IRPA

The International Radiation Protection Association (IRPA) is a world-wide international association made up of individual members who are members of an affiliated national or regional Associate Society.

IRPA now has more than 15.000 individual members in more than 35 Associate Societies which are active in over 40 different countries.

The primary purpose of IRPA is to provide a medium whereby those engaged in radiation protection activities in all countries may communicate more readily with each other and through this process advance radiation protection in many parts of the world. This includes relevant aspects of such branches of knowledge as science, medicine, engineering, technology and law, to provide for the protection of man and his environment from the hazards caused by radiation, and thereby to facilitate the safe use of medical, scientific and industrial radiological practices for the benefit of mankind.

It is a major task of IRPA to provide for and support international meetings on radiation protection. The Congresses of IRPA itself are the most important of these meetings. These have been held about every four years since 1966.

1966	Rome, Italy	1980	Jerusalem, Israel
1970	Brighton, UK	1984	West Berlin, FRG
1973	Washington, DC, USA	1988	Sydney, Australia
1977	Paris, France	1992	Montreal, Canada

For all Associate Societies of IRPA and individual members, it is an important objective to attend the next International IRPA Congress in Vienna. For many other related professions it is an excellent opportunity to communicate their achievements, scientific knowledge and operational experience in radiation protection.

Professional training will be an important part of the Congress programme. Additional to the scientific sessions, the IRPA9 Congress offers a wide selection of refresher courses.

During the Congress the General Assembly of IRPA will be convened. As an adjunct to the business function of this meeting, the Associate Societies Forum will take place.

IRPA and the Austrian host society, with the help of related international organizations and the Associate Societies of IRPA, will provide support mechanisms for a substantial number of qualified colleagues who otherwise would be unable to participate in the Vienna Congress, solely for financial reasons. A particular reason for IRPA to hold the Congress in Vienna is to enable a larger participation by colleagues from the Central and Eastern European regions.

It is my privilege to invite you all on behalf of IRPA to the international IRPA9 Congress in Vienna, Austria.

Charles B. Meinhold, IRPA President

WELCOME ADDRESS TO THE PARTICIPANTS

Dear Colleagues,

The preparations for the IRPA9 Congress in Vienna are finished and the proceedings being printed. We have totally received almost 1000 abstracts from 52 countries, most of the abstracts have been accepted for poster presentation, some also for oral „mini-presentations". The details of the scientific programme have been finalised by the scientific programme committee. It consists of seven plenary lectures, including the „Sievert Lecture" by Dan Beninson, four parallel "Symposia" each day with 2 - 4 invited speakers, who will discuss general aspects and new developments of 16 particular topics in radiation protection. There will be totally 12 "Mini-Presentations", four in parallel on Monday, Tuesday and Thursday, where selected poster authors present the salient points of their work, to be seen afterwards on the poster and discussed during the successive "Posterdiscussions". Friday will be devoted to Chairmen Summaries, which will condense and recapitulate important trends and new developments presented during the congress, to provide a complete overview and the basic message of IRPA9. As during IRPA8, there will be 16 early morning „Refresher Courses", four in parallel every day except Monday. So we can expect an excellent scientific programme, bringing together world-renowned experts with a representative group of today's Radiation Protection Community.

To complete the scientific programme there will be an extensive Technical Exhibition comprising all modern instrumentation in ionising and non-ionising radiation protection by the leading manufacturers from all over the world. The exhibition will be located directly adjacent to the conference rooms and the posters and open during the whole week.

In Montreal we have promised to spend every effort, that IRPA9 will enjoy a much larger participation by our colleagues from the countries of the former "Eastern Block", as it has been possible for the previous IRPA Congresses. As a first step towards this goal, the organising committee, in agreement with the IRPA Executive Council has decided to reduce to conference fee by 50% for participants from these countries. We are aware, that this alone will not be sufficient, and therefore we raised Sponsoring money from different sources, such as IRPA Associate Societies, IRPA8, the CEC, the Austrian government. Thanks to our sponsors we have been able to additionally support about 100 colleagues from the Eastern European Countries.

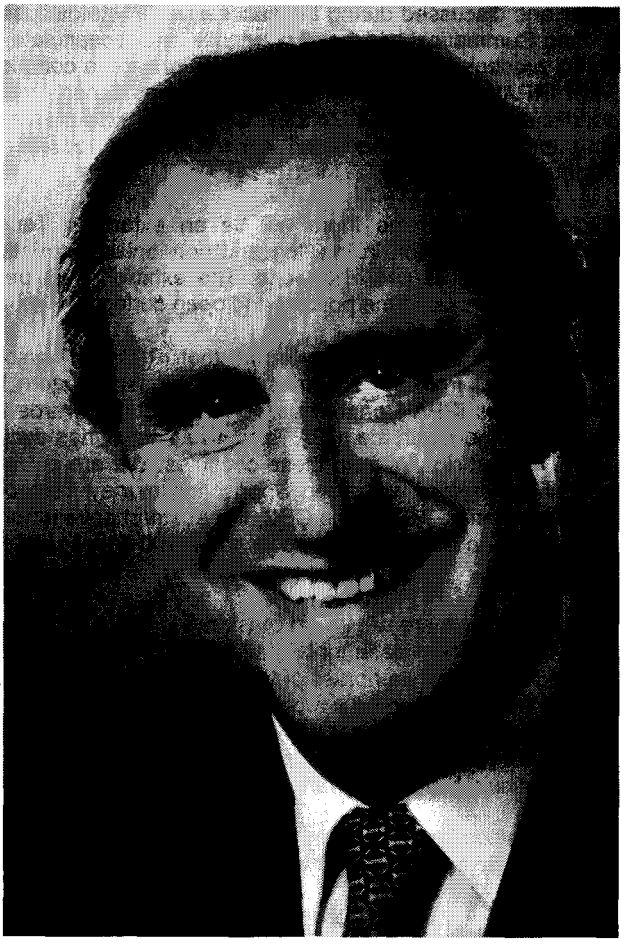
Apart from the scientific events, there will be an outstanding social programme, including a Baroque Concert in the magnificent ceremonial hall of the Imperial Palace, and a special performance of the world-famous white horses of the "Spanish Riding School", shown in our LOGO on the first page. There will also be a reception by the Major of Vienna at the Vienna City Hall and a Congress dinner at a typical Viennese „Heurigen-Restaurant". There will be plenty of other opportunities for cultural events, for the Ladies Programme and for pre- and post-congress tours to particularly beautiful parts of Austria and it neighbouring countries.

So we look forward to welcoming you all in April 1996 in the magnificent halls of the Vienna Imperial Palace and wish IRPA9 every success.

Klaus E. Duftschmid
Chairman, Organising Committee

Herwig G. Paretzke
Chairman, Programme Committee

Under the Patronage of
The President of
the Republic of Austria
Dr. Thomas Klestil



Welcome address to the participants

I greet all participants to the 9th Congress of the "International Radiation Protection Association" and I welcome them very warmly to the Congress Centre at the Vienna Hofburg Palace. I congratulate the Austrian Radiation Protection Association (ÖVS) on the honourable task of organising this important convention.

Ever since nuclear energy was first applied for peaceful purposes, radiation protection has assumed increasing importance for the general public. In this respect the Austrian Association, in cooperation with the other members of IRPA, fulfils the important responsibility of raising the awareness of the public by providing objective and honest information. In addition, I also would like to thank you for your important work towards the task of deducing, from the body of scientific knowledge, the appropriate suggestions on how the protection of the population can best be guaranteed above all by means of effective legal provisions in the various countries.

I therefore wish this 9th Congress of the IRPA every success in its debates, analyses and resolutions!

RISK OF RADIATION AT LOW DOSES

D. Beninson
Nuclear Regulatory Authority, Buenos Aires, Argentina

1. INTRODUCTION

Risk and risk sources have been increasingly studied in recent years. The essentials of risk consist of a combination of the idea of loss with that of chance or probability. The idea of chance is crucial: the inevitable can be utterly unpleasant but, lacking the element of chance, is not a risk.

Even without analyzing the different components of the concept of "loss", it should be recognized that to be exposed to risk is not necessarily bad. The achievements of modern life imply the exposure to several sources of risk, and past evolution would have been impossible without the risk incurred by our ancestors.

A special type of risk, pertinent to our discussion, is exemplified by the health threats due to low levels of natural or man-made chemicals and low radiation levels. It constitutes a risk very difficult to analyze, not because the effects are unknown but because they are already very familiar, and exposed groups only manifest a slightly increased frequency of such effects.

2. RADIATION RISK

At high doses ionizing radiation is clearly detrimental, the scene being dominated by the deterministic effects, e.g. death via the acute radiation syndrome. There is no doubt here of the causal relation between radiation exposure and effect. At somewhat lower doses, deterministic effects are not produced but, if the exposed group of individuals is large enough, a clear increase of induction of cancer over the spontaneous rate can be demonstrated. While the relationship between radiation and cancer is quite clear in these cases, it is not possible to state with certainty if a given individual will be affected or if a given case of cancer is the result of the exposure.

At even further lower doses, the observed relationship between radiation and cancer blurs due to increasingly larger uncertainties, reaching a point where an effect, if it exists, can not be detected. Many discussions have stemmed from this fact, where defenders of the existence of a threshold have claimed that no effect exists at all below such doses. This, of course, could be true but certainly not because of the lack of observation.

2.1. STATISTICAL DETECTABILITY AND CLAIMS OF THRESHOLD

Even assuming a non-threshold linear relation between risk (here used in a loose way meaning probability as the considered effect is only cancer) and dose, the required number of individuals, N, incurring a dose D, for achieving detectability increases steadily with a reduction of dose. If all other influencing factors are kept constant, the excess number of cancers attributable to radiation and its standard deviation are given by

$$\text{Excess} = rDN$$

$$\sigma = \sqrt{2bN + rDN}$$

where b is the "natural" risk of cancer, appropriate to the group under study, and r is the risk per unit dose in the group.
In order to be detectable the excess must be larger than a stipulated number of standard deviations (usually two, for a level of significance of about 95%). Therefore

$$rDN \geq 2\sqrt{2bN + rDN}$$

In most cases, the "natural" cancer risk is substantially larger than rD and therefore (2b + rD) is practically constant. It follows after a simple algebraic manipulation that, for that stipulated level of significance,

$D^2 N \geq$ constant

For example, if a given type of cancer has been shown to be related to radiation in a group of a few thousands having incurred a dose of the order of 1 Gy, then to show the same relation with doses of the order of 100 mGy one would require groups of a few hundred thousand individuals.

This argument is simplistic as it ignores most of the complicating factors involved in epidemiological studies but is sufficient to dismiss most of the reported efforts to prove significant thresholds. On the other hand, it must be recognized that epidemiological studies at the lower dose, specially those of cancer types of smaller "natural" incidence can contribute to the progress of our knowledge, but extreme prudence is required when the results are negative.

2.2. ANIMAL EXPERIMENTS AND THE DOSE-EFFECT RELATION AT LOW DOSE

Experiments with animals, usually small, offer the possibility of increasing the number when necessary and to plan the exposures in order to cover the required range. Obviously the results are not directly applicable to man (for example the observed slopes), but general information can be derived on the shape of the dose-effect relationship and on the action of parameters thought to influence the relationship.

On the other hand, the same problem of detectability appears at low doses. To improve (but not solve) the situation, the experiments would require, as it is usually stated, too many "mice", too much money and too much time to be practicable. Even if the experiments were possible, they would always leave a region of dose where direct observations are not available, and it is that region that interest us the most. The main issue is how valid are the extrapolations of results observed at higher dose to the dark region.

2.3. EXTRAPOLATION FROM DOSES AT WHICH OBSERVATIONS WERE MADE

Sometimes it is claimed that searching for the function that best fits the observations would provide the solution to the extrapolation problem. This, of course is nonsense: there are infinite functions that would pass exactly through all the points representing the observations.

In order to carry out regression analysis, it is necessary *first to select the functions to be tested.* It is then possible to make conclusions about the goodness of the fit, to compare the two or more pre-selected functions, etc.. It seems, then, unavoidable to conclude: a) neither epidemiology nor animal experiments will establish the shape of the dose-effect relationship at low doses; b) if a shape is selected on other grounds, they will help in obtaining values of the parameters applicable to man and in testing the model when any new datum is obtained below the existing set of data.

2.4. CELLULAR AND MOLECULAR RADIOBIOLOGY AND THE MODEL DOSE- EFFECT RELATIONSHIP

One common criticism against the use of modeling of the dose-effect relationship (on the basis of the results of fundamental radiobiological research) is that the predictions made by such modeling are "unscientific", because of the lack of epidemiological data in the region of doses of the prediction.

This criticism is in itself utterly unscientific. It is sufficient just to mention the discovery of a new planet and the observation of the predictions of relativity to dispose of the criticism. While some natural science is description of what is observed, most of it is the blend of modeling from some observations, predictions sometimes leading to other observations, theoretical constructions and searching for new and crucial experiments.

A very wide knowledge exists on the effects of radiation on cells. At present the consensus is that for all effects of interest the target of radiation is the DNA. Energy deposition by ionizing radiation occurs by ionisation and excitation. About half the energy deposited in the cells is due to

excitation, but this is of less consequence of ionisation. Energy deposited in DNA affects the molecule either by direct ionisation or by the action of free radicals generated by ionisation in the immediate vicinity.

The immediate effects of such energy deposition are the loss or damage of one of the bases or a segmental loss in the DNA molecule. Sophisticated and efficient repair mechanisms become operative and usually cancel the effect, except in a small proportion of cases, resulting in what is called a misrepair.

The existence of the natural background of radiation reduces the importance of the dose-response relationship at doses close to zero. Almost all the data on stochastic changes in cells, irradiates "in vitro" with low LET radiation can be summarized and interpreted as follows:

a) at low doses (and even at higher doses but with low dose rates) it is very unlikely that more than one ionizing event will occur in the relevant parts of DNA within the time the repair mechanisms operate. Taking account of the Poissonian distribution of ionizing events, the small exponent involved and a small fraction of misrepairs, the dose-response relationship will be linear, as in fact it is.

b) at higher doses and dose rates, two ionizing events may be able to combine effects before the repair mechanisms could cancel the effect of the first event, producing an enhanced probability of DNA transformation, which is reflected by a dose quadratic term in the dose-response relationship.

Obviously, there is quite a distance between transformed cell and clinical cancer. There is, at present, consensus that cancer initiates in a single cell. When the stem cells of a tissue are irradiated, more than one transformation is likely to occur and the number of such transformations is a Poissonian random variable with an average of NP, where N is the number of stem cells and P the probability per cell of transformation. In turn this probability is a linear-quadratic function of dose.

It can be shown that, provided the transformed cell has a developing advantage (somewhat shorter division time), the over all probability that at least one transformed cell results in an established clone that would grow without bound, is also related to dose by a linear-quadratic relationship.

It should be noted that as the dose increases, another cell effect becomes competitive with transformation: interference with cell division and cell death. This would result in a decrease of the probability of inducing cancer.

2.5. LINEAR-QUADRATIC RELATIONSHIP AND EPIDEMIOLOGY

Good epidemiological results (at high doses and dose rates) correspond presumably to the region of dose where the effects are most probable. It is interesting to predict the location of this region of dose using the linear-quadratic relationship:

$$P = (a\,D + b\,D^2)\,e^{-cD}$$

where p is the probability of cancer, a and b are constants and the factor e^{-cD} is the survival fraction of exposed cells.

Deriving and equalizing to zero, the following expression can be obtained:

$$cD_m = \frac{\frac{a}{b} + 2D_m}{\frac{a}{b} + D_m}$$

where D_m is the dose that maximizes the probability of induction of cancers.

Without indulging in discussions of the values of a and b, one can take two extreme cases: in one the ratio $\frac{a}{b}$ is assumed to be vanishingly small compared to D, and in the second ratio $\frac{a}{b}$ is assumed to be very much larger than D_m. For these two cases the product cD_m would tend to the values of 2 and 1 respectively. The cell killing coefficient c has been experimentally measured for many tissues, and for humans a value of 1 Gy^{-1} can be taken as typical.

It follows that the region of dose with good epidemiological results is predicted to be between one and two gray, in very good correspondence with reality.

A very important issue in the evaluation of the risk (probability of attributable cancer death) per unit dose at low doses, is the extrapolation to the low dose region of the epidemiological observation at high doses and dose rates. A usual procedure is firstly to assume a straight line between the observation and the origin of the coordinates and then divide the resulting slope by the so-called Dose and Dose Rate Effectiveness Factor.

In terms of the linear-quadratic relationship, the risk (probability of attributable cancer death) at a high dose D with high dose rate extrapolated linearly to the origin would give a slope of a + bD, and the DDREF is given, therefore,

by the ratio $\frac{a + bD}{a}$

$$DDREF = 1 + \frac{b}{a} D$$

It can be observed that the factor will increase linearly with D, the dose at which the epidemiological results apply. At typical values, where the linear component of the relationship contributes to the probability about the same than the quadratic in the vicinity of one gray and taking the range of observations as one to two grays, the factor appears to be in the range of two to three. This range of values agrees well with many reported human data. Animal experiments that have a wider range of factors, have also a range of doses greater than the human experience.

2.6. CRITICISM OF THE LINEAR NON-THRESHOLD RELATION

As always with emerging solutions of scientific issues there is a main stream of consonant opinions and voices of dissent. The dissent is sometimes a valid scientific discussion but in other cases reflects an assortment of gut feelings, reactions to public opinion and even interests.

a) Scientific discussions

Of the many issues raised, two recent ones are dealt with here. One stems from the genetics of cancer development and the other from consideration of the "adaptive" response to radiation.

It has been shown that several mutations are required for transformation and acquisition of malignancy of given cancer types. If this is true, the argument goes, then radiation cancer probability should be strongly curvilinear with dose with negligible risk at low doses. If the target for each mutation requires at least one ionizing event then the probability of mutation can be expressed as $[1 - e^{-kD}]$ and for similar n targets the overall probability P will be given by

$$P = [1 - e^{-kD}]^n$$

With usual values of k (mutation rate per unit dose) and with n having reported values ranging from 2 to 7, the argument seems quite correct. However it should be remembered that there are also "spontaneous" mutation rates for the same targets. These rates must be substantial to account for the cancer frequency prevailing in man. The radiation attributable cancer probability is then given by the difference

$$\Delta P = [1 - e^{-(St + kD)}]^n - [1 - e^{-St}]^n$$

where S is the rate of spontaneous mutation of a target and t the age. Two basic concepts emerge from the analysis and graphical representation of the above expression: a) provided St is substantially larger than kD, then the radiation attributable risk AP appears to be linear with dose. b) it is necessary to have important spontaneous mutation frequencies to experience radiation risks at low doses. Our risk values per unit dose would then be valid for our present environment.

Another scientific argument against the linear-quadratic relationship (which at low doses or low dose rates becomes the linear non-threshold relation) relates to the denominated adaptive response to radiation. It has been shown by experiments involving irradiation following a pregiven dose, that repair mechanism can be stimulated and the repair rate increased. This, it is claimed, would completely change the shape of the relation at low doses.

The issue is very complex. An increased rate of repair could also increase the rate of misrepairs, being the misrepairs a fraction (small) of the repairs. In an extensive analysis, UNSCEAR has concluded that "Extensive animal experiments and limited human data provide at present no evidence to support the view that the adaptive response in cells either decreases or increases human risk at low doses".

b) Other types of criticism:

It is difficult even to attempt to classify all the non-scientific criticism raised against the linear non-threshold relation. In most of them one can find elements of arrogant ignorance, apparent concern for the peace of mind of the public and gut feelings.

In many cases the criticism is only one component of a larger "defense" of a particular risk source. This is particularly the case of nuclear power, which does not need nor it deserves these self-appointed defenders. Even the more honest types of such defenders indulge in statements such as "if the public would just know the facts (of course not presented as the radiation protection community would present) then"...

Some criticisms are really requests for "putting the risk in perspective", referring to a risk source, usually nuclear power. Since a risk source has many attributes, the comparison must involve comparable attributes. An essential fact, many time ignored is called the principle of "ceteris paribus", which means that all factors which are not explicitly presented in the risk characterizations must be mutually equivalent, in a valid risk comparison.

3. CONCLUDING REMARKS

The linear non-threshold relationship, is at present the best tool to predict the risk probability of radiation at low doses. It fulfills all the requirements to be considered "realistically representative", using modeling terminology.

Practical decisions can be made under this relationship, and the radiation protection system recommended by the ICRP provides a method for such decisions.

ONE HUNDRED YEARS OF X RAYS AND RADIOACTIVITY-- RADIATION PROTECTION: THEN AND NOW

Charles B. Meinhold
Brookhaven National Laboratory, Upton, NY 11973-5000
and
National Council on Radiation Protection & Measurements, Bethesda, MD 20814-3095

It is not particularly remarkable that this topic was one that I chose for an IAEA Symposium which I presented in 1974 (1). My thesis in 1974 was that the basic recommendations and regulations on dose limitation were unchanged from the early 1920s to the date of that lecture. What is remarkable is that during the middle to late 1970s the basis for such recommendations changed to a scientific approach based on risk, and as a result, the recommendations have been under change and modification ever since, although perhaps, as we will see, we may be at a point of some stability once again. I will return to the historical developments, particularly relevant during this Congress when we are celebrating the discovery of the X ray by William Conrad Roentgen just 100 years ago this past November, and the discovery of radioactivity by Becquerel 100 years ago last month. You should also understand that much of this presentation will focus primarily on activities of both the National Council of Radiation Protection and Measurements (NCRP), with particular emphasis on the International Commission on Radiological Protection (ICRP).

Of course, man has evolved in a sea of ionizing radiation. Enhanced exposure to natural radiation took place the first time man moved to a cave where the radon progenies were there for him to inhale. The first occupational exposure that we can trace back in recorded history was to the miners of Joachimsthal and Schneeburg in the 15th and 16th Century Czechoslovakia and Saxony who developed lung cancer from breathing radon progeny while mining for lead (2).

In the middle to late 1850s, gas-discharge physics was a hot topic and the source of wide-ranging experiments in virtually every physics laboratory. These tubes could be found in every high school science laboratory and in any university physics laboratory. On November 8, 1985, Wilhelm Conrad Roentgen was working in his Würzburg laboratory with a Crookes discharge tube. As he was adjusting the high voltage on his gas-discharge tube that he had covered with dark cardboard, he saw his screen of florescent materials lying on the table nearby fluoresce. He realized that he was observing the results of a highly penetrating ray, which he called the X ray. He spent the next two months carefully investigating in detail the properties of this new X ray. During this period, he discovered virtually all of the classical physics properties of the X ray. During these two months he told no one about this discovery except for an anecdotal story which relates that his wife was complaining about his missing meals and being extremely introspective and uncommunicative. Roentgen reportedly took her to his lab where he took an X-ray photograph of her hand -- to her complete astonishment and to his great relief -- he was not, after all, losing his mind! He submitted a paper describing his observations in less than 60 days, during December of 1895 (3). The results of his work were reported in the popular press in Vienna on January 5, and in London and New York by the middle of January 1896. Everyone who owned a gas-discharge tube learned that if they applied high enough voltage they could generate X rays. Thomas Alva Edison was one of the first to see the potential commercial applications of these X rays. For example, in early February, he began a highly publicized attempt to X ray the human brain. Edison had hoped to market an X-ray light bulb, but eventually came to understand the inherent dangers associated with such practices when his assistant, Clarence Dally, died in 1904 as a result of his excessive exposures (4). Dally's death, which was widely reported, had a sobering effect on all of those who were using X rays. In fact, Edison completely stopped working with X rays at this point, although he had already developed a hand-held fluoroscope (5).

When Antoine Henri Becquerel learned of Roentgen's discovery of the X ray using fluorescent materials, he was determined to study these processes in more detail. The material Becquerel chose to work with, fortunately, was a double sulfate of uranium and potassium, which he exposed to sunlight and then placed on photographic plates wrapped in black paper. When developed, the plates revealed an image of the uranium crystals (6). His conclusion was that "The phosphorescent substance in question emits radiation which penetrates paper opaque to the light." He believed that the sun's energy was being absorbed by the uranium which then emitted Roentgen's X rays. However, because the weather was poor on the 26th and 27th of February, Becquerel returned to a desk drawer the uranium-covered plates that he had intended to expose to the sun. On the first of March, when he developed these plates, he expected only very faint images. To his surprise, however, they were clear and strong.

He now realized that the uranium itself was emitting radiation without an external source of energy, and he had discovered radioactivity (7). All by the first of March 1886.

Marie and Pierre Curie, quickly realizing the importance of Becquerel's findings, separated the uranium from pitch blend and eventually found the elements radium (8) and polonium (9), which they laboriously separated from the ore over a period of four years. By 1902, they had a tenth of a gram of radium. During this period, Henri Becquerel had obtained a sample of radioactive material from the Curies, which he placed in a waistcoat pocket. He observed that having worn this waistcoat for less than six hours, he had received a deep burn on his chest (10). He recognized that if this could be destructive to healthy tissue, it should also be destructive to cancerous tissue. As a result of his and the Curies' work, radium followed the same path as X rays in the development of both the medical and nonmedical use of radiation.

By and large, it was the medical community that recognized the enormous potential of the X ray and radium. It was interesting that medicine at that time was dealing with a difficult problem of the use of electrotherapy. Although this practice was being discouraged by the medical community as a whole, the practitioners were still there, and their equipment was ideally suited to the generation of X rays.

During the next few years, medical use of the X ray expanded rapidly, and indeed, this became known as the era of "bullets, bones, and kidney stones." The physicians realized from the beginning that while the medical benefits were unlimited, there were potential hazards from radiation exposure. There were reports in the scientific literature and in the popular press of ulcers that did not heal and scores of skin burns, both among the patients and the physicians (11). The first ulcerating skin lesion was reported by an electrotherapist named Grubbé on January 26, 1886, within a month of the discovery of the X ray (12). By 1915, only 15 years after the introduction of the X ray, both the German Radiological Society and the British Radiological Society had prepared recommendations for physicians on avoiding unnecessary exposure (13). Although these rules were not very definitive, they demonstrated that the societies understood that there was a problem.

As indicated above, the medical community had adopted this technology, and once a medical association takes ownership of a modality of this kind, they tend to protect it as their own. In the United States, and pretty much in England and in France, a physicist could not publish an article unless he had a physician sponsoring the paper. As a result, most of the literature was related to clinical effects and to clinical use. The situation was different in Germany, where physics and medicine grew up together, and the medical community embraced the physics community as its equal. This was primarily because medicine was more heavily regulated in Germany than it had been in these other countries.

Protection advice was not heavily organized until, in 1921, the newly organized X-Ray and Radiation Protection Committee in England presented a set of detailed recommendations as rules that every physician was expected to use (14). The pressure for these recommendations resulted from the development of the hot cathode tube by Coolidge, an engineer at General Electric (15). This tube was able to produce much higher currents and much higher energies. Many of the radiologists now recognized the significant hazard that the use of this equipment posed for them and their patients. Second, World War I had just ended, and hundreds of X-ray machines, mostly with the new Coolidge tube, had been used in the battlefield and were implicated in the many reports in the public press about anemia in the returning soldiers.

It is interesting to note that these military X-ray machines had an enormous impact on the course of radiation measurements as well. The Army Quartermaster Corps wanted to be certain they got what they paid for, i.e., these battlefield machines had to meet military standards. As a result, the National Bureau of Standards was called upon to provide standards, and the physicists involved became more interested in measurement and quantification than had the physicians who had depended upon the redness of skin and whether or not they obtained a good image (16).

Radium commerce also had an impact on measurement. The only way one could specify the quantity of radium was through detailed measurement, which at $100,000 per gram, was very important. Commerce ensured that, at last, there was attention being paid to the measurement of radiation and radioactivity.

In 1922, Mutscheller, in the United States, and Sievert, in Sweden, were concerned about the adequacy of radiation protection. Mutscheller visited a number of well-run clinics in New York City and found that they could operate quite well without anyone being exposed to more than .01 of an erythema dose in 30 days (17). The erythema dose, which is the dose to cause reddening of the skin, had become a common measure of exposure

at this time, primarily since there was no generally accepted physical measurement. Nearly every X-ray operator knew how long it would take to develop an erythema at given locations around their X-ray facilities. At the time Mutscheller made this recommendation, Sievert, in Sweden, arrived at a recommendation of .1 erythema dose in a year (18). It is remarkable that these two independent investigators ended up with virtually the same number. Inherent in their recommendation is the concept of a threshold dose. For example, Mutscheller stated, "for in order to be able to calculate the thickness of a protective shield, there must be known the dose which an operator can, for prolonged period of time, tolerate without ultimately suffering injury." Mutscheller's assumption of a "tolerance" level is consistent with the classical threshold response curve so common in toxicological studies. In fact, it is the kind of relationship we see now in most toxicological studies.

In 1925, the International Congress of Radiology at its meeting in London, formed an X-ray unit committee which was to become the International Commission on Radiation Units (ICRU) (19). Even at the time of formation, the international society recognized the need for an internally accepted definition of an exposure quantity. In 1928, the International Congress held in Stockholm adopted a recommendation from this new committee that defined the Roentgen as "the exposure when the X- or gamma- ray field produces 1 e.s.u. of positive charge and 1 e.s.u. of negative charge in 0.00129 grams of air" (20). This definition remained essentially unchanged for 50 years.

