, Saudi Arabia

Abstract
This paper reports the results of detailed calculations of the different contributions to the total dose, where bremsstrahlung, annihilation and decay are considered. The calculations are carried for some ten radionuclides and for radiation protection purposes . The results were obtained by using analytical methods and Monte-Carlo techniquues. In order to have a presentation being consistent with gamma- emitting radionuclides, the results are given in terms of kerma rate constant in air of a shielded positron source.

INTRODUCTION

Positron emitting sources are becoming increasingly important in many applications of radiation. Sources are positron emitting radionuclides, positron beams, and induced as contamination at accelerators. Positron emitting radionuclides are used in nuclear medicine, e.g. positron emission tomography (PET) or in scientific applications. They are produced by accelerators (e.g. N-15(p,n)0-15 or by reactors (e.g.Cu-63(n,γ)Cu-64.
Since these sources both emit and produce some different kinds of radiation (positrons, bremsstrahlung, annihilation radiation), they contribute in different forms to all problems interesting in radiation protection, where dose assessment and shielding are the most important.

In order to make quantitative assessments, some aspects will considered in turn. The beta spectrum of the radionuclide were recalculated. Since detailed knowledge of positron interaction with matter is required to calculate quantities needed for shielding and dosimetry.
The work was separated into the following subchapters: calculation of positron spectra, assessment of the required absorber thickness, annihilation and bremsstrahlung production in the absorber leading to photon spectra for moneenergetic positrons. Radionuclide spectra, taking into account decay photons, are used for dose rate constant calculation

CALCULATION OF PHOTON PRODUCTION

Photons are produced in the absorber while the positron is slowing down via bremsstrahlung and annihilation processes. In addition, there are the decay photons in many of positron emitting nuclides, which are characteristic of the individual nuclide. From the Monte Carlo calculations, Fig. 2 shows as an example the relative intensity of the bremsstrahlung and the annihilation photons from a 1MeV positron beam with the respect to the thickness of the aluminium slabs.

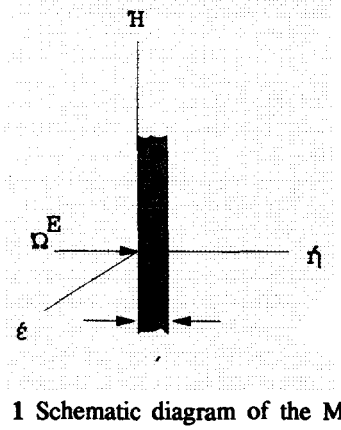

Fig. 1 Schematic diagram of the Monte Carlo simulation in which a positron beam is normally incident on the foil along the Z-axis.

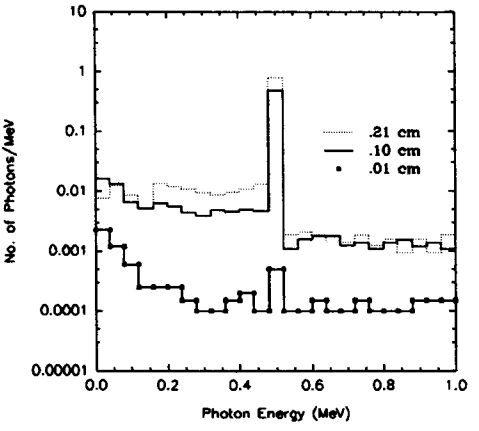

Fig. 2 Transmitted spectra of bremsstrahlung and annihilation photons from 1 MeV positrons on aluminium foils 0.1, 1.0, 2.1 mm thick.

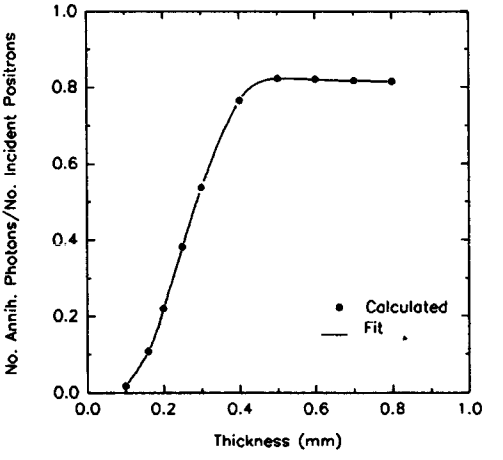

Fig. 3 Number of annihilation photons per incident positron from Cu-64 produced in aluminium foils.

PRODUCTION OF ANNIHILATION PHOTONS

The production of annihilation photons increases with the increase of the absorber thickness reaching a maximum when the thickness is equal to or more than the range of the maximum energy of the positrons, as shown in Fig 3 for Cu-64 source incident on aluminium absorber.

PRODUCTION OF BREMSSTRAHLUNG PHOTONS

As the production of the bremsstrahlung photons increases with the increase of the atomic number, and since only low Z-material is of concern here for the shielding of the positron emitting nuclides, it is expected that the contribution from bremsstrahlung would be minimal. However it is instructive to see how much this contribution is, especially that most of the work in the literature dealt with electrons only. Calculations of the bremsstrahlung production were first done for beams of 1, 2, and 3 MeV normally incident on aluminium slabs of different thicknesses, to obtain the

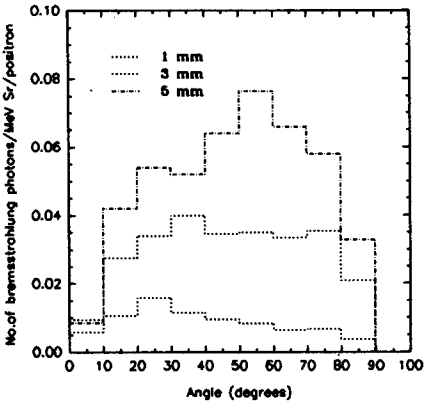

Fig. 4 Transmitted angular distribution of bremsstrahlung photons produced by 2 MeV positrons in aluminium foils.

average energy and number of photons produced per incident positron. For bremsstrahlung production in aluminium from a 1 MeV positron beam, there is a preference for transmission in the forward direction between 20° and 30° for a slab of 0.01 cm thickness. Increasing the thickness by a factor of 10, the magnitude of the spectrum increases by more than a factor of 2, and maximum direction is in 50°- 60°. Further increase of the thickness of the slab by a factor of 2, increases the bremsstrahlung production by about a factor of 2, and the maximum direction is shifted to 60°- 70°, but in a broader direction. In the case of the 3 MeV positron beam, the bremsstrahlung photons are transmitted in the forward direction with maximum between 10° and 20° when the thickness is 0.05 and 0.10 cm. The increase in the maximum is about a factor of 2 between 0.05 and 0.10 cm. With the increase in thickness the scattering increases and the photons leave the slab with higher probability of larger angles as can be seen in Fig. 4.

TOTAL PHOTON SPECTRA

As an example, transmitted spectrum of photons from a positron emitting nuclide is given below in Fig. 5 for Na-22, incident on aluminium slab whose thickness was equal to the range of the respective nuclide. It is clear from the spectra that the bremsstrahlung is low energy photons. These bremsstrahlung photons are comparable to the 0.511 MeV annihilation photons in number.

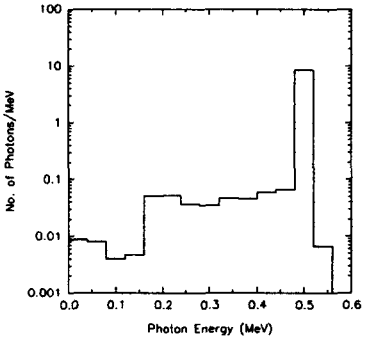

Fig. 5 Transmitted photon spectrum of Na-22 through aluminium foil whose thickness is equal to the range of the endpoint energy of Na-22.

DOSE RATE CONSTANT

The results of the calculation are compiled in the following table.

NUCLIDE	Air kerma rate constant (mGy m²/GBq hr)			
	Decay	Annih.	Brems.	TOTAL
C-11	0	2.309E-1	3.587E-4	2.313E-1

EVALUATION OF THE W-VALUE OF VARIOUS GASES INCLUDING He-3 AND H-2 USING TRITIUM BETA PARTICULER

Yoichi Sakuma[1] and Hiroo Sato[2]

[1] National Institute for Fusion Science, Nagoya 464-01, Japan
[2] Aloca Co., Ltd., Ohme 198, Japan

1. Introduction

A new technique was studied and developed to aim at precise determination of W-values[1-4] of various gases using unit litter ionization chambers and tritium, which emits low energy β-ray. What was studied and developed :
(1) Ionization chamber and measuring gases filling system were designed and constructed. Characteristics of the ionization chambers were observed.
(2) Wall effect was examined.
(3) Effects of hydrogen as impurity on the ionization current were examined.
(4) The W-values of $^1H_2$, $^2H_2$, ^3He, ^4He, N_2 and Ar were respectively estimated.

2. Experimental Method

2.1. Ionization Chamber

The cross-sectional view of the measuring ionization chamber is shown in Fig.1. The chamber consisted of a stainless steel cylindrical high voltage supplying electrode and a collecting electrode, which was set on the central axis of the cylinder. The two electrodes were air tightly connected by pure alumina insulator with a guard ring. The inside of the cylindrical chamber was well polished like a mirror finish. The ionization chamber was electrically isolated from the filling system by the insulator tube.

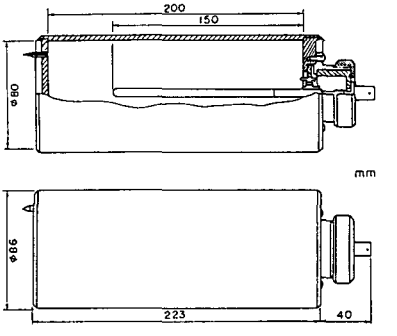

Fig.1 Unit litter ionization chamber

2.2. Measuring System

The block diagram of a measuring system is shown in Fig.2. Current measurements were made of a vibrating-reed electrometer. The ionization chamber electrodes were joined to the preamplifier of the vibrating-reed electrometer with a flexible shielded co-axial cable. The guard ring was operated at the level of the ground potential. A high voltage source supplied negative voltage from zero to 5kV to the cylindrical electrode.

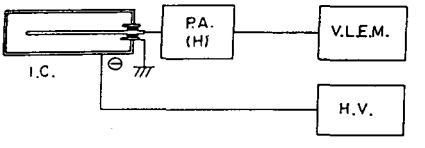

Fig.2 Block diagram of measuring system

2.3. Gas Filling System

The schematic diagram of the gas filling system is shown in Fig.3. This system was used for supply, recovery and storage of various gases and tritium gas. The system composed of stainless tubing, tube fittings and metal bellows valves, was joined to a vacuum pumping system. The gas filling system was evacuated routinely below 3×10^{-7}mbar. Tritium gas was supplied from a glass ampoule with a breakable seal. Tritium gas was stored into four unit litter vessels. Then, tritium in the vessel was conducted into an empty ionization chamber at first. Measuring gas was added to it.

2.4. Gamma-Ray Irradiation

The γ -ray irradiation facility, which has 89TBq of ^{60}Co, belongs to Nagoya University. The ionization chambers were installed at a distance of 2.0m from the center of the ^{60}Co source.