At the Stockholm meeting, the International Congress formed the origins of the International Commission on Radiological Protection, the Advisory Group on X-ray and Radium Protection. The U.S. representative to that meeting was Dr. Lauriston S. Taylor, of the National Bureau of Standards. Dr. Taylor was instructed to return to the United States and form a similar organization for the United States so that they could bring a unified position to the future meetings of International Congresses. Taylor returned to the United States and formed the origins of the National Council on Radiation Protection (the U.S. Advisory Committee on X-ray and Radium Safety). Lauriston Taylor was to chair this advisory committee and its successor organizations, the National Committee on Radiation Protection and Measurements and the National Council on Radiation Protection and Measurements, for 49 years until his retirement in 1977.

Shortly after the ICRU provided the definition of the Rontgen, both the International Commission on Radiological Protection (ICRP) and the National Council on Radiation Protection and Measurements (NCRP) made recommendations dealing with exposure levels. The ICRP recommended no more than .2 R/day (21). This is a reasonable measure of the exposure that would result in about .01 of the erythema dose in thirty days. What they had done was to adopt, in a way that could be measured, what Mutscheller and Sievert had recommended earlier. This recommendation, although quantifiable, was still based on skin reddening. Three years earlier, in 1931, the NCRP recommended .1 R/day (22). The ICRP recommendations applied to measurements made at the surface of the body, while the NCRP recommendations applied to measurements made free in air. Measurements of exposure made at the surface of the body with low energy X rays would indeed be just about twice what they would be free in air. In fact, the NCRP and the ICRP recommendations provided virtually the same level of protection.

Dr. Failla noted, in the 1960 hearings before the U.S. Congress' Joint Committee on Atomic Energy, that he endorsed a limit of .1 R/day based on his observation that two technicians who received that level of exposure showed no observable effects and this limit could thereby be judged to be safe (23).

In the middle 1920s, there were a number of young women working as radium dial painters in New Jersey and elsewhere who tipped their brushes between their lips -- the famous radium dial cases. A New York dentist, Theodore Blum, noted in a three-line footnote to a paper on osteomyelitis of the jaw that he had seen what he termed "radium jaw" in a girl working in a New Jersey dial-painting plant (24).

Much of the early attention to the dial painters came from the National Consumers League, which began under Florence Kelly, and became a virtual crusade (25). By the end of 1926, most of the dial painting intakes had stopped; however, the medical and quasi-medical use of radium and its emanation products were booming. In 1932, a prominent steel executive named Eben Byers, who was a well known amateur golf champion, died of excessive use of a patent medicine, Radithor. Since each one-half bottle contained one microcurie of 226-Radium and one microcurie of 228-Radium, it is not surprising that Mr. Byers' habit of ingesting four bottles per day over an extended period of time resulted in radium poisoning (26). The Los Angeles County Health Department simply could not understand how such a thing could be happening in California, so they went to the California Institute of Technology, where they were put in touch with Robley Evans. This began a long and careful analysis of the effects of radium in bone. By 1941, Evans had studied twenty-seven cases of Radium ingestion, and noted

that there were seven cases with residual body burdens below 0.5 micrograms of Radium and no injuries, and 20 with 1.2 to 23 micrograms with various degrees of injury. He presented this data to the Advisory Committee on X-Ray and Radium Protection. Their consensus opinion was that they would accept Dr. Evans' suggestion of .1 microgram (.1 microcuries) of radium as a level "we would feel perfectly confident if our wife or daughter were the subject" (27). This value was published in NBS Handbook 27, March 2, 1941.

Eisenbud has made the point that I will reiterate here, that it was remarkably fortuitous that, before Pearl Harbor and just after the discovery of plutonium, the community had at its disposal two recommendations, an external exposure limit of .1 R/day and body burden limit on internally deposited radium of .1 ug Ra. Without these numbers, it is hard to imagine what the consequences to workers might have been during the Manhattan Project.

During the Second World War there was extensive research in radiation biology going on in places like Oak Ridge, the University of Rochester, the University of California at Berkeley, and the University of Washington, to try to obtain information on the effects of ionizing radiation. Data was obtained on dose and dose rate effects, depth dose, R.B.E.s, radionuclide metabolism, and dosimetry. Perhaps the most influential radiation protection recommendation to come out of this work was that developed by a committee at the Tripartite Conference Meetings held among scientists from Canada, the United States, and Great Britain, countries with access to extensive wartime data (28). They brought their recommendations to the ICRP and the NCRP in the late 1940s. By the middle 1950s, both the NCRP and ICRP had produced new sets of dose limits derived from all the data obtained during World War II (29,30).

They recommended 600 mrem per week for the skin, and 300 mrem per week for other organs. I was fascinated to realize that .1 R/day is .6 R/week, which is 600 mrem per week, which means that the 600 mrem per week for the skin is based on the .01 of the erythema dose of 1928. The 300 mrem per week limit is more interesting. If the body is irradiated with 150 kV X rays, the dose at a depth of 5 cm is just about half of that at the surface. If protected by a limit of .1 R/day with soft X rays, the limiting dose to the organs at 5 cm would be .05 R/day. If, however, the body is irradiated with high-energy gamma rays, and the same level of protection is desired as that with 150 Kv X rays, then the limit for the skin must be 600 mrem/wk (.1 R/day) and one half of that value or 300 mrem/wk (0.5 R/day) for the organs taken to be at 5 cm.

Starting in about 1954, we entered a new era characterized by weapons testing and the public response to it. Perhaps one of the most important contributors to the public's fear of radiation can be traced to the worldwide reaction to the fallout from the Bravo Weapons Test on Bikini in March 1954. The subsequent plight of the crew of the Lucky Dragon fishing vessel made headlines, and was coupled in the U.S. with the *Life* magazine cover published on April 29, 1954 depicting, for the first time, a thermonuclear explosion. Now people all over the world became concerned about radioactive fallout. Specifically, there were two individuals in the U.S. who led the scientific community in expressing concern: Mueller, a geneticist, who had been speaking about the linearity of genetic effects even during the late 1930s, and Linus Pauling, who worried about internal exposures. As a result of the public concern about fallout, a National Academy of Sciences Committee on the Biological Effects of Atomic Radiation (BEAR) in the United States and the Medical Research Council (MRC) in the United Kingdom were asked to review the radiobiological data (31,32). Both committees came up with about the same estimate of detriment, having focused their attention on genetics. They said that it was unlikely that all of man's suffering and pain from genetic abnormalities came from natural radiation background, but that some of it did. Such a consideration bracketed the genetic risk since they knew the natural radiation background levels and the natural incidence of genetic effects. Based on this analysis, both committees came up with an estimate that suggested individuals (workers) should not receive more than 50 rem to age 30 and another 50 rem to age 40. (The MRC actually recommended 50 R to age 30 and 200 R lifetime). For the population the BEAR Committee suggested a limit of 10 rem to age 30 for all exposure except natural background. I might add that I was able to discuss this with Eugene Cronkite many years ago. Dr. Cronkite was Chairman of the Hematological Effects Subcommittee of the BEAR Committee at the time of the preparation of the 1956 report. I asked him if the recommendations on exposure limitation came from considerations of the radiologists who had been shown to have an excess incidence of leukemia. He answered that the dosimetry was so uncertain that they could not estimate the dose nor the risk per unit dose associated with leukemia among the radiologists. He noted that what they did decide was that they would accept the genetic panel recommendations, and the Academy recommendations were therefore based almost entirely on the genetic estimates based on a linear extrapolation.

The NCRP and ICRP had to decide the way in which they would recommend that the worker be protected under these new recommendations (33,34). As we know, the answer was an annual limit of (age - 18) x 5 rem,

which delivered 60 rem to age 30, etc. The whole-body limit was 3 rem/quarter and (age - 18) x 5 and 15 rem/year for individual organs. By the way, 300 mrem/wk for 50 weeks results in 15 rem/year. Again, the organ limit of 15 rem finds its way back to .01 of the erythema dose in 30 days.

As noted above, my thesis on this subject in 1974 was that there was not a very strong scientific basis for our dose limits. However, this situation changed dramatically by 1977. This was a result of information that came, not in 1977, but from the period 1960-77, and was based primarily on data that was becoming available from the Japanese survivors of the atomic bombing of Hiroshima and Nagasaki who had been under study from the time of the bombs. This study is performed by the Radiation Effects Research Foundation (RERF) under sponsorship by the U.S. Department of Energy (DOE) through the National Academy of Sciences and by the Government of Japan.

I would like to stop here for a moment because everyone should understand the enormous contribution those survivors and the government of Japan have made by their continuing participation in this study. I should add that funding for continuing this important work is now is in question by the U.S. DOE, and it is incumbent on us all to see if we can help to maintain it and to support the absolute necessity for the RERF Directors and Scientific Councillors to set the research agenda.

The United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) and the National Academy of Science's Biological Effects of Ionizing Radiation (BEIR) Committee review the data that comes from RERF. The UNSCEAR was a product of the same issue that brought about the 1956 NAS BEIR Committee: worldwide fallout from atmospheric nuclear weapons tests. It was created by the United Nations General Assembly in December 1955. The UNSCEAR noted that in 1962 the incidence of solid cancer in the Japanese survivors was slightly greater than might have been expected in that population if it had been unirradiated, but that excess leukemia was clearly evident (35), and in 1964, they estimated that other cancers were about equal to leukemia (36). In the early 1970s, they estimated that other cancers were about two times leukemia (37). In 1977, the UNSCEAR provided a fatal leukemia risk estimate of 2×10^{-5} per rem and a total fatal cancer risk estimate of 1×10^{-4} per rem, i.e., the solid tumor risk is about five times the leukemia risk (38).

Based on its own review, the ICRP adopted in 1977 total nominal risk of fatal cancer of about 1×10^{-4}/rem (39). They then compared this radiation risk with the average risk of accidental death in safety industries. In safe industries at that time, one person in ten thousand died each year (1×10^{-4}/year) from accidents, and the ICRP suggested that the radiation workers ought to have at least that level of protection. The ICRP then set a limit of 5 rem/year on the expectation that most people who were protected by a limit of 5 rem/year would be unlikely to exceed 1 rem/year, and, therefore, the average risk fatal cancer will be the same as that for workers in safe industries. In addition, the ICRP suggested that the annual limit on intake (ALI) of radionuclides be based on the specific fatal cancer risk of each tissue results from that intake over the next 50 years. Inherent in the total risk approach is the need to combine internal and external radiation.

The recommendations of the ICRP Publication 60 are based on further changes (40). In 1986, a later set of data from Japan became available which suggested two things. First, there is evidence of increased risks based on new dosimetry and some additional solid cancers. This new data also gave further evidence that cancer from exposure to radiation follows a multiplicative projection model, i.e., attributable cancers will occur at the age they would if there were no exposure, so it isn't until people approach their mid-seventies that these cancers are likely to occur. The ICRP and NCRP have adopted this new risk projection model. Having such a model is needed to estimate what is going to happen to the Japanese survivors over the next 40 years or so. The ICRP and the NCRP had both used an additive model prior to 1990. It is very clear from the Japanese survivor data that exposure to radiation at high dose rates results in excess cancer. You will note "high dose rate" since the doses that show these excess cancers are about 1 Sv, but 1-2 Sv is on the order of the lifetime exposure we might expect for the most highly exposed radiation workers. Therefore, we are talking about an extrapolation from high dose rates to low dose rates, and we must ask the question of whether there is time for recovery and repair which might alter our estimate of risks at lower dose rates. ICRP's Task Group on Risk, chaired by Dr. Arthur Upton, suggested you might be able to reduce estimates from very high doses (dose rates) by about a factor of two to get the best estimate in the risk at low doses (low dose rates) (41). The NCRP Committee on Risk, chaired by Dr. Michael Fry, suggested the risk at high doses (dose rates) could be reduced by a factor of two to three (42). What all this means is that although we now are on a very firm basis in stating that there is excess cancer in the Japanese, we still have concern about whether we are overestimating the risk by a factor of two or three, or underestimating it by about the same factor. But at least this gives us confidence that we have a fairly firm understanding of the risks that people face. In fact, the latest data from the former Soviet Union suggest that this reduction factor

might be about three (43). As we apply these risk estimates to deriving dose limits, the ICRP and the NCRP recognized that the risk estimates had increased by about a factor of four since 1977, when ICRP Publication 26 was published. Since the annual limit was 5 rem in 1977, they might logically have been expected to divide by four and obtain a new limit of 1 rem/yr. The ICRP did note, however, that the new projection model also changed the most likely age of death from an attributable cancer. That changed from an expectation of death in the middle sixties to expectation of death in the late seventies. As a result, the ICRP felt it was important to base the limit on the risk to the most highly exposed individuals (for whom the limit is needed). In this regard, they also noted that the risk of accidental death in industry has been decreasing by ~2% per year. "Safe" industries are now at ~5 x 10^{-5} rather than 1 x 10^{-4} yr^{-1}. Rather than using the safe worker criteria, the Commission felt that it was more appropriate to base their limits on a comparison with an individual worker at the upper end of safe industry risks. This turned out to be about 10^{-3}/year. On this basis, the ICRP recommended a limit of 100 mSv over 5 years and the NCRP recommended a limit based on age in tens of mSv, i.e., if you are 45, you shall not have a cumulative dose >450 mSv (45 rem).

These approaches are tolerable for the rare individual operating at the dose limit, but are totally unacceptable to use for any kind of average exposure for individuals who are working in the industry. It is for this reason that both the NCRP and the ICRP stress that the dose limits themselves are entirely unsatisfactory as a basis for designing a protection system and that optimization should be the focus of our efforts.

The data on exposure to workers and the general public demonstrate the remarkable effectiveness in the application of the optimization philosophy. We can rest assured that the breathtaking advances in medicine and industry can flourish for the benefit of all mankind.

It is only the fear of radiation engendered by incidence the fallout from atmospheric weapons testing (the Lucky Dragon incident), reactor accidents (Three Mile Island, Unit 2), and reactor disasters (Chernobyl) which threaten to derail this remarkable resource. It is essential that those of us in the radiation protection sciences begin to understand public perception and public value so that we can be active and effective participants in public decision-making efforts.

ASSESSMENTS BY UNSCEAR OF RADIATION SOURCES AND EFFECTS

B.G. Bennett
United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR), Vienna, Austria

ABSTRACT

Since 1955, the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) has evaluated the exposures of the world population to the various sources of ionizing radiation and from available radiobiological and epidemiological data has assessed the health effects and risks of radiation. The latest scientific evaluations of the Committee were published in the UNSCEAR 1993 and 1994 Reports. In this paper a summary is presented of the main results of analyses in each of the scientific annexes of these reports.

EXPOSURES FROM NATURAL SOURCES OF RADIATION

The assessment in the UNSCEAR 1993 Report [2] of the annual effective dose from natural sources of ionizing radiation in areas of normal background has not changed from the previous estimate of 2.4 mSv provided in the UNSCEAR 1988 Report [1], although there have been minor adjustments in the various components. One third of the total is due to external exposure to cosmic rays and terrestrial radionuclides and two thirds to internal exposure. The largest component of exposure, half of the total, is from radon and its decay products.

Additional data have been compiled from national surveys of external exposure rates and of radon concentrations. The population-weighted average dose rate in air in areas of normal background is 57 nGy h^{-1} outdoors and 80 nGy h^{-1} indoors. The indoor-to-outdoor ratio is thus 1.5, but the ratio can vary from less than 1 for lightweight houses to around 2 when the construction materials make substantial contributions to exposures. The concentration of radon is typically 10 Bq m^{-3} outdoors and 40 Bq m^{-3} indoors. In tropical areas with houses of lightweight construction and high ventilation, there should be little difference in indoor and outdoor levels. There are, however, too many factors that determine the concentrations, and measurements are necessary in all areas.

The dosimetry of radon is presently under review. UNSCEAR has retained the assumptions used previously, namely equilibrium factors of 0.4 indoors and 0.8 outdoors and a dose conversion factor of 9 nSv h^{-1} per Bq m^{-3} of equilibrium equivalent concentration (EEC) of radon. With these parameters the average annual effective dose from radon and its decay products is estimated to be 0.13 mSv for exposures outdoors and 1.0 mSv for exposures indoors. The average annual effective dose from inhalation of thoron (^{220}Rn) and its decay products is 0.07 mSv.

UNSCEAR has assessed the natural radiation exposures resulting from energy production using coal, oil, peat, natural gas and geothermal energy and the use of phosphate rock in fertilizers and building materials and of mineral sands. The highest exposures result from the use of phosphate by-products in buildings, the domestic use of coal for cooking and heating, and the use of phosphate fertilizers. The overall annual effective dose from all such sources averaged over the world's population is 0.02 mSv.

EXPOSURES FROM MAN-MADE SOURCES OF RADIATION

The assessment of the radiation exposures caused by releases of radionuclides to the environment from man-made practices or events has been updated in the UNSCEAR 1993 Report. Atmospheric testing of nuclear weapons resulted in the largest releases of radionuclides into the environment from man-made sources. Most of the testing occurred in 1952-1958 and 1961-1962. The last atmospheric test was conducted in 1980. From the many measurements that have been made throughout the years, UNSCEAR has evaluated transfer coefficients relating the input of radionuclides into the atmosphere to the resulting dose to humans. The collective effective dose to the world's population from atmospheric nuclear testing is estimated to be 30 million man Sv. Of this total, 86% is due to long-term, low-level exposure from ^{14}C. The contributions to dose in decreasing order of importance are ^{14}C, ^{137}Cs, ^{95}Zr, ^{90}Sr, ^{106}Ru, ^{144}Ce and ^{3}H. Only residual irradiation from ^{14}C, ^{137}Cs, ^{90}Sr and ^{3}H remains to be received by the present and future world population. The collective dose from this practice is equivalent the 2.4 years of exposure of the present world population to natural radiation sources.

There has been an increasing trend in electrical energy generation by nuclear reactors since the practice began in 1956. At present, about 20% of the world's electrical energy is generated by nuclear means. At the end of 1994 there were 432 reactors operating in 29 countries. During routine operation of installations associated with the nuclear fuel cycle (uranium mining and milling, fuel fabrication, reactor operation, reprocessing and waste disposal) radionuclides are released to the environment. The data on radionuclides released are quite extensive and complete, especially for reactor operations.

There have been generally decreasing trends in normalized releases of radionuclides from nuclear fuel cycle installations as operating practices have improved. This has meant that the trend in collective dose to the world population has been increasing somewhat less than the trend in electrical energy generated. The estimate of collective dose from nuclear power production was 43,000 man Sv during 1990 and 400,000 man Sv for the entire period 1956-1990. Even when the collective dose caused by the Chernobyl accident (600,000 man Sv) is added, the total collective dose has been just 8% of that which the world's population receives in one year from natural radiation sources.

Other man-made sources of radiation exposures caused by releases of radionuclides to the environment that have been assessed in the UNSCEAR 1993 Report include exposures to local populations near the Semipalatinsk, Nevada, Australian and Pacific nuclear test sites, exposures from underground nuclear testing, exposures from nuclear weapons fabrication, exposures from radioisotope production and use and exposures from accidents at the Three Mile Island and Chernobyl reactors, Kyshtym and Windscale plutonium production plants, crashes of airplanes carrying nuclear weapons, satellite re-entries and lost or mishandled radiation sources, as at Goiânia.

MEDICAL RADIATION EXPOSURES

The use of x rays and radiopharmaceuticals for diagnostic examinations and therapeutic treatments is quite common throughout the world. Most of the equipment and the procedures

performed are in industrialized countries, in which 25% of the world's population is located. UNSCEAR has assessed the exposures from medical radiation exposures from information obtained in questionnaires distributed to all countries. Four regions of health care have been designated, based on availability of facilities, and the data have been extrapolated to the world's population. The variations in medical radiation exposures among individuals are great, ranging from no dose to those not examined or treated to high doses to those receiving therapeutic treatments. The largest portion of the total dose from medical radiation sources arises from diagnostic examinations due to their relatively high frequency. At the highest level of health care the annual effective dose averaged over the population from all diagnostic examinations is 1.1 mSv. The comparable value is 0.05 mSv at the lowest level of health care. The population-weighted world average is 0.3 mSv, and the annual collective effective dose is 1.8 million man Sv. The collective effective dose from medical radiation usage has been evaluated to allow comparisons among countries and the evaluation of trends. Much, and optimally most, of the collective dose from medical uses of radiation is offset by direct benefits to the examined or treated patients.

OCCUPATIONAL RADIATION EXPOSURES

Occupational radiation exposures have been assessed from data submitted to UNSCEAR by national authorities in response to questionnaires. The data summarized in the UNSCEAR 1993 Report are quite extensive. Five-year average data for various occupations are reported for the period 1975-1989. The exposures from man-made sources are given the most attention; these data are usually required in countries for regulatory purposes.

The collective effective dose depends on the average individual doses and the number of exposed workers. The highest component of collective dose from man-made sources is from the nuclear fuel cycle (2,500 man Sv). There are 880,000 workers in this industry worldwide. For the 2.2 million medical radiation workers the annual collective dose is 1,000 man Sv. Fewer workers and lower collective doses arise in industrial uses of radiation (510 man Sv) and in defence activities (250 man Sv).

The collective effective dose to workers exposed to natural radiation sources is estimated to be 8,600 man Sv, which is two times higher than that from man-made sources. Some 5.2 million workers have been considered. The individual doses are more uncertain than from man-made sources. The largest component of occupational exposures from natural sources is from underground mining of coal and other minerals. Aircrew and some other occupations form secondary components.

MECHANISMS OF RADIATION ONCOGENESIS

Recent advances in molecular biology have been considered in one of several annexes in the UNSCEAR 1993 Report that deal with biological topics. The principal theories of oncogenesis and the results of experimental cellular and molecular studies are reviewed. The basic processes of induction, promotion and progression are recognized in oncogenesis, but it is not always possible to clearly differentiate these stages. Point mutations, chromosomal translocations and deletions, some of which are common and others specific to different neoplasms, may play roles in initiation and progression. Loss of function of tumour suppressor genes is considered a major

initiating factor in oncogenesis. Evidence of these genes being targets of radiation action comes from studies of germ-line mutations that predispose to cancer. Some of these genes appear to play a central role in control of the cell cycle.

The action of specific chemicals, hormones and growth factors on cell surface receptors alter proliferative responses of cells and lead to neoplastic progression. In some cases, the enzyme protein kinase C is thought to mediate promotional processes. Mutagenesis and repair of DNA damage are being studied in *in vivo* and *in vitro* systems. Although the complexities are great, the application of modern methods of cell and molecular biology in studies of radiation oncogenesis offer promising prospects of better understanding. Some aspects of research needs and future perspectives are briefly considered in this annex.

INFLUENCE OF DOSE AND DOSE RATE ON STOCHASTIC EFFECTS OF RADIATION

It is generally recognized that the effectiveness of radiation exposures becomes more than proportionally less at low doses and low dose rates. This is reflected in a quadratic term usually needed in describing the radiation response relationship. The factor of reduction may vary with the specific neoplasm and the physical and biological conditions of the exposure. In this annex of the UNSCEAR 1993 Report, the biological models of dose response in cells and organisms are reviewed and the experimental data available from studies of animals and cells in culture are analysed to derive the range of dose and dose-rate effectiveness factors.

The human epidemiological data on dose response are limited. Data from the survivors of the atomic bombings in Japan indicate that a reduction factor of about 2 would be appropriate for leukaemia but not much in excess of 1 for solid tumours. The results of studies of radiation workers are consistent with low values of the reduction factor. Information on thyroid cancer induction by acute external irradiation compared with low dose-rate exposure from intakes of ^{131}I are consistent with a reduction factor of about 3, although there are questions about the heterogeneity of the dose and uncertainties in the dose estimates and the effect that age makes to the overall reduction in risk. For female breast cancer, the information is conflicting, and a range of reduction factors from 1 to 3 can be derived.

For application of reduction factors the Committee considered that dose rates less than 0.1 mGy min^{-1} (averaged over about an hour) or acute doses less than 200 mGy may be regarded as low. The Committee concluded that reduction factors for low-LET exposures should be considered to be similar to those derived from the atomic bomb survivor data. Insufficient data are available to make recommendations for specific tissues. For high-LET radiation, there is little evidence of a consistent dose-rate or dose fractionation effect at low to intermediate doses. For hereditary disease, the adoption of a reduction factor of 3 is supported by experimental data in male mice; one study indicated the factor may be higher for female mice.

HEREDITARY EFFECTS OF RADIATION

It has not been possible to directly confirm radiation-induced mutations in human populations, so genetic risk estimates have had to rely on general knowledge of human genetics and extrapolation of results from animal experiments.

The understanding of human genetics at the molecular level is increasing rapidly. More precise analysis of the type of genetic damage caused by various agents, including radiation, is possible with new laboratory techniques. More recognition is also being obtained of non-traditional types of inheritance, such as mosaicism, genomic imprinting, uniparental disomy, gene amplification and cytoplasmic inheritance. The complexities involved may seem to make genetic risk estimation even more difficult and uncertain.

The specification of the genetic component of diseases and especially of the many so-called multifactorial diseases, which may occur throughout life and with varying severity, is a difficult problem. If some of the non-traditional mechanisms are involved, there could be trans-generational effects with manifestation of effects only after the F_1 or F_2 generations. There are few data to quantify these risks.

The Committee has concluded that there is no basis to alter present genetic risk estimates. Both the direct and indirect (doubling dose) methods of analysing animal data should be used, with due recognition of limitations of both methods. Radiation effects on multifactorial disease, gene regulation and non-traditional forms of inheritance are not well understood and may require different methods of estimation. The study of children of the atomic bomb survivors may be useful in setting outside limits on genetic risk estimates. These data indicate that hereditary effects from moderate acute exposure of a large human population are minimal. Further results are needed of both human and animal data analysed at the molecular level.

RADIATION EFFECTS ON THE DEVELOPING HUMAN BRAIN

The developing human brain is especially sensitive to ionizing radiation. This sensitivity reflects the structural complexity of the brain, its long developmental (and hence sensitive) period, the vulnerability of the undifferentiated neural cells, the need for cell migration to functional positions and the inability of the brain to replace most lost neurons.

The main effects of radiation and the sensitive periods have been derived from survivors of the atomic bombings in Japan exposed *in utero*. Thirty cases of severe mental retardation have been observed in 1,541 survivors. Most cases occurred in those exposed during the period 8-15 weeks following conception. A secondary period of reduced sensitivity occurred 16-25 weeks following conception.

The results indicate that damage caused by exposure to 1 Gy within the most vulnerable period (8-15 weeks following conception) increases the frequency of mental retardation to about 40% (background frequency: 0.8%) and lowers IQ by 25-30 points. The latter result is consistent with the observed increase in mental retardation. Exposure in the critical period also causes a decrement in average school performance and increases the risk of unprovoked seizures. There are no clear indications of thresholds for effects in those exposed in the most critical period. For the period 16-25 weeks, no cases of severe mental retardation were observed at exposure of less than 0.5 Gy. It is reasonable to assume the risks would be smaller for chronic exposures, but the data are too limited to provide quantitative estimates.

LATE DETERMINISTIC EFFECTS IN CHILDREN

Deterministic effects of ionizing radiation are the result of exposures that cause sufficient cell damage or killing to impair function in the irradiated tissue or organ. All tissues and organs may be affected, but tissues vary in their sensitivity to radiation. The ovary, testis, bone marrow, lymphatic tissue and lens of the eye belong to the most radiosensitive tissues.

Deterministic effects in children, with tissues actively growing, are often more severe than in adults. Examples of deterministic damage following radiation exposure in childhood include effects on growth and development, hormonal deficiencies, organ dysfunctions and effects on intellectual and cognitive functions. The review of deterministic effects of radiation in children stems mainly from the study of late clinical effects in children given radiotherapy treatments. As survival rates increase, some of the effects are becoming more apparent. The study groups are small, however, and the follow-up times are limited. The treatment modalities have usually included surgery and chemotherapy in addition to radiotherapy; it is thus not always possible to single out the effects of radiation alone.

The effects in tissues reviewed in this annex include those in the brain, endocrine system, gonads, skeleton, eye, cardiovascular system, lung, breast, liver and gastrointestinal tract, kidney and bone marrow. One objective was to determine the critical dose levels for the appearance of clinical deterministic effects. In general, younger children are more sensitive than older children. Owing to the paucity of data, however, it is not possible to quantify the effects by age in most situations.

EPIDEMIOLOGICAL STUDIES

The Committee previously reviewed the results of epidemiological studies in the UNSCEAR 1988 Report. The main basis for risk estimates in that report was the results of the Life Span Study of survivors of the atomic bombings of Hiroshima and Nagasaki. In the first of two annexes in the UNSCEAR 1994 Report [3], "Epidemiological studies of radiation carcinogenesis", the Committee presents a review of the wide range of epidemiological studies and provides comparative listings of risk estimates that can be derived from these results. The Committee feels that such broader analyses are necessary to establish more reliably the risk estimates. Results from a single study, although ostensibly providing statistically significant results for a particular site or type of cancer, may not represent the general case for one reason or another.

The epidemiological studies considered in the annex, in addition to the Life Span Study of survivors of the atomic bombings, include medically irradiated patients, occupationally exposed workers, individuals exposed to radionuclides released to the environment on various occasions and those exposed to elevated levels of natural background radiation. The characteristics of these studies, along with their strengths and weaknesses, are tabulated in the report.