2.5. Experimental Procedure

Saturation curves of various gases filled in the ionization chambers were measured. Tritium filled in the vessel was introduced to four ionization chambers at the same pressure to repeat other gases in the same procedure. Then, $^{1}H_2$, $^{2}H_2$, ^{3}He, ^{4}He, N_2 and Ar were added into the each ionization chamber at 5×10^{3}mbar respectively, afterwards, negative potential was applied to the cylindrical electrode and elevated stepwise. The collection current was measured out in each chamber. Measurements of the wall effect of various gases were carried out. In the same tritium content, ionization currents were measured by stepwise increased pressure and various gases respectively. Used tritium was provided a mixture of $^{1}H_2$ and $^{3}H_2$. In order to examine impurity effect in the gases used in the chambers, ionization currents of the chambers filled with mixed gases, $N_2 + {}^{1}H_2$ and $Ar + {}^{1}H_2$, were measured in the ^{60}Co γ -ray field.

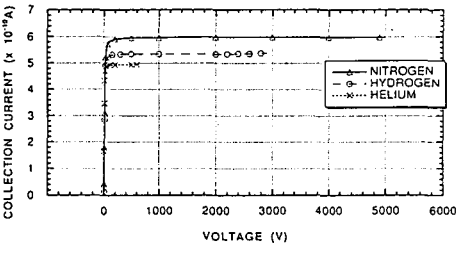

Fig.4 Saturation curves

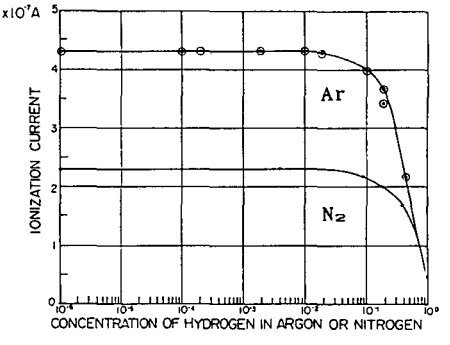

Fig.5 Ionization current versus concentration of H_2 in N_2 & Ar

3. Results and Discussion

3.1. Saturation Characteristics

The saturation-currents on N_2, H_2 and He are shown in Fig.4. The voltage ranges of the flat saturation-currents on N_2, H_2 and He were 5×10^2 to 4.9×10^3, 2.0×10^2 to 2.8×10^3 and 5.0×10 to 6.0×10^2V at 5.0×10^3mbar respectively. The ionization chambers were operated at the middle voltage of each range.

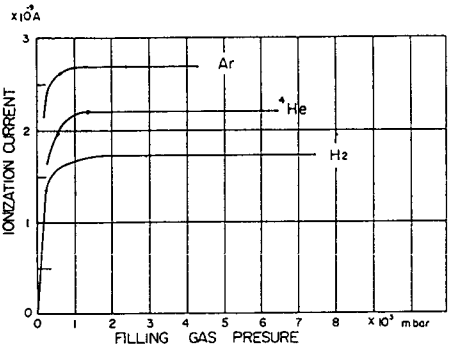

Fig.6 Ionization current versus filling gas pressure

3.2. Effects of Impurity Hydrogen

The ionization currents versus to hydrogen concentration in argon or nitrogen by γ -ray irradiation are shown in Fig.5. The ionization currents were unaffected below 1% of hydrogen mixture. Therefore, each character of the ionization chamber was unaffected to add $^1H_2$ & $^3H_2$ below 10^{-2}% in measuring gases.

3.3. Wall Effect

Results of the measurement of the wall effect are shown Fig.6. The ionization current decreased as low as to the pressure of the measuring gas. The decreased current was mainly occurred by absorption of tritium β-ray on the chamber wall. Though the wall absorption was decreased at high pressure. Above 1×10^3mbar, the ionization currents were saturated. The wall effect was neglected above the 2×10^3mbar.

From above results, the W-values of the various gases will be obtained by the techniques easily. The W-values of N_2, $^1H_2$ and He were estimated 34.6, 37.0 and 43.5eV respectively.

4. Conclusions

From the above experimental results, it was concluded that the tritium adding method was satisfactorily used to measure the ionization current in the various gases to determine the W-values. The conclusions about the present studies are the followings;

1) Ionization chambers were designed and manufactured.
2) A metallic gas filling system was constructed.
3) Saturation-currents on N_2, H_2 and He were flat over a wide voltage range.
4) When the gases contained hydrogen below 1%, the ionization current did not change, in the case of γ -ray irradiation.
5) Wall effect was neglected at pressure above 2×10^3mbar.
6) W-values of N_2, $^1H_2$ and He were obtained and the value of other gases will be reported at the IRPA9.

MAJOR SCIENTIFIC TOPIC NUMBER 3.2 (see page 7)

ABSTRACT (See instructions overleaf)

Spectral distributions of an ambient dose equivalent for different environmental radiation fields were modelled using a Monte Carlo method. The radiation fields considered include both the natural as well as the man-made fields. Further, conversion factors from the air kerma into the ambient dose equivalent, H^*/K_a, were calculated for the fields. These were compared with experimental values of conversion factors obtained from *in-situ* gamma spectrometry. Variations of H^*/K_a and their influence on dosimetry of the environmental radiation fields will be discussed.

SEPARATION OF SR/Y-90 AND TL-204 BETA PARTICLES WITH MODIFIED TELEDYNE P-300-AS BADGE TO MEET THE REVISED ANSI N13.11(1993) REQUIREMENTS

Jang-Lyul Kim, Si-Young Chang and Bong-Hwan Kim
Korea Atomic Energy Research Institute, Taejon, Korea

ABSTRACT

This paper describes a method to separate Sr/Y-90 and Tl-204 beta particles by a simple modification of Teledyne P-300-AS TLD badge system, which is currently used in the Korea Atomic Energy Research Institute for personnel dosimetry, by attaching small ^{7}LiF disk to the back-up open window filter area(A5). This modified badge system can evaluate the delivered dose from both Sr/Y-90 and Tl-204 within ±5% error bound even in the randomly selected irradiation condition

INTRODUCTION

The response of many personnel thermoluminescence dosimeters is extremely energy dependent when they are used in beta particle fields of somewhat significant levels in many working places. This energy dependence is generally taken into account by considering the response of the TL dosimeters as a function of the beta energy, and for this reason, low energy Tl-204 beta source was newly added in personnel dosimeter performance test criteria in addition to high energy Sr/Y-90 beta source in the revised ANSI N13.11(1). Both sources are recommended for use as reference beta sources by ISO Standards 6980(2).

In most cases the dosimeters for measuring beta doses use only one filter area, generally called open-window area, and usually evaluate beta doses by gross amounts of energy response not by separating their energies. To separate beta particles by energies, it is possible to improve the badge design by adding one more supplementary dosimeter with different filter in the badge case.

The Teledyne P-300-AS TL dosimeter badge system, used in the KAERI for personnel dosimetry, could not separately evaluate the beta doses from Sr/Y-90 and Tl-204 beta particles because this badge had an originally thick beta shield area(A2) enough to stop all the weakly penetrating beta particles. If we evaluate the beta dose only using open window filter area(A1) for beta particle mixtures, it would result in underestimation for Tl-204 beta dose because of the shielding effect by 7 mg/cm^2 mylar on the open window filter area(A1).

So, the purpose of this paper is to describe a method to separate Sr/Y-90 and Tl-204 beta particles by attaching small ^{7}LiF disk to the back-up open window filter area(A5) of the original Teledyne P-300-AS badge system, and to verify the performance of this method.

EXPERIMENTAL DETAILS

Teledyne P-300-AS multi-element badge case and C-300-A beta/gamma TLD card are used to determine the response of the TLDs to the beta particles. This badge system consists of 4 main areas and 4 back-up areas. The open window filter area(A1) simulates body surface and consists of a 7 mg/cm^2 black polyethylene mylar on the open window of the badge case. The beta shield filter area(A2) attenuates most beta energies less than approximately 2.2 MeV. To separate the beta particles with energies, it was covered with small ^{7}LiF disk on the back-up open window filter area(A5) to attenuate most of the Tl-204 beta particles and to measure Sr/Y-90 beta only. The filter materials in badge case are given in Table 1.

Table 1. Filter Materials for Each Area of Modified P-300-AS Badge Case.

Area	Filter Materials and Thicknesses
A1	7 mg/cm^2 Black Polyethylene
A5	7 mg/cm^2 Black Polyethylene + 211 mg/cm^2 ^{7}LiF
A2 & A6	863 mg/cm^2 , Plastic
A3 & A7	866 mg/cm^2 , Al
A4 & A8	1,245 mg/cm^2 , Al + Cu + Sn/Pb

The dosimeters were placed on a 30 X 30 X 5 cm PMMA slab phantom and irradiated by the PTB certified Sr/Y-90(74 MBq) and Tl-204(18.5 MBq) source in the Beta Secondary Standard System(Buchler Co., Germany) at the Calibration Laboratory in KAERI. The absorbed dose rate was given by the PTB certificate of each source at specified distances.

RESULTS AND DISCUSSIONS

The TL response as a function of absorbed dose was measured for Sr/Y-90 and Tl-204 radiations between 1.5 mGy and 10 mGy according to the requirements of ANSI N13.11. The linearity of TL response in this range is shown in Fig. 1. The response for Sr/Y-90 betas is linear and the measured doses are quite the same as the delivered doses. But even though the response of the TL dosimeters to the Tl-204 is linear, the measured doses are about 20 % lower than the delivered. From this a beta correction factor(BCF) for Tl-204 was derived to be 1.25, and the measured TL response for Tl-204 was then corrected by this BCF. The corrected dose shows good agreement with the delivered as seen in the same figure.

If the types of beta particles are known, the beta doses can be easily evaluated by multiplying the BCF obtained above. But in the case of randomly choosing beta sources to irradiate each dosimeter as defined in ANSI N13.11, the delivered dose would be underestimated by about 20 % for the Tl-204 beta if it is not separated into Sr/Y-90 and Tl-204 betas as shown in Fig.1. To separate two betas, the ratios of A1 to A5 for the case of covering and uncovering ^{7}LiF disk on A5 were obtained and the results are given in Table 2.

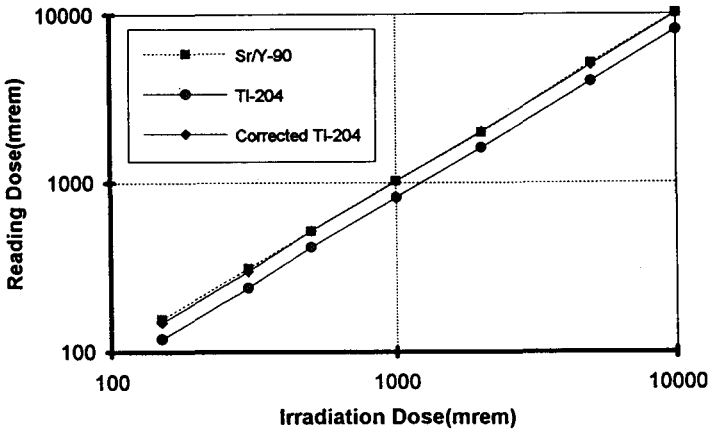

Figure 1. Linearity of Sr/Y-90 and Tl-204 Beta Particles.

Dose evaluation algorithm detects the beta or beta mixtures at first, separates the type of beta sources by A1/A5 ratio, and then evaluates beta dose by multiplying the relevant beta correction factor which is 1.0 for Sr/Y-90, 1.2 for Tl-204.

Table 2. Delivered to Evaluated Dose Ratios with and without Cover of ^{7}LiF Disk.