The Life Span Study of survivors of the atomic bombings continues to be a primary source of epidemiological data on radiation effects. The large cohort includes individuals of both sexes and all ages with good dosimetric data covering a wide range of doses. Cancer incidence data for 1958-1987 are available for the first time, and the cancer mortality data have been extended for

another two years, available now for the period 1950-1987, for use in analysis of risk estimates in this annex.

The Life Span Study incidence and mortality data are broadly similar, with both sets of data demonstrating statistically significant effects for all solid tumours as a group, as well as for cancers of the stomach, colon, liver, lung, breast, ovary and bladder. The incidence data also provide evidence of excess radiation risks for thyroid cancer and non-melanoma skin cancers. Statistically significant risks were not seen in either the incidence or the mortality data for cancers of the rectum, gall-bladder, pancreas, larynx, uterine cervix, uterine corpus, prostate, and kidney or renal pelvis. An association with radiation exposure is noted for several types of leukaemia but not for lymphoma or multiple myeloma. Earlier data had indicated a possible association between radiation and multiple myeloma, but the new, extended analyses no longer indicate a statistically significant relationship.

Of the some 86,300 individuals in the Life Span Study cohort there were 6,900 deaths from solid tumours during 1950-1987. From comparisons with the control group, approximately 300 of these cancer deaths can be attributed to radiation exposure. The data for leukaemia incidence in this same period indicate that 75 cases can be attributed to radiation exposure.

The numbers of solid tumours associated with radiation exposure are not sufficient to permit detailed analysis of the dose response for specific sites or types of cancer. For all solid tumours together the slope of the dose-response curve is linear up to about 2 Sv. The dose-response curve for leukaemia is non-linear and is best described by a linear-quadratic function. Statistically significant risks for solid tumours in the Life Span Study are presently seen only above 0.2 Sv. The relative risks in the lower dose categories (0.01-0.05, 0.06-0.09, 0.10-0.19 Sv) all have positive nominal risk estimates, but they are not statistically different from unity. The slope of the dose response for doses lower than 0.5 Sv, while lower than the slope for all doses up to 4 Sv, does not differ significantly from it. An inherent limitation of epidemiological studies is to quantify results at doses less than 0.2 Sv because of the low statistical power of the available results.

Because of concerns about the role of cell-killing and the impact of errors in individual dose estimates on the slope of the dose-response curves at high doses, and because the Life Span Study risk estimates are primarily used to evaluate the effects at low doses, the analysis by UNSCEAR in this annex of lifetime risks have been limited to use of the data on individuals with shielded kerma of less than 4 Gy. The models for lifetime risk estimation allowed for differences in age at exposure and sex of the exposed individuals. Alternative assumptions were used for projections of risk beyond the present observational period. The relative risk was either assumed to remain constant to the end of life or to decrease to lower values at times greater than 40 years after exposure, as has been indicated to be the case in some epidemiological studies. The relative risks of leukaemia or lung cancer, for example, seem to decline after more than 20 years after exposure, although cancers of the GI tract can continue to occur for years longer.

The estimates of lifetime risk following exposure of 1 Sv, computed using sex- and age-at-exposure-specific relative risks estimated from the Life Span Study mortality data for 1950-1987 and using the demographic structure for Japan and the Japanese background cancer mortality rates for 1985, are 1.1% for leukaemia and 10.9% for solid tumours. These results may be compared with comparable values derived in the UNSCEAR 1988 Report of 1.0% for leukaemia and 9.7%

for solid tumours. The estimates for the alternative assumptions of risk beyond 40 years after exposure are 20%-30% less than the total risk estimate quoted above of 12% for an exposure of 1 Sv.

The estimates of risk are presented without adjustment for decreased effectiveness of radiation at low doses and low dose rates. The application of a small (<3) dose and dose-rate effectiveness factor was recommended in the UNSCEAR 1993 Report. If a factor of 2 is applied (as was used by ICRP in their 1990 recommendations), the risk estimate derived from the UNSCEAR 1988 Report would be 5% per Sv and from the 1994 Report 6% per Sv for a constant relative risk projection. The alternative projection methods would yield values from 4%-6% in the Japanese population (the applicability to other populations involves some additional uncertainty). Consequently, the use of a nominal value of 5% per Sv for mortality due to leukaemia and solid tumours from irradiation at low doses for a population of all ages (4% per Sv for an adult working population), as recommended by ICRP, still seems valid to the Committee based on these latest analyses.

Studies of other radiation-exposed populations, such as cervical cancer patients, ankylosing spondylitics and children treated for tinea capitis, provide risk estimates that generally support those derived from the data of the survivors of the atomic bombings. The other epidemiological studies provide additional information on issues that cannot be addressed by the atomic bomb survivor data, such as the effects of low chronic doses, highly fractionated exposures and variability among populations. For some sites of cancer, including leukaemia, breast and thyroid, and for bone and liver cancer from exposure to radium and thorium radionuclides, there are a number of very useful results from studies other than the Life Span Study. Large studies of occupationally exposed persons are also contributing tentative risk estimates. In general, there are no great discrepancies in risk estimates between the Life Span Study and the other studies.

Two studies provide some indications of risk at doses less than 0.2 Sv in sensitive subgroups of the population. These studies include cancers among those prenatally exposed to x rays with doses of about 0.01 Gy and thyroid cancer in children with doses of roughly 0.1 Gy. The risk estimates are in both cases, however, not yet well established.

UNSCEAR has further considered the reported incidences of leukaemia near nuclear installations in the United Kingdom, now thought unlikely to be related to environmental radiation or paternal exposure, and the evidence of cancer occurrence among participants of atmospheric nuclear tests. All such issues and results of epidemiological studies are reviewed in some detail in this annex.

ADAPTIVE RESPONSES

In a second annex in the UNSCEAR 1994 Report, "Adaptive responses to radiation in cells and organisms", the Committee considers the more recent research findings that are being reported on this interesting aspect of radiation response. The main impetus for the studies of adaptive responses has been the observation that human lymphocytes exposed to a conditioning dose of some 10 mGy while maintained with growth stimulants in culture media suffer about 50% fewer chromosome aberrations when subsequently irradiated with x rays to a dose of 1.5 Gy than when

exposed without the conditioning dose. It seems likely that the effect is linked to an increased capacity for DNA repair.

The adaptive response has been observed, as well, with proliferating bone marrow cells, spermatocytes and fibroblasts, but not with pre-implantation embryo cells. In some cases, *in vivo* exposure of an experimental animal (mouse or rabbit) has been able to provide the conditioning features which result in an adaptive response during subsequent *in vitro* exposure of lymphocytes.

Investigators have determined that the adaptive response for lymphocytes *in vitro* requires a conditioning dose of at least 5 mGy, delivered at a dose rate greater than 200 mGy min^{-1}, and no more than 200 mGy. The adaptive response occurs between 4 and 6 hours after conditioning and lasts for 3 cell cycles. The composition of the culture medium is quite important; it requires a narrow range of pH to be maintained and growth stimulating factors to be present. The degree of response depends on the stage of the cell cycle. Cells in active phases just prior to cell division are more likely to show the response than cells in other stages. Lymphocytes from different donors show variable response. Thus, the adaptive response is by no means a generally occurring phenomena; it requires rather carefully controlled experimental conditions to elicit the behaviour.

The possible mechanisms of adaptive responses are being investigated in current research. Cell cycle delay has been noted at relatively higher conditioning doses (>200 mGy). The delay allows cell damage to be repaired before the cell proceeds through the cell cycle. Since the adaptive response occurs at lower doses when this type of cell cycle delay is not apparent, this cannot be a central mechanism in the response at lower doses.

The evidence becoming available indicates that following radiation damage to cells a number of changes occur. Among these changes are the activation of genes that code for the synthesis of enzymes involved in the control of the cell cycle, proliferation of cells and repair of damage. Some of the enzymes seem to be similar to those induced by damage caused by other toxic agents. The adaptive response may therefore be part of a common mechanism involving cellular response to damage.

In addition to gene activation, enzyme production and at higher doses cell cycle delay, other cellular mechanisms involved may be detoxification of reactive radicals and activation of membrane-bound receptors stimulating cell proliferation. The immune response of the organism may operate at least transiently following radiation exposures in accelerating programmed cell death of damaged cells. All of these process are subjects of continuing investigation.

It is generally more difficult to demonstrate adaptive responses in the whole organism. Some earlier experiments reported seemingly stimulatory effects following low-level exposures. More recent experiments with rodents and beagle dogs exposed at various ages to low dose rates of low-LET radiation have been unable to demonstrate statistically significant differences in life-span of irradiated and control groups after accumulated doses of up to about one gray nor has reduced tumour induction been an outcome of low-dose exposures in these experiments. An important point to note is that along with adaptive response in cells, selective damage leading to malignant cellular transformations may also occur in parallel. This may explain the observed responses in these animal experiments.

The Committee thus judges that adaptive responses manifested by improved repair of cellular damage that take place under specific conditions in experimental cellular studies probably do not completely eliminate residual damage in cells that may ultimately result in malignant transformation. It will be important to continue these studies in order to understand more fully the molecular processes that occur following radiation exposure of cells and how these changes might be manifested in overall response of the organism. The Committee states that "at this stage it would be premature to draw conclusions for radiological protection purposes".

UNSCEAR has now begun a new programme of review of the sources and effects of ionizing radiation. The next scientific report of the Committee will be published probably in 1998.

Developments in the Work of the International Commission on Radiological Protection of Importance for Radiation Protection

Roger H Clarke
Chairman, ICRP

ABSTRACT

The membership of the Main Commission and its four Committees for the period 1993-1997 was established in July 1993. The programmes of work are now well established and the Committees have met at least three times. Their progress is summarised in this paper.

INTRODUCTION

The Commission has four standing Committees on, Biological Effects, Secondary Standards, Protection in Medicine, and Application of the Commission's Recommendations. In July 1993 the four committees were reconstituted and by now have met at least three times to progress their programmes of work. This paper presents an overview of that work.

The method of working within ICRP and its Committees is also perhaps worth noting. When a Committee decides that it would wish to develop guidance on a particular issue, it proposes a Task Group on the subject to the Main Commission who approve its terms of reference and membership including the chairman, who will be a member of the sponsoring Committee. The other Task Group members will probably not be members of any Committee of ICRP. This procedure is necessary because the Commission supports the travel and subsistence costs of the Task Group meetings. In addition, the chairman of any Committee may appoint a Working Party within the Committee which is composed of one or more members of the Committee. The Commission takes no financial responsibility for Working Parties and they are usually formed to prepare papers for the Committee and their work often leads to the formation of a Task Group.

The distribution by country of people in ICRP is of interest. The largest contingent of 18 comes from the USA, followed by the UK with 11, France and Germany having 9 each, Japan and Sweden 5 each, China and Russia have 4, and 2 from each of the Netherlands, Argentina and India, and single membership from 9 other countries.

MAIN COMMISSION

The International Commission on Radiological Protection and its Committees met at Würzburg in September of the centennial year of Röntgen's discovery of x rays.

The Commission adopted three reports for publication in the *Annals of the ICRP*. The first was the report from a Task Group of Committee 2 and entitled 'Age Dependent Doses to Members of the Public from Intakes of Radionuclides: Part 4, Inhalation Dose Coefficients'. This report complements Publications 56, 67, and 69, which principally give ingestion doses for different age groups in the population, by presenting results using the new model of the respiratory tract. Only Publication 56 gave inhalation doses, using the old lung model, and these are now replaced.

The data presented in the age-dependent dose reports are restricted to radionuclides from the range of elements that are most likely to be of concern in environmental materials. For all of these elements, a detailed review of biokinetic behaviour has been undertaken.

In the second report adopted by the Commission, all data on dose coefficients from the four separate parts dealing with the public are brought together in a single issue for easy reference. As an annex, dose coefficients for the public are presented covering all the additional elements required for the IAEA Basic Safety Standards but for which biokinetic data had not been specifically reviewed in this case, the calculations are based on biokinetic data from Publication 30 and must be used with caution since they were derived for worker rather than public exposures. From now on, the work on internal dosimetry will mainly be directed at a comprehensive review of models and data applicable to workers and the public, the outcome of which will form the basis of calculated dose coefficients five or six years from now.

The third report approved was from the joint Task Group with the International Commission on Radiation Units and Measurements entitled 'Conversion Coefficients for use in Radiological Protection against External Radiation'. This has now also been approved by ICRU; it was agreed that it would be published by both Commissions in the *Annals of the ICRP*. A remarkable amount of work has been undertaken to obtain a large number of calculations for electron, neutron and photon exposures. The major concern for both Commissions was to ensure that the operational quantities recommended by ICRU achieved the objective of providing measurable quantities adequately representing the protection quantities of Publication 60. The analysis of the data in the report indicates that the operational quantities generally achieve this objective with only minor exceptions that are not important in practical circumstances; they are therefore a satisfactory basis for measurements in radiological protection against external radiations.

COMMITTEE 1

Committee 1 of the International Commission on Radiological Protection has the responsibility for maintaining the biological effects of ionising radiation under review and developing documents that relate such effects to the needs of radiological protection. During the last three years, two new task groups have commenced work and working parties have been formed to review a broad range of biological, biophysical and epidemiological topics.

Committee 1 met in Würzburg, Germany, in September 1995 and the outcome of this meeting is selectively summarised here.

TASK GROUPS

Genetic susceptibility to cancer

The Task Group on Genetic Susceptibility to Cancer had been set up by the Commission in order to provide an overview of human genetic predisposition to cancer and to make interim judgements on the possible implications for the estimation of cancer risk after radiation.
The first draft of the main body of the review contains sections on: DNA damage and repair, mechanisms and genetics of solid tumours and lympho-haemopoietic neoplasia, tumorigenic radiosensitivity and heritable

predisposition to cancer, together with computational modelling of genetically determined cancer risk after radiation.

There is particular emphasis on the potential importance of the repair of DNA double strand lesions for carcinogenic response and the relative genetic contributions to solid and lympho-haemopoietic neoplasia. Attention is also given to uncertainties on the apparently high genetic contributions to spontaneously arising breast and colon cancer and the limited extent of the database on which to estimate the degree to which cancer-prone human genetic disorders may contribute to excess cancer in irradiated human populations. These issues are critical to the computational modelling that has been proposed and will be the subject of further review and deliberation by the Task Group. A second draft of the report will be considered by Committee 1 in 1996.

Risk estimation for multifactorial diseases

It is recognised that considerable uncertainty surrounds the estimation of risk of induction of multifactorial diseases which depend upon genetic-environmental interactions for their expression. The brief of the Task Group on Risk Estimation for Multifactorial Diseases from the Commission is to review the classification, prevalence and genetics of human multifactorial diseases and to propose computational modelling procedures that will allow for more confident estimation of the impact of new radiation-induced mutations on disease incidence in the population. Major issues are the relative roles and multiplicity of major and minor genes in different disorders and the inherent difficulties of modelling the genetic and environmental interactions that may be involved.

One particularly important aspect of the current work is clarification by the Task Group of the dynamic nature of the mutational component of multifactorial disease. This had not been fully appreciated during the estimation of genetic risk in Publication 60 but was not deemed to have introduced a major source of further uncertainty. The first draft of the report of the Task Group is expected in 1996.

WORKING PARTIES

Committee 1 received reports from fifteen working parties and some of the topics reviewed are

Uncertainties in cancer risk estimates

The main uncertainties under review are those associated with the transfer of risk between different populations, calculation of lifetime cancer risks for tumour types and A-bomb dosimetry. The draft of an NCRP commentary on all these issues was circulated for comment. The overall conclusion from this and from the working party was that uncertainty on risk was not likely to exceed the current risk of around 5% Sv^{-1} for a whole population by more than a factor of around two in either direction.

Populations for new epidemiological study

Of particular note in this working party discussion was the potential for dosimetric and epidemiological follow-up of the population that had been exposed in the Altai region of the former Soviet Union as a consequence of explosions in 1949 and 1962. While the extent and magnitude of these population exposures was judged to be sufficient for such studies, there are inherent difficulties associated with such retrospective analyses, particularly since the Altai region has experienced a considerable degree of post-exposure migration.

Review of epidemiological data

Each year this working party provides a broad review of published epidemiological studies. In 1994–95 the working party had considered over 100 publications covering population studies, RERF reports, post-Chernobyl studies and studies on occupational and therapeutic exposures. Of particular importance were RERF studies on the induction of benign tumours of the gastrointestinal tract and stomach, and studies on lung cancer incidence in fluoroscopy patients, risk factors for breast cancer, and radon studies in China and West Bohemia together with studies on radon exposed miners showing no excess of extrathoracic tumours. In addition, the working party stressed the importance for low dose risk estimates of recent combined analyses of cancer in occupationally exposed nuclear workers.

Relative biological effectiveness and radiation weighting factors

The Committee has been reviewing data relevant to judgements on RBE and w_R and discussed the uncertainties involved, particularly those for different neutron energies and for heavy ions with LET values greater than 100 keV μm^{-1}. In spite of some justifiable concern on w_R values for these radiations, the Commission's current system for obtaining equivalent dose was, because of its simplicity, thought to have considerable practical merit; any proposed changes to the current system would need careful evaluation.

Attention was also given to a recent suggestion that a quality factor of 10 for alpha particles, particularly in respect of lung carcinogenesis, was more appropriate than the value of 20 or 25 advocated by the Commission and the International Commission on Radiation Units and Measurements, respectively. Following discussion of the relevant biological data and critical appraisal of the biophysical approach that had been used to justify an alpha particle RBE of 10, it was concluded that at present there was no good reason to contemplate such a change.

Tissue weighting for bone

A joint working party between Committees 1 and 2 had been seeking to develop an appropriate value for w_T for bone that took full account of the location of target cells for bone cancer at endosteal bone surfaces. It was agreed by Committee 1 that the ^{224}Ra patients provided the best epidemiological source of risk estimation and that a w_R of 20 remained appropriate for alpha particles. With due attention both to the factor necessary to convert the risk based on average bone dose to that which applies to bone surface and to the risk of fatal bone cancer suggested by the A-bomb data, a rounded w_T for bone surface of 0.01 was judged by the working party to be appropriate. A written report on the issue is expected in 1996 and this will include comment upon the implications of the new biokinetic model for radium. It is expected that this report will help to resolve uncertainties on w_T for bone that have existed since Publication 26.

Other working parties discussed new data on genetic effects, deterministic effects, target cells for carcinogenesis, the possible use of animal data for risk estimation, *in utero* effects, comparative aspects of radiation and chemical carcinogenesis, and adaptive responses to radiation. Good progress was being made in relating new findings in these areas to future judgements in radiological protection. Of particular note were new animal studies that strongly challenge earlier data on radiation-induced transgenerational carcinogenesis and the absence, so far, of a significant risk of *in utero* induced cancer in the A-bomb survivors.

COMMITTEE 2

Committee 2 has the responsibility for establishing secondary standards based on the Commission's recommended dose limits. The Committee and its task groups have been developing a series of documents related to both external radiation and internally incorporated radionuclides. The programme of work of Committee 2 was reviewed at the September meeting and is summarised here.

AGE-DEPENDENT DOSIMETRY

A number of reports have been prepared by the Committee giving age-dependent biokinetic models and dose coefficients (doses per unit intake) for members of the public for ingestion of selected radionuclides of 29 elements (Publications 56, 67 and 69). The elements/radionuclides were selected as those most likely to be of concern for public exposure. Following the issue of the new respiratory tract model (Publication 66) a report has now been prepared by the Task Groups on Internal Dosimetry (INDOS) and Dose Calculations (TGDC) giving age-dependent inhalation dose coefficients for these elements. The report, now adopted by the Commission, is expected to be issued as Publication 71, contains a summary of the new respiratory tract model, particularly in relation to age-dependent aspects. It also includes the results of literature reviews on the lung clearance of various chemical forms of the different elements, with the emphasis on the behaviour of environmental forms. The new respiratory tract model gives default absorption parameters for three default Types (Fast, Moderate and Slow). For radionuclides present in the environment, it will frequently be difficult to identify the chemical form. Dose coefficients will therefore be given in the report for all three absorption Types, with a summary of what is known about the behaviour of specific materials and guidance on the default Type to use when no information

is available. The summaries of data on the lung absorption of different chemical forms can be used as a guide for selecting absorption Types when there is more material-specific information. In general, the default Type adopted is M, on the basis that the calculated dose coefficient is unlikely to be greatly in error. In addition to the elements covered in the previous publications, dose coefficients will also be included for isotopes of calcium and curium. Annexes will be included in the document giving the biokinetic models for these elements which will be based on the generic models for the alkaline earths and actinides, respectively, as described in Publication 67. The table summarises the information given in these publications.

The publication of this report will complete the programme of work on dose coefficients for infants, children and adult members of the public. A summary report will therefore be issued giving a compilation of dose coefficients for both ingestion and inhalation from the above publications. The report will give doses to individual tissues, as well as effective dose. The Commission has also agreed that age-dependent dose coefficients for the radionuclides of the elements in Publication 30 not covered in Publications 56, 67, 69 and 72 will be given in an Annexe. These additional values are required by both IAEA, for the Basic Safety Standards, and EC, for the new EURATOM Directive. The biokinetic models used for these dose coefficients will be those given in Publication 30 for adults and allowance will be made only for changes in body mass and for doses from material in the excretion pathways. They must therefore be used with care for infants and children.

EMBRYO AND FETUS

A draft document has been prepared by INDOS, giving dose coefficients for the embryo and fetus following acute and chronic intakes of radionuclides by the mother, either before or during pregnancy. The report is at an advanced stage and it is expected that it will be completed in time for the next Committee 2 meeting to be held in the autumn of 1996. Dose coefficients for intakes by inhalation and ingestion will be given for radionuclides of the 31 elements for which age-dependent dose coefficients have already been prepared for infants, children and adults. Wherever possible, element-specific dosimetric models will be used (eg tritium, carbon, iodine, caesium and strontium). Where this is not possible, a generic model will be applied based on relative concentrations of radionuclides in fetal and maternal tissues obtained from studies with experimental animals. The report will include a comprehensive chapter on the development of the embryo and fetus, as well as the results of literature reviews on data in man and animals on the transfer of radionuclides to the developing embryo and fetus following intakes by the mother. Inhalation dose coefficients will be calculated for intakes of both 1 μm AMAD and 5 μm AMAD aerosols by the mother (default particle sizes for the public and workers, respectively). Dose coefficients for ingestion of radionuclides by the mother will be based on gut transfer factors, appropriate for both workers and members of the public.

DOSE COEFFICIENTS FOR WORKERS

Publication 68, giving dose coefficients for the inhalation and ingestion of radionuclides by workers, has recently been issued as a replacement for Publication 61. The dose coefficients apply the most recent biokinetic models recommended by the Commission, including the new respiratory tract model described in Publication 66. A revision of Publication 54 (Individual Monitoring for Intakes of Radionuclides by Workers) is now to be prepared, on a timescale of about a year, to provide information for interpreting monitoring data consistent with these models. The Commission has set up a working party of Committees 2 and 4 to develop this report. The models used for the calculations will be those adopted for Publication 68, for which extensive quality assurance checks have been carried out by the members of TGDC at BfS in Germany, NRPB, and ORNL in North America.

With the revision of Publication 54, Committee 2 and the Commission consider that there should now be some stability in these dose coefficients for workers. There remains, however, a need to develop a full revision of Publication 30. With the move to physiologically-based biokinetic models, the aim is to develop models that are appropriate both for bioassay interpretation and for dosimetry calculation. Thus the full revision of Publication 30 will take into account the work done for the revision of Publication 54. As it will be necessary to review the biokinetic models for all the elements that have not been reviewed in Publications 56, 67, 69 and 72, it is considered unlikely that the work will be ready for publication before the year 2000.

A technical report is to be prepared by INDOS giving guidance on the application of the new respiratory tract model to situations in which material-specific information is available which enables more accurate dose assessments to be made than would the use of general default parameter values. It is intended that in the revision of Publication 30, dose coefficients will be given for specific chemical forms of various radionuclides, in addition to those based on the default absorption Types. No ALIs are to be given as the Commission now considers that these should be established by management from a knowledge of local conditions. This technical report will provide information on the likely approach to be adopted in applying material-specific data.

RELIABILITY OF DOSE COEFFICIENTS

INDOS is preparing a report on the reliability of dose coefficients. This will examine the quality of the data used in the development of dosimetric models taking into account the extent to which they are based on human and animal data. The report will cover intakes by inhalation and ingestion, as well as the biokinetic models which describe the behaviour of systemic activity. Although it is unlikely that the document will be completed until 1997, a structured approach has been adopted which will be used to illustrate how the reliability of models for different elements can be judged.

MODEL DEVELOPMENT

It had been agreed at a previous meeting of Committee 2 that it would no longer be practicable to develop a full revision of Reference Man (Publication 23, 1975). Instead, a series of reports is in preparation covering the main information necessary for model development and for dose calculations. The first report, on the skeleton, has been approved for publication by the Commission and should be issued later in 1995. The next report, on basic anatomical and physiological data, should be completed in 1996. A third report will cover the regions of the gastrointestinal tract, as well as the pancreas, gall bladder and liver.

Summary of reports on age-dependent dose coefficients for members of the public from intakes of radionuclides

	PART 1[a]	PART 2[b]	PART 3[c]	PART 4[d]	PART 5[e]
ICRP Publication	56	67	69	72	–
Ingestion dose coefficients	+	+	+	–	+
Gastrointestinal tract model	30	30	30	30	30
Inhalation dose coefficients	+	–	–	+	+
Respiratory tract model	30	–	–	66	66
Tissue weighting factors	30	60	60	60	60

Notes

(a) For radioisotopes of H, C, Sr, Zr, Nb, Ru, I, Cs, Ce, Pu, Am and Np.
(b) For radioisotopes of S, Co, Ni, Zn, Mo, Tc, Ag, Te, Ba, Pb, Po and Ra.
(c) For radioisotopes of Fe, Sb, Se, Th and U.
(d) Elements in Parts 1, 2 and 3, plus Ca and Cm.
(e) Compilation of dose coefficients in Parts 1–4.

\+ Dose coefficients given in report.

In the development of ingestion dose coefficients for the public, the adult model for the gastrointestinal tract described in Publication 30 was used, as no age-dependent model is available. The Committee now intends to develop a new model for the gastrointestinal tract which will take into account the most recent information on anatomy and physiology as well as age-dependent characteristics. Additional information on the radiation sensitivity of different regions of the gastrointestinal tract and on the location of stem cells will also be considered. A working party has been set up, with membership from Committees 2 and 1, to develop the terms of reference for a task group. The aim is that the new model should be complete in time for the full revision of Publication 30.

The need to develop agreed phantoms for use in both internal and external dosimetry was considered by the Committee at some length. The MIRD phantom presently used for dose calculations has severe limitations as it is based on fixed geometrical shapes. This makes it difficult to introduce additional organs and tissues when the need arises as a result of new information on the sensitivity of tissues to irradiation. Comprehensive data are now becoming available from medical imaging and a number of laboratories are working towards developing realistic phantoms based on such data. Although there are difficulties in using such phantoms for dosimetry purposes, it was felt that this will be necessary before the revision of Publication 30. A working party is to consider how the Committee should proceed to develop new phantoms for the Commission.

COMMITTEE 3

The major work under this heading is the Task Group report on radiological protection and safety in medicine. Committee 3 had carefully considered a draft report and presented a revised outline to the Commission for agreement on a proposed way forward. The Commission accepted the proposals and decided that it was appropriate to form a joint task group between itself and Committee 3 with the objective of producing a report for adoption early in 1996; it would be aimed at relevant professional bodies and practising radiologists. The report would also serve as a source for the development of specific practical advice for protection in three important areas: nuclear medicine; diagnostic, dental and interventional radiology; radiotherapy.

COMMITTEE 4

Committee 4 of the International Commission on Radiological Protection has the responsibility for considering the practical application of the Commission's recommendations. This section reviews the deliberations of Committee 4 during its meeting in Würzburg in September immediately prior to the meeting of the Commission.

TASK GROUP REPORTS

The Committee had three draft reports from task groups to consider, all the titles of which contained qualifiers of the word 'exposure': namely, occupational, potential and chronic. The report on occupational exposure was the furthest advanced, although substantial progress had also been made with the other two.

Occupational exposure

The principal objective of the Task Group on General Principles for the Radiation Protection of Workers was to prepare a report that would replace Publication 35, which deals with the monitoring of workers, the intention being to take account of the developments in Publication 60. An additional objective was to review Publication 28, which deals with the procedures for handling emergency and accidental exposures of workers. However, it became apparent to the Task Group that this latter document should be subject to a separate review since it is mainly concerned with medical aspects of overexposure.

The general reaction of the Commission was favourable, although it recognised that there were issues of a policy nature and these needed careful consideration. The principal issues were the use of the public dose limits in the context of occupational exposure in Publication 60, the meaning and use of dose constraints, protection of the fetus of female workers, management of overexposed workers, and the grouping of workers for monitoring and dose

recording purposes.

This Task Group now plans to produce the next draft for review by the Commission early in 1996 before being considered by the Committee in May. Approval by the Commission will be sought towards the end of 1996.

Potential exposure

The report of the Task Group on Protection from Potential Exposure dealt with non-nuclear radiation sources, essentially those that present a significant risk. Particular examples are industrial irradiators and particle accelerators. There was no precedent for work in this area and as such the Task Group had to start with a 'clean sheet of paper'. The work is of considerable importance because such sources have been the cause of death and severe injury. The focus of the report was on the means of assessing the risks associated with such sources, rather than operational considerations. Nevertheless, recognising the significant contribution that human factors have played in the various accidents that have occurred in the past, the Committee felt that there was a need to include some consideration of these matters.