Sources	A1	A5 Without Cover	A5 With Cover	A1/A5(With Cover)
Sr/Y-90	1	1	0.9	1.1
Tl-204	0.8	0.8	0.05	16.0

To verify the performance of the modified badge system, a simple performance test was conducted and the results are given in Table 3. The test categories and delivered doses were selected from ANSI N13.11. It is shown that all results meet the performance test criteria even without any modification of original P-300-AS badge case, but the performance index (bias plus standard deviation) is much larger than that of modified P-300-AS badge case, by which the accuracy can be improved by more than 20 % compared with the original Teledyne design.

Table 3. Results of Performance Test for the Modified P-300-AS Badge Case.

ANSI N13.11 Test Categoriy	Delivered Dose(mSv)	Reported Dose(mSv)	Test Results | B | + S[(1)]	Tolerance Level
VA Sr/Y-90	10	9.8 (9.8)[(2)]	0.03 (0.04)	0.5
VB Tl-204	10	9.7 (7.8)	0.04 (0.25)	0.5
VC Sr/Y-90 + Tl-204	10	9.8 (8.7)	0.05 (0.16)	0.5

(1) B : Bias, S : Standard Deviation
(2) Values in parentheses are results from original P-300-AS Badge Case.

CONCLUSION

Teledyne P-300-AS badge case and dosimeters used for personnel monitoring of beta radiations suffer from an energy dependent problem because this does not provide the filters needed to evaluate different types of betas separately. To improve this, back-up filter area A5, having same filter material and thickness as open window filter area A1 for beta measurement, was covered with a small ^{7}LiF disk to provide multi-element filter areas for separating beta energies.

The TL response to beta radiation energy showed that the evaluation data for Tl-204 was about 80 % of the response obtained with Sr/Y-90 source. However, by separating Tl-204 and Sr/Y-90 beta sources with a modified badge system, the delivered dose can be evaluated within $\pm$5 % error bound even in the randomly selected irradiation condition.

TRITIUM DETECTION WITH $BeO:TiO_2$ -CERAMIC TL DETECTORS

Igor Milman,[1] V. Kortov,[1] A. Slesarev,[1] V. Fominych,[2] S. Fedina,[2]

INTRODUCTION

The problems associated with registration of alpha and very soft beta radiation are well known and they spur a search for new ways of their solution (1). We used new thermoluminescent (TL) detectors on the basis of $BeO:TiO_2$ ceramics for ^3H ($E_{\beta\ max}$ =18 keV) detection. A characteristic feature of the detectors is their complete optical opacity and existence of a thin (20 μm) sensitive)layer on the $BeO:TiO_2$ surface (2). Thanks to these properties the detector sensitivity to irradiation with short-range charged particles was much higher than to irradiation with accompanying quanta (3).

EXPERIMENTAL

Thermoluminescence was measured using a DTU-01 instrument (Lithuania) The TL peak of the glow curve in the temperature range from 420 to 440 K is used only for the read-out procedure.

Two methods of tritium detection were used in the study. According to one method the detector was irradiated by a standard source of tritium arranged at a distance of 0.5-1 mm from its surface. The TL signal amplitude increased linearly with an increasein the exposure time. The measurement results showed that the lower detection limit is 10 of β-particles found on the detector surface.

According to the other method the detector was brought into a momentary mechanical contact with the surface of the source. It was found that the detector based on the $BeO:TiO_2$ ceramic possesses the ability to accumulate and retain for a long time tritium diffusing into the sensitive layer of the material. The TL signal of such a detector is induced by its self-irradiation. The measurements showed that the TL output is proportional to the time of the detector self-irradiation, i.e. the effect of "dose accumulation" takes place. This property persisted for several weeks, even when a few tens of cycles of TL read-outs were performed during that period. Shown in the Figure is the measured TL response vs. the "self-irradiation" time of two detectors (curves 1 and 2).

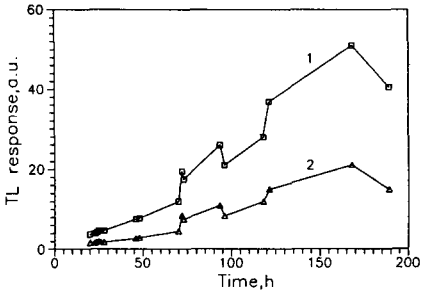

Figure. TL response vs. self-irradiation time of two $BeO:TiO_2$ ceramic detectors

These experiments were carried out using purposefully chosen detectors, which had different TL sensitivities determined by the former method as described above. It follows from the Figure that an increase in the self-irradiation time is indeed accompanied by an almost linear rise of the TL response. A comparison of the two methods under discussion shows that an increase in the TL output due to the "dose accumulation" effect provides an additional 10- to 100-fold rise of the tritium detection sensitivity. Besides, as is seen from the Figure, the curves 1 and 2 have sharply nonlinear portions. Most surprisingly, the said portions are fully coincident. It is unlikely that this synchronous change in the TL sensitivity is caused by migration of tritium in the detector surfacc. Thcn diffusion constants of tritium in thin surface layers of two different detectors should be ideally coincident, which is, in our opinion, highly improbable. We believe the most plausible explanation of the presence of synchronous "steps" in "TL response - accumulation time" curves 1 and 2 obtained for two detectors with different sensitivity is instability of the TL read-out device. Specifically, we attribute the observed effect to instability of the detector heating unit. During the measurement procedure sensitivity of the recording circuit before and after heating of the detectors was constant as determined using a radioisotope reference light source. It may be assumed with a certain degree of confidence that the said two detectors helped us reveal a time fluctuation of the stability of the read-out device; the time fluctuation could not be detected with the reference light source.

The self-irradiation effect was examined additionally by the method of thermally stimulated exoemission (TSEE). The measurements were made in vacuum. The effect was fully reproducible for several hours but its sensitivity dropped with every heating-measurement cycle. The effect ceased if the samples were kept in vacuum for a few days. When TL was measured in air, sensitivity of the detectors lowered only 1.6-1.8 times in 2 months. This fact can be accounted for by a more intensive withdrawal of tritium from the surface layer of the detectors subject to heating and storage in vacuum. This inference does not contradict the mechanism of tritium diffusion in the lattice of the BeO ceramic (4).

CONCLUSION

Our preliminary studies of TL in BeO:TiO_2 -based detectors show that they may be useful for determination of tritium contamination and serve as TL standards for testing of read-out devices.

RADIATION VOICE MONITORS

N. Suzuki
JGC Corporation
Yokohama, Japan

1. ABSTRACT

Radiation voice monitors, which serve to announce the dose equivalent (or dose rate) by voice to a worker wearing bulky protective clothing in high-radiation level and high-contamination areas, were developed to reduce the exposure to radiation of the worker. Examples of the applications of such monitors are introduced hereunder.

2. PURPOSE OF DEVELOPMENT

In developing radiation voice monitors, the aim was to enable a worker and his supervisor, while working in high-radiation level and high-contamination areas, to hear the dose equivalent (or dose rate) in real time and select working locations which would minimize the dose equivalent, increase working efficiency and reduce the collective dose equivalent (man Sv).

3. BACKGROUND

In Japan where the utmost efforts are being made to reduce exposure to radiation, the average yearly dose per worker at nuclear power stations is as low as 1.0 mSv/year. However, the need inevitably arises for workers wearing heavy protective clothing to perform duties at certain times in high-radiation level and high-contamination areas.

In the past, an alarm meter carried inside the pocket of the protective clothing sounded when the specified period of time was completed, whereupon the worker ceased working and exited from such areas. Time controls were in place to prevent the worker's dose rate from exceeding the planned dose. However, the dose rate in the working environment varied widely depending on both location and time.

4. PERFORMANCE

Radiation voice monitors enable the worker to continue his duties while being informed through his earphone of the changing dose equivalent or dose rate encountered, this being particularly convenient in cases where, due to the bulky clothing, it is difficult to see the dose equivalent or dose rate displayed on the dosimeter. As the new type of monitor transmits such audio-data wirelessly, a supervisor far away can hear the dose equivalent of the worker in real time and provide him with adequate instructions.

The radiation voice monitor is equipped with an additional audio-communication function enabling communications to be exchanged between workers and their supervisors.

The specifications of the radiation voice monitor are shown in and Table-1.

5. EXAMPLE OF APPLICATION

Place	:	Nuclear facility A
Dose equivalent	:	0.5 ~ 20 mSv/h
Surface contamination density	:	$\sim 8 \times 10^2$ Bq/cm^2
Noise	:	70 ~ 90 dB
Protective clothing	:	Anorak suit, full-face mask
Planned collective dose equivalent	:	13-man mSv/period
Actual collective dose equivalent	:	8-man mSv/period

6. STUDIES ON REDUCTION OF DOSE EQUIVALENT

It was determined that the dose equivalent in the application example given in the above section 5. was reduced as a result of the following:

(1) Workers could perform their duties while constantly being informed by earphone of their dose equivalent. Therefore, work was not suspended as it became unnecessary to exit the radiation area merely to satisfy the time control of the dose equivalent. 40%

(2) As the high-dose equivalent locations were known, workers were able to avoid working in these locations. 20%

(3) Because the supervisors heard the workers' dose equivalents in real time, they were able to supply adequate instructions.20%

(4) Workers were able to carry out work while hearing other co-workers' dose equivalents; that is to say, respective dose equivalents could readily be identified. 20%

100%

Furthermore, studies on the following index were conducted from the standpoint of optimization of radiation protection.

$$\frac{\Delta X}{\Delta S} \leq \alpha$$

ΔX: Cost of radiation voice monitor (¥)

ΔS: Collective effective dose-equivalent (man Sv)
α : Dimensional constant expressing monetary cost assigned to a unit of collective dose for radiation protection rate (¥/man Sv)
Δ : Finite increment

Application time (total time) of radiation voice monitors will affect the index ΔX .

7. CONCLUSION

Radiation voice monitors were developed to optimize radiation protection and have been used over the past five years. The results of the application of the monitors indicate a very satisfactory reduction of dose equivalent.

DOSIMETRY CHARACTERISTICS OF GLASSES FOR GAMMA HIGH DOSES

Valéria A. C. Quezada and Linda V. E. Caldas

Instituto de Pesquisas Energéticas e Nucleares
Comissão Nacional de Energia Nuclear
CP 1109 - CEP 05422-970
São Paulo - Brasil

INTRODUCTION

The vitreous materials present non-comum characteristics; they also own special and useful technological properties, because of their atypical nature. Although a glass doesn't present the elevated crystal order, it is not destituted of a structure.

Ionizing radiation induces in glasses absorption bands that depend on the material constitution and on the irradiation conditions. The colour change is due to the mechanism of oxidation and reduction of their elements and to the colour centers formation (1). Several high dose dosimetry methods have been developed, because of the increasing radiation use in industrial processes, as the sterilization of medical and food products(2).

In the present work the possibility of use of commercial glasses in gamma dosimetry was studied between 18Gy and 7.5kGy, through optical density measurements, using a densitometer and a spectrophotometer.

MATERIALS AND METHODS

Commercial glass samples, with dimensions of 11.50 x 50.00 mm and thicknesses between 2.00 and 2.07mm, were initially analysed (neutron activation method) and they showed several components as SiO_2 (71%), Al_2O_3 (0.90%), Fe(0.13%), Mg (4%), Na (15%), K_2O (0.40%) and Ca (0.13%).

Reutilization of the material was achieved by thermal treatments at 300° C during 15 minutes. All irradiations were made in air, using a panoramic ^{60}Co source Yoshizawa Kiko Co. Ltd. (10.8 Tbq).

Optical absorption spectra were obtained (air as reference) between 300 and 700nm, always 20 minutes after the irradiations, using the spectrophotometer Femto, model 482, Brazil, simple beam. A special densitometer was provided by MRA, Brazil, in order to allow measurements up to high doses using glass samples, with transmission between 400 and 550 nm.

RESULTS

In Figure 1 the optical absorption spectra of the studied glasses are shown. The glass samples are transparent in the visible region, before the exposition to ^{60} Co radiation, presenting an optical absorption band at about 310nm. After irradiation they become light brown coloured and a main large band at 420nm is shown; its intensity increases with the absorbed dose.

In order to test the batch uniformity and the response repeatability, the samples were 10 times irradiated with 1 kGy (^{60}Co). The batch uniformity presented variation coefficients of 1.8 and 3.5%, and the response repeatability, of 1.8 and 3.6%, for measurements taken at respectively the densitometer and at the spectrophotometer.

The thermal fading at room temperature can be seen in Figure 2 for both cases of densitometer and spectrophotometer. A steady initial decay (25% in 24 hours) and a subsequent slow decay can be observed. Only after 18 days the samples showed a constant response.

Figure 3 presents the calibration curves of the glass samples irradiated between 18 Gy and 7.5 kGy. A linear behaviour can be observed from 30 Gy to 7.5 kGy, for the spectrophotometer measurements. In the case of the results obtained with the densitometer, the linear region resulted from 0.1 to 1.5 kGy, with a subsequent supralinear behaviour up to 7.5 kGy and a tendency to saturation.

The low dose limits were determined for these glass samples as 19 and 100 Gy using as measuring instruments respectively the spectrophotometer and the densitometer. These same results can be obtained from Figure 3.

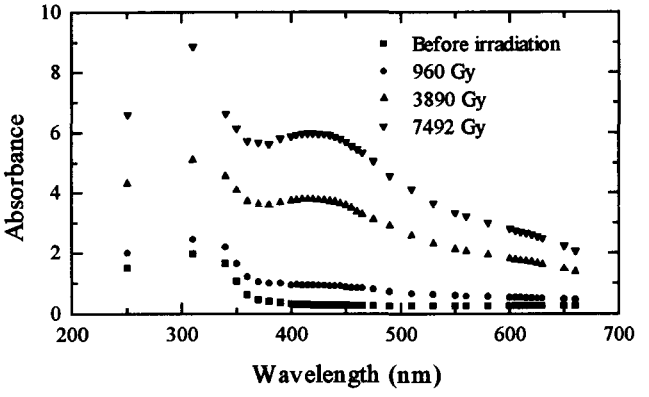

Figure 1 - Absorption spectra of the glasses before and after irradiation.

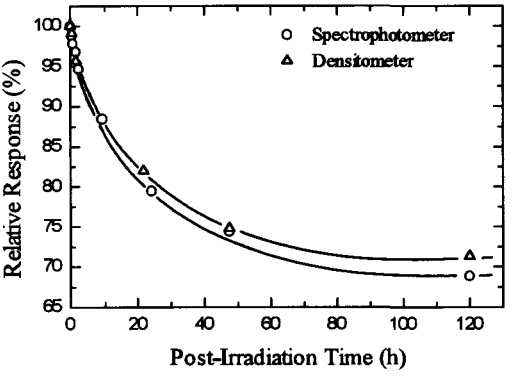

Figure 2 - Thermal fading at room temperature of the glasses irradiated with ^{60}Co.

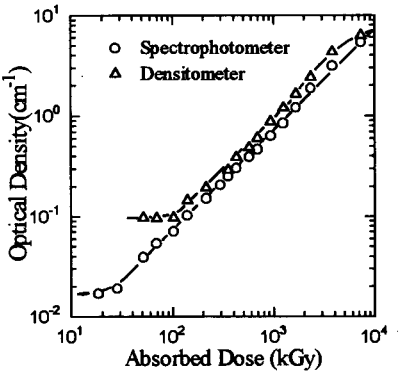

Figure 3 - Calibration curves of the glasses irradiated with ^{60}Co (2.3 kGy)

CONCLUSIONS

The commercial glass samples studied in this work present adequate dosimetric characteristics as batch uniformity, response repeatability, reutilization and linear behaviour in determined dose intervals, which make them suitable detectors for routine high dose dosimetry in the range of 18 Gy to 7.5 kGy. However, these glasses present an undesirable thermal fading effect, which does not constitute a great problem even in routine work, because the dose evaluations are normally made after a certain time interval. A correction factor has to be applied to the results.

The main advantages of these radiation detectors for gamma high doses are the very low cost and the measuring simplicity. The glasses can also be used as Yes/No detectors, because of their colour change with the absorbed dose.

INTRODUCTION

Radiophotoluminescent glass dosimeters made of silver activated metaphosphate glass are widely used for dosimetry of gamma-ray fields because of the unique characteristics such as repeatability, integrity during intermittent monitoring and reading, and extremely low fading. In addition, by utilizing a pulsed N_2-gas laser in readout system, the performance of the glass dosimeter has been improved on reproducibility of low-dose measurement(1) and expected to be widely used for personnel dosimeter.

The characteristics of the dosimeter, including the energy response for photons up to about 20 keV, had reported. However, few experimental data were presented for monochromatized low energy photons. Recently, high intensity photons with low energy has been widely used in synchrotron radiation facilities and the dosimetries including the personnel one is one of the serious safety problems for the low energy photons. Therefore, the responses of glass dosimeter badge, made by Toshiba Glass Corp., have been measured for low energy photons by using monochromatized synchrotron radiation and compared with the results by using X-ray tube. In order to get the knowledge of characteristics of the detector response, radiation transport phenomena have been simulated and compared with the experimental results.

EXPERIMENT

The GD-403 type glass dosimeter(2) consists of 4 elements with respective different filters (Al of 1mmt,Sn of 1mmt, polyester films of 35 μ mt and 250 μ mt), as illustrated in Fig.1. The response of glass dosimeter for low energy photon ranging from 7 keV to 37keV have been

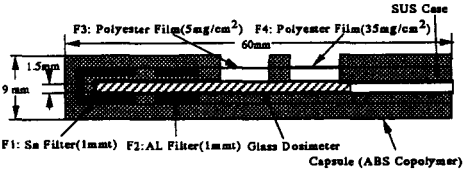

Fig.1 Cross-sectional view of GD403 type glass dosimeter badge

measured by using monochromatized synchrotron radiations at a vertically polarized wiggler beamline, BL-14C, at Photon Factory in KEK. Synchrotron radiation from the wiggler was monochromized to $\Delta E/E \sim 10^{-3}$ - 10^{-4} band width. Absolute photon intensities were monitored with a free air ion chamber calibrated with a new type calorimeter(3). The dosimeters were scanned horizontally in order to uniformly irradiated. The higher harmonic components of monochromatized photons reduced to less than 0.3% by detuning the double crystal monochromater, which components were monitored by a HP-Ge detector.

The detector was irradiated by using an X-ray tube operated at 30kV with Al

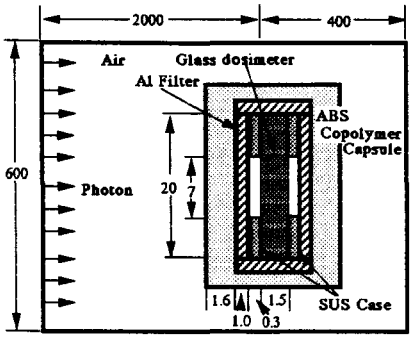

Fig.2 Calculational configuration of glass dosimeter with Al filter

filter of 4.01mm thickness for 24.1keV effective energy and at 50kV with Cu filter of 0.59mm for 39.4keV. The quality indices that is photon effective energy to tube voltage ratio, are 0.8 and 0.79, respectively. Gamma-ray of ^{137}Cs (662keV) was also used for normalization.

In readout operation, the FDG-60 automatic system(4) was used. On the system, the N_2-gas laser incidents with slightly inclined on the side of glass dosimeter and the radiophotoluminescences were detected outside the front of the dosimeter.

MODEL CALCULATION

CYLTRANP was used in ITS3.0 and 4 models were employed for the 4 filters. For example, figure 2 shows the calculated configuration of slab-cylinder model of glass dosimeter with Al filter. To obtain an effective radius and thickness, calculations were made under the following conditions; (a)deposited energy is independent of the depth of detector for 37keV and 662keV photons, (b)deposited energy is reduced by shadow effect of SUS case , and (c) deposited energy is dependent upon the readout thickness of the detector for 7keV photons.

The effective radius of the detector can be expressed as a function of the ratio of the energy deposition with 37keV photons to 662keV photons and determined by the interpolation using the function. After knowing the effective radius, the effective thickness can be estimated from the ratio of the energy deposition with 7keV photons to 37keV photons. Energy responses of the glass dosimeter were calculated by using the effective radius and the thickness.

Table1 Comparison of the measurements with X-ray tube and synchrotron radiation for GD403 type dosimeter with various filters. The data are normalized at 662 keV photon energy per unit exposure.

	Filter1 (Sn)	Filter2 (Al)	Filter3 (Poly.5mg/cm^2)	Filter4 (Poly.35mg/cm^2)
X-ray (39.4keV)	0.0418	3.20	3.35	3.57
SR(36.86keV)	0.028	3.02	3.42	3.50
Ratio	1.49	1.06	0.980	1.02
X-ray (24.1keV)	-	1.83	2.98	3.05
SR(23.74keV)	0.007	1.56	2.69	2.75
Ratio	-	1.17	1.11	1.11

RESULTS

The responses of the dosimeter are indicated in table 1, and good agreements are obtained between the responses for 39.4keV effective photon by X-ray tube and 36.86keV photon of synchrotron radiation, except for the case of the Sn filter element. At 24keV photon energy, the responses by using the X-ray tube are more 10% higher than those of synchrotron radiation. This is pointed out that the higher energy components of X-ray are introduced to high sensitivities.

On the calculation of the energy deposition as a function of the depth of detector, it is confirmed to be depth independent of the photon energies above 30keV, that is, the ratio of the energy deposition for 37keV photon to that for 662keV photon is independent of the depth of the detector. From the model calculations mentioned above, 5.1±0.3mm was obtained for the effective radius of the detector. In Fig.3, the two solid lines show the calculations of the functions of the ratio of the energy deposition with 7keV photons to 37keV photons, indicating that the ratio depends on the detector thickness and

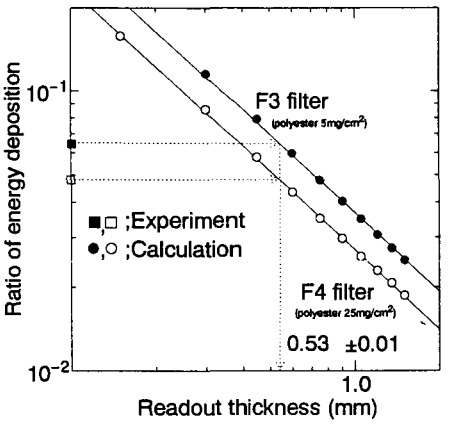

Fig.3 Dependencies of Proportion of deposited energy upon the readout thickness of the detector with 7keV to 37 keV photons.

experimental data for the detectors with polyester film filters, and obtained the effective thickness as 0.53±0.01mm.

The energy responses of the detector with each filters are shown in Fig.4 as the comparison between the experimental results and calculations with the effective radius and the thickness. As shown in Fig.4, fairly good agreements are obtained between the experiments and calculations, except the response of the detector with Sn filter because of the insufficient accuracy in the calculation.