The general reaction of the Commission was that the report represented a major step forward. However, the Task Group was asked to give further consideration to detriment (including endpoints other than fatality), risk constraints and the role of the principle of optimisation of protection.

The intention is for the Task Group to meet again and a revised draft to return to the Commission late in 1996, after a further review by the Committee at its next meeting.

Chronic exposure

The report of the Task Group on Principles for Protection of the Public against Chronic Exposure Situations dealt with topics such as the exposure of the public from land contaminated by past practices. There are particular difficulties here in neatly fitting each situation into the categories of practice and intervention and the Committee felt that this needed to be more clearly recognised in the document. It was agreed that high natural background should be mentioned but the topic excluded from detailed treatment. Otherwise, the general approach was endorsed.

The Task Group intends to meet again in 1996 and the Committee will discuss the topic at its next meeting. The target date for final approval remains 1996-97.

WORKING PARTIES

The Committee considered a report from its working party on Publication 46, which deals with solid waste disposal. While it was felt that much of this publication remained valid, it was recognised that the material was not 'user friendly'. There were also questions over the use of future collective doses from waste repositories. It was agreed that a short policy document on radiological protection matters aimed at decision makers and their advisors involved in radioactive waste management would be useful, but not as a replacement for Publication 46. To undertake this work, the Committee proposed a task group. The Commission did not immediately accept this and has asked for an elaboration of the specific issues that the document would address, including long timescales and their influence on risk criteria and the use of collective doses for probabilistic events.

FUTURE PROGRAMME

The Commission intends to meet twice in 1996. The first meeting in March is planned for discussion of several of the reports being prepared by Task Groups prior to the Committees finally reviewing them. They include those on genetic susceptibility, protection in medicine, and occupational exposure. The second meeting is planned for November when, in addition to adopting any reports from the four Committee meetings, the major item will be preparation for the new Commission and Committees for the period 1997 - 2001.

THE ICRU PROGRAMME IN RADIATION PROTECTION

PAST, PRESENT AND FUTURE

A. Allisy
Bureau International des Poids et Mesures, F-92310 Sèvres, France

It is the purpose of this paper to present a panorama of the work that the ICRU has devoted - often in cooperation with the ICRP - to radiation protection. More precise information on recent achievements will be given in two companion papers by R.H. Thomas and P. Jacob. The first deals with an ICRP-ICRU joint report of great importance, the second is characteristic of one of the trends concerning the treatment by the ICRU of radiation protection problems.

The ICRU was created in 1925 to study the problem of "dosage" in radiotherapy and more specifically the unit to be used. It is thus not surprising that for three decades the major preoccupation of the ICRU concerned radiation units for radiotherapy with x and gamma rays and guidance for clinical applications.

In the 50's the energy domain as well as the quality (LET) domain of newly available sources of ionizing radiations were greatly increased and this presented the radiation protection community with two questions. The first, concerning the unit röntgen which is restricted to x and gamma rays, was in the process of being resolved by the introduction of the absorbed dose. The second, which is still today not entirely resolved, concerns the weighting of the absorbed dose according to the different biological effectiveness of the various radiations. The usage of the concept of RBE developed in biological research and the corresponding quantity "RBE dose" was reluctantly adopted by the ICRU, as the RBE of any radiation depends on many factors such as the type and degree of biological damage, the absorbed dose and its rate, the fractionation, the oxygen tension, the pH and the temperature. In trying to find a solution, the ICRP and the ICRU appointed in 1960 a Joint Committee to study the concept and use of RBE in considerations of radiation protection (1). The conclusion of the report was essentially as follows. The decision by ICRU to replace "RBE" in protection work by "quality factor" (*QF*) is endorsed. It is very necessary that a clear distinction should be made between the term "RBE" used in experimental work and the term used in protection calculations. The replacement of the term "RBE dose" by "dose equivalent" (*DE*), as defined below, is also endorsed. *DE* is defined as the product of absorbed dose, *D*, quality factor, (*QF*), dose distribution factor, *DF*, and other necessary modifying factors. The unit of dose equivalent is the "rem". The report also proposed an LET-*QF* relationship which is kept under review by the ICRP even today.

The same quantity, dose equivalent, is defined with a less cumbersome notation (*H* replaces *DE* and *Q* replaces *QF*) and appears in ICRU Report 19 (2) and its supplement (3) together with two new considerations. The first states that although *Q* is dimensionless and therefore *H* and *D* can be expressed in the same unit, it is highly desirable, for safety reasons, to keep the name rem instead of rad for expressing a dose equivalent. The second is the first attempt made by the ICRU to define quantities which are easy to measure for the specification of ambient radiation levels. These quantities, the absorbed dose index and the dose equivalent index, are defined at a point as the maximum absorbed dose or dose equivalent, respectively, within a 30 cm diameter sphere centered at this point and consisting of specified material. These quantities were developed later (4, 5) but finally abandoned mainly because of their lack of additivity.

During the same period (1970) the ICRU issued a report on radiation protection instrumentation and its applications (6), where instrument characteristics are reviewed to facilitate their choice and use.

In 1980, the ICRP and the ICRU established a Joint Task Group on Radiation Protection Quantities. The task group carried out a broad inquiry into basic approaches to radiation protection, an examination of the quantities that are required in their formulation, and a review of pertinent biological data. The corresponding report (7) was primarily focussed on the problem of radiation quality and its quantitative treatment in

radiation protection. It was intended to be an input *to* the two Commissions (and in particular to the ICRP) for their consideration in formulating subsequent recommendations *from* the Commissions.

A major breakthrough in the field of practical measurements in radiation protection was achieved in 1985 by the publication of ICRU Report 39 (8). This report gives definitions of *operational quantities* to be employed in the monitoring of ionizing radiation that provide a basis for effective radiation protection. These quantities are intended to supplement, for practical measurements, the recommendations concerning the use of the absorbed dose index and the dose equivalent index. A second report (9) indicates how the dose equivalents received by exposed individuals may be determined when it is appropriate to utilize additional data on irradiation or different calibration conditions. A third report (10) contains guidance on the design, calibration and use of instruments required to implement the recommended system.

In 1991, the ICRP (11) introduced two new quantities, based on radiation weighting factors, replacing the organ dose equivalent and the effective dose equivalent. These quantities are termed equivalent dose and effective dose, respectively. As these quantities cannot be evaluated experimentally, the quantities defined in terms of Q, namely *ambient dose equivalent, directional dose equivalent* and *personal dose equivalent*, are to be used for measurement purposes (11, 12). The compatibility of the operational quantities with the new protection quantities expressing dose limits will be analysed by R.H. Thomas.

In the future, the centre of interest of the ICRU will continue to be on concepts and measurement techniques. In addition to a report, in press, on dosimetry of external beta radiation for radiological protection, two main directions are being pursued in the field of radiation protection.

The first direction encompasses *methods and measurement techniques related to the assessment of radionuclides*. P. Jacob will present a report recently issued on gamma-ray spectrometry in the environment (13).

All measurements made in the environment are based on the sampling method. In order to be able to draw inferences for scientific interpretation or monitoring, requirements for radiological sampling have to be stated and this is new work which is just starting.

Another report - which is nearing completion - is concerned with direct (*in vivo*) measurement of radionuclides in the whole body or in specified organs or regions of the body.

The second direction is concerned with *patient dosimetry in diagnostic radiology*. A report is being prepared on the determination of absorbed dose in a patient from x rays used in diagnostic and interventional radiology.

The ICRU has an extensive programme on the assessment of image quality in medical imaging. A report which provides the theoretical framework for image quality evaluation of all the conventional imaging systems is in print (14). It will be followed by specific reports on image quality in mammography, nuclear medicine and chest radiography. All these reports will also deal with the problem of dose reduction which cannot be separated from considerations on image quality.

CONVERSION COEFFICIENTS FOR EXTERNAL RADIATIONS

Ralph H. Thomas
Lawrence Livermore National Laboratory, University of California, USA

Early in September 1995, at its meeting in Würzburg, the International Commission on Radiological Protection (ICRP) accepted the report of a Joint ICRP/ICRU Task Group on External Radiation. A week later, some 230 km to the northwest in Lennep, the report was also endorsed by the International Commission on Radiation Units and Measurements (ICRU).

The report will be of general interest to dosimetrists and in particular to those interested in the estimation of the doses arising as a result of the irradiation of the human body by ionizing radiations from sources outside the body.

Two sets of quantities are of importance in radiological protection. Dose limits are expressed in terms of *protection quantities* and compliance with these limits can be demonstrated by a determination of the appropriate *operational quantity*.

In Publication 60 the ICRP made significant changes in its definitions of the protection quantities and recommended that the equivalent dose, D_T, and effective dose, E, be used in radiological protection (1). These protection quantities are not directly measurable. For exposure of humans by sources of radiation outside the body (external radiations), the convention has been adopted that operational quantities defined by the ICRU should be used for practical measurements. The two sets of quantities may be related to radiation field quantities such as particle fluence and in turn, by sets of conversion coefficients, to each other.

The operational quantities now in use, ambient, directional and personal dose equivalent, [$H^*(d)$, $H'(d)$ and $H_p(d)$], were originally defined to be compatible with protection quantities defined by ICRP in the seventies (2, 3, 4). Since that time ICRU has published clarifications to the definitions of the operational quantities; new physical data bases have become available and improvements have been made in the

methods of performing radiation transport calculations. These improvements in physical data and computational techniques would alone warrant a review of the conversion coefficient data provided in ICRP Publication 51 (5).

The significant changes made in the definitions of the protection quantities in ICRP Publication 60 and the modifications to the definitions of the operational quantities naturally raise questions as to whether the operational quantities, as currently defined, are still a good measure of the new protection quantities.

In 1991 the ICRP and ICRU set up a Joint Task Group that was requested to review published conversion coefficients and related data and to provide to an agreed set of reference conversion coefficients data for application to external dosimetry for radiological protection.[1]

The Joint Task Group was asked to:

- provide conversion coefficients for protection quantities,
- provide conversion coefficients for operational quantities,
- examine the relationship between protection and operational quantities.

The new report, which will be published next year, revises and replaces much of the data given in ICRP Publication 51 and in ICRU Report 43 (4).

The report analyses the consequences of the changes in the definitions of the protection quantities recommended in ICRP Publication 60 and, finally, demonstrates that the operational quantities still function as adequate predictors of the protection quantities, *i.e.*, that in most practical circumstances they neither under-estimate nor significantly over-estimate protection quantities.

Published data were reviewed for photons with energies up to 10 MeV, for neutrons with energies up to 180 MeV and for electrons with energies up to 45 MeV. The review was not extended to higher energies because data are not yet available for the protection quantities defined in ICRP Publication 60.

Reference conversion coefficients relating the protection and operational quantities to the appropriate physical quantities (*e.g.*, air kerma, absorbed dose or particle fluence) are in the report.

ICRP Publication 60 redefined the Protection Quantity recommended in ICRP Publication 26 (Effective Dose Equivalent) essentially by changing the organs and tissues to be considered, recommending new tissue weighting factors and finally by changing the methods by which absorbed doses be modified to account for radiation quality. The operational quantities have been changed both by the revision of the *Q-L* relationship in ICRP Publication 60 and new stopping power data reported in ICRU Report 49. The Joint Task Group Report examines the consequences of these changes in some detail and concludes that, in most practical circumstances, the operational quantities defined by ICRU in 1985 still provide a satisfactory basis for measurements for radiological protection against external radiations. Remarkably, this is so despite changes in the definitions of the protection quantities, changes in the specifications of the operational quantities, new physical data and improved methods of calculation.

For photons and electrons, measurement of the operational quantities for area monitoring will continue to provide a reasonable over-estimate (typically 20 % or more) of the protection quantities in all irradiation geometries. For neutrons the results are

more complicated. In most, but not all, irradiation geometries the situation is similar to that for photons and electrons. There is a particularly important exception for the AP geometry at low neutron energies (about 1 eV) where underestimates of the protection quantity by about 25 % can occur. Particular caution is also required when dealing with neutrons (and other radiations) having energies above about 20 MeV, because the operational quantities defined at a depth of 10 mm in tissue may not provide sufficient over-estimation of protection quantities. In those cases where the operational quantities prove to be unsatisfactory the data provided in the report provide a basis for the design of adequately protective measurement programmes, the correct interpretation of measurements results and their relation to the protection quantities. It is most important to stress that, if reliable results are to be obtained, knowledge of the neutron spectrum in which measurements are to be made is always highly recommended.

GAMMA-RAY SPECTROMETRY IN THE ENVIRONMENT

Peter Jacob
GSF Institut für Strahlenschutz, Postfach 1129, D-85758 Oberschleißheim, Deutschland

INTRODUCTION

The term gamma-ray spectrometry in the environment comprises methods based on an *in-situ* measurement of the spectral distribution of the photon fluence rate (1). The first main chapter of ICRU Report 53 (2) summarises the basic principles of gamma-ray spectrometry. If the measurement devices are coupled to computing devices with appropriate evaluation programs, they constitute rapid methods for an *in-situ* determination of environmental radioactive contaminations being capable to give radionuclide specific results. The methods considered mainly in ICRU Report 53 refer to gamma-ray spectrometry at ground-level, to gamma-ray spectrometry operated from aircraft, and to measurements of spectral distributions of the photon fluence rate and of absorbed dose rates in air.

Historically, the term *in-situ gamma-ray spectrometry* has been adopted for measurements that are performed close to the source, especially for ground-level gamma-ray spectrometry, mostly performed at a height of 1 m above ground. It is

mostly performed with high purity n-type germanium detectors. These detectors are capable to measure the spectral photon fluence in the energy range of 10 keV to 10 MeV, they have a high energy resolution (in the energy range of 100 keV to 1 MeV it is in the order of 1 keV), they are robust and need to be cooled only during the measurements. In ICRU 53, *in-situ* gamma-ray spectrometry is reviewed and updated by recent results of photon transport calculations. The sensitivity and the uncertainties are discussed. Methods for an *in-situ* determination of the attenuation of the radiation due to the surface roughness of the ground and the depth distribution in the soil are described. Some advanced methods in structured terrain (*e.g.*, in urban environments), with shielded and with unshielded detectors, and the application of on-ground gamma-ray spectrometry to the determination of radionuclide concentrations in air are reviewed.

Airborne gamma-ray spectrometry, *i.e.*, when spectrometers are operated from aircraft, is a uniquely rapid method, capable and economical for total mapping of large areas and for the location of lost radioactive sources. Standard equipment and methodologies based on geophysical survey techniques with scintillation detectors had been reviewed by the International Atomic Energy Agency (3) and an IEC standard (4) defines additionally technical and safety requirements for the equipment. ICRU Report 53 describes the types of equipment currently being used or developed for airborne gamma-ray spectrometry. Essential features of mapping natural and anthropogenic radionuclides are summarised. While it is recognized that the many years of practical application of airborne gamma-ray spectrometry have led to effective empirical approaches, some progress towards absolute methods involving photon transport calculations and towards systems incorporating high resolution detectors elements are discussed.

The last main chapter comprises methods to derive radionuclide specific gamma dose rates in air from the measured spectra. In addition, methods to determine the full spectral photon fluence in air, *i.e.*, not only the peaks, are reviewed, expressing the large potential of photon transport calculations in this field.

GROUND-LEVEL GAMMA-RAY SPECTROMETRY

Radionuclide distributions in the ground are parameterized by the mass per unit area, z (g cm^{-2}), of soil above a given source element. Photons with the same energy as source photons are called primary photons. A mathematical annex comprises relations between fluences of primary photons in air and radionuclide concentration in the ground and in the air for various kinds of source distributions. An important parameter in these relations is the total mass attenuation coefficient excluding coherent scattering, μ'/r (cm^2 g^{-1}), and its dependence on soil type is discussed.

One criterium for characterising n-type detectors is the ratio L/D of the length to the diameter of the sensitive detector region. The angular response to various radionuclide distributions in the ground is shown for detectors with different L/D ratios.

For monoenergetic sources distributed exponentially in the ground, primary photon fluences in air are given. Extensive calculation results are presented for anthropogenic radionuclides. Observations on depth distributions in dependence on the time after the deposition of anthropogenic radionuclides are summarised. Recommendations are given, which depth distributions might be assumed for an evaluation of *in-situ* spectra, if no site-specific information is available. Minimum detectable activities are given for characteristic cases and main sources of uncertainties are discussed. Methods for an *in-situ* determination of the attenuation by the ground are reviewed. For the first years after a cesium deposition, a method based on the simultaneous measurements of primary fluences of x-ray and gamma lines is shown to be applicable.

In-situ gamma-ray spectrometry in urban environments is reviewed. Shielded detectors are favourable for determinations of activities per unit area of urban surfaces like streets, walls or roofs, unshielded detectors are favourable for dose determinations. Fluences of primary photons in air due to horizontally finite radionuclide distributions in the ground are discussed.

Primary photon fluences in air at a height of one meter above ground are tabulated for natural radionuclides with uniform distributions in the ground and for radionuclides with uniform distributions in air. Over- and underestimations of radionuclide activities per unit air volume at the site of measurement due to applying these factors to finite clouds are discussed. Minimal detectable activities per unit volume are given for some common radionuclides in air after atmospheric releases of nuclear-technological plants.

AIRBORNE GAMMA-RAY SPECTROMETRY

The detector types discussed comprise standard geological systems, semiconductor detectors and combined systems. The main principles of various calibration approaches are discussed. Currently, the approach mainly used is to calibrate the detector system in small heights (about 1 m) over finite calibration pads. This type of approach needs approximations to take properly into account the scattering of the photons in the air between the source and the aircraft. For standard geological systems with NaI-detectors, this involves the derivation of the height dependence of the stripping ratios between the various spectral windows. The corresponding task is much simpler for germanium detectors with a high resolution. To support further developments on calibrations comparable to the ground-level gamma-ray spectrometry, tables with primary photon fluences in three flight heights above ground are supplied for various exponential source distributions in the ground.

Airborne systems equipped with air samplers are common in determining radionuclides in air. Nevertheless, airborne *in-situ* gamma-ray spectrometry has the advantage of measuring average concentrations over relatively large volumes without being subjected to local fluctuations. Also, in the case of accidental releases with high air concentrations, results may be obtained by overflying the highly contaminated cloud without flying directly through it. An approach of deriving radionuclide releases from spectra obtained by overflying a radioactive cloud is reviewed.

DETERMINATION OF GAMMA-RAY DOSE QUANTITIES

Assuming the shape of depth distributions of radionuclides in the ground, radionuclide-specific gamma dose rates in air may be derived from *in-situ* gamma ray spectra. The results for the dose rates depend less on the assumption on the depth distribution than corresponding results for radionuclide activities per unit area. The attenuation of the photon fluence is relatively simple to determine by *in-situ* gamma-ray spectrometry and laboratory measurements of the radionuclide active per unit area in soil samples. It is shown, under which conditions this information is sufficient to determine the radionuclide specific absorbed dose in air with good accuracy.

Extensive tables are given for gamma dose rates absorbed in air due to exponential distributions of anthropogenic radionuclides in the soil. The tables base on recent photon transport calculations (5) and a recent compilation of nuclear decay data (6). Further tables give corresponding results for uniform distributions of natural radionuclides in the ground and for uniform distributions of anthropogenic radionuclides in the air.

Measurement procedures of spectral photon fluence and absorbed dose rate distributions in air are reviewed. Methods to establish detector response functions by exposing them to monoenergetic or bienergetic gamma sources and applying appropriate interpolation functions are discussed. The high accuracy being obtainable by photon transport calculations of the response function of high purity n-type germanium detectors is demonstrated for applications to spectral photon fluences close to a ^{152}Eu source, in air over a contaminated free field and inside a house that is exposed to a ^{60}Co source.

ELECTROMAGNETIC FIELDS AND CANCER: HOW ICNIRP HAS DEALT WITH THE ISSUE

Michael H Repacholi
Chairman, International Commission on Non-Ionizing Radiation Protection.
Radiation Specialist, World Health Organization, 1211 Geneva 27 Switzerland

INTRODUCTION

Whether exposure to electromagnetic fields (EMFs) cause cancer has been vigorously debated for many years and has been the most vexing issue with which ICNIRP has had to deal during its short existence. There have been three parts of the electromagnetic spectrum that the issue of cancer has raised: static (0 Hz) magnetic fields, extremely low frequency (ELF) fields (defined as >0 - 300 Hz, but concerns have been raised almost exclusively at the power frequencies of 50/60 Hz), and radiofrequency (RF) fields (300 Hz - 300 GHz). By far the major problems have arisen during the contruction of new high voltage transmission lines and mobile telephone systems. Actions by protest groups concerned with possible health effects, especially with cancer in children, has now reached such a scale that it is costing electrical utilities and communications companies billions of dollars annually world-wide. With such high stakes, ICNIRP has had to be extremely careful in its evaluation of the scientific literature, use valid and defensible methods of literature review, and be completely independent of any special interest groups.

ICNIRP has had to continuously monitor the scientific literature to determine if any studies provide evidence strong enough to warrent a re-evaluation of the guidelines on exposure limits. This has been an increasing problem, particularly in this age of rapid communications (eg INTERNET), where information on new studies is quickly disseminated, evaluated and distributed to various special interest groups around the world who want to know what these studies will mean with respect to standards.

ICNIRP is a collaborator in a the International EMF Project with WHO, the International Agency for Research on Cancer, and many other international and national organizations having responsibility for EMF protection. The objectives of the Project are as follows:

(i) Pool resources of international and national agencies and key scientific institutions in the environmental health domain working on the biological effects of electromagnetic fields.

(ii) Identify gaps in scientific knowledge, provide protocols for the conduct of this research and encourage research in those areas that will lead to better health risk assessments.

(iii) Provide authoritative, independent, scientific, peer-review of the scientific literature, with fully substantiated recommendations.

(iv) Publish an updated EHC monograph giving a health risk assessment using results obtained during the Project on health effects of exposure to static, ELF and RF fields. This monograph would clearly differentiate between well established effects and those requiring further research.

(v) Publish an EHC monograph on risk perception, risk communication and risk management,

and public and occupational health policy.

(vi) Publish reports on appropriate topics to assist and support national health programs.

(vii) Use modern efficient means of communicating essential research information and findings which develop during the project.

It should be clearly understood that ICNIRP is a full partner in this Project and that the conclusions on health risk will assist ICNIRP to draft its own guidelines on exposure limits. A more complete description of the Project is available from WHO.

This paper summarises what criteria ICNIRP uses to review the literature, its response to EMF exposure and cancer, and its current position on static, ELF and RF fields.

HOW ICNIRP ASSESSES THE SCIENTIFIC LITERATURE

Scientific studies are in three categories:

(i) ***In-vitro studies*** conducted on isolated components of biological systems such as solutions of molecules (eg DNA), cultures of cells, or pieces of tissue. These studies are important for determining possible mechanisms by which EMF fields interact with biological systems and for identifying appropriate end-points and exposure conditions to be tested in whole animals. Determining mechanisms of interaction is important to give an understanding of how EMF fields act at the molecular or cellular level, and thus allow an extrapolation to the whole animal level. Studying simple systems allows interactions to be detected that may be masked in the complexity of interactions that occur normally at the whole animal level. It is because of this that biological effects found to occur at the molecular or cellular level cannot be assumed to occur at the whole animal level. Thus biological end-points found in-vitro must still be tested *in-vivo.*

(ii) ***In-vivo studies*** are conducted on complete biological systems such as laboratory animals. The great advantage of these studies is that they are conducted under carefully controlled laboratory conditions where all environmental and exposure parameters are kept constant. The only difference between exposed and unexposed animals should be the actual exposure to EMF fields they receive. Since experiments cannot normally be conducted on humans, animal studies are very useful for making health risk assessments related to human exposure. However, when evaluating animal studies, it is important to remember that the results of these studies are only applicable to humans if the effects observed occur in a number of different animal models. This is necessary because one particular animal model may be extremely sensitive to a particular end-point and have characteristics that are not observed in humans.

(iii) ***Human studies*** can be conducted on volunteers in the laboratory or on different populations of people in the living and working environment. Laboratory studies are conducted with the approval of the volunteer, and have the advantage of allowing exposures under strictly controlled conditions (as with animal studies). However the end-points that can be studied are limited. End-points such as cancer and mortality obviously cannot be studied on laboratory volunteers.

Studies on populations are called ***epidemiological studies*** and have the advantage of being non-intrusive. They compare the differences in the incidence of or mortality from some predetermined disease or diseases in populations. Generally one population is exposed to EMF fields and is compared with a population not exposed or at least having a much lower exposure to EMF fields. The major difficulty is to obtain two identical groups in sufficient numbers where the only difference is their exposure. This can become a significant problem when studying rare diseases such as cancer. However, these studies can indicate differences in the incidence of disease; the difficulty then being to attribute this difference to the EMF exposure and not some other factor in the living or working environment that is not detected as a difference between the two groups (eg chemical exposure in the workplace).

Criteria for evaluating scientific studies

When reviewing the scientific literature, certain criteria must be met if claims of a positive or negative effect are to be accepted into the database for conducting a human health risk assessment (Repacholi & Stolwijk 1991):

1) Experimental techniques, methods and conclusions should be as completely objective as possible, using biological systems appropriate to the end-points studied. To safeguard against bias, researchers should use double-blind techniques. Appropriate controls must be used for valid comparison of results. The sensitivity of the experiment must be such that there is a reasonable probability that an effect could be detected if it exists.

2) All data analyses should be fully and completely objective, no relevant data should be deleted from consideration and uniform analytical methods used. Data from experiments within the same protocol should be internally consistent.

3) The published descriptions of the methods should be given in sufficient detail that a critical reader would be convinced that all reasonable precautions have been taken to meet requirements 1 and 2.

4) Results should demonstrate an effect of the relevant variable at a high level of statistical significance using appropriate tests. The effects of interest should ordinarily be shown by a majority of test organisms and the responses found should be consistent.

5) Results should be quantifiable and susceptible to confirmation by independent researchers. Preferably the experiments should be repeated and the results confirmed independently; or the claimed effects should be consistent with results of similar experiments, where the biological systems are comparable.

6) Results should be viewed with respect to previously accepted scientific principles before ascribing them new ones.

While it will not be possible for all the above criteria to be applied to all experiments, these criteria provide a guide when determining what effects are established and can be used in a health risk assessment, and those that merely raise a hypothesis that needs to be tested, or those results which should be considered as preliminary and needing confirmation. Information from the

various types of laboratory and human studies, including the limitations in the amount of information they can provide, is also taken into account when conducting health risk assessments.

Assessment of epidemiological studies

Epidemiological demonstration of an association between two variables need not imply causality - both may be due to a common factor. However, establishment of causality is enhanced if (Miller 1986, 1989):

a) the presumed causal event precedes the effect,

b) one rather than multiple cancers are caused by a given exposure; giving specificity of effect,

c) a dose-response relationship exists,

d) there is consistency with other observations on cause and effect,

e) there is the exclusion of concomitant variables, or no alternative explanations,

f) the effect disappears when the cause is removed, and

g) the results are consistent with those from animal experimentation and other human observations.

Not all of these factors can be evaluated or will be true for even the most fully studied effects of an environmental exposure. It is known for example, that ionizing radiation induces various but not all forms of cancer. However, laboratory evidence is normally necessary to support the human studies. In other words, if there is truly a link between exposure to EMF and cancer, one would expect that laboratory studies on animals should show that EMF can cause cancer. If the laboratory studies do not show this and the human studies suggest only a weak association, then most likely there are problems with the human studies and they are not reaching valid conclusions.

What are the factors that must be taken into account when reviewing the epidemiological studies? What problems could affect the validity of associations found in epidemiological studies? There are four factors that could result in false associations in epidemiological studies:

- **inadequate dose assessment:** It is necessary to determine with some reasonable accurately a person's exposure to EMF. If these fields are associated with cancer, what aspect of the field is involved? To date it has been very difficult to gain incites into what should be considered as our concept of "dose" for EMFs.

- **confounders:** Other cancer risk factors could be causing a false association between exposure to EMFs and risk of cancer. Associations between things are not always evidence for causality. Exposure may be associated with a cancer risk other than EMFs. If such an associated

cancer risk were identified it would be called a "confounder" of the epidemiological study. An essential part of epidemiological studies is to identify and eliminate possible confounders. Possible confounders may be exposure to herbicides and chemicals such as PCBs, traffic density, socio-economic class and population mobility.

- **inappropriate controls:** The control groups must be selected to match as closely as possible all aspects (age, sex, socio-economic status, occupation etc) of the cancer cases (in a case-control study, which most of the epidemiological study reports are). An inherent problem with many epidemiological studies is the selection of a "control" group that is identical to the "exposed" group for all characteristics related to the disease except the exposure. This is especially difficult for rare disease such as leukaemia and brain cancer where the risk factors are poorly known. An additional complication is that people must consent to be in a "control" in a study, and participation in such studies is known to depend on many factors such as socio-economic class, race and occupation which are linked to differences in cancer rates.