CONCLUDING REMARKS

The energy responses of the glass dosimeter badge for monochromatized low energy photons ranging from 7 to 37 keV have been measured by using synchrotron radiation and the sensitivities have been investigated accurately. The comparison between the experimental results of synchrotron radiation and the Monte Carlo calculations, showed close agreements as to the energy response.

We found that sensitivity of detector was estimated highly in the results for low energy photons, especially below 24keV in conventinal method of X-rays, and that the response functions depended on the readout system, especially readout radius and thickness.

Dose estimation for the personnel within fields of low energy photons mixed with β-rays is currently underway for future studies.

ABSTRACT (See instructions overleaf)

Photon radiation in the energy range below 15 keV occurs in many practical situations encountered in research, industry and medicine, and like beta radiation, belongs to the class of low-penetrating radiations. The dosimetry of such radiations is a concern in radiation protection as well as in radiation diagnostic when areas of unprotected superficial organs, such as the skin, are exposed. In order to monitor individuals in terms of the personal dose equivalent Hp(0.07), the operational quantity recommended by ICRU, specific thin detectors are required and their energy and angle responses must be known. The investigation of the dosimetric characteristics of such detectors implies the availability of well-characterised calibration beams. This paper describes the establishment and characterisation of low-energy photon calibration beams based on two radiation facilities, namely an X-ray facility providing 3 narrow spectrum photon beams centered at resp. 6.5, 8.5 and 12 keV, and a Fe-55 (6 keV) irradiation facility. As shown by Boehm et al.(1), an air-filled extrapolation chamber can be used as a primary standard from which absorbed dose to a given tissue equivalent material can be derived reliably. In the present work the extrapolation chamber method was used to characterise photon beams in terms of Hp(0.07;α°), the dose equivalent at a depth of 0.07 mm in the 4-element ICRU tissue slab for different angle of incidence (α) of the radiation. Furthermore, the air kerma Ka was measured at the same point enabling the determination of the necessary reference conversion coefficients from Ka to Hp(0.07;α°). Measured values are compared with calculated values (2) and, in addition, results are presented concerning the application of the established calibration fields to investigate and typetest individual dosemeters and to check how they comply with required performances.

THEORETICAL CALCULATION OF GAMMA DOSE CONVERSION FACTORS FOR PERSONNEL EXTREMITY DOSIMETER

S. C. Yoon,[1] J. S. Kim,[1] K. P. Kim,[2] and W. K. Lee,[2]

[1]Korea Atomic Energy Research Institute, Taejon, Korea,
[2]Kyeonghee University, Suwon, Korea

ABSTRACT

In late 1996, The ANSI is planning to release a standard for the performance testing of personnel extremity dosimeters as ANSI N13.32 standard. The standard includes experimentally-determined gamma dose conversion factors used for determining the dose equivalents to the extremities at the reference depth of 7mg/cm^2. In this study, theoretical calculations of the gamma dose conversion factors for two types of extremity phantom, finger and arm phantoms which were specified in the ANSI N13.32, were performed using a MCNP code and compared with the experimental values of the ANSI N13.32. Finally, it is concluded that the all conversion factors for the two types of the extremity phantom show good agreement with the values of the ANSI N13.32 for each energy within 4.8% except for about 12% at less than 50keV energies.

INTRODUCTION

In Korea, over past one decade, personnel dosimetry researches for external, whole-body dose evaluation were primarily focused with little attention to dosimetry research for extremity dose evaluation. In the case of the United States, the draft American National Standards Institute(ANSI) N13.32 "Standard for the Performance Testing of Extremity Dosimeters" established the methods for testing extremity dosimetry systems, specifies the sources, energy ranges and irradiation geometries to be used during the performance testing[1]. In this study, for determination of the gamma dose conversion factors theoretical calculations of them for two types of extremity phantom, finger and arm phantom which were specified in the ANSI N13.32, were performed using a Monte Carlo N-Particle(MCNP) code and compared with the experimental values of the ANSI N13.32[2].

THEORETICAL BACKGROUND

In order to provide the accurate calculation necessary for dose evaluation with different extremity dosimeter systems, the use of well-determined gamma dose conversion factors is required. With computational geometry in mind, the coefficient, gamma dose conversion factor, $H_p(d)/K_a$ for converting air kerma to dose equivalent for primary photon beam of mono-energy(E) can be calculated according to the following equation:

$$\frac{H_p(0.07)}{K_a} = \frac{C\int \phi_{\text{ICRU tissue}}(E,d)\cdot E\cdot\left[\frac{\mu_{tr}(E)}{\rho}\right]_{\text{ICRU tissue}}}{\phi(E)\cdot E\cdot\left(\frac{\mu_{tr}}{\rho}\right)_{air}}$$

where C is the unit conversion factor [10^{12} Gy/(J/kg)],

$\phi_{ICRU\ tissue}$ is the fluence in the ICRU soft tissue material of extremity cylindrical phantom,

$\left[\frac{\mu_{tr}(E)}{\rho} \right]_{ICRU\ tissue}$ is the mass energy transfer coefficient of ICRU tisssue,

$\left(\frac{\mu_{tr}}{\rho} \right)_{air}$ is mass energy transfer coefficient of air, and

K_{air} = air kerma.

COMPUTATIONAL METHODS

Theoretical calculations of the gamma dose conversion factors for two types of extremity phantom, finger and arm phantoms using a MCNP transport code[3]. The gamma dose conversion factors in the range between 15keV and 1.5MeV were calculated using the MCNP code with the kerma approximation. The back-scatter factors are not considered in this calculation, since all dosimeters do not respond equally to backscatter. Each phantom was assumed to be irradiated by the idealized case of broad, unidirectional, and monoenergetic source particles normally incident on the front face of the phantom, which was assumed to be surrounded by vacuum. The computational irradiation geometry and cell arrangement for each extremity phantom is shown in Figure 1. The mass energy transfer coefficients of tissue and air for theoretical calculation of gamma dose conversion factors were determined using Storm and Israel data and Hubbel data, respectively[4, 5].

RESULT & DICUSSIONS

The gamma dose conversion factors calculated in this study and specified in the ANSI N13.32 for each phantom are shown in Figures 2 and 3. In the case of finger phantom, the gamma dose conversion factors theoretically-determined by using the MCNP code show good agreement with the values of the ANSI N13.32 standard for all energies within 3.5% except for about 10% in the range of less than 50keV energy as shown in Figure 2. And in the case of arm phantom, the gamma dose conversion factors theoretically-determined by using the MCNP code also show good agreement with the values of the ANSI N13.32 standard for all energies within 4.8% except for about 12% in the range of less than 50keV energy as shown in Figure 3. The cause of bigger difference at less than 50keV energies than at higher than 50keV energies for both phantoms may primarily be due to inherent difficulty of experimental measurements occurred by using a x-ray generator.

CONCLUSIONS

As a result of comparing theoretically calculated gamma dose conversion factors with experimental data specified in the ANSI N13.32, it is shown that there is a reasonable good agreement with the maximum difference ratio, 4.8% at all energies except for about 12% at less than 50keV energies. Therefore, it is concluded that gamma dose conversion factors determined by using a MCNP code in this study for finger and arm phantoms could be used for considerably reliable extremity dose evaluation in addition toss the experimental values of the ANSI N13.32.

PERFORMANCE OF A DIRECT ION STORAGE (DIS) DOSEMETER FOR INDIVIDUAL MONITORING

C. Wernli[1], J. Kahilainen[2]

[1]Paul Scherrer Institut, Villigen, Switzerland
[2]RADOS Technology Oy, Turku, Finland

INTRODUCTION

The development of the Direct Ion Storage dosemeter was triggered by the need to find an electronic successor for the aging Film- and TLD-dosemeters. As the basis of any passive dosemeter, there must always be a reliable means of storing information, such as the electron traps in TL materials. The new development was based on the same principle for information storage as is used in almost all microelectronic devices today; a nonvolatile FAMOS (Floating Gate Avalanche-injected MOS) memory cell. In electronics these devices are known as EPROMS, EEPROMS and Flash-Memories. In order for a memory cell to act as a dosemeter, it must be sufficiently sensitive to ionizing radiation to the extend that the small dose levels down to a few μGy encountered in radiation protection applications can be reliably detected.

In a nonvolatile solid-state memory cell the information is stored in the form of electronic charge being trapped on the floating gate of a MOSFET transistor. Original memory designs were only used to store digital information which meant that in each memory cell there was either a low amount or a high amount of charge stored to represent one of the two binary digits 0 or 1. In the recent years new types of nonvolatile memories have been developed and made commercially available to be used for storing analog information. This means that the amount of charge in each memory cell can be made fully variable and therefore, these memory cells can be used to store analog information directly. Analog-EEPROM memories are used today in speech recording applications for example in electronic telephone answering systems.

The radiation sensitivity of normal solid-state memory cells is inherently too low for use as detectors in radiation protection applications. The main reason for this is that these devices are specifically designed to be as insensitive as possible to ionizing radiation so that they could be used in space, military and nuclear industry applications without damage.

In an Analog-EEPROM memory cell, the charge on the floating gate can be set to a predetermined level by injecting electrons through the oxide layer. The charge is then permanently stored on the gate because in the normal operating temperature range the electrons have a very low probability to exceed the energy barriers in the metal-oxide and oxide-silicon interfaces. These types of memory cells are known to retain the stored charge for hundreds of years.

In order for ionizing radiation to have an effect on the stored charge, either new charge has to be brought to the gate or some existing charge removed. Ionizing radiation incident on the oxide layer does produce electron-ion pairs but due to the relatively poor mobility of charge carriers in the oxide, recombination occurrs and most of the free charge is neutralized before it has a chance to cross the metal-oxide interface. MOS dosemeters that are based on this principle are not sensitive enough for most radiation protection applications. The Direct Ion Storage (DIS) principle is based on allowing the surface of the floating gate to be in direct contact with the surrounding air. Ionizing radiation incident in the air space produces electron-ion pairs with extremely high mobility and if there is an electric field surrounding the floating gate, these charge carriers can very efficiently be

transferred to the gate before recombination occurrs. The electric field around the gate is generated by injecting an initial charge on the gate. By surrounding the whole memory structure with a conductive wall, effectively an ion chamber is formed between the wall and the floating gate (Figure 1). For photon radiation, the interactions take place mainly in the wall and the secondary electrons ionize the air between the wall and the floating gate. For other charged particle radiation, if the wall is sufficiently thin, the charged particles are allowed to transfer their energy directly into the air space. The dosimetric characteristics can therefore be adjusted by altering the properties of the wall material and other fill-gases instead of air could also be used[1].

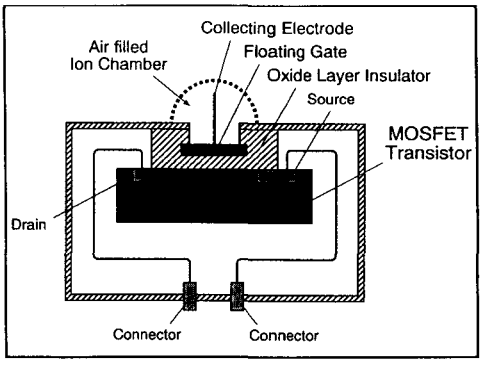

Figure 1. Schematic of a dosemeter based on DIS

Figure 2. The complete electronic Dosemeter

IONIZATION CHAMBER DESIGN

The operating voltage of an ionization chamber based on DIS is 25 to 30 Volt. To obtain an electric field strength in the order 10 kVm^{-1}, necessary for linearity up to high dose rates, the distance between electrodes has to be 2 to 3 mm. The extremely high sensitivity of the DIS methods allows for the use of chamber volumes of 1 cm^3 and less with a resulting detection limit well below 10 mSv. The size of a detector containing two sets of chambers, one to determine $H_p(10)$ and one to determine $H_p(0.07)$ is 35 mm x 50 mm x 7 mm. This detector may be used as a passive dosemeter or it can be combined with an on line readout device to build an electronic dosemeter[2] (Figure 2).