- **publication bias:** Studies reporting positive results are much more likely to be accepted for publication than those with negative results. This would have the effect of skewing any analyses of a number of studies and severely bias meta-analyses that attempt to combine all studies (positive and negative) to investigate trends from a group of studies. Such study groups may erroneously contain more positive studies if negative studies are not published. This can happen because scientific journals are more interested in these for sales and publicity purposes or authors may not feel inclined to publish. Publication bias can thus increase apparent risks. This can effect both epidemiological as well as laboratory studies. Several specific examples of publication bias are known in studies of electrical occupations and cancer (see NRPB 1992). In their review Coleman and Beral (1988) reported the results of a Canadian study that found a RR of 2.4 for leukaemia in electrical workers. However, NRPB (1992) found that further follow-up of the same Canadian workers showed a deficiency of leukaemia (a RR of 0.6), but that this has never been published.

In reviewing the scientific literature, these factors must be taken into account to reach valid, supportable conclusions.

STATIC MAGNETIC FIELDS

There has been increasing concern among workers and the general public that exposure to static magnetic fields may be detrimental to health. This concern has been heightened by the increasing number of sources of exposure to these fields, and the ongoing debate about the possibility that exposure to 50/60 Hz magnetic fields may increase the incidence of cancer, with the implication that static magnetic fields may also be carcinogenic. Concerns have also been expressed because the next generation of train will use static magnetic fields (the magnetic levitation trains). The trains would expose very large numbers of people to quite strong static magnetic fields. In the field of medical diagnosis, magnetic resonance imaging units now expose patients and operators to magnetic fields as strong as 2 T. In the future, magnetic resonance spectroscopy could expose patients to fields up to 10 T.

Static magnetic fields are produced either by permanent magnets or whenever a direct current (DC) flows in a conductor. Direct currents are used to plate metals onto electrodes and

so static magnetic fields are produced around the electrolysis tanks. Magnetic fields are not appreciably distorted or attenuated by the human body. However they induce electrical currents in the body wherever there are moving parts (eg heart pumping or the body moving through the magnetic field). Thus, while adverse effects (such as involuntary nerve and muscle stimulation) could occur as a result of these induced currents, the cancer issue still had to be addressed.

ICNIRP completed a thorough review of the available literature on static magnetic fields in conjunction with the World Health Organization (UNEP/WHO/IRPA, 1987) and published a statement on magnetic resonance imaging (INIRC/IRPA, 1991). ICNIRP guidelines on exposure limits to static magnetic fields were published in 1994 (ICNIRP, 1994). No substantiated evidence was found to suggest that exposure to these fields is in anyway carcinogenic.

ELF FIELDS

Many studies have suggested that children exposed to 50/60 Hz magnetic fields, determined by residence near high current electrical installations (high voltage transmission lines, high current distribution lines, pole transformers etc) were at an increased risk of leukaemia or brain tumours. Later studies, using direct measurements and calculations of historical magnetic fields, have also suggested an increased risk of childhood cancer, and an increased carcinogenic risk in workers whose occupations have a higher exposure to magnetic fields.

Childhood epidemiological studies, when considered together, suggest there may be an association between cancer and exposure to 50/60 Hz magnetic fields. However, the average odds ratio for these studies is only of the order of 2.0. These odds ratios are quite small when one compares the odds ratios for cancer induction reported for smoking and X-ray exposure. When the odds ratios are so low, it would be more convincing that a true association exists if there were well conducted and independently confirmed laboratory studies indicating that 50/60 Hz field-exposure of animals or some recognised biological systems would either cause cancer directly or provide reasonable evidence that these fields influence the process of carcinogenesis. It is not necessary that a mechanism be found which would explain how such exposure had a carcinogenic effect, but merely that when the effect was found, it was statistically significant and independently replicated, and that a clear link with human cancer was established. Evidence from the animal studies to support the epidemiological evidence is lacking (Repacholi 1995).

Another major problem with these studies has been the lack of a clearly defined magnetic field measure (no concept of "dose" or the biologically active component of the magnetic field). In addition, many studies have had very low numbers of cases. To determine if a subtle effect exists on the incidence of rare cancers from magnetic field exposure, large numbers of cases and controls are needed. Of great concern has been the lack of consistency between study results. Some studies have suggested an increased leukaemia risk but not brain tumours while others have suggested exactly the opposite or reported no effect on cancer incidence at all. The problems with the 50/60 Hz epidemiological studies has lead to the necessity to conduct large animal studies to determine if indeed magnetic field exposure leads to an increased incidence of cancer.

ICNIRP has had to be very vigilent in this area because of the division of scientific opinion and more recently because of the unfortunate "leak" of a draft report from a National Commission on Radiological Protection and Measurement (NCRP) subcommittee responsible for identifying

health effects of ELF fields. Aside from the guidelines on exposure limits to 50/60 Hz fields issued in 1990 (INIRC/IRPA, 1990), ICNIRP reviewed the literature and reaffirmed the guidelines by issue a press release in 1993 (ICNIRP, 1993). ICNIRP is currently reviewing the scientific literature and drafting a set of guidelines that will provide exposure limits for electromagnetic fields from 0-300 GHz.

RADIOFREQUENCY FIELDS

It has also been suggected for many years that exposure to radiofrequency fields may also be associated with an increased incidence of cancer. Most recently ICNIRP has been confronted with concerns of people who find mobile telephone towers built near their home or schools. In addition there is the problem of the use of the mobile telephones themselves. They present an near-field exposure situation not anticipated by the RF guidelines published in 1988 (INIRC/IRPA 1988). In collaboration with WHO, INIRC/IRPA reviewed the RF literature and this was published in 1993 (UNEP/WHO/IRPA 1993). However, the issue of mobile telephones and their base stations resulted in the need to study possible effects from pulsed RF fields. ICNIRP has completed a review and is publishing the statement entitled "Health issues related to the use of hand-held radiotelephones and base transmitters" (ICNIRP 1996). A briefly summary of the reviewe is given below.

No consistent biological effect has been found in molecules or components of body cells exposed to RF fields, other than those effects caused by temperature increases. Researchers in the US reported that modulated microwave exposure of chromosomally abnormal cells which were treated with X-rays and a chemical promoter showed an accelerated rate of change from normal to cancer cells (Balcer-Kubiczek and Harrison 1991). While inconsistencies have been noted between various of these studies, the results are important. However, their implications for carcinogenesis in humans are not clear. This type of study tends to be susceptible to a variety of experimental confounding factors and needs independent confirmation.

Possible effects on DNA and chromosome structure are an important consideration in somatic cells, where such changes could lead to cell death or the development of cancers. If these changes occur in the male or female germ cells, surviving mutations might be passed on to the next generation. A large number of studies have been conducted in various somatic cells (Saunders et al 1991; NRPB 1992, 1993; UNEP/WHO/IRPA 1993) and most have reported a lack of effect on chromosome aberrations and single or double strand breaks in the DNA. Studies on the germ cells also suggests that acute or chronic exposure to RF does not result in increases in mutation or chromosome aberration frequency when the temperature is maintained within physiological limits. Where increased frequencies of chromosomal aberrations have been reported, these studies have not been successfully replicated. Chronic exposure experiments, which are relevant to long term RF exposure from base stations, have not produced any evidence of chromosomal aberrations in rodents exposed to SARs from 1-5 W/kg (UNEP/WHO/IRPA 1993).

In two recent rodent studies, there is the suggestion that RF fields may affect DNA directly. When mice were exposed to 2.45 GHz fields at 1 mW/cm^2 (SAR 1.18 W/kg) for 2 h/d for 120, 150 and 200 days, there was an indication of structural genomic rearrangement in brain and testes cells (Sarkar et al 1994). Lai and Singh (1995) report that rats exposed to pulsed (2 μs pulses, 500 pps) or continuous wave 2.45 GHz fields with SARs of 0.6 or 1.2 W/kg for 2 h

increased the number of single stand breaks in brain DNA. Both these papers produce quantitative data subject to sources of inter-trial variation and experimental error such as incomplete DNA digestion (Sarkar et al) or unusually high levels of background DNA fragmentation (Lai and Singh). These experiments should be replicated before the results can be used in any health risk assessment, especially given the weight of evidence suggesting that RF fields are not genotoxic (UNEP/WHO/IRPA1993).

A review of the laboratory studies conducted with WHO (UNEP/WHO/IRPA1993) concluded that RF field exposure is not mutagenic and is therefore unlikely to initiate damage directly to the DNA which would lead to cancer. The evidence for RF exposure causing tumour promotion or progression is not convincing but deserves further investigation.

Epidemiological studies have been conducted to assess the general health patterns and cancer risk among several groups of workers that were occupationally exposed to RF fields. These studies involved radar workers (Robinette et al 1980) and Moscow embassy workers chronically exposed to low-intensity microwaves for surveillance purposes (Lillienfeld et al. 1978). One of the more important studies conducted so far were the large epidemiological studies on Korean War radar technicians exposed to various levels of RF. No adverse health effects were established.

CONCLUSIONS

There is very little evidence to suggest that static fields have an effect on any stage of carcinogenesis. The major animal studies provide little convincing evidence that 50 Hz fields can promote cancer. There is some evidence that 50/60 Hz magnetic fields may be cancer co-promoters in tissues that are in the process of carcinogenesis, but the health impact of such a finding remains unclear.

With respect to whole-body RF exposure, the conclusions of the 1988 IRPA/INIRC guidelines remain valid. However, additional guidance has been given for mobile telephones. The conclusions of the ICNIRP (1996) statement are given below.

1. The results of published epidemiological studies do not form a basis for health hazard assessments of exposure to RF fields, neither can they be used for setting quantitative restrictions on human exposure. They do not provide a basis for hazard assessments in relation to the use of hand-held radiotelephones and base transmitters.

2. Data from laboratory studies relevant to cancer do not provide a basis for limiting exposure to the fields associated with the use of hand-held radiotelephones and base transmitters.

3. Limits for human exposure to the fields associated with the use of hand-held radiotelephones and base transmitters should be those of the INIRC (IRPA/INIRC 1988) for whole body average SAR and those of ICNIRP for localised SAR set out in this document.

4. There is no substantive evidence that adverse health effects, including cancer, can occur

in people exposed to levels at or below the limits on whole body average SAR recommended by INIRC (IRPA/INIRC 1988), or, at or below the ICNIRP limits for localised SAR set out in this document.

5. At the frequencies and power levels involved in the use of hand-held radiotelephones there will be no concern about shocks and burns.

6. The localised SARs in the head associated with the use of hand-held radiotelephones must be assessed for each frequency and configuration used.

7. For hand-held radiotelephones used in occupational situations, ICNIRP recommends that the localised SAR in the head be limited to 10 W kg^{-1} averaged over any 10 g mass of tissue in the head (0.1 W absorbed in any 10 g mass of tissue in the head).

8. For hand-held radiotelephones used by the general public, ICNIRP recommends that the localised SAR in the head be limited to 2 W kg^{-1} averaged over any 10 g mass of tissue in the head (0.02 W absorbed in any 10 g mass of tissue in the head).

9. The use of radiotelephones should be restricted to areas where interference effects are unlikely to occur (for example, well away from hospital intensive care departments and similar locations). Manufacturers of electrical equipment are encouraged to design and manufacture equipment that is insensitive to RF interference.

Basic Principles for Intervention after a Nuclear or Radiological Emergency

Per Hedemann Jensen
Risø National Laboratory
DK-4000 Roskilde, Denmark

Abstract. The current status of internationally agreed principles for intervention after a nuclear accident or radiological emergency and the international development of intervention guidance since the Chernobyl accident are reviewed. The experience gained after the Chernobyl accident indicates that the international advice on intervention existing at the time of the Chernobyl accident was not fully understood by decision makers neither in Western Europe nor in the former USSR and that the guidance failed to address adequately the difficult social problems which can arise after a serious nuclear accident. The radiation protection philosophy of today distinguishes between practices and interventions. The radiological protection system of intervention includes justification of the protective action and optimization of the level of protection achieved by that action. Dose limits do not apply in intervention situations. The inputs to justification and optimization studies include factors that are related to radiological protection, whereas the final decisions on introduction of countermeasures would also depend on other factors. The basic principles for intervention as recommended by international organisations are discussed in detail and the application of the principles on a generic basis is illustrated for long-term protective actions. The concepts of intervention level, operational intervention level and action level are presented and the relation between these quantities is illustrated. The numerical guidance on intervention in a nuclear accident or radiological emergency or a chronic exposure situation given by ICRP, IAEA and in the Basic Safety Standards is presented.

1 Practices and interventions

The latest recommendations from the International Commission on Radiological Protection [1] outline the systems of protection for *practices* and *interventions*. Human activities that *add* radiation exposure to that which people normally incur due to background radiation, or that increase the likelihood of their incurring exposure, are termed *practices*. The human activities that seek to reduce the existing exposure, or the existing likelihood of incurring exposure which is not part of a controlled practice, are termed *interventions*. The concepts of *dose addition* in a practice and *dose reduction* in an intervention are shown in Fig. 1.

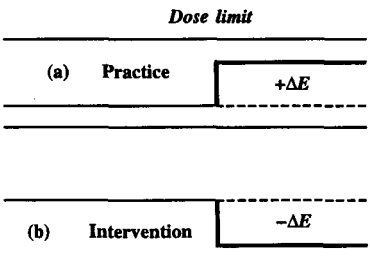

Fig. 1. Exposure situations for practices (a) and interventions (b). In a practice the dose increments $+\Delta E$ are controlled within the dose limit. In an intervention situation the dose decrement $-\Delta E$ or avertable dose is the result of the protective action.

For practices where the occurrence of the exposure is foreseen, the recommendations include the control of the source and limitation of exposure. Such situations include medical exposure, occupational exposure and exposure of the general public, and the system of protection includes the justification of the practice, optimisation of protection and imposition of overall dose limits.

In some situations the sources, the pathways and the exposed individuals are already in place when the decisions about control measures are being considered, and protection can therefore only be achieved by interventions, which always have some disadvantages. The system of protection for interventions include the justification of the intervention and the optimisation of the form, scale and duration of the intervention so as to maximize the net benefit.

The dose limits recommended by the Commission are intended for use in the control of practices. The use of these dose limits, or of any other pre-determined dose limits, as the basis for deciding on intervention might involve measures that would be out of all proportion to the benefit obtained and would then conflict with the principle of justification. The two different protection systems for practices and interventions are shown in Fig. 2.

Practice	**Intervention**
Each practice should be justified	**Each protective measure should be justified**
The doses *adding up* in a practice should be kept as low as reasonably achievable	**The level of protective measures resulting in *dose subtraction* should be optimized**
The *sum* of doses in a practice should be kept below specified dose limits	

Fig. 2. Systems of radiation protection for practices and interventions. The major differences between the two systems are that dose limits do not apply in the system of interventions and that different dose quantities apply.

2 Basic principles for intervention

An intervention should be *justified* in the sense that the introduction of protective measures should achieve *more good than harm*, and the level at which an intervention is introduced, and the level at which it is later withdrawn, should be *optimized* so that it will produce the maximum net benefit, i.e. *do the most good.*

A. JUSTIFICATION AND OPTIMIZATION OF PROTECTIVE ACTIONS

The avertable dose by the protective action, ΔE, can be found as the difference between the dose *without* any actions, and the dose *after implementation* of a protective action. The process of justification and optimization *both* apply to the protective action, so it is necessary to consider them *together* when reaching a decision.

Justification is the process of deciding that the disadvantages of each component of intervention, i.e. of each protective action or, in the case of accidents, each countermeasure, are more than offset by the reductions in the dose (avertable dose) likely to be achieved.

Optimization is the process of deciding on the method, scale and duration of the action so as to obtain the *maximum net benefit.* In simple terms, the difference between the disadvantages and the benefits, expressed in the same terms, e.g. monetary terms, should be positive for each countermeasure adopted and should be *maximised* by setting the details of that countermeasure.

Each of the factors describing the net benefit achieved by the protective measure have to be expressed in the same units. These units can be dimensionless quantities as used in multiattribute analysis, or values could be expressed in equivalent years of lost life. Normally in cost-benefit methods values are expressed in monetary units. However, it is the relative values placed on the components and their weighting one to another that is important, rather than the absolute unit. The use of a particular currency is relatively unimportant, as all terms could be evaluated as fractions of a country's gross national product (GNP) per head to allow for differences per head between countries.

If a protective measure were introduced at time t_1 and lifted at time t_2, the avertable dose, ΔE would be equal to the time-integral of the dose per unit time, $\dot{E}(t)$, over this time interval, τ.

The avertable effective dose, ΔE, and the effective dose per unit time, $\dot{E}$, are shown in Fig. 3.

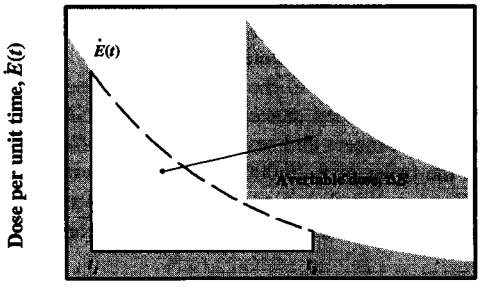

Fig. 3. Avertable dose, ΔE, when the protective measure is introduced at time t_1 and lifted again at time t_2.

B. INTERVENTION LEVELS

Intervention levels refer to the dose that is expected to be averted (avertable dose) by a *specific countermeasure* over the period it is in action. If an intervention level is exceeded, *ie*, if the expected avertable individual dose is greater than the intervention level, then it is indicated that the specific protective action is likely to be appropriate for that situation. Intervention levels (ILs) are specific to accident situations. The intervention level is defined as [5]:

> *Intervention level* is the level of *avertable dose* at which *a specific protective action* or *remedial action* is taken in an *emergency exposure* situation or a *chronic exposure* situation

Recommended intervention levels from the IAEA and ICRP for the major protective actions in a nuclear emergency are shown in Table 1 [2,3,5]. These recommendations are based on generic optimization as shown below.

Table 1. Summary of Recommended intervention levels from ICRP Publication 63 and IAEA Safety Series No. 109.

Protective measure	IAEA generically optimized intervention levels	ICRP range of optimized values
Sheltering (less than 1 day)	10 mSv	5 - 50 mSv
Administration of stable iodine	100 mGy to thyroid	50 - 500 mSv to thyroid
Evacuation (less than 1 week)	50 mSv	50 - 500 mSv
Temporary relocation	initiate at 30 mSv in a month and suspend at 10 mSv in a month	almost always justified at a dose level of 1 Sv 5 - 15 mSv/month as an optimized range
Permanent resettlement	if lifetime dose would exceed 1 Sv	

The optimized intervention level could either be expressed as an *individual dose, $\dot{E}$*, averted per unit time or as a *collective dose, S*, averted per unit mass of a given foodstuff, both given at the end of the interval, τ, for which the countermeasure, introduced at time t_1, would have to be in action [2,3,4]:

$$\dot{E}(t_1+\tau) = \frac{c}{\alpha} \quad \text{or} \quad S(t_1+\tau) = \frac{b}{\alpha}$$

The costs parameters in the above expressions, c (cost per unit time of implementing a given

countermeasure), b (cost per unit mass of restricting a given foodstuff) and α (monetary value of a unit dose averted) are likely to be similarly correlated to national wealth and thus susceptible to a relatively large variation between countries. However, their ratios would in general be much less sensitive to geographical location than either of the cost parameters alone.

The monetary value of a unit dose, α, would be related to the risk per unit dose, R, and the statistical loss of life expectancy, ΔL, per radiation induced cancer as $\alpha = R\ \Delta L\ GNP$, with some allowance for loss of quality of life for non-fatal cancers and severe hereditary effects. For rich developed countries the value of *GNP* is of the order of \$ 25,000 year^{-1} which would give a reference value of α of \$ 25,000 per sievert. For less developed countries α-values would be correspondingly lower. Generically optimized intervention levels would, however, be more or less country independent.

C. OPERATIONAL INTERVENTION LEVELS

Because of the inherent difficulty of forecasting doses that could be averted, there is a merit in establishing surrogate quantities such as *dose rate in air*, *surface contamination density* and *activity concentration in air*. The relationship between these quantities and the avertable dose will vary considerably with the circumstances of the accident and nature of contamination. The operational quantities would, therefore, be both accident and site specific but would still be inextricably linked to the avertable dose.

The term "*operational intervention level (OIL)*" is reserved for quantities that can be more easily assessed at the time of decision on intervention such as dose rate, activity concentration, surface contamination density, etc. OILs are related to the dose that could be averted by a *specific protective action* like evacuation, relocation and banning of foodstuffs.

In general terms, the avertable dose, ΔE, from *all exposure pathways* by implementing a given countermeasure can be expressed by a measurable quantity, q. The operational intervention level can be determined from the intervention level (IL) as follows:

$$OIL = \frac{IL}{\sum_{pathways} \Delta E(q=1)}$$

It should be recognised that in the calculation of $\Sigma\Delta E(q=1)$, summed over all pathways, p, site specific parameters like location/filtration factors and indoor/outdoor occupancy have to be used. For long-lived γ-emitting radionuclides like $^{137}Cs/^{134}Cs$ the value of $\Sigma\Delta E(q=1)$ would be approximately 200 mSv·month^{-1}/mSv·h^{-1} for a time-averaged location factor of 0.3, q being the outdoor dose rate. The OIL_{rel} for relocation corresponding to an IL of 10 mSv·month^{-1} can thus be calculated from the above formula to be about 50 μSv·h^{-1}. When the outdoor dose rate from long-lived γ-emitting radionuclides therefore exceeds 50 μSv·h^{-1}, it is indicated that temporary relocation might be needed.

D. ACTION LEVELS

Action levels refer to different protective measures or strategies of actions like agricultural countermeasures or radon reducing measures in houses and they relate to the residual dose without remedial actions. The action level is defined as [5]:

> *Action level* is the level of *dose rate* or *activity concentration* above which *remedial actions* or *protective actions* should be carried out in *chronic* or *emergency exposure* situations

Action levels are levels above which remedial actions are taken and below which they are not. An action level is set such that the dose averted by taking the remedial action is always worthwhile in terms of the costs and other disadvantages involved. Justified action levels would

begin at the minimum value of the avertable individual dose at which the remedial action is just beginning to do more good than harm.

The action level can thus be defined as the lowest level at which remedial actions to reduce doses are justified and optimized. The equivalent definition would be that the action level is equal to the maximum acceptable level of dose attributable to the contamination without any protective actions taken. If an action level is exceeded, it is indicated that some form of remedial action specific to the situation considered is likely to be appropriate. Action levels have, therefore, the same character as operational intervention levels. The concept of an action level is illustrated in Fig. 4.

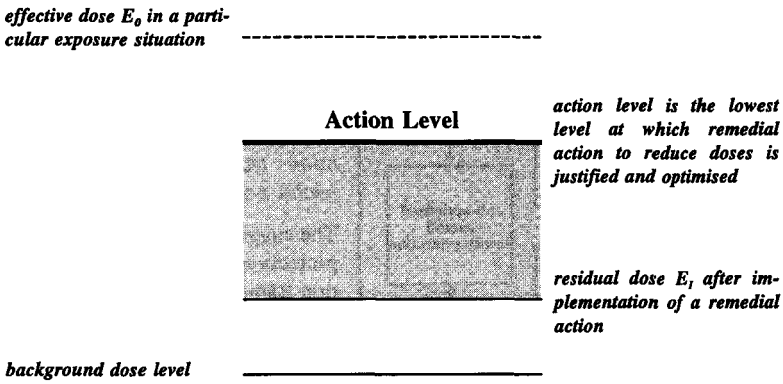

Fig. 4. The action level (AL) is the maximum acceptable residual dose without a remedial action which is equivalent to the minimum avertable dose by that action. The avertable dose in the figure is given as $\Delta E = E_0 - E_I$.

Action levels would also be used for the reduction of radon in dwellings. Recommended action levels from ICRP for radon in dwellings are shown in Table 2 [6]. The action level for remedial actions relating to chronic exposure situations involving radon in workplaces is a yearly average concentration of ^{222}Rn of 1,000 $Bq \cdot m^{-3}$ in air.

Annual dose (mSv)	3 - 10
Concentration ($Bq \cdot m^{-3}$)	200 - 600

Table 2. Action levels for radon in dwellings.

Bone marrow	0.4
Lens of the eye	0.1
Gonads	0.2

Table 3. Action levels for chronic exposure of single organs (Gy y^{-1}*).*

Different tissues have a wide range of sensitivity for radiation induced deterministic effects. Threshold dose rates for deterministic effects under conditions of prolonged exposure over many years have been used in the Basic Safety Standards (BSS) [5] as action levels for chronic exposure. The values for permanent sterility, for clinically significant depression of the blood-forming process and for opacities sufficient to cause impairment of vision are shown as action levels in Table 3 [1,5].

3 Unresolved issues

Following a nuclear or radiological emergency, especially in the later phases, many complex human, social and economic considerations will have to be taken into account by the responsible authorities. The decisions and protective actions taken may themselves induce social and

psychological impacts. Internationally, the application of different intervention levels in similar circumstances resulting from a single accident would cause much confusion in the public mind. At the national level, taking decisions about lines of demarcation between those areas where protective measures are applied and those where they are not, might create anxiety or even fear by people living on the 'safe' side of the demarcation line.

From the experience in CIS following the Chernobyl accident, countermeasures to mitigate social-psychological impacts have obviously been needed and they have been identified to be a new category of action. It has even been argued that radiation protection philosophy has not yet been developed to fully include these countermeasures, as being reflected in Fig. 5, but that the two 'lines' of optimization should be merged into one system of 'radiation protection'.

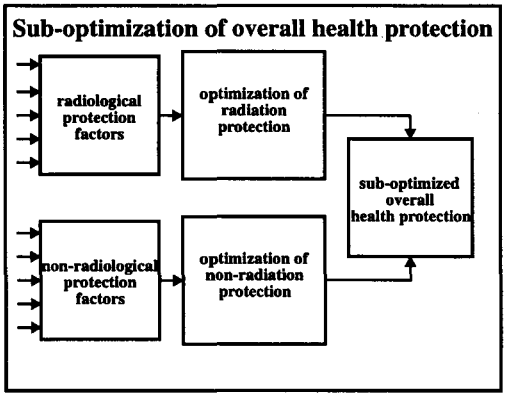

Figure 5. Sub-optimization of overall health protection where radiological protection and non-radiological protection factors each are used for separate optimizations leading to a sub-optimized overall health protection.

The suggestion to include non-radiological protection factors in the radiation protection framework seems awkward. Radiation protection factors are related to the level of protection achieved including those factors describing the dose distribution averted and costs and other disadvantages incurred in averting doses. The level of socio-psychological impact would depend not only on the presence of radiation but to a large extent on other non-radiological protection factors, such as the attitude of the mass media, the political climate and the general level of information in the population. Non-radiological protection factors would also be different from country to country, and would probably be highly dependent on the existing political situation. To include socio-psychological factors in the radiation protection framework would thus give very random levels of 'radiation protection'.

Therefore, to achieve an optimized overall health protection, non-radiological protection factors should enter the optimization process in parallel with radiological protection factors to form an optimized countermeasure strategy as shown in Fig. 6.

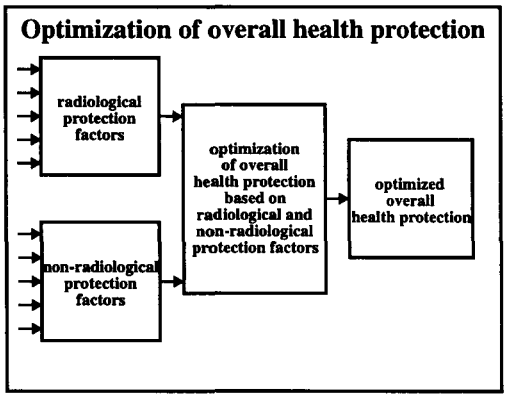

Figure 6. Optimization of overall health protection where radiological and non-radiological protection factors are included simultaneously in the optimization process.

Optimization of overall health protection would thus be the responsibility of the decision maker with guidance from radiation protection experts as well as experts in the fields of social and psychological sciences. Optimization of overall health protection is therefore a discipline for decision makers and not an extension of the radiation protection philosophy. It is also of great importance that decision makers present the optimized protection strategy to the public in a transparent way so that all the factors and their relative importance in reaching the optimized strategy are revealed.

4 Summary

The distinction between practices and interventions has created some confusion. The fact that dose levels for introduction of protective measures have been interpreted as doses *received* and not as doses *averted* is, however, awkward and prone to suggest to people that the levels are dose limits. The experience after the Chernobyl accident was that many actions taken led to an unnecessarily large expenditure of national resources, and many instances occurred of contradictory national responses. Therefore, there was a strong need for a simple set of internationally consistent intervention levels and action levels and for clear guidance on application of the principles in planning and preparedness for response to nuclear accidents or radiological emergencies.

Intervention levels have therefore been established by ICRP and IAEA for both short-term and longer-term countermeasures. These intervention levels are expressed in terms of dose *averted* by the specific action. Since the dose that will be averted cannot easily be estimated in the period immediately after the accident, derived quantities of *operational intervention levels* (*OILs*) or *action levels* (*ALs*) can be established (dose rate or activity concentration, for example). The appropriate protective action will be invoked if these levels are exceeded, but the action will normally not be taken if they are not.