PRELIMINARY DATA ON DETECTOR CHARACTERISTICS

Photon energy dependence

The photon energy dependence of a prototype ionization chamber was tested on the ISO water slab phantom (30 cm x 30 cm x 15 cm, PMMA walls, water filling) using ISO narrow series (N) photon radiation qualities and the most recent conversion coefficients $h_{pK}(0.07)$ and $h_{pK}(10)$ proposed by ISO. The results show that after further optimization of the detector construction an excellent photon energy dependence down to 15 keV for $H_p(10)$ detectors and to at least 6-8 keV for $H_p(0.07)$ detectors can be expected (Figure 3).

Sensitivity to beta radiation

Tests to determine the sensitivity for beta radiation have been performed with ^{204}Tl irradiations of a NPL beta secondary standard ($E_{\beta_{max}}$ = 0.8 MeV). The response for $H_p(0.07)$ varied between 0.47 and 0.75 for different entrance window designs.

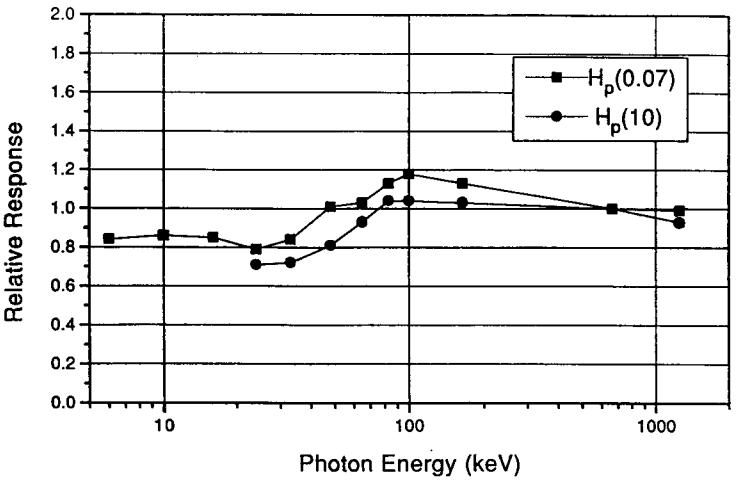

Figure 3. Photon energy dependence of a prototype DIS-dosemeter for $H_p(10)$ and $H_p(0.07)$.

Dose and dose rate range

Linearity of the dose rate has been tested up to 10 Sv/h with deviations of less than 10 %. The dose range can only be fully tested with a complete unit with a final design of the electronics. The intention is to reach a resolution for low dose values of 1 μSv and an upper range of 5 Sv.

CONCLUSIONS

The DIS based dosimetry system is quite simple but highly sensitive. It covers a wide range of photon and beta radiation energies and can be applied as a passive or an electronic device to measure $H_p(10)$ and $H_p(0.07)$. The system seems not to be sensitive to electromagnetic fields.

The tests were performed on prototype instruments, therefore, all test results obtained so far are preliminary. Further optimization of the detector design is possible. The system has a potential to fulfil the requirements of a legal electronic dosemeter. Applications in neutron and radon dosimetry as well as in other fields will be studied.

A photon spectrometer to investigate the energy spectrum and the angular distribution of photon radiation incident on a personal dosemeter

P. Ambrosi [a], J. Böhm [a], G. Hilgers [a], M. Jordan [b] and K.-H. Ritzenhoff [b]

[a] Phys.-Techn. Bundesanstalt, Bundesallee 100, D-38116 Braunschweig, Germany

Introduction

The design of a personal dosemeter depends on the energy and the direction of the radiation to be measured by the dosemeter. The wider the energy range and the larger the solid angle of the incident radiation, the more complicated the dosemeter must be to maintain the same measurement accuracy. The angular distribution of the radiation incident on the dosemeter is strongly affected by the motion of the dosemeter's wearer in the radiation field. Measurements of the energy spectrum and of the angular distribution of photon radiation incident on personal dosemeters actually worn at workplaces are significant only if the measuring instrument follows these motions, i. e. if it is worn by the person in the radiation field. To our knowledge, such measurements have not, however, been carried out yet. To make such measurements possible, a portable photon spectrometer has been developed.

Design and calibration of the portable photon spectrometer

For a portable photon spectrometer to be worn together with a personal dosemeter by a person working in a radiation field it is most important to be sufficiently small and light in order not to handicap its wearer during his work. Hemispherical CdTe detectors with an active volume of about 50 mm^3 and an integrated charge-sensitive preamplifier were therefore chosen as detectors. These detectors are sufficiently small, light and robust and can be operated without any cooling, and their sensitivity and energy resolution are sufficient for this application (1). The photon spectrometer contains a stack of three hemispherical CdTe detectors (see fig. 1(a)). Each detector is surrounded by a cylindrical shielding of lead and copper to allow the photon radiation incident on the wearer of the spectrometer to be measured from three different cylindrical segments of the solid angle.

Fig. 1(b) shows the measured angular dependence of the response of the photon spectrometer for the ISO N-80 X-ray field (operating voltage of the X-ray tube: 80 kV, mean photon energy: 65 keV). The three angular ranges of the three different detectors, which do not overlap, can be clearly distinguished. Due to decreasing absorption by the shielding material, the separation of the angular ranges of the detectors becomes less pronounced with increasing photon energy.

As the radiation fields encountered at workplaces can be expected to consist mainly of continuous contributions such as scattered radiation or radiation transmitted through shieldings, the spectral distributions are rather broad and an unfolding procedure is necessary to obtain the spectral fluence from the measured pulse-height spectra. It is therefore necessary to determine the detector's response matrix including the effects originating from the electronic devices arranged behind.

The response matrix of the CdTe detectors was determined experimentally (2). For this purpose, the pulse-height spectra of 11 isotopes emitting monoenergetic gamma radiation were measured. The resulting spectra represent the response of the CdTe detectors to monoenergetic photons of the respective energy. These spectra were approximated by a model

function which makes use of 19 energy-dependent parameters. The interpolation of these parameters with respect to the energy and the calculation of the corresponding pulse-height spectra yields the response matrix. The response matrix and the unfolding procedure was tested by comparing measured and unfolded pulse-height spectra of different isotopes with the corresponding reference data.

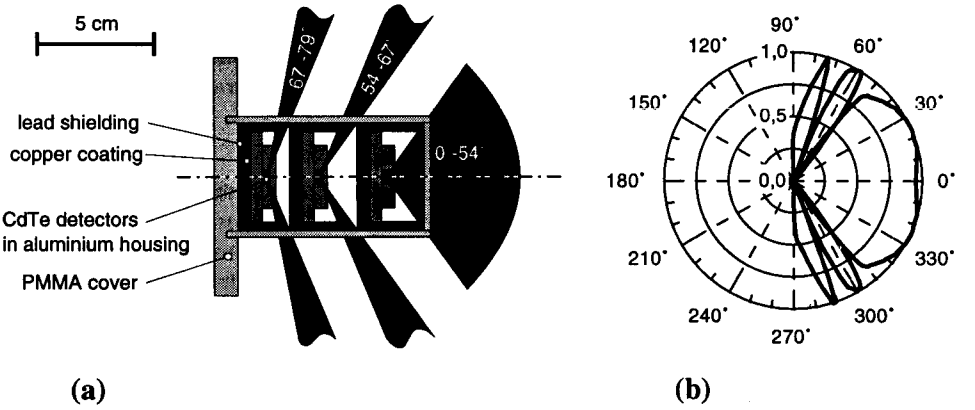

Figure 1. *(a) Setup of the portable photon spectrometer. The figure shows the arrangement of the CdTe detectors with their cylindrical lead shieldings which are coated on the inside with copper to suppress the lead's fluorescence radiation. The spectrometer is covered with PMMA. The whole assembly is of cylindrical symmetry. The dark grey areas indicate the angular range covered by the different detectors. The ratio of the sizes of the segments of the solid angle is 2 (0°-54°) : 1 (54°-67°) : 1 (67°-79°).*
(b) Angular dependence of the response of the photon spectrometer in the angular range from 0° to 360° for the ISO N-80 X-ray field (3).

Results

First measurements at real workplaces were carried out in the Physikalisch-Technische Bundesanstalt during the type testing of three different X-ray emitters, namely X-ray tubes with maximum operating voltages of 160 kV, 225 kV and 300 kV. Fig. 2 shows the measured angular distributions of the personal dose equivalent $H_p(10)$ for the three X-ray tubes. In the measurements with the X-ray tubes with maximum operating voltages of 225 kV and 300 kV, the contributions to the personal dose equivalent $H_p(10)$ of radiation incident from the different segments of the solid angle roughly correspond to the size of these segments, indicating an almost isotropic angular distribution of the incident photon radiation. In contrast, the measurement with the X-ray tube with a maximum operating voltage of 160 kV shows a pronounced maximum at angles of incidence ranging from 54° to 67°.

Fig. 3 shows the unfolded spectral distributions of the personal dose equivalent $H_p(10)$ corresponding to the angular distributions shown in fig. 2. For the X-ray tube with a maximum operating voltage of 160 kV, the main contribution to the total dose originates from the radiation transmitted through the housing of the emitter, whereas for the X-ray tubes with maximum operating voltages of 225 kV and 300 kV also scattered radiation and, especially for the X-ray tube with 300 kV maximum operating voltage, the primary bremsstrahlung considerably contribute to the total dose. The measurements agree in showing that the whole energy range below the maximum energy determined by the maximum operating voltage and all ranges of the solid angle, also those with very oblique angles of incidence, contribute significantly to the personal dose equivalent $H_p(10)$.

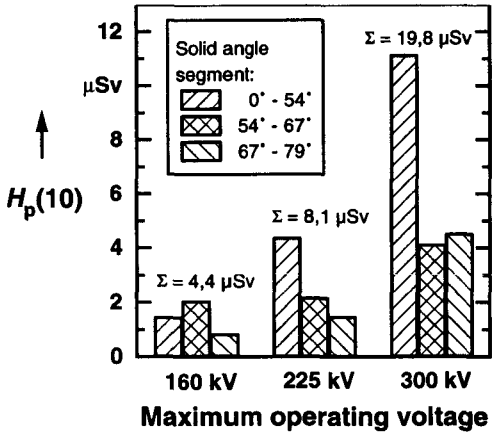

Figure 2. Angular distributions of the personal dose equivalent $H_p(10)$ during the type testing of three different X-ray emitters (X-ray tubes with maximum operating voltages of 160 kV, 225 kV and 300 kV). Σ denotes the total dose measured during the respective type tests.

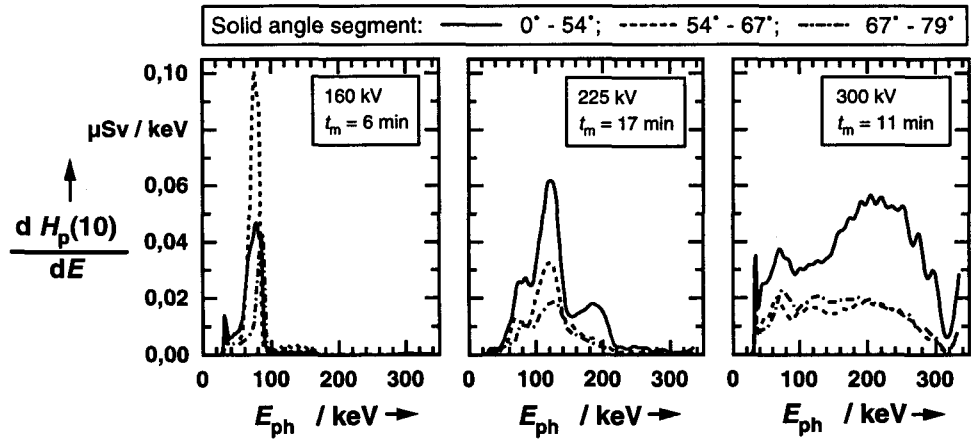

Figure 3. Unfolded spectral distributions of the personal dose equivalent $H_p(10)$ during the type testing (duration of measurement t_m) of three different X-ray emitters (X-ray tubes with maximum operating voltages of 160 kV, 225 kV and 300 kV). E_{ph}: photon energy.

A new film badge for the measurement of the personal dose equivalent $H_p(10)$ using the gliding-shadow method

K.-H. Ritzenhoff [a], M. Jordan [a], G. Hilgers [b], J. Böhm [b] and P. Ambrosi [b]

[a] Materialprüfungsamt NRW, Marsbruchstraße 186, D-44287 Dortmund, Germany
[b] Phys.-Techn. Bundesanstalt, Bundesallee 100, D-38116 Braunschweig, Germany

Introduction

The gliding-shadow method (1) is a novel design principle for filters of a personal dosemeter badge which allows the energy and angular dependence of the dosemeter response to be considerably reduced. This is demonstrated with the aid of a new film dosemeter, because film dosemeters are used worldwide in routine individual monitoring predominantly because of their advantages in dose record documentation and in the retrospective investigation of the conditions of exposures. The new film badge was developed and optimized for the new measurand $H_p(10)$.

The gliding-shadow method

In the new film badge, filters are used which have been designed and optimized using the gliding-shadow method. With the gliding-shadow method a filter F of the size of detector D is placed at a certain distance d in front of the detector (see fig. 1). In the case of normal incident radiation, the shadow of the filter exactly hits the detector (fig. 1, on the left). If the direction of radiation incidence changes to oblique angles, the shadow of the filter glides apart and parts of the detector are exposed to unattenuated radiation (fig. 1, middle). The more oblique the angle of incidence becomes, the more the shadow glides beside the detector (fig. 1, on the right). Obviously, the response of the detector increases with increasing angle of incidence, depending on the distance and the thickness of the filter. The variation in the response of a detector shielded in this way is contrary to the variation of the response of detectors shielded with conventional filters, where the filter is much larger than the detector and very close to it ($d \cong 0$). Consequently, the combination of a conventional filter with a filter designed by the gliding-shadow method enables the construction of a personal dosemeter with a low variation of the response even at large angles of incidence over a wide energy range.

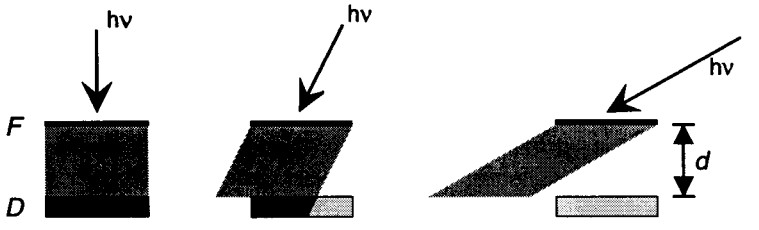

Figure 1. *Principle of the gliding-shadow method: with increasing oblique angle of incidence, the shadow of the filter F glides beside detector D depending on the distance d between filter and detector.*

Design of the new film badge

Due to the strong energy dependence of the response of the bare film, a satisfactorily low variation of the response cannot be achieved with a single filter, even if the gliding-shadow

method is used. It has, however, been found that two filters, a metal filter and a plastic filter, are sufficient. Fig. 2 shows the setup of the two optimized filters. The filters are of circular symmetry in relation to a vertical axis through the center of the respective filter and are designed for a diameter of 8 mm of the detector which is the area on the film directly below the filter. The metal filter is made up of two concentric discs, each consisting of an Sn and Pb layer. A PE disc serves as a spacer between both discs. The plastic filter consists of a thin PE layer (0,5 mm) with a PE ring 2 mm thick arranged below. Thus the gliding shadow is replaced by a gliding illuminated area. This design is necessary, because, at low energies, the bare film itself has nearly the required response to $H_p(10)$ at normal incidence, and only at oblique incidence is an additional shielding necessary to simulate the additional attenuation due to the longer path through the 10 mm ICRU tissue layer in the definition of $H_p(10)$.

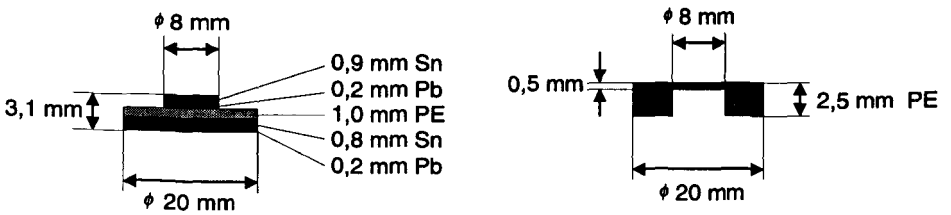

***Figure 2.** Design of the metal filter (on the left) and of the plastic filter (on the right) in the new film badge. A set of identical filters is placed below the film.*

Results and conclusions

The performance of the dosemeter was tested using X-ray fields of the ISO narrow spectrum series with mean photon energies ranging from 17 keV to 250 keV, gamma radiation of ^{137}Cs and ^{60}Co, and high-energy photon fields of 4,4 MeV and 6,7 MeV. The X-ray irradiations were carried out on slab phantoms (size 30 cm × 30 cm × 15 cm) according to ISO/CD 4037-3 at a distance of 250 cm from the focus of the X-ray tube, the irradiations with ^{137}Cs and ^{60}Co at a distance of 100 cm from the gamma source and the irradiations in the high-energy photon fields at a distance of 50 cm from the source. The angle of incidence α ranged from normal incidence (0°) to 75°.

The conventional true value of the personal dose equivalent for the ISO water slab phantom, $H_p(10)$, was calculated from the air collision kerma K_a using appropriate conversion coefficients from ISO/CD 4037-3. The dose values, H_{pla} and H_{met}, were obtained by first measuring the optical density on the film behind the plastic filter and the metal filter as mean values over areas 8 mm in diameter which are fixed irrespective of the angle of incidence. In the second step, these values of the optical density were converted to the dose values using calibration curves and corrections for the background. The calibration curves of H_{pla} were obtained with X-rays with a mean photon energy of 37 keV, and those of H_{met} with gamma radiation of ^{137}Cs.

The measured dose value M_p of the whole dosemeter results from a linear combination (2, 3) of the measured values, H_{pla} and H_{met}:

$$M_p = 1{,}05 \cdot H_{met} + 0{,}82 \cdot H_{pla}$$

In fig. 3 the response, i. e. the ratio $M_p / H_p(10)$, is shown as a function of the mean photon energy and of the angle of incidence. The response shows a maximum deviation of ± 34% (dashed lines) from unity over an energy range from 17 keV (N-20) to 1250 keV (^{60}Co) and

over an angular range from 0° to 60°. For angles of incidence of 75°, most of the measured data are within or slightly outside the range of ± 34% except for energies of 17 keV (N-20) and 48 keV (N-60). In the case of high-energy photon radiation with energies of 4,4 MeV and 6,7 MeV, the dosemeter shows an overresponse of between 70% and 110%.

From the ratio H_{pla} / H_{met} of the measured values, an estimation of the mean energy of the incident photon radiation is possible for energies up to about 300 keV.

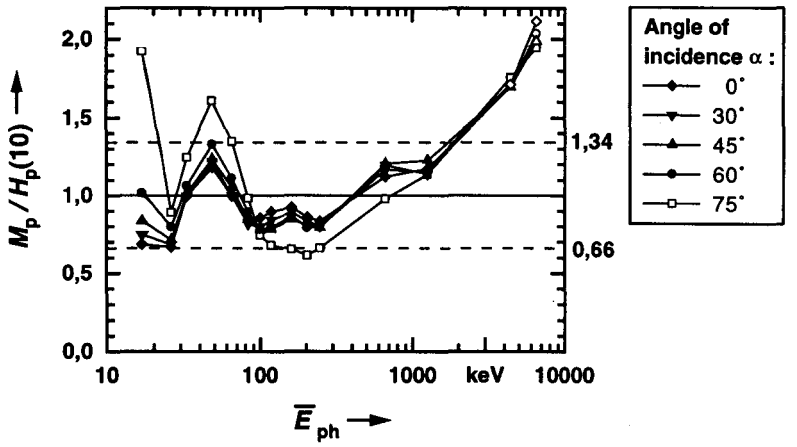

Figure 3. *Response of the new film dosemeter to $H_p(10)$ as a function of the mean photon energy $\overline{E}_{ph}$ for different angles of incidence α. The dashed lines indicate a deviation of the response of ± 34% from unity. The open symbols denote irradiation conditions outside the suggested rated range of use, which is 17 keV - 1250 keV for the energy and 0° - 60° for the angle of incidence.*

All these results can be obtained by a fully automated read-out procedure, because the measuring positions of the densitometer are fixed. The whole dosemeter is enclosed by a lead shielding frame to prevent incorrect measurements due to radiation incident parallel to the film plane. In addition, the badge contains two small filters which are not used to determine the dose but to detect beta radiation, and four lead pins to determine the direction of the incident radiation.

It is also possible to design other dosemeters, e. g. TL-dosemeters, using the new gliding-shadow method, and to calculate other measurands for the personal dose equivalent by exchanging the coefficients for the linear combination.

INTRODUCTION

In 1985, ICRU (1) introduced two operational dose equivalent quantities, $H_p(d)$ and $H_s(d)$, for individual monitoring, which were recently (2) substituted by a single quantity $H_p(d)$ called the personal dose equivalent. These quantities are defined as the dose equivalent in soft tissue below a specified point on the body at depth d. Since its introduction, the implementation of these quantities in practical calibration procedures has encountered many difficulties, mainly because of the impossibility of reproducing them in a laboratory (3). To overcome this problem, ICRU, in its Report n° 47 (2), recommends the use of a 30 cm x 30 cm x 15 cm depth PMMA phantom in dosimeter calibrations. Some other phantoms are also accepted, thus the PMMA slab one is recommended to achieve uniformity in calibration procedures. To be able to determine the individual monitoring operational quantities, the quantity to be used for calibration purposes is defined as the dose equivalent in a phantom having the composition of ICRU tissue and the same size and shape as the calibration phantom. Consequently, conversion factors relating air kerma and photon fluence to personal dose equivalent $H_p(10)$ for normal photon incidence on a 30 cm x 30 cm x 15 cm depth slab phantom of ICRU tissue are given in ICRU 47. Corresponding values for $H_p(0.07)$ are given by Grosswendt (4).

Although ICRU 47 has clarified and simplified personal dosimeter calibration procedures, two main aspects remain unsolved. First of all, the report does not provide conversion coefficients for filtered X radiation specified by ISO 4037 and its amendment (5), which are very often used in personal dosimetry calibrations. Moreover, no correction is considered for backscatter differences in PMMA and ICRU tissue. The aim of this study is to obtain conversion coefficients relating air kerma to $H_p(10)$ and $H_p(0.07)$ for ISO X ray narrow spectrum series using an ICRU slab phantom and to propose a backscatter correction factor for ISO spectra when calibration is performed with the recommended PMMA slab phantom.