There are still unresolved issues for different intervention situations, especially for long-term exposure situations; these issues would involve both optimization of radiation protection and optimization of overall health protection:

- So far, no international agreed numerical guidance have been established on action levels for protection of populations against different chronic or semi-chronic exposure situations from natural and artificial radionuclides in the environment (except for radon in dwellings).
- Clean-up levels for residues from previous events or past practices, *eg*, uranium mining and milling, might - due to their origin from intervention optimization - result in a lower level of protection than for still operating practices of a similar type because of the dose constraints for practices. It would be peculiar to operate with different levels of protection in two similar situations and, obviously, optimized action levels for such intervention situations might have to be constrained to an equal protection level as in the similar practice.
- Interaction between radiological and non-radiological factors in decision making has been identified to be an important issue. Both radiological and non-radiological factors will influence the level of protective actions being introduced. From the experience in CIS following the Chernobyl accident, the need for social-psychological countermeasures is obvious. However, the quantification of non-radiological protection factors needs further development.
- It has been suggested that the inclusion of socio-psychological factors into the intervention decision making framework should be as a part of the radiation protection framework. This suggestion seems awkward as the level of socio-psychological impact would depend not only on the presence of radiation but to a large extent on other non-radiological protection factors, such as the attitude of the mass media, the political climate and the general level of information in the population. Inclusion of socio-psychological factors in the radiation protection framework would therefore give very random levels of 'radiation protection'.
- Non-radiological protection factors such as public anxiety and risk perception will play a legitimate role in the decision making. These factors should be addressed by the decision maker and *not* by the radiation protection community. The optimization of overall health protection is thus the responsibility of the decision maker. It is of great importance that the decision maker present the protection strategy to the public in a transparent way so that all factors and their relative importance in reaching an optimized strategy are revealed.

There are at least two areas where the radiation protection community should clarify its

recommendations in the years to come. Firstly, convincing guidance needs to be prepared for the 'grey area' of similar intervention/practice situations for which the optimized level of radiation protection of populations might be different. Secondly, only radiological protection factors should be included in generically optimized intervention levels. The socio-psychological and political factors should be included by *the decision maker* in the optimization of overall health protection based on inputs from radiation protection experts and from experts in the fields of social and psychological sciences.

COUNTERMEASURES IN AGRICULTURE AND FORESTRY AFTER A NUCLEAR ACCIDENT

Malcolm J. Crick[1], R.J. Hance[2] and J.I. Richards[2]

[1]International Atomic Energy Agency
[2]Joint FAO/IAEA Division, IAEA
A-1400 Vienna, Austria

INTRODUCTION

During the past 35 years, three major accidents at nuclear facilities have given cause for concern and required the implementation of countermeasures in agriculture. These accidents occurred at Windscale (United Kingdom) in 1957, Kyshtym (former Soviet Union) in 1957 and Chernobyl (former Soviet Union) in 1986. Despite the increased knowledge on the safety of nuclear power plants and the implementation of improved procedures, it would be naive to exclude the possibility of other accidents occurring in the future and the consequent deposition of radioactive material into the environment.

As nuclear facilities are not normally sited in densely population areas, the adjacent land is likely to be agricultural or at least rural. Furthermore, the accident at Chernobyl, albeit a severe one, showed that agricultural practices can be affected hundreds and even thousands of kilometres from the accident site. Therefore contingency plans are needed to initiate countermeasures that can be used to reduce contamination of agricultural produce, even in countries with no nuclear power of their own.

This paper presents an overview of the principles for intervention to protect the public from the perspective of agricultural countermeasures, the development of generic and specific intervention and action levels, the range of countermeasures available at various times after an aciident and some of the factors involved in developing an overall strategy for decision making and implementation. For further information on these subjects the reader is referred to an IAEA/FAO Technical Report(1).

PROTECTIVE MEASURES

In the event of a nuclear accident, the ICRP principles relating to intervention situations apply (2). In these circumstances, three major principles have evolved to protect and maintain human health against the effects associated with radiation exposure (3); these principles appear to have almost universal acceptance:

- a) All possible efforts should be made to prevent serious deterministic health effects;
- b) The intervention should be justified, in the sense that introduction of the protective measure should achieve more good than harm.
- c) The levels at which the intervention is introduced and at which it is later withdrawn should be optmised, so that the protective measure will produce a maximum net benefit.

In practice, agricultural countermeasures normally address stochastic health effects in the human population, although the more immediate impact of possible deterministic effects, particularly on farm animals, should be considered. In general, countermeasures to protect foodstuffs will normally be taken at levels much lower than those at which such effects occur (4).

In the event of a nuclear accident, the effectiveness of measures taken to protect the agricultural sector (people, land, crops and livestock) will depend heavily upon the adequacy of emergency plans prepared in advance. In these emergency plans, criteria are specified for taking particular prompt actions. Even after the immediate emergency, having predefined criteria for longer term actions will do much to counter any loss of confidence in the competence and integrity of the authorities on the part of the public. Such criteria for intervention are based primarily on radiological protection principles.

There are two distinct phases in which optimisation of protective measures should be considered:

- In the phase of planning and preparation, prior to accidents, a *generic* optimisation of protective actions should be established, based on *generic* accident scenario calculations. This should result, for each protective measure and each selected scenario, in an optimised *generic* intervention level, which is meant to be the first criterion for action to be used immediately and for a short time after the occurrence of an accident.
- Some time after the beginning of a real accident, specific information on its nature and likely consequences and evolution would be expected to be available. in this case a more precise and *specific* optimisation analysis should be carried out in the basis of actual data and the actual efficiency of protective measures. This should result in a *specific* intervention level for each protective measure, to be used as a criteria in the medium and long term. However, in many cases the optimisation will be constrained by sociopolitical factors, which may make it difficult to alter the generic intervention levels unless there are overriding reasons to do so.

Radionuclide Group	*Optimized intervention level (Bq/kg)*				
	Specifically for withdrawal of foodstuff		Specifically for substitution of clean fodder		
	Fresh milk, vegetables, grain, fruit	Meat, milk products	Milk		Meat
Group 1	~1000 - ~10,000	~10,000 - ~100,000	~100 - ~1000	Cs-137	~few 100 - several 1000
				I-131	~100 or so - ~1000 or so
Group 2	~100 - ~1000	~1000 - ~10,000	~10 - ~100	Sr-90	Several 10s - several 1000s
Group 3	~10 - ~100	~100 - ~1000	~1 - ~10	Pu-239	Few 100 - few 1000

Table 1 Optimised intervention levels for food. Optimised intervention levels for various food categories and nuclide groups have been shown to be of the order given in the table. The nuclide groups are delineated according to the effective dose per unit activity ingested: Group 1 - ~10^{-8} Sv/Bq; Group 2 - ~10^{-7} Sv/Bq; Group 3 - ~10^{-6} Sv/Bq.

Commonly, situations will arise where contaminated food and water can be withdrawn and uncontaminated replacements can be readily substituted, at costs approximately equal to the value of the foodstuff without seriously distorting supply and demand and without introducing major disruption of lifestyles. In these cases it is reasonable as a first approximation to apply simple methods to estimate optimized intervention levels specifically for withdrawing food (1). Ranges of values are given in Table 1. Whilst the optimised values have been derived on the

assumption of withdrawing contaminated foodstuffs and substituting uncontaminated ones, there exist a wide range of other less extreme measures that are often more cost effective. Also given in Table 1 are ranges for optimised intervention levels for providing clean feed to cattle otherwise grazing contaminated land. The latter set of values are significantly lower than the set for a complete food ban.

GENERIC ACTION LEVELS FOR FOODS

Whilst it is possible to develop intervention levels for each agricultural countermeasure of interest, it is more practical to establish action levels, which are not specified for any particular countermeasure, but are defined as levels above which some action is needed.

There are a number of advantages in using internationally recognized values for the action levels: 1) maintaining credibility, confidence and trust in the authorities; 2) preventing anomalies that might otherwise exist along borders of neighbouring countries; 3) strong arguments can be made to adopt international values as national intervention levels for the control of food.

The Codex Alimentarius Commission of the FAO and WHO has addressed the situation of international standards in order to maintain widespread international trading in food. Guideline levels for radionuclides in international trade following accidental nuclear contamination have been agreed (5). It should be recognised that these levels are a compromise between what is appropriate on radiological protection grounds (which would often give rise to significantly higher values) and the natural wish of countries unaffected by an accident to avoid importing produce with any contamination at all, no matter how small, even compared with natural radiation. The values have been adopted by the FAO, IAEA, ILO, OECD/NEA, PAHO and WHO in developing the new International Basic Safety Standards for Radiation Protection (6) and are presented in Table 2.

Radionuclides	*Foods destined for general consumption (kBq/kg)*	*Milk, infant foods and drinking water (kBq/kg)*
Cs-134, Cs-137, Ru-103, Ru-106, Sr-89	1	1
I-131		0.1
Sr-90	0.1	
Am-241, Pu-238, Pu-239	0.01	0.001

Table 2 Generic Action Levels for Foodstuffs. For practical reasons, the criteria for separate radionuclide groups shall be applied independently to the sum of the activities of the radionuclides in each group.

It should always be recognised that accident and site specific conditions, as well as political considerations, might lead to different *specific* action levels. In particular, where the numbers of people and area of land potentially affected by a protective action become extremely large, the cost of resources and societal disruption become more and more important in comparison with available national resources, and relaxation of the intervention levels may be necessary. On the other hand, when the numbers of people and area of land potentially affected are very small, additional costs incurred in order to gain public confidence can be readily absorbed by society.

An indication of how the costs and doses associated with a countermeasure depend on an intervention/action level is given in Figure 1. This figure shows for example, that increasing an action level by a factor of two also increases the dose to the hypothetical critical group for that pathway by a factor of two, assuming it is the dominant pathway (7). However the collective dose saved is lower by only 20% while the associated costs fall by 60%. Similarly reducing an intervention/action level by a factor of ten will decrease the dose to the hypothetical critical group for that pathway also by a factor of ten (assuming it is the dominant pathway). However, the collective dose saved is increased by only a factor of two, while the costs increase by a factor of 20.

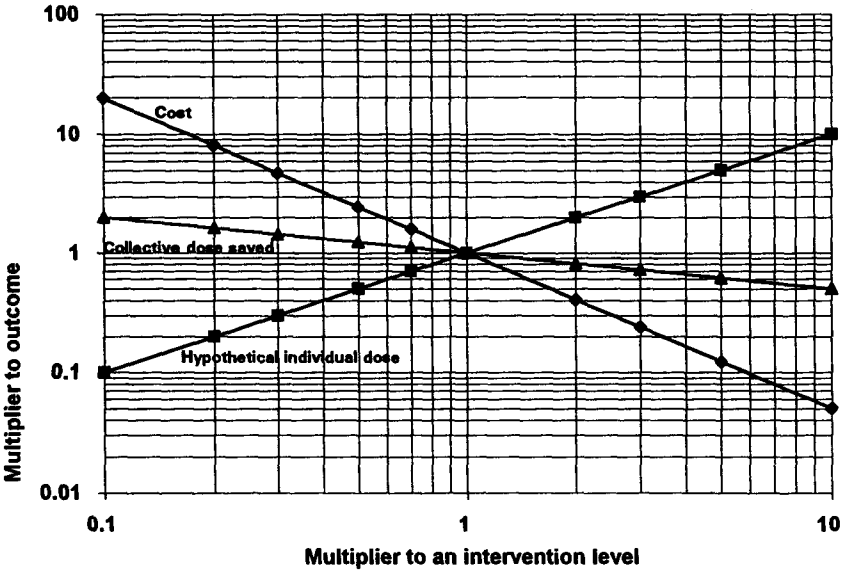

Figure 1. The effects of modifications to an intervention/action level on the cost and collective dose saved by a countermeasure and the residual dose to a hypothetical critical individual.

COUNTERMEASURES STRATEGY AND DECISION MAKING

The main considerations for government (from central down to local) in preparing an agricultural countermeasures strategy is to :

- define measures to be applied before and during fallout, and in the consequent medium and long term;
- protect human health by reducing radioactive contamination of agricultural products;
- return the land to normal use as far as possible;
- ensure that the countermeasures applied balance health protection measures, cost, disruption to daily life and the well-being of communities.

For the early phase of an accident, authorities will rely in the main on their own emergency plans. These plans will have been drawn up prior to an accident; the need for elaborate decision making in real time on the introduction of countermeasures will to a large extent be obviated by the existence of plans and there will anyway be a lack of time in which to react. After the early phase is over and as more detailed information becomes available and the potential for large expenditure becomes more apparent, more considered decisions will need to be made about the need for specific longer term countermeasures and/or the relaxation of countermeasures. These may well involve the use of decision aiding tools.

There can be no single generic strategy for the introduction of agricultural countermeasures because environmental conditions vary from place to place, and the nature and size of accidental release, the size of the affected population and the social, economic and agricultural conditions will all differ. As discussed earlier, the main objective of a countermeasure should be to effectively reduce radiation doses to the population and hence diminish health risks. In practice, this translates into selecting a countermeasure strategy that will allow production of food with activity levels below the action levels in as cost effective a manner as possible, with minimum side effects. On this basis the simplest way to compare the cost effectiveness of countermeasure options is to calculate the monetary cost per unit collective dose saved. However, the side effects of some countermeasures, which can include ecological, economic and social factors can be substantial. For example, agriculture could become unsustainable, farmers and their dependent communities could be made redundant, and the psychological consequences could be large, even leading to clinical health problems. There may be practical reasons why countermeasures must be adopted in a particular area in order to limit the spread of contaminated produce outside that area. Markets could be severely distorted in the short to medium term by the introduction of a particular strategy. Subsidies and compensation to farmers may introduce their own market distortions. These additional factors will have to be taken into account in the drawing up of recommendations to farmers. Some sophisticated techniques exist that can be used to aid decisions between different alternatives. Nevertheless, these methods can only be used if the problem is relatively simple and well structured, and persons with specialist knowledge are available. Such methods have not as yet been used in practice for deciding on agricultural countermeasures; decisions have to date been based on the cost effectiveness of the particular countermeasure and a subjective weighing of other factors.

AGRICULTURAL COUNTERMEASURES

The timing and nature of countermeasures depend on the quantity and composition of the radionuclides in the release, the season of the year and site specific factors. The post-accident period can be conveniently divided into three overlapping phases. Examples are given below of the measures available. For further details the reader is referred to Ref. (1).

Early Phase

The early phase may begin before fallout arrives if sufficient warning is available, and ends when the 'cloud' has passed and the acute deposition finished. It is self-evident that countermeasures taken during this phase must be applied promptly to be effective. However, since they will be based on predictions derived from incomplete information there is a high degree of uncertainty. There will be a tendency to be cautious and therefore countermeasures invoked should be inexpensive and with only short term implications in case they turn out to have been unwarranted.

Countermeasures that might be invoked in this phase include:

- Generic ban on collection of milk and other products pending monitoring;
- Housing animals that are grazing outdoors (or preventing the return of stalled animals to pasture) and providing uncontaminated forage prevents the contamination of milk, meat and offal. Moreover, it may, in the event of a large radioiodine release protect against acute deterministic effects to the animals' thyroids;
- Covering uncovered feed/food stores and open sources of water with impermeable sheeting. Covering haystacks, heaps of potatoes etc. with plastic sheeting is effective and relatively easy to arrange where suitable covering is commonly available;
- Harvesting ripe crops before contamination occurs: this is only possible where there is sufficient warning available. Priority would normally be given to high value crops.

Intermediate Phase

The intermediate phase lasts several weeks or months until contamination from short-lived radionuclides or from the direct deposition is no longer of concern or the first crop is harvested. Countermeasures may be needed to deal with the direct deposition of activity onto crops or pastures, and the subsequent contamination of food products.

Typical countermeasures that can be efficient in this phase include:

- Prohibiting hunting, fishing, mushroom collection, and consumption of vegetables and water derived from surface water or precipitation;
- Harvesting crops and grass for disposal or storage; or
- Delaying the harvesting of forage/crops;
- Processing milk contaminated with I-131 to storable products, e.g. butter, skimmed milk powder, cheese etc.

Late Phase

In the late phase the radioactive contamination is mainly due to long lived radionuclides and contamination of foodstuffs occurs primarily through root uptake of radionuclides by plants. The need to implement long term agricultural countermeasures needs to be carefully assessed since any actions are likely to have to last for long periods with often high associated costs.

Typical countermeasures in the late phase include:

- Ploughing to dilute the radionuclides in the rooting layer;
- Removing a shallow surface layer of the contaminated soil;
- Selecting suitable varieties of a crop, or alternative crops that accumulate lower levels of the contaminating radionculide than the variety normally grown in the area;
- Growing crops such as flax, cotton, ornamental plants or oil seed rape where the product is non-edible;
- Using contaminated land for non-dairy animals or for animals non intended for immediate slaughter;
- Changing land use to forestry;
- Applying potassium fertilizers;
- Changing slaughter time to reduce contamination levels in animals;

- Administering chemical binders to reduce radiocaesium absorption in the gut of grazing animals;
- Prohibiting fishing;
- Restricting access to forests;
- Changing forest management, including hunting schedules, reforestation etc.;
- Optimising food processing to minimise the contamination of final products.

LEGAL CONSIDERATIONS

A clear legal basis should be established for intervention in the event of an accident. Prevailing food law and consumer protection legislation should be sufficiently comprehensive so that it is not necessary to pass any new laws in the period immediately following an accident.

Specific numerical action levels for radioactive contamination in food in an emergency should be laid down in advance. The internationally agreed FAO/WHO *Codex Alimentarius* Commission Guidelines for foods moving in international trade mentioned above will form the basis for these limits. Such levels may have to be reviewed in the light of the specific conditions of an accident within a predefined period of time (e.g. 3 months).

Legal aspects specifically related to agricultural countermeasures that should be considered include:

- any legal obstacles to the implementation of countermeasures
- the need to license chemicals planned for soil treatment or feed additives (e.g. Prussian Blue)
- legal action that may be necessary to ensure the stockpiling of uncontaminated feed, chemical agents, etc.
- the legal basis for compensation for losses in agriculture following accidental contaminate of farmlands
- the liability of an operator responsible for an accident.

FUTURE DIRECTIONS

There is a need for authorities to develop secondary reference levels (so-called 'operational intervention levels') for quantities such as animal feeds and levels of contamination of pasture on which animals should normally graze. These working quantities are specified in their own appropriate units (e.g. Bq/m^2). International guidance on these is to be expected.

Also, whereas parameter values for the prediction of radionuclide transfers exist for the soil-plant system in temperate environments (8), such values are not currently available for warmer climates and sub-tropical soils and plants. The IAEA has recently initiated a Coordinated Research Programme to predict radionuclide transfer in these environments.

The application of formal decision aiding techniques in various scenarios that can encountered following an accident will likely lead to the development of more generic guidance on countermeasures strategies for various scenarios and environments in the future. The experience gained in the former Soviet Union following the Chernobyl accident will be invaluable in the validation of these techniques.

Decision Making on Remedial Actions after a Nuclear or Radiological Emergency

G N Kelly
European Commission, DG XII/F/6
Rue de la Loi 200, B-1040 Brussels, Belgium

Abstract. Guidance developed at an international level for longer term countermeasures (eg, relocation, decontamination, restoration of contaminated areas, removal of countermeasures, etc) is largely outline in nature. The considered view is that, for such countermeasures, sufficient time will be available for the benefits and disadvantages of different options to be carefully weighed and balanced in the circumstances then prevailing. The wide range of circumstances that might be encountered after an accident is also judged to constrain the degree to which detailed, practicable guidance can be prepared in advance. The availability of more time, however, is unlikely to make the process of deciding what remedial measures to adopt easier, indeed probably the reverse. Various approaches and techniques are available to aid the development of more detailed guidance in advance of an accident and/or decisions on intervention following an accident. These are summarised with particular reference to their relative strengths and weaknesses. Consideration is also given to whether these techniques should find greater application in advance of an accident with a view to facilitating the development of more detailed, practical guidance should the need ever arise.

1. Introduction

In general, for longer term countermeasures (eg, relocation, decontamination, restoration of contaminated areas, removal of countermeasures, etc) only outline guidance has been developed for use in the event of an accident. The considered view is that, for such countermeasures, sufficient time will be available for the benefits and disadvantages of different options to be carefully weighed and balanced taking account of the particular circumstances then prevailing. The wide range of circumstances that might be encountered after an accident is judged to constrain the degree to which detailed, practicable guidance can be prepared in advance. The availability of more time, however, is unlikely to make the process of deciding what remedial measures to adopt easier, indeed probably the reverse. Pressures will be exerted by various interest groups with differing and probably conflicting objectives that will be difficult to reconcile, in particular as the issues would be exposed to wide public debate and media attention.

Two issues are addressed in this paper: firstly, the merits of developing more detailed, practical guidance for long term countermeasures in advance of an accident and, secondly, techniques that could be used to facilitate the development of such guidance, irrespective of whether this was prior to or after an accident had occurred.

2. Development of more detailed guidance

Only limited guidance is available internationally on longer term countermeasures and that which does exist is largely outline in nature and constrained in the range of factors that have been considered in its development. Various international bodies have issued quantitative guidance on relocation [1-3] but little yet exists on the restoration of contaminated land or the so called "return to normality" when all remedial measures taken after an accident are removed. These latter topics are, however, currently being addressed by the IAEA, ICRP and others. The factors taken into account in developing the current quantitative guidance on relocation were essentially limited to the monetary cost of the intervention and the resulting decrease in radiation health detriment. Such guidance must, therefore, be qualified with respect to its practical application. The qualifications placed on the guidance developed in reference [1] include the following: *"... The guidance developed here has been kept deliberately simple and is intended to be broadly applicable. Of necessity, it will need to be refined in light of the particular circumstances of an accident and to take account of other factors of a more social nature that have not been addressed here. The guidance is intended to provide a basic*

framework for decision making within which other factors or considerations could be readily integrated ..... These levels (ie, the quantitative guidance) *provide a useful starting point for making decisions on relocation"*

In practice a number of other factors or considerations will need to be taken into account in determining both the nature and extent of longer term interventions following an accident. In their absence, both the credibility and acceptability of the approach or criteria established are likely to be strongly challenged with consequential implications. This is exemplified by experience following the Chernobyl accident and the contamination of land by other carcinogenic or toxic agents. It is difficult to be prescriptive or complete with respect to the other factors to be considered since much will depend on the circumstances prevailing at the time of the accident, in particular the social, economic and political situation. Some of the more obvious factors that will need to be addressed, in the context of relocation, include the following:

- the health detriment resulting from relocation itself (ie, there is some evidence that the imposed movement of people leads to a reduced life expectancy)
- anxiety and stress consequent upon living in a "contaminated" environment
- pressures for compensation for damage caused by an accident and from continuing to live in a "contaminated" area over the long term
- the apparent conflict between radiological standards used for practices and intervention (notwithstanding their intellectual soundness, these differences are perceived very differently by the layman compared to the radiation protection community and are a continuing source of difficulty in practical policy formulation)
- utilisation of resources and constraints, particularly achieving a balance in terms of expenditure on other health and environmental risks
- use of the issue as part of a broader political objective.

These, together with other potentially important factors, are considered more fully in another of the papers presented in this IRPA Symposium [4].

Because of the diversity of these factors and their potential variability (ie, depending on the scale and extent of an accident and the prevailing social, economic and political conditions), there are clearly limits to the level to which detailed planning for relocation can be made or, indeed, would be sensible. At an international level [1-3] there is a broad consensus on both the level of detail that is appropriate in developing guidance on relocation (ie, outline guidance taking account essentially of only two factors, monetary cost and the reduction in radiation health detriment from the intervention) and on the quantitative guidance itself. Whether more detailed guidance should be developed in advance of an accident at a national level, however, is less clear and subject to judgement. This issue is finely balanced and judgements on it may be influenced, *inter alia*, by the following considerations:

- the degree to which it is possible to foresee those additional factors that may significantly influence relocation policy and the extent to which their influence can be evaluated (ie, quantitatively or qualitatively) with reasonable confidence in advance of an accident
- the scope for developing generically applicable guidance at a national level (ie, would it be precluded because of marked sensitivity to the nature and scale of the accident scenario, to variations in socio-economic conditions within a country, etc)
- would the resources needed for the development of more detailed guidance (in particular the significant demands it would place on those at a decision or policy making level) be justified in relation to the very low probability claimed for an accident of magnitude sufficient to warrant relocation.

Clearly, there is scope for very different judgements on each of these issues (ie, depending on national conditions and the level of risk foreseen from various types of nuclear installation). This has consequential implications for judgements on whether resources should be allocated to developing more detailed guidance in advance of an accident or whether, on balance, these matters would best be dealt with at the time an accident occurred.

Notwithstanding what judgement is reached on the above issue, there can be little or no dispute over the need to have in place, in advance of an accident, effective procedures to transform outline guidance into a practicable and generally acceptable policy taking due account of other influential factors. These procedures should, *inter alia*, address organisational and methodological issues and also identify the key information needed as an input to this process; to the extent practicable, this information should be assembled in advance. Ideally, these procedures should be exercised to demonstrate their efficacy and limitations; such exercises would provide useful insights into the degree to which more detailed guidance could be developed in advance and also a useful forum for identifying other factors that may need to be taken into account in the development of practical policies.

The methodological approaches or techniques that can be used to assist the development of more detailed guidance are essentially the same irrespective of whether the guidance is developed in advance of or in response to an accident. Some of these techniques are summarised in the next Section, with particular reference to the use of multi-attribute decision analysis techniques.

3. Decision aiding methods

Many techniques are available to assist in the resolution of complex decision problems with each having different strengths and weaknesses. No simple generally applicable guidance can be given on which approach is best: much will depend on the nature of the application and the preferences and experience of the analyst and/or those responsible for the decision. Cost benefit or cost effectiveness analysis is perhaps the simplest form of decision aid and has found widescale use. Inevitably it requires the values of all attributes relevant to a particular decision problem to be expressed in monetary terms. In principle this can be done but, in some cases, it can be difficult where "non tangible" attributes (eg, aesthetics, public acceptability, etc) play a major role in the decision. Strong opposition to using the approach is often experienced on ethical grounds, in particular in those cases where a trade-off has to be made between monetary cost and human life and suffering (ie, an explicit or implicit monetary cost is placed on human life). Such criticism, however, is not unique to cost benefit analysis; it can equally be levelled against all decision analytic techniques where trade-offs have to be made involving such matters; however, by its very nature, the trade off in cost benefit analysis is often more explicit and visible and, therefore, more open to criticism.

Cost benefit or cost effectiveness analysis is most suited for use in decision problems which involve only tangible attributes which, in general, can be readily transformed into monetary terms. Guidance on the use of the technique in radiation protection can be found, *inter alia*, in [5, 6] and is not discussed further here. Cost benefit analysis has found increasing use over the past decade or so as a useful aid to the optimisation of protection and resource allocation more generally. Where non-tangible attributes (eg, socio-political considerations, etc) are important, techniques such as multi attribute value or utility analysis (MAVA) are more appropriate. There are many forms of multi-attribute decision aiding techniques (eg, see [7-9]) and a judgement has to be made on which technique to use and in what manner it should be applied. Much again will depend on the nature of the problem to be addressed and in what forum it is to be resolved. These aspects, however, are largely outside the scope of this paper, as is the theory of multi-attribute analysis itself and limitations on its applicability. The focus here is on the generalities of the MAVA approach and how it can be applied, with relative simplicity, using commercially available software to aid the resolution of complex decision problems. To demonstrate the potential of the technique, particular reference is made here to its use within the framework of the International Chernobyl Project [10] to evaluate and clarify the policy options for relocation then being considered in the former Soviet Union in response to the Chernobyl accident.

3.1 Multi-attribute value analysis

The first stage in the use of MAVA (or for that matter in any decision problem) is to identify the set of attributes which describe the success or otherwise of each option or alternative that is being considered. In other words, the first stage is to answer the question: what factors matter to the analyst or decision maker/s in considering the relative merits of the alternatives? The second stage is to establish an attribute hierarchy to facilitate the analysis of the decision problem.

This process is most easily illustrated by reference to a specific example. The example used here are the Decision Conferences (for further information see [10-12]) carried out within the International Chernobyl Project, in particular as they are directly relevant to the topic of this Symposium, that of countermeasures and remediation following an accident. The attributes that were identified to be of most importance by those participating in the Decision Conferences (essentially those responsible for formulating policy in this area together with their technical advisers) are illustrated in Figure 1 in the form of an attribute hierarchy. The main objective of these Decision Conferences was to evaluate and clarify a number of policy

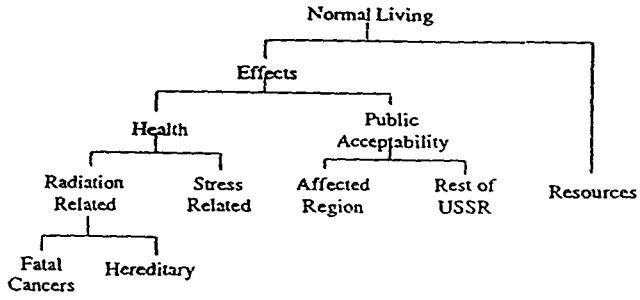

Figure 1: The Attribute Hierarchy

options that could be adopted to restore "normal living" conditions in those areas significantly contaminated as a result of the accident; these options involved taking various remedial measures (eg, relocation of some settlements, agricultural countermeasures, etc), to improve the situation of those affected. The two major attributes identified were the resources required to achieve a policy option (principally but not solely monetary costs) and the effects on the population. The effects on the population were broken down into impacts on health and the public acceptability of the policy which was deemed to be an important consideration. The health impact was further broken down into those resulting from radiation exposure from continuing to live in the contaminated areas and from stress and anxiety which could arise either as a result of remaining in the affected areas or of being relocated. Public acceptability was broken down further into the impact on those directly affected by the policy and on those in the rest of the former Soviet Union who would be indirectly affected through having to meet its costs.

It should be recognised that no simple or universally applicable procedure exists for generating attribute hierarchies - they result from careful analysis and/or discussion of the issues and emerge as much by the art of the analyst as application of any formal procedure. Similarly, there is no right or wrong hierarchy nor is a hierarchy "objective" in the sense that any analyst or group of decision makers would construct precisely the same hierarchy for the same problem. Inevitably, it will be based on the perception or perceptions of the analyst or decision maker/s charged with the particular decision. Notwithstanding this, it is common for different analysts or groups of decision makers facing similar problems to construct very similar hierarchies.

Having established an attribute hierarchy it remains for the analyst or decision maker/s to assign values to each attribute for each of the policy options or alternatives under consideration and to then assign relative weights between the different attributes reflecting the values or preferences of the analyst. Simple linear arithmetic is then involved in determining the "value" of the various options and differentiating between them. Assigning values to attributes is, in principle, simple but invariably it involves much judgement and various techniques are available to help with this. The process is simplest where the attribute is a tangible quantity (eg, monetary cost, etc) but, even here, matters may not be straightforward as the relationship between such a physical quantity and the value placed on it is not necessarily linear. Where the attribute is less tangible (eg, public acceptability) the valuation becomes even more judgemental and must reflect the preferences and beliefs of the analyst or decision maker/s and, inevitably, will be associated with much uncertainty. Assessing the robustness or sensitivity of the conclusions of a MAVA is, therefore, essential. Fortunately, one of the strengths of the approach is that the sensitivity of different judgements or input data can be readily and efficiently evaluated,

thus enabling the analyst or decision maker/s to focus attention on key issues and not be distracted by detail or matters of secondary concern.

Notwithstanding the potential of these techniques, their use is greatly under-exploited both within the radiological protection community and elsewhere. There may be several reasons for this but probably the greatest is a widely held, but misconceived, view that the techniques are complex (indeed even the terminology, MAVA, appears complex) and must, therefore, be very difficult to use other than by a decision analyst. Nothing could be further from the truth. Commercially available software (eg, [13-14] is widely available at a modest cost for carrying out MAVA; these software packages, which are user friendly, require few resources to become proficient in their use and place little or no demands on users in terms of their knowledge or understanding of multi attribute or utility theory. The software facilitates the construction of attribute hierarchies, provides an effective framework for assigning values to attributes for different decision alternatives and relative weights to attributes and, most importantly, is able to display directly the impact of adopting a range of differing judgements or preferences expressed by the analyst or decision maker. What it does **not** do, however, is remove from the analyst or decision maker/s the need to make difficult and complex judgements. Through structuring the problem and breaking it into its component parts it does, however, provide greater clarity and transparency to the decision process and, above all, enables the analyst or decision maker/s to better understand the problem and thus focus on the key issues.

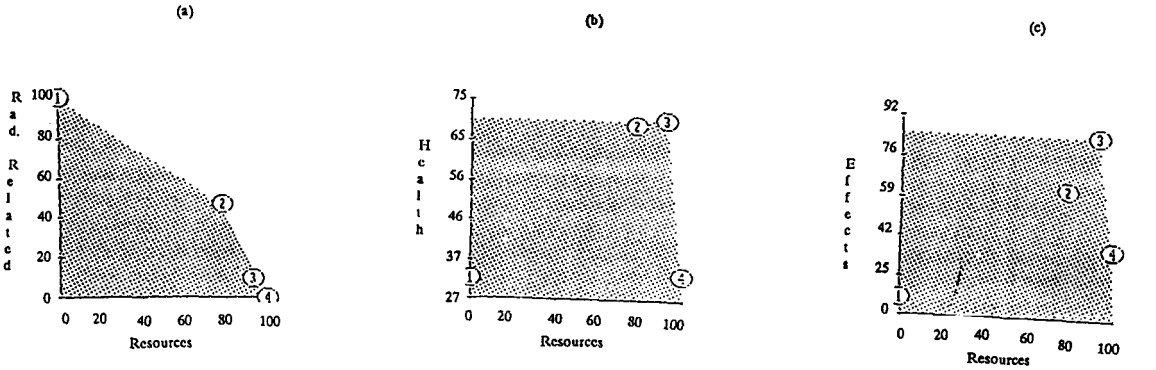
3.2 Illustration of the potential of MAVA

The potential of the techniques is most easily illustrated by an example of an application; selected results from the Decision Conferences referred to above are used here for this purpose. It should be recognised that the emphasis in the following is on demonstrating the potential of MAVA rather than on the results themselves which, within the present context, are largely of academic interest. Consequently, only very limited information is presented here on the Conferences themselves and the quantitative data or judgements that were input into the model in Figure 1 (ie, the values and weights assigned to the various attributes); such information has been kept to an absolute minimum commensurate with providing enough background to comprehend the generality of the results presented. For those with a deeper interest in the Decision Conferences and their detailed content and results, further information can be found in [10-12].

In the last of the five Decision Conferences that were held, the group decided to evaluate four strategies or options for achieving "normal living" conditions which were designated **SL(a-b)** where **a** refers to a lower level of dose below which no restrictions would be imposed, and **b** refers to an upper level of dose above which people would be relocated. In the intermediate region of dose (ie, a to b), various protective measures (eg, agricultural countermeasures, etc) would be taken. The quantities, a and b (expressed in rem), were the additional dose that would be received over a lifetime as a result of remaining in the contaminated areas assuming no protective measures were taken. Quantitative input to the model was provided on the expected reduction in radiation induced health effects and costs consequent upon different options. Values assigned to the other attributes and to their relative weights represented judgements of the group. Extensive sensitivity analyses were carried out with the model to evaluate the sensitivity of the results obtained to uncertainties in the judgements expressed. The following selection of illustrative results shows that the conclusions reached were remarkably robust to changes in the values and weights within the ranges judged reasonable by the group.

Figure 2 shows a sequence of plots of "effects" against the costs of the strategies or options. In Figure 2(a) the **Radiation Related** effects are plotted against **Resources**, ie, the costs of the strategies. Note first that the **Resources** scale is a preference scale (as are all the scales in the model). This means that greater scores correspond to increasing preference and, in this case, decreasing cost. Moreover, conventionally all scales are re-normalised to have a range 0-100. Thus on the **Resources** scale, here the horizonal axis, **SL2-40** has a score of 100 since it is the cheapest, whereas **SL2-2** has a score of 0 since it is the most expensive. The vertical axis gives the scores for the strategies on the **Radiation Related** effects, again re-normalised to a 0-100 scale with the most preferred strategy **SL2-2** under this attribute scoring 100.

Figure 2(b) gives a similar plot in which the vertical axis now represents the overall **Health Effects**, given by combining **Radiation Related** and **Stress** scales. Figure 2(c) again differs in the vertical scale. In this case the attribute is **Effects** which arises from combining the **Radiation Related, Stress** and **Public Acceptability** scales.

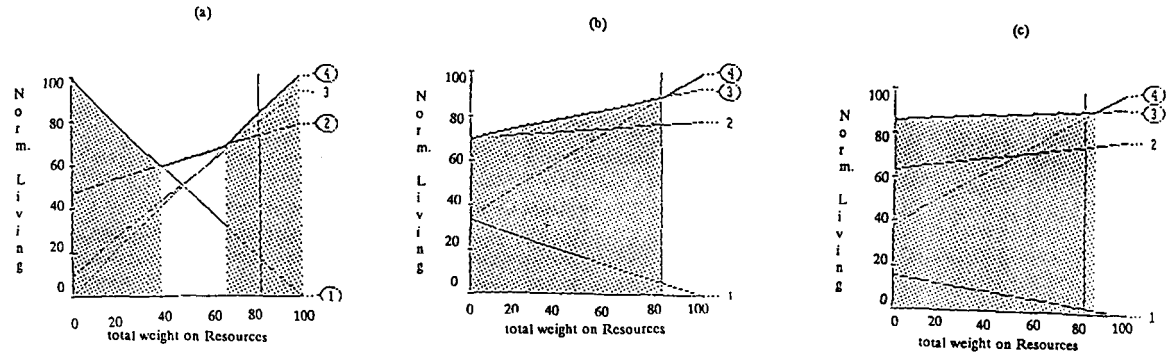


(a) Plot of Radiation Related effects against Resources.

(b) Plot of Health effects against Resources.

(c) Plot of Effects against Resources.

Figure 2: Plots of effects against resources

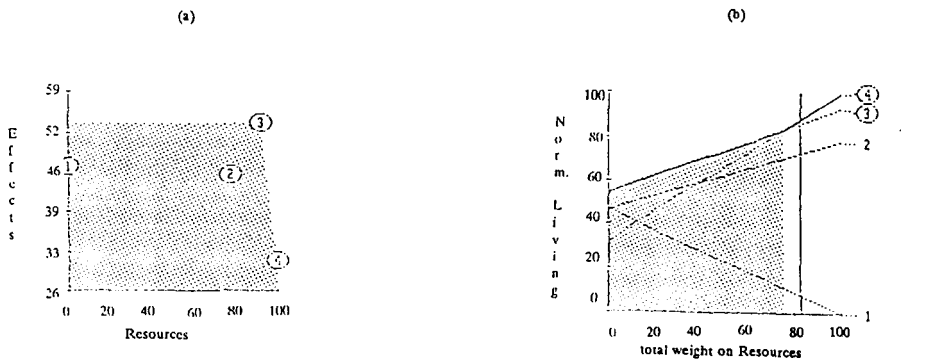


(a) Sensitivity plot when neither Stress nor Public Acceptability included.

(b) Sensitivity plot when Public Acceptability not included

(c) Sensitivity plot when all Effects attributes included.

Figure 3: Sensitivity plots when different attributes included in model



(a) Plot of Effects against Resources.

(b) Sensitivity plot when all Effects attributes included.

Figure 4: Plots for the model when SL2-2 is most acceptable to those living in the Affected Region

Key 1: - SL2-2 2: - SL2-10 3: - SL2-20 4: - SL2-40

In each of Figures 2(a-c) "ideal" strategies would lie at the top right hand corner, because such strategies would score 100 on both the horizontal and vertical preference scales. When **Stress** and **Public Acceptability** are included, as in Figure 2(c), it may be seen that **SL2-20** (Strategy 3) moves towards the top right hand corner.

Figure 3(a-c) shows the results of a number of sensitivity analyses which illustrate the influence of varying the weights assigned to different attributes. The vertical line in each plot is set to a weight on **Resources** which corresponds approximately to a cost of 100 Roubles (1990 prices) per man rem saved.
Figure 3(a) gives the sensitivity plot when zero weight is applied to both the **Stress** and **Public Acceptability** attributes. With the weight on **Resources** equivalent to assigning a value of 100 Rouble for saving 1 man rem, **SL2-40** is optimal. As the weight on **Resources** is decreased (ie, as the number of Roubles per man rem is increased), **SL2-10** then **SL2-2** become optimal. In a very rough way, Figure 3(a) corresponds to a simple cost benefit analysis of the strategies in which trade offs are made between the radiological protection benefits and the resources required.

Figure 3(b) shows the same sensitivity plot when **Stress** is given its assessed weight, but **Public Acceptability** is still given zero weight. **SL2-20** is now optimal, but only just so. If the weight on **Resources** is increased very slightly, then **SL2-40** becomes optimal. This can be seen by the fact that the vertical line representing the weight on **Resources** given by the equivalence of 1 man rem with 100 Roubles is right on the boundary between the range of values for which **SL2-20** is optimal and the range for which **SL2-40** is optimal. Note that with the weight on **Stress** included, **SL2-2** and **SL2-10** are not optimal for any value of the weight on **Resources**.

Figure 3(c) shows the same sensitivity plot when **Public Acceptability** is given its assessed weight. **SL2-20** remains optimal over a wider range of weights on the **Resources** attribute. Furthermore, with the weight on **Resources** set at a value equivalent to 100 Rouble per man rem saved, **SL2-20** is optimal and remains optimal if the weight is slightly increased.

From Figures 2 and 3, it is clear that the introduction of the attributes **Stress** and **Public Acceptability** into the model suggests that **SL2-20** is the preferred strategy in place of **SL2-40**, which is the strategy that a simple trade-off between costs and radiation effects would suggest.

Much the same conclusion may be drawn if the scores on the public acceptability in the **Affected Region** are changed to make **SL2-2** the most preferred strategy. Figure 4 gives plots corresponding to Figure 2(c) and 3(c) for this model. Now it is not the case that **SL2-20** is the preferred strategy when **Stress** and **Public Acceptability** are included in the evaluation; the model suggests that **SL2-40** is. However, this observation is relatively less important than the observation that **SL2-2** is not suggested as the most preferred strategy even when it receives a score of 100 on the **Public Acceptability** scale and **SL2-20** and **SL2-40** are both scored at 0, as they are in the model on which Figure 4 is based. In other words, with the weight currently assigned to **Public Acceptability**, neither **SL2-2** nor **SL2-10** can be made optimal simply by giving them a high **Public Acceptability** score. Sensitivity analysis of the weight on **Public Acceptability** confirmed that this observation holds for all values of this weight which the group felt reasonable.

The main conclusion drawn from the above analysis was that, if only **Radiation Related** and **Resources** attributes were included in the model, then **SL2-40** would be the strategy that provides the best balance. However, once **Stress** and **Public Acceptability** attributes are included, it became quite clear that **SL2-20** was the strategy that provided the best balance. This is shown particularly clearly by the sequence of plots shown in Figures 2 and 3. These conclusions must of course be qualified in the sense that they are particular to the values and weights assigned by the group to the respective attributes and to what they judged were reasonable variations in them.

The above results illustrate the potential of MAVA for effectively structuring and evaluating complex decision problems. A particular strength of MAVA is the ease with which it enables the sensitivity or robustness of conclusions reached to be evaluated. It is equally amenable for use by an individual analyst or a group but is particularly effective in aiding group decision making, especially where the group comprises differing levels of skill and experience and possibly divergent opinions. Further information on the use of MAVA in structured Decision Conferences can be found in [15-18]. The shared understanding and clarification of the issues which MAVA can provide, together with the ease with which the implications of different viewpoints within a group can be evaluated, greatly facilitate the decision process. The process itself encourages shared ownership of a

problem and, as a result, can lead to greater commitment and accountability from the various stakeholders in any decision reached.

4. Summary

For longer term countermeasures only outline guidance is currently available at an international level. Arguments can be made both in favour of and against developing more detailed guidance in advance of an accident and judgements on this issue are finely balanced. Notwithstanding what judgement is made on this issue, as a minimum, there is a need to have in place in advance of an accident adequate procedures to transform outline guidance into a practical and defensible policy which takes account of all influential factors. Techniques that could be used to aid this process have been reviewed, notably multi-attribute value analysis which is particularly suited for such applications.

Psychological and Social Impacts of Post-Accident Situations : Lessons from the Chernobyl Accident

Jacques LOCHARD

Centre d'étude sur l'Evaluation de la Protection dans le domaine Nucléaire

Fontenay-aux-Roses, France

Abstract. *This paper presents the main features, from the psychological and social points of view, of the post-accident situation in the contaminated areas around Chernobyl. This is based on a series of surveys performed in the concerned territories of the CIS republics. The high level of stress affecting a large segment of the population is related to the perception of the situation by those living in a durably contaminated environment but also to the side-effects of some of the countermeasures adopted to mitigate the radiological consequences or to compensate the affected population. The distinction between the accident and the post-accident phase is enlarged to take into account the various phases characterizing the dynamics of the social response. Although the size of the catastrophe as well as the economic and political conditions that were prevailing at the time and after the accident have resulted in a maximal intensity of the reactions of the population, many lessons can be drawn for the management of potential post-accident situations.*

INTRODUCTION

The knowledge of the psychological and social impacts of severe accidents involving radioactivity as well as the comprehension of the mechanisms driving the acceptability of post-accident situations characterized by large contaminated areas were rather limited before the Chernobyl accident. The first attempts in the late eighties to explain the reaction of the population in the affected territories after the accident were superficial. They were founded on the observation that the general public was generally ignorant about the potential effect of radiation, rather suspicious with regard to any official information, largely influenced by media having a strong propensity to spread alarmist news or perturbed by the on-going controversy between experts on the nature and the scope of the measures to be adopted to improve the situation.

Although these various aspects have certainly played a role, they were not sufficient to explain how a high level of stress was dominant in a large fraction of the population living in the contaminated territories in the three affected Republics and leading to a profound social crisis many years after the accident. This paper is first presenting the psychological situation as well as some of the factors that have been identified at the origin of the chronic and acute stress which is still characterizing the situation and preventing a return to normal living conditions from the psychological and social points of view. It is based on the results of a series of studies carried out from 1990 to 1995 in the contaminated areas in Belarus, Russia and Ukraine, first in the framework of the International Chernobyl Project initiated by the International Atomic Energy Agency [1, 2] then within the Evaluation Programme of the Consequences of the Chernobyl Nuclear Accident (Joint Study Project n°2) from the European Commission [3, 4, 5]. The second part of the paper describes the successive steps reflecting the social response during the emergency and the post-accident phases following the accident. This dynamics allows to better take into account the symbolization process driving the social acceptability of the post-accident situation. Finally some considerations for improving post-accident management and restoring social trust in the affected population in case of future accidents are presented in conclusion.

THE PSYCHOLOGICAL SITUATION

Ten years after the Chernobyl accident, any well informed observer can notice that a large anxiety is still existing among the population living in the contaminated territories around Chernobyl. Quantitative studies on the psychological and social effects carried out in 1992 and 1993 [3, 4] highlight an acute feeling of lack of control over individual living conditions clearly linked to a high level of psychological distress in the affected population. This anxiety is essentially related to the potential effect of radioactivity on health and particularly the one of children. Without being able to verify the accuracy of their allegations, interviewed persons are mentioning an abnormal number of somatic effects which are all attributed to the ambient contamination. This last one is a permanent concern for the population who seems in the impossibility to forget the accident and its real or supposed consequences.

As early as 1987, a few Soviet experts have put forward the rather confusing notion of radiophobia to try to explain the psychological reaction of the population. This notion was a convenient explanation for the fears noticed by many individuals inside the population, fears being considered groundless by the experts taking into account the prevailing radiological conditions. The investigations carried out in the contaminated areas have demonstrated that questioned people were expressing fears always supported by rational speeches on the basis of their observations related to the situation [5]. It is difficult to conceive how the concept of phobia, which in psychiatric terms means an unfounded and irrational fear concerning objects and situations that are not in themselves hazardous, could apply to a situation where on the contrary, there were objective reasons to be anxious. It is also interesting to note that this hypothesis of radiophobia, which is now definitively abandoned, received initially a large echo at the international level among experts dealing with the consequences of the Chernobyl accident to explain the attitude of the population in the contaminated areas.

Over the recent years, the concept of chronic and acute stress has progressively emerged to explain some of the symptoms to be observed in the affected population. This stress, which meaning is different from the one given in media and everyday language, can be described as a «continuing inability to adapt at the biological, psychological and social levels. The body, the nervous system and the psychology of those affected enter a state of alert or excitation involving a permanent expenditure of energy. The result is bodily dysfunction and pathological effects manifesting themselves both organically and psychologically (extreme fatigue, insomnia and depression)... A characteristic of the stress situation is that habitual, regular and familiar responses are dislocated, and that the subject is unable to find satisfactory solutions to the problems with which he or she is confronted» [6]. In the post-accident context of Chernobyl, this stress is observable in all groups affected i.e. the re-settled population, the one living in the contaminated areas and of course the liquidators. The anxiety mainly focuses on health, and particularly on the health of children, with a constant reference to somatic disorders. There is also a great concern of the population about its future with the conviction by many people that the situation is not going to improve with time but on the contrary can only get worse thus reinforcing their fatalist and passive attitude.

Many stress factors have been identified which are closely linked with the management of the accident and post-accident phases of the Chernobyl accident. To better understand some of these factors it is useful to distinguish between the Soviet period of the accident management from 1986 to 1990 and the national period with the takeover, from 1991, of the post-accident management directly by Belarus, Russia and Ukraine.

The first period is characterized by the relative failure of the protective measures adopted. Evacuations and iodine distributions were often organized too late and the population affected by the radioactive releases received in some circumstances very high doses. This is in part explaining the growing number of health effects over years that have been observed reinforcing the fear of the population. The context of secrecy and censure which prevailed during this period also largely contributed to the development of distrust towards the authorities. Globally the accompanying symbolization process which normally follows an

accident did not take place and the population has attributed all the negative consequences of the accident to the remaining contamination. The occultation of the importance of the accident and of its potential delayed effects by the authorities associated with the fact that the population was permanently confronted to lasting countermeasures led to over-amplify the risk of the post-accident phase. Furthermore, the presence of about 800,000 liquidators disseminated among the general population was a supplementary factor of disturbance. Their greater vulnerability from the health point of view reinforced the distorted perception of the situation as regard to the potential effects of the residual contamination and contributed to maintain or even increase the level of stress in the general population.

The second period has been fundamentally characterized by the willingness of the national authorities to differentiate their management from the previous centralized one by adopting a more realistic and democratic perspective. However, the emphasize put on the defense of the victims of Chernobyl has mainly focused the attention of the new authorities on the post-accident situation. The various national laws adopted by the Republics in the early nineties have established rather generous compensation systems which were supposed to be financed by the Russian Federation. Besides the fact these systems have never been properly financed, they have established a close link between the level of contamination of the environment and the level of compensation thus reinforcing the idea that the risk is first associated with living in contaminated territories. As a consequence, the population many years after the accident tends to attribute all the problems it is facing to the residual contamination and the general feeling is that difficulties will even grow with time. It is evident that such a perception of the situation is a powerful factor for reinforcing the general stress of the population as well as a mental trap to which it is difficult to escape. One can also understand the devastating impact of a lack of objective information on the potential consequences of a large nuclear accident in the early phase and even before.

Another important stress factor is the loss of trust of the population in the scientific, medical and political authorities. Beyond the negative impact of the lack of transparency of the authorities at the time of the accident, the on-going debates on the criteria for establishing countermeasures as well as on the potential health effects associated with the remaining contamination have slowly turned the situation into a very complex one where individuals did not trust anymore experts and felt totally insecure and unable to contribute to resolve the problems themselves. A general feeling of loss of control is thus reinforcing the climate of social distrust.

Observations in the contaminated areas have also shown the paradoxical effects, from a psychological point of view, of many of the countermeasures adopted. The zoning of the contaminated areas has induced a ghetto effect leading to a loss of identity of the population and some forms of exclusion. The definitive resettlement was a strong factor of stress because in most cases the area of relocation was imposed without taking into account the social and cultural affinities of the relocated persons. Moreover, the conditions of relocation into blocks of flats in urban areas was also creating a ghetto effect installing the relocated population into a social status of «Chernobylites». Finally, the compensation system also contributes to develop jealousy in the non compensated population and a reinforcement of the segregation with those affected who are feeling more and more isolated.

It is worthwhile, to complete this rapid overview of the psychological situation, to mention the situation of the few hundreds of persons called the «samossiols» who were initially evacuated at the time of the accident and despite administrative interdictions, came back in the thirty kilometer zone to stay again in their own houses. These generally old persons who are living in an hostile environment and in poor material conditions seem to be in a better psychological situation than the population living in the other contaminated areas. Their willingness to live as before without the financial support of the state can be interpreted as a positive factor to restore their autonomy and thus could explain a lower level of distress than the one observed in the territories affected by the accident.

THE SOCIAL DYNAMICS OF ACCIDENTS

From the accident management point of view, it is usual to distinguish two main phases: the emergency one which is following immediately after the accident and during which a series of actions are implemented according to plans prepared in advance, and the post-accident phase during which countermeasures are adopted along the justification and the optimization principles taking into account the specificity of the situation resulting from the accident. This simple scheme does not reflect properly the dynamics of the accident from the point of view of the reaction of the population. In the perspective of better taking into account the psychological and social dimensions, it is worthwhile to envisage a more detailed sequence characterized by the collective behavior of the population directly affected by the accident as well as the rest of the population which can be observed each time a large accident or a catastrophe occurs [7].

The sequence generally starts with the implementation of emergency measures planned in advance. The level of preparation including the information of the public is an essential element for the success of this phase which perception is largely influencing the next ones. This reflex phase is followed by a strong reaction expressed by both the affected population and the general public. Besides an inevitable feeling of revolt which normally turns rapidly into a social debate about negligence and responsibilities about the causes of the accident, heroic actions to save persons or to eliminate remaining acute dangers reinforce a strong feeling of solidarity by identification to the victims especially among the non directly affected population. Past experiences with large industrial accident or natural disasters show that during this rather short period, the affected people as well as the society as a whole are able to endure exceptional constraints and particularly to face much higher levels of risk than in normal situations.

The heroism phase is normally followed by a transition period during which a set of technical and administrative measures are implemented with the objectives to control the residual risk for the population, to repair if necessary the physical and health damages or to restore the general environment and to reorganize the social activities. This phase can be compared to a convalescence during which society is recovering progressively and return to a situation considered as normal. Parallel to this evolution, the symbolization process around victims is engaged to allow the construction of a collective memory indispensable to reaching social acceptance of the accident and its consequences. This last dimension is very similar to a mourning process involving both the affected population and the society as a whole. It is important to note that the compensation of victims for the damages they supported is part of this general process of symbolization and it is therefore important to properly assess the various losses of each affected individual. In this perspective, the reconstitution of doses received by each individual at the time of a nuclear accident is a key element to objectify the risk and to set up an effective compensation system.

The return to normal living conditions after a large accident affecting a society is a complex process involving a rearrangement of the mental representations of most of the affected people and in some severe cases the establishment of a new social regulation to overcome the discredit of the old system which failed. The success of this process is not only depending on technical measures but heavily rely on the ability of authorities to restore as soon as possible social trust in the society and particularly some confidence with regard to experts and authorities. The return to normality expression must be well understood and used properly. By no means it is a return to the situation that was prevailing before the accident. This is impossible in most cases and particularly after a large nuclear accident followed by a durable contamination of the environment. The objective is to restore a situation where those involved can again focus their attention to their individual day-to-day activities and plans in a context of vigilance towards the ambient contamination. This does not mean that society behaves like nothing has happened, but on the contrary that the consequences of the accident have been fully integrated at both the rationale and symbolic levels, are taken into account in the day-to-day behavior of the population and finally serve for the whole society as a learning experience for the future.

The above described evolution is ideal. In reality some of the key factors for restoring the situation cannot play their curative role and it is even possible that, as it was the case with the Chernobyl accident, a post-accident crisis is taking place due to the rejection of the situation by the affected population. The mechanisms leading after the solidarity phase to a non-acceptance of the situation and then a revolt are not completely identified. At Chernobyl, the high level of stress in the population has certainly played an important role but there was also a conjunction of other factors going far beyond the psychological dimensions. It is evident that the social, economic and political context was extremely favorable as well as the very poor level of information and preparation of the population with regard to a potential nuclear accident. Interviews in the population around Chernobyl and in the contaminated areas have shown that the accident was simply not possible in the mind of people.

It is evident that the intensity of the accident and the extent of its consequences in terms of the number of persons having received high individual doses, the surface of the severely contaminated territories, the number of people to be relocated and the economic cost to try to restore a tolerable situation have contributed to rapidly build a collective representation closer to a disaster and a catastrophe than a large accident. It is not by chance that the population in the contaminated areas is speaking about the accident and the post-accident phase with a lot of words coming from the war vocabulary.

PERSPECTIVES

Although still limited, the analysis of the post-accident situation at Chernobyl allows to delineate some elements first for designing better communication with the public in case of an accident and, secondly, for establishing criteria and strategies for setting up protection objectives and selecting countermeasures which should be compatible with the progressive restoration of social trust among the affected population.

The Chernobyl experience has demonstrated that beyond a certain level of contamination of the environment, the situation is not manageable and it is necessary to relocate the population and to abandon the concerned territories. This is of course true when the level of exposure of the population may lead to the appearance of deterministic effects but also when it is impossible to maintain the integrity of the basic social functions. At the opposite of these unacceptable situations, it is possible to define a level of residual contamination below which the risk can be considered as negligible. This situation must be characterized by the total absence of restrictions on the day-to-day life to allow the population to slowly forget the accident and its consequences after the process of mourning and symbolization leading to a certain form of return to normality.

Between these two situations (unacceptable and negligible), the population is facing a large spectrum of situations that can be qualified as tolerable. They are characterized by the existence of more or less severe restrictions on normal living conditions affecting the production, the distribution and the consumption of goods as well as the social organization related to education, the health care system or the collective leisure activities. Some of these constraints (countermeasures) which are implemented to last on rather long periods need to be adjusted with time and must be accompanied with an effective and independent structure of surveillance and control of the contamination to insure the transparency of the measurements of the residual contamination. This is a very important element to objectify the level of risk as well as to decide about the actions to be adopted. Transparency must also prevail as far as the effectiveness and the cost of countermeasures are concerned.