CALCULATION PROCEDURES

Conversion coefficients relating air kerma in free air to personal dose equivalent for ISO X ray narrow spectrum series have been calculated by means of equation 1, integrating the conversion coefficients for monoenergetic photons (4) over the X-ray spectra given by Seelentag et al (6), corresponding to the ISO narrow spectra.

$$\overline{F}_K = \frac{\int_0^{E_{max}} K_{air,E}\, F_K(E)\, dE}{\int_0^{E_{max}} K_{air,E}\, dE} \qquad (1)$$

where $K_{air,E}$ is the energy spectral distribution of air kerma, namely, $\frac{dK_{air}}{dE}$, E_{max} is the maximum energy of the considered spectrum and $F_k(E)$ is the conversion coefficient for energy E.

To simplify the calculation, the coefficients for monoenergetic photons $F_k(E)$ have been fitted to two analytical functions similar to the ones proposed by Wagner (7), for coefficients in the ICRU sphere. $F_k(10)$

and $F_k(0,07)$ for ISO X ray spectra are shown in table 1.

Calculations have also been performed using the spectral distribution of air kerma from experimental X ray spectra obtained in our laboratory and the differences with the values stated in table 1 were lower than 1 %.

Generating Voltage (kV)	GSF spectrum n°	Mean energy (keV)	$\overline{F}_K(10)$ (Sv/Gy)	$\overline{F}_K(0,07)$ (Sv/Gy)	k'_p
40	37	32,5	1,174	1,265	0,925
60	54	47,3	1,650	1,551	0,922
80	65	64,5	1,884	1,718	0,932

Table 1. Conversion coefficients and backscatter correction factors for calibrations using a 30 cm x 30 cm x 15 cm depth PMMA phantom for the X ray narrow ISO spectra series from reference (6).

A PMMA phantom produces a different scatter at its surface than an ICRU phantom. To estimate this difference the ratio between the backscatter phantom of both materials is calculated as

$$k'_p = \frac{B_m^{ICRU}}{B_m^{PMMA}} = \frac{(K_m)_{ICRU}}{(K_m)_{PMMA}} \qquad (2)$$

where k'_p is the backscatter correction factor which quantifies the difference of kerma in the dosimeter material m if it is situated on the surface of a PMMA slab or an ICRU slab. We consider that this factor should not be disregarded and that the dosimeter reading should be adequately corrected. Variations of k'_p in air and tissue are within 1%, and since most detectors are good substitutes of air or tissue k'_p is obtained as

$$k'_p = \frac{(K_{ICRU})_{ICRU}}{(K_{ICRU})_{PMMA}} \qquad (3)$$

In the energy range considered in this study, kerma ratio indicated in equation (3) can be substituted by air collision kerma ratio which in turn can be approximated to dose equivalent at 0 mm depth on the PMMA and ICRU tissue slab. k'_p for monoenergetic photon has been obtained from Grosswendt data (4) as the ratio of dose equivalent in the two phantoms. k'_p varies with energy, therefore, as it was done with $F_k(d)$, a mean backscatter correction factor is calculated for the ISO X ray narrow spectrum series as

$$\overline{k'}_p = \frac{\int_0^{E_{max}} K_{air,E}\, k'_p dE}{\int_0^{E_{max}} K_{air,E}\, dE} \qquad (4)$$

Calculated values for Seelentag spectra (5) are shown in Table 1. Correction factor can be seen to range between 2 % and 8 %, which we think is not negligible.

Another problem that arises with the use of personal dose equivalent quantities is the difficulty to assign an uncertainty to the conversion coefficients; obviously this is not suitable for a calibration procedure. To achieve the desired good uniformity, some agreed conversion coefficients should be established by international organisations such as ICRU or ISO and the associated uncertainty evaluated comparing different authors' calculations or when possible comparing experiment and calculation. At the moment, little information is available concerning this (8,9).

CONCLUSIONS

From these results it can be stated that the use of a backscatter correction factor improves uniformity between calibration procedures which is very desirable despite the uncertainty inherent in personal dosimetry. Consequently when a PMMA slab phantom is used for calibration the personal dose assigned to the dosimeter should be

$$\frac{H_p(d)}{k'_p} = \frac{F_k(d) \cdot K_{air}}{k'_p} \qquad (5)$$

and for calibration beams,

$$\frac{H_p(d)}{\overline{k'_p}} = \frac{\overline{F_k(d)} \cdot K_{air}}{\overline{k'_p}} \qquad (6)$$

Since ICRU recommends a practical phantom such as the PMMA slab phantom, we believe that calibration procedures in this field should make this the standard phantom. If this was so it would be much easier to establish a set of internationally-agreed conversion coefficients for all ISO calibration qualities and to reasonably estimate the associated uncertainty.

Introduction

Multi-element dosemeters are frequently used in individual monitoring. Each element can be regarded as an individual dosemeter with its own individual dose measurement value. In general, the individual dose values of one dosemeter vary according to the exposure conditions, i. e. the energy and angle of incidence of the radiation. The (final) dose measurement value of the personal dosemeter is calculated from the individual dose values by means of an evaluation algorithm. The best possible dose value, i. e. that of the smallest systematic (type B) uncertainty if the exposure conditions are changed in the dosemeter's rated range of use, is obtained by the method of linear programming.

Mathematical basis

The mathematical problem of determining the measured dose value H of the entire dosemeter from the individual dose values of each detector element $\{D_k,\ k = 1, \cdots, m\}$ has been described by Bermann and Chanourdie [1] in the form of a set of linear algebraic equations:

$$D_k = \sum_{i=1}^{n} a_{i,k} \cdot H_i \qquad k = 1, \cdots, m \tag{1}$$

$$H = \sum_{i=1}^{n} H_i \tag{2}$$

Here n denotes the number of the different radiation fields used for the calibration, and m denotes the number of the individual detector elements in the dosemeter. In the evaluation of the dose value H, m individual dose values $\{D_k,\ k = 1, \cdots, m\}$ are therefore measured. The response matrix $a_{i,k}$ contains the response of the m individual detector elements of the dosemeter to the n different radiation fields used for calibration. In the evaluation of H it is assumed that the dosemeter has been exposed to a radiation field which can be described as a linear combination of these n calibration fields with dose contributions H_i, see eq. (2).

The solution of a set of linear algebraic equations of the form of eq. (1) and (2), i. e. here the determination of a set of dose contributions $\{H_i,\ i = 1, \cdots, n\}$, is completely covered by the theory of linear programming and was described in [2] including the following two problems:

- Frequently the set of equations (1) cannot be solved for a set of measured individual dose values.
- If the set of equations (1) can be solved, usually the solution is not a unique one. In this case, the dose values H, see eq. (2), form an interval:

  $$H_{min} \leq H \leq H_{max} \tag{3}$$

  with all values of H within the interval being solutions of the set of equations (1) and (2). This problem has been described in [3].

At present, in radiation protection the dose evaluation algorithms listed in table 1 are applied to determine the dose value H from the individual dose values $\{D_k,\ k = 1, \cdots, m\}$. Each of these evaluation algorithms can be interpreted as an attempt at finding a solution of the set of

equations (1) and (2). The algorithms differ with respect to the information made available concerning the uncertainty of the dose value H and concerning the dose contributions $\{H_i, i = 1, \cdots, n\}$ to the dose value H, i. e. the spectrum of the radiation field.

***Table 1.** Additional information resulting from the various dose evaluation algorithms.*

Evaluation method	Additional information about:	
	uncertainty	spectrum
(A) Methods using ratios of the individual values	No	Yes
(B) Linear combination method	Yes	No
(C) Linear programming method	Yes	Yes

At least in Germany, above all the algorithm (A) is applied at present. To support the dose evaluation by algorithms (B) and (C) a program named »LINOP« and the corresponding manual were developed [4]. The program allows both the determination of the optimum coefficients for the linear combination method and the dose evaluations by linear programming using the simplex method to be carried out in the routine monitoring of a dosimetry service.

In the following, the evaluation algorithms mentioned previously are described in more detail. The results of a test of »LINOP« by corresponding measurements are presented.

Methods using ratios of the individual values

By the methods using ratios of the individual values (A), one single dose value compatible with the set of equations (1) and (2) and the corresponding spectrum are determined. The set of equations is not completely solved, i. e. the interval $[H_{min}, H_{max}]$ is not determined. The uncertainty of the measured dose value must therefore be assumed to be of the size found in performance tests carried out with well-defined radiation fields and well-defined irradiation conditions. The actual uncertainty cannot, however, be determined by these methods.

Linear combination method

By the linear combination method (B), the set of equations (1) and (2) is solved neglecting the information concerning the spectrum, which are contained in the individual dose values:

$$H = \sum_{k=1}^{m} \sigma_k \cdot D_k \qquad (4)$$

The optimum coefficients σ_k minimizing the uncertainty of measurement of this method are obtained by linear programming [2, 4] using eq. (1) and (2) together with the minimization of the maximum uncertainty of measurement of all calibration measurements. The uncertainty of measurement to be specified in the evaluation of the dose value is independent of the individual dose values $\{D_k, k = 1, \cdots, m\}$ of a single measurement, but is equal to the maximum interval $[H_{min}, H_{max}]$ resulting from all individual dose values of all calibration measurements. Neglection of the information about the spectrum therefore leads to an increasing uncertainty of measurement.

Linear programming method

For every measurement the method of linear programming (C) [2, 4] furnishes the set of dose values compatible with the set of equations (1) and (2), i. e. the dose interval $[H_{min}, H_{max}]$ depending on the individual dose values $\{D_k, k = 1, \cdots, m\}$ of the respective measurement. The spectra corresponding to H_{min} and H_{max} can be specified. This method is applicable to

every measurand and to every multi-element dosemeter and, in every case, yields the minimum uncertainty of measurement.

The results of the »LINOP« program were verified by measurements with a four-element laser TLD dosemeter [5] (see table 2). The response matrix $a_{i,k}$ of this TL-dosemeter consists of the responses of the four single elements to X-ray radiation of the ISO narrow spectrum series (N-30 to N-300) and to gamma radiation of ^{137}Cs and ^{60}Co at angles of 0°, 30°, 45° and 60° on an ISO water slab phantom. The measured value M_p of the personal dose equivalent is the geometric mean of H_{min} and H_{max}. The maximum possible dose interval $[H_{min}, H_{max}]$ was calculated by »LINOP«. The calculation of the maximum dose interval not only furnishes the corresponding calculated individual dose values D_k^c of the four single elements but also the irradiation conditions, i. e. the dose contributions H_i of the radiation qualities Q_r at the angles of incidence α, which lead to these individual dose values D_k^c. These irradiation conditions are calculated for $H = H_{min}$ and $H = H_{max}$, H being the dose to which the dosemeter is exposed. Irradiation of the dosemeter in a radiation field satisfying these calculated irradiation conditions and subsequent evaluation of the dosemeter lead to the measured individual dose values D_k^m which are slightly different from the calculated dose values D_k^c which then result in a slightly different dose interval $[H_{min}, H_{max}]$.

The comparison of the calculated and measured individual dose values and the resulting dose interval listed in table 2 yields good agreement between calculation and experiment. The calculated and measured data differ only slightly within the uncertainty which can be achieved with the TL-detectors used.