The main difficulty with the management of post-accident situations concerns the establishment of criteria expressed as numerical values that could serve as reference to define the negligible, the tolerable and unacceptable levels. Various considerations have to be taken into account to elaborate these criteria. The Chernobyl experience is clearly demonstrating that it is impossible to set up reference values for structuring decision making processes related to the post-accident management without referring to those which are universally adopted for the protection of the public and workers in normal situations. Furthermore, the control of exposure

in the contaminated areas necessarily involves to take into account the diversity of sources and in this perspective it is extremely difficult to envisage centralized and generic measures that could be applied to large areas. The implementation of a decentralized approach relying on the commitment of those directly affected by the accident seems to be the most effective way of attacking the problem.

The Chernobyl experience has also revealed the complexity of managing post-accident situations with the need to reconcile the radiological protection imperative with the various psychological and social dimensions. Taking only into account the radiological considerations may lead to a difficult situation because of the perverse effects of many countermeasures which are reinforcing the feeling of exclusion of the affected population and maintaining the doubt on the risk really at stake. At the opposite, giving priority to the psychological factors may involve serious consequences from the radiation protection point of view if the population is not fully aware about the exposure pathways and the mechanisms through which it is possible to control exposures. Observations have been made over the recent years confirming that the doses received by some part of the population living in the contaminated areas were increasing because of a lack of precaution or even in some cases of a denial of the potential impact of the contamination.

The main difficulty for restoring normal living conditions in contaminated territories is to build collective modalities to cope with the radiological residual risk in order to lead progressively to an acceptable situation from the psychological and social points of view. The success of this approach largely depends on the capability to set up an individual and collective management of residual risk, in spite of the implementation of long lasting countermeasures. Anticipating a benefit, the involved persons must be in a position to actively and voluntarily manage the level of their exposure taking into account the specific situation they are facing. From a collective point of view, adequate means to control the risk must be available: concepts, assessment tools, equipment, budget... Such an approach is at the opposite of the one which inspired the various systems implemented so far in the affected Republics where the persons exposed to the residual contamination are compensated for the risk they take and not for the one they contribute to avoid for themselves and the others. Furthermore, these compensation schemes reinforce the existing risk by objectifying it in financial terms and perquisites.

In practice, the adoption of a pro-active approach involving the commitment of the concerned population should result in the implementation of an ALARA type process close to the day-to-day activities of the population (at schools, in the plants, within families, at the farm level...). This decentralized approach should be implemented in the framework of a more global system ensuring the coherence and the rationale use of the material and financial support indispensable to restore satisfactory living conditions. An independent system for controlling the situation, particularly the contamination of food products and the close environment of the population, should also allow to facilitate the restoration of a climate of social trust within the population with regard to the experts and the authorities. Such mechanisms must rely on solid ethical basis clearly displayed in view to establish the transparency of the decision making processes and the responsibilization of all concerned actors and primarily the affected population. To respond to the question: Is it possible to live here? it is inevitable to begin with a true characterization of the situation in term of risk which is the first element to develop a commitment to the situation with a protection culture based on the responsibility of each individual to the risk he or she is going to take freely and voluntarily.

INTRODUCTION

Heavy ion accelerators are finding increased application in both the fundamental and applied sciences around the world. While the use of these accelerators in the applied sciences and industry has perhaps been slower, and is less extensive, than has been the case for proton accelerators, it is now rapidly increasing. Ion species and their energies used in these facilities spread in wide ranges. Heavy ion beam intensities can vary over a wide range from hundreds of microamperes downwards. Some of these beams have the potential to produce radiation, principally neutrons, which may expose prsonnel or be detrimental to sensitive detectors or equipment. The paper gives a brief overview of the radiological safety aspects of heavy ion accelerators. Information available on radiation environments of the accelerators, angular distribution and neutron spectra around thick targets bombarded by ion beams, induced radioactivity in irradiated targets and shielding problems are considered. Operational health physics of a superconducting heavy ion collider and associated design criteria for prompt radiation are also discussed.

THICK TARGETS PARTICLE YIELDS

It is sometimes necessary for personnel to work in areas where heavy ions interacting with targets, target holders or beam transport equipment produce prompt radiation levels significantly above background. Since neutrons are responsible for a major part of this background and, it would be helpful to be able to predict neutron radiation levels as a function of ion mass and energy. For a shielding design of heavy ion accelerators, inclusive neutron yield data are fundamental to estimate source terms of the calculation. For a detailed calculation of accelerator shielding more information than the total number of neutrons produced by heavy ions on thick targets is required: in particular the energy and angular distribution of neutrons must be known.

Experimental information on neutron production by heavy ions on thick targets of various materials over the energy range from 0.9 to 3650 MeV/A is given in Table 1, together with references to the original sources. The data presented in Table 1 were obtained for the most part with targets thick enough to completely stop the incident ions.

TABLE 1. Information on neutron production by heavy ions on thick targets.

[a)] Dose equivalent rate at 1 m, 90° from beam direction

Measurements of the neutron yield were made for variety of ions with thin or thick targets. However, the measurements are still not enough in the number to estimate the systematics in the neutron yields.

A theoretical model for estimating the potential radiation hazards associated with low energy heavy ion accelerators was proposed by B.B.Back [11]. The model is based on procedures for estimating the fusion cross section, fission competition, neutron evaporation and stopping powers. The range of applicability of the model is limited to energies less than about 15 MeV/nucleon.

A number of empirical formulae to estimate yield and angular distribution of neutrons produced by heavy ions on thick targets of various materials were proposed.

Based on the existing in the beginning of eightieth data the formula for the neutron dose equivalent rate caused by an intermediate energy heavy ion beam impinging on a thick target was proposed by F.Clapier and C.S.Zaidins [12]:

$$R(\theta,r,i,Z,w) = Y(Z,w)\, i\, f(\theta,\gamma) / 7.2\, r^2 \quad \text{mrem/h}, \qquad (1)$$

where $f(\theta,\gamma) = \frac{1}{4\pi} \frac{1}{\ln(1+1/\gamma)} \frac{1}{\gamma + \sin^2(\theta/2)}$, $Y(Z,w) = C(Z) w^{\beta(Z)}$,

i is heavy ion current in particles/s, r is distance from the target in meters, w is beam energy in MeV/A, Z is atomic number of the projectile and the empirical parameters C, β and γ can be interpolated or approximately calculated from table 2 of ref. [12]. This formula allows to predict the rate within a factor 2 for values of w up to 10 - 20 MeV/A.

The thick target neutron dose for a range of heavy ion reactions covering the projectile mass range 6<A<58 and the target mass range 6<A<197 have been measured at five different angles and over the energy range $0.9 \leq E/A \leq 6.0$ MeV/A and represented by simple empirical formulae[1]:

$$D = D_0\, e^{mP} \text{ when } P < 0 \text{ and } D = \alpha^2 (P+\beta)^2 \text{ when } P > 0, \qquad (2)$$

where D is the mean dose rate at a distance of 1 m from the target, $P = (E_b - CB)/A_b$, where E_b is the beam energy, A_b is the mass of ion in beam, CB the Coulomb barrier for a specific beam-target combination and α, β, D_0 and m are fitting parameters tabulated in table 1 of ref. [1].

The dose rate $D(\theta_L)$ at angle θ_L to the direction of the incoming particle is defined as follows:

$$D(\theta_L) = DK_m\, e^{S\theta_L}, \qquad (3)$$

the quantities $D(\theta_L)$, D, S and K_m for a specific beam-target combination are given in ref. [2].

Differential thick target neutron yields by several heavy ions with energies of about 10 MeV/amu for several thick targets were measured and fitted by two component moving source model and simple expressions which represented the systematic dependence of the yields on the target, incident ions and their energies were proposed [13]:

$$\phi(E_n,\theta) = \sum_{i=1}^{2} M_i \frac{E_n}{2(\pi\tau_i)^{3/2}} \exp(-\frac{E_s}{\tau_i}), \qquad (4)$$

$E_s = E_n - 2\varepsilon_i E_n \cos\theta + \varepsilon_i$, where M_i is the source intensity, τ_i is the nuclear temperature, ε_i is the source moving energy in terms of the kinetic energy of nucleon, E_n is the neutron energy and θ is the neutron emission angle in the laboratory frame. To extend these formulations to a much higher energy range inclusive neutron production cross sections were systematically calculated [14] for heavy ions of the energy of 337 MeV/amu by the intranuclear cascade evaporation code HIC [15]. Using the calculation results, the above expressions were modified [14] so that the systematics of the calculated neutron production cross sections were described by the formulae.

L.G.Beskrovnaja and M.M.Komochkov [16,17] have summarized neutron yields for ^{12}C and ^{238}U reactions in thick iron target in the energy range 2.5 MeV/nucleon to 3.65 GeV/ nucleon. The yield, $Y(E_i)$, for ^{12}C in the energy range 2.5 MeV/nucleon to 6 MeV/nucleon was calculated based on formula (3) and in the energy range 4 MeV/nucleon to 100 MeV/nucleon the yield was taken form ref.[12]. At energies more than 60 MeV/nucleon the yield, $Y(E_i)$, was calculated by formula:

$$Y(E_i) = N(\sigma_n \eta_n / \sigma_p \eta_p)\, f\, Y_p(E_i), \qquad (5)$$

where N is number of equivalent protons [18]: $N = (A_i)^{0.25} + (A_i - 1)^{0.6}\, 0.078 [\ln A_i - 1.85]$, E_i is energy of the projectile in MeV/nucleon, σ_n and σ_p are inelastic interaction cross section of nuclear-nuclear and proton-nuclear, respectively; η_n and η_p are number of inelastic interactions of nuclei and protons in the target, respectively; $Y_p(E_i)$ is yield of neutrons from the same target bombarded by protons with the energy E_i, $f = 1 + 0.19\eta_n \sqrt{A_n}$. The yield, $Y(E_i)$, for ^{238}U in the energy range 7 MeV/nucleon to 20 MeV/nucleon was calculated based on calculation of dose equivalent taken from ref. [11]. At energies more than 60 MeV/nucleon the yield, $Y(E_i)$, was calculated by formula (5).

A series of radiation measurements were carried out with high energy ^{12}C ion beams in CERN [7] (86 MeV/nucleon) and JINR [9,10,18,19] (3.65 GeV/nucleon) to determine secondary - particles production on thick targets. Three different targets (Fe, Al and C) in CERN and two targets (Cu, Pb) in JINR were used. Various threshold detectors were used to obtain information about angular neutron energy distribution and hadron yields[7,10]. Scintillation counter telescope was used to measure angular charged particles distribution from Cu [19] and Pb [20] targets. Neutron energy distribution at 71° and 105° was measured by time-of-flight spectrometer [11]. The calculated [15] angular flux density distribution around the Fe target is compared [7] with the measured flux densities. The difference between the different target results is small. The the theoretical data never differ by more than factor 2 from the experimental results. Experimental results [11] together with calculated [20] neutron spectra are shown in Fig. 1.

RADIATION SHIELDING

The estimation of shielding for accelerators requires a detailed understanding of the production of particles by the interaction of the primary ions, their transport through the shield and determination of the energy spectrum of the radiation that penetrate the shield. The vast literature on the shielding of proton accelerators was reviewed by R.H.Thomas and G.R.Stevenson [23]. In principle, the radiation shielding problems at proton and at heavy ion accelerators are equal ones with the exception of source terms. Consideration of the source term was given in previous section. In this section experimental and calculated data on neutron attenuation in shield, neutron dose equivalent and spectra outside heavy ion accelerators shield is considered.

Experimental attenuation length in heavy concrete (density 3.4 g/cm^2) have been obtained by J.W.N.Tuyn et al. [7] with various threshold detectors under 0° and 45° with the incident 86 MeV/nucleon ^{12}C ion beam on Fe, Al and C thick targets. The attenuation length under 0° derived from the S detectors is 78±9 g/cm^2 while derived from ^{11}C detectors an attenuation length of 104±2 g/cm^2 is found as an average for all three targets. Under 45° an attenuation length of 80±4 g/cm^2 is found for the S detectors and 91±12 g/cm^2 for the ^{11}C detectors. These values shall be considered as upper limits due to the unknown contribution of scattered neutrons.

Attenuation of neutrons through a concrete shield was measured by J.B.McCaslin et al. [3] at 7°, 54° and 72° to the beams direction. Beams of neon and silicon at 670 MeV•A were stopped in copper target. The attenuation curves are shown in Fig. 2. Values of the effective attenuation length observed at 7°, λ_{conc}= 114 and 109 g cm^{-2} for Ne and Si, respectively, are consistent with those at high energy proton accelerators and represent the maximum value. For the range of concrete shielding thickness used, the effective attenuation length decreases with increasing angle. Values obtained are 64 and 56 g cm^{-2}, for secondaries from Ne at 54° and 72°, respectively, and 61 g cm^{-2} for Si at 72°. For a beam of Ne ions on Cu, $\lambda_{conc}(\theta)$ may be represented by the equations [3]:

$$\text{for } \theta<75°: \qquad \lambda_{conc}(\theta) = 115\, e^{-0.01\theta} \text{ g cm}^{-2} \qquad (6a)$$

$$\text{for } \theta>75°: \qquad \lambda_{conc}(\theta) = 55 \text{ g cm}^{-2}, \qquad (6b)$$

where the angle θ is in degrees. The second of these expressions (6b) is a conservative assumption and is used because of inadequate data at larger angles.

On the basis of the measured attenuation lengths and angular distributions [3], an empirical model was devised to fit measured dose equivalents, H(θ), outside thin shield [3] :

$$H(\theta)=8.67\times10^{-12} N C_1 \theta^{-1} r^{-2} e^{-l(\theta)/\lambda(\theta)} \qquad (7)$$

where H is in Sv and θ is in degrees, N is the number of Ne ions stopped in Cu target, C_1 accounts for that fraction of the dose equivalent due to neutrons of energy greater than 20 MeV, r(θ) is the distance from the target to the detector (m), l(θ) is the shield thickness in the direction θ (g cm^{-2}), λ(θ) is the attenuation length (g cm^{-2}). For the estimation of dose equivalent outside thick shields where particle equilibrium is achieved, following expressions were proposed [3]:

$$\text{for } 0°<\theta<20°: \qquad H(\theta) = 12\times10^{-12} N e^{-0.20\theta} r^{-2} e^{-l(\theta)/115} \qquad (8a)$$

$$\text{for } 20°<\theta<120°: \qquad H(\theta) = 12\times10^{-12} N e^{-0.038\theta} r^{-2} e^{-l(\theta)/115} \qquad (8b)$$

where H is in Sv, r is in meters and l is in g cm^{-2}

L.G.Beskrovnaja and M.M.Komochkov [16] proposed a phenomenological model for calculation of differential yields of neutrons, $d^2 Y/dEd\Omega$, produced by heavy ions on thick targets and for estimation of heavy

ion accelerators shielding. The model covers the projectile mass range $4 \leq A \leq 238$ and energy range from Coulomb barrier to 10 GeV/nucleon. Comparison of attenuation curve calculated for heavy concrete [16] with measurements [7] shows reasonable agreement.

T.A.Gabriel et al.[24] presented a heavy ion transport code, HIT, and the results of calculations which compare the number and total energy of neutrons ($E_n \geq 100$ MeV) emitted external to a central shielding block (radius = 20 cm, height = 60 cm) composed of iron by incident heavy ion beams to those expected from incident proton beams. The heavy ion collision model used in HIT is the HIC [25] code. The number and total energy of neutrons ($E_n \geq 100$ MeV) per source particle energy emerging form the side and back of the central shielding block composed of iron as a function of the atomic number of the projectile are calculated for 3.0 GeV/nucleon incident ions.

RADIATION ENVIRONMENT OUTSIDE HEAVY ION ACCELERATORS SHIELD

Theoretical[26] and experimental[27] studies of neutron fields outside shield of the JINR synchrophasotron were carried out in two geometries: 1) Outside the lateral concrete shield of 1 m thickness irradiated with particles generated in thick copper target by beam of ^{12}C at 3.65 GeV/nucleon and 2) Outside the 2 m concrete beam stopper of ^{12}C at 3.65 GeV/nucleon beam. Neutron fluences, dose equivalents and high-energy neutron spectra were measured and calculated. Measured[26] and calculated[26] lateral distribution of high-energy hadron fluence and measured[26] high-energy neutron spectra outside the stopper are given in Fig. 3 and Fig. 4, respectively.

The calculation[28] of the shielding at the SIS (heavy ion synchrotron) of the GSI was checked experimentally by J. G. Festag [29]. The measurements of the radiation outside the shielding of SIS have shown that in general more than 90% of the equivalent dose are due to neutrons. These measurements are done with ionization chambers, proportional counters and different models of REM counters. There are also used REM counters with an extended range[30]. At the same place and during the same time intervals measurements with a pair of REM counters (one original and one modified) have been taken. They show that sometimes only 50% of the equivalent dose are recorded by a normal REM counter. The proportion of the registered doses (modified /unmodified Rem counter) seems to diminish in reactions of very heavy ions at very high energies[31,32].

INDUCED RADIOACTIVITY

In addition to the prompt radiation, a residual radiation field is also produced that remains after shutdown of the accelerator beam. This radiation field results from the decay of radioactivity induced in the accelerator structure and its ancillary components by the interaction of particles of the prompt radiation field. The induced activity depends on many factors such as the type and energy of the ions accelerated, the mean value of the losses of accelerated ions in the accelerator or in the beam pipes and targets, the duration of these losses and materials irradiated.

The basic information needed for the calculation of dose rates from irradiated materials are radionuclide production rates for the production of a given radionuclide from a target material bombarded by specified ions. An expression for estimating radionucleus production rate, R, in target irradiated by heavy ions with energy less than about 15 MeV/nucleon was proposed by B.B.Back [11]:

$$R = \frac{3761I}{A_{tgt}} \int_0^{R_e} \left(\sigma_{er} + 2\sigma_f\right) dx, \qquad (9)$$

where I is beam intensity measured in particle nanoampheres, A_{tgt} is the atomic weight of the target material, σ_{er} and σ_f are cross section of evaporation residue and fission-like reactions, respectively, R_e is the total effective range of beam particles penetrating the target material. R_e may be calculated as follows

$$R_e = \int_{E_0}^{E_1} \left(\frac{dE}{dx}\right)^{-1} dE,$$

where E_1 is the original beam energy and dE/dx is the energy dependent stopping power, E_0 is the lowest energy at which heavy ion fusion reactions occur.

M.M.Komochkov[18] suggested simple expression for estimation of specific radioactivity induced by light high energy ions with the energy E_i (MeV/nucleon) depending on the specific radioactivity induced by protons with the energy $E_p = E_i \ A_i$ (MeV) in the same target:

$$q_n \cong N \, q_p, \qquad (10)$$

where $N = (A_i)^{0.25} + (A_i - 1)^{0.6} 0.078[\ln A_i - 1.85]$, A_i is atomic mass of the ion.

DESIGN CRITERIA FOR PROMPT RADIATION ON THE RHIC SITE

A worst-case fault in the Relativistic Heavy Ion Collider (RHIC) would be the loss of the full beam at full energy at an arbitrary point (any magnet or device which intrudes into the physical aperture). Harrison and Stevens[33] concluded that the maximum credible fault would be full beam loss at points which are near the limiting aperture of the collider and loss of one half of the full beam at other locations, and that such occurrences should be allowed for at a rate of once in several years[33]. For the purpose of evaluating necessary shielding and access restrictions as applied to a specific location, the design-basis accident (DBA) will be assumed to be the maximum credible fault once per year.

Design criteria for dose limits for the Collider are shown below. They were chosen to be consistent with the Laboratory design goal of 0.25 mSv y^{-1}. Low occupancy is defined as 1/16 [34]. Both normal loss limitations and DBA fault limitations are considered. The annual dose fault limitation applies to both the Injection Line and the Collider.

I. Classification "A": Radiation workers; high occupancy
   1. Normal loss
      0.002 mSv h^{-1}
   2. DBA Fault
      5 mSv y^{-1} limit

II. Classification "B": Radiation workers; low occupancy
   1. Normal loss
      0.032 mSv h^{-1}
   2. DBA Fault
      10 mSv y^{-1} limit

III. Classification "C": Non-radiation workers; high occupancy
   1. Normal loss
      0.15 mSv y^{-1}
   2. DBA Fault
      0.1 mSv y^{-1} limit

IV. Classification "D": Non-radiation workers; low occupancy
   1. Normal loss
      2.4 mSv y^{-1}
   2. DBA Fault
      1.6 mSv y^{-1} limit

Existing regulatory requirements do not explicitly consider low probability fault situations for accelerators[35, 36, 37]. These criteria use the International Commission on Radiological Protection (ICRP) concept of dose averaging[38] and adopts the philosophy that both low occupancy and low probability of faults mitigate allowable dose in a single year if a multi-year average dose for a given individual is acceptably low. With this in mind, this approach asserts that the allowable dose from normal loss should be well within any existing or proposed regulatory requirement, but the DBA scenario, given the fault assumptions made herein, be allowed to exceed yearly dose limitations by a small amount comparable to either: (a) the annual dose from normal losses for radiation workers; or (b) an amount comparable to the natural background for non-radiation workers. In either case, it is important to realize that an actual DBA fault occurrence would most likely represent a once-in-a-lifetime event for a given individual.

Comparisons with known requirements are as follows:

1. Radiation Workers

A. The 0.002 mSv h^{-1} criteria is below the 0.005 mSv h^{-1} design goal specified in DOE Order 5480.11 [35].

B. The annual dose from losses of 0.002 mSv h^{-1} × 2000 h y^{-1} = 4.0 mSv y^{-1} is well below the Federal Dose Limit of 50 mSv y^{-1} [39], the Department of Energy (DOE) Administrative Control Level (ACL) of 20 mSv y^{-1} [37], the Laboratory ACL of 12.5 mSv y^{-1} [40].

C. A worst-case scenario, given the assumptions specified above, would pertain to an individual who spent 15/16 of a year in a Class A area and 1/16 of a year in a Class B area during which he/she was exposed to 10 mSv during fault conditions. The upper limit for annual dose to this individual would be (15/16) × 2000 h × 0.002 mSv h^{-1} + (1/16) × 2000 h × 0.032 mSv h^{-1} + 10 mSv = 18.69 mSv. For the vast majority of the worker population on the RHIC site, this upper limit is not credible because shielding designed for the possibility of a fault in the region of the collider limits the normal-loss hourly dose to values far lower than specified by the criteria[41]. The most likely dose

to a radiation worker exposed to an accident in a Class B area would, therefore, be the fault value itself of 10 mSv. Of the total dose in this extremely improbable situation, 14 mSv would occur in the low-occupancy region which exceeds the design goal of 10 mSv y^{-1} in low occupancy areas in DOE Order 5480.11 Section 9.J.1.b [35].

2. Non-radiation workers

A. The annual normal loss dose of 0.15 mSv is below the Laboratory design goal of 0.25 mSv y^{-1} per facility. With allowance of a worst case fault, the goal is exactly met.

B. A worst-case scenario would pertain to an individual who spent 15/16 of a year in a Class C area and 1/16 of a year in a Class D area during which he/she was exposed to 1.6 mSv during fault conditions. The maximum annual dose here would be ~1.89 mSv which is both comparable with natural background and is expected to represent a very rare occurrence for a given individual. In addition it is reasonable to assume that the exposed population for this case is one person or at most a very few people.

3. Regulatory limits and guidance for the general public

The following are the existing regulatory requirements and guidance for the general public which do not explicitly address low probability faults[42]:

ICRP-60
- Limit annual effective dose to 1.0 mSv averaged over any 5 consecutive years

NCRP-91
- Limit annual effective dose to 1.0 mSv for continuous or repeated exposure
- Limit annual effective dose to 5.0 mSv for infrequent exposure

10 CFR 20
- Limit annual effective dose to 1.0 mSv
- Limit dose in 1 h to 2.0 mSv

DOE Order 5400.5
- Limit annual effective dose to 1.0 mSv
- If avoidance of higher exposure is impractical, temporary limit not to exceed 5.0 mSv may be authorized

Four area classifications are proposed for the RHIC site for regions accessible without restriction by physical barriers. The classifications are distinguished by occupancy and by whether radiation worker training is required for entry. Each classification is specified by limits on dose equivalent resulting from both anticipated beam loss and from design basis accident faults. Although no explicit regulatory requirements exist for low probability faults, the highest proposed fault limits, 10 mSv y^{-1} in low occupancy regions restricted to radiation workers and 1.6 mSv y^{-1} in low occupancy uncontrolled regions, are compatible with several recommendations[42] that consider infrequent exposures and multi-year dose averaging for given individuals.

Note: A more complete explanation of the Criteria can be found in Health Physics, Vol. 66, No. 3, (1994).

CONCLUSIONS

The data presented here demonstrate the need for more detailed measurements. Neutron yields, spectral and angular distributions produced by ions in thick target as function of ion energy, ion species and target material are required. Detailed investigation of the radiation environment at heavy ion accelerators as function of ion energy, ion species as well as attenuation measurements in shielding are needed.

Radiological safety aspects of the operation of heavy ion accelerators does not essentially differ from proton accelerators, but a heavy ion accelerator is able to accelerate a number of ions species with different energies, therefor the operational health physics of heavy ion accelerators is more difficult than the operational health physics of proton or electron accelerators, since the radiation fields is varying to some extent with the different accelerated ions.

INTRODUCTION

The increasing use of high energy and intense particle accelerators has brought the importance of detection and monitoring of high energy neutrons which are most penetrating. The spectrometry and dosimetry of high energy neutrons at accelerator facilities are however very difficult and many works have ever been done, but no established instrumentation still exists.

We have newly developed two types of high energy neutron spectrometers, Bi spallation detector and organic liquid scintillation detector with plastic veto counter, and also two types of wide-energy range personal neutron dosimeters, real-time Si semiconductor detector and CR39 track detector.

The 12.5-cm diam by 12.5-cm long organic liquid scintillation detector, such as NE-213 and BC-501A, was used to measure neutron spectra in the energy range from about 1 MeV up to about 130 MeV, by coupling with the n-γ discrimination technique. The thin (5 mm thick) plastic scintillator (NE-102A) was set in front of the neutron detector as a veto counter to discriminate the incoming charged particles. The Bi spallation detector utilizes the Bi(n,xn) reactions up to Bi(n,14n), which have different threshold energies. This detector is very small and light, and can give the gross neutron spectrum over the energy range beyond 100 MeV.

A real time personal dosimeter consists of three types of Si detectors, thermal neutron sensor, fast neutron sensor and gamma-ray sensor (1,2). The thermal neutron sensor which is B-10 doped n-type silicon with a polyethylene radiator detects alpha particles from $^{10}B(n,\alpha)$ and protons from H(n,n) reactions, which is mainly sensitive to neutrons from thermal to 1 MeV. The fast neutron sensor which is p-type silicon with polyethylene is sensitive above 1 MeV, and the gamma-ray sensor is the same as the fast neutron sensor without polyethylene. By taking the weighted sum of two neutron sensor counts, this dosimeter can give the neutron dose equivalent within about 50% errors in wide energy range from thermal to several tens MeV.

A passive personal neutron dosimeter using CR39 was also developed (3). The dosimeter has two pieces of CR39 which are contacted with boron nitride and polyethylene radiators. The former is sensitive to lower energy neutrons and the latter to higher energy neutrons. The weighted sum of two CR39 etch-pits gives neutron dose equivalent within about 30% errors in the energy range from thermal to 15 MeV.

The response functions of these four detectors as a function of neutron energy were measured using the monoenergetic neutron field from 8 keV to 15 MeV at the Dynamitron facility, Department of Nuclear Engineering of Tohoku University (FNL), and the quasi-monoenergetic neutron fields produced by $^{7}Li(p,n)$ reaction at four cyclotron facilities; Cyclotron and Radioisotope Center of Tohoku University (CYRIC), Institute for Nuclear Study of University of Tokyo (INS), Takasaki Research Establishment of Japan Atomic Energy Research Institute (JAERI) and Institute of Physical and Chemical Research (RIKEN).

ESTABLISHMENT OF MONOENERGETIC AND QUASI-MONOENERGETIC NEUTRON CALIBRATION FIELDS

Dynamitron Neutron Field

The monoenergetic neutron field was developed at the Dynamitron accelerator facility, FNL. Monoenergetic neutrons of 8 and 27 keV, 0.25 and 0.55 MeV, 1.0 and 2.0 MeV, 5 MeV, 15 MeV were

obtained in the forward direction to the incident beam axis by Sc(p,n), ^{7}Li(p,n), T(p,n), D(d,n), T(d,n) reactions, respectively. The absolute neutron fluences were measured with ^{6}LiF-SSD for 8 and 27 keV neutrons and with ^{235}U fission chamber for other neutrons. The neutron fluence during the experiment was monitored simultaneously with the proton-recoil proportional counter. The neutron fluences were 1.0×10^{2} n cm^{-2} μC^{-1} for 8 keV, 2.4×10^{1} n cm^{-2} μC^{-1} for 24 keV, 1.0 - 4.0×10^{4} n cm^{-2} μC^{-1} for others.

CYRIC Neutron Field

The CYRIC neutron field has the 45 m long neutron TOF facility coupled with the beam chopping system and the beam swinger system. The quasi-monoenergetic neutrons of 22.0 and 32.5 MeV having 1.7 and 1.4 MeV FWHM were obtained from 2 mm thick ^{7}Li target bombarded by 25 and 35 MeV protons, respectively, and the proton beam hit the target at 10 deg through the swinger magnet and was fully stopped at the Faraday cup. The neutrons were extracted in the TOF facility through the 50 cm thick iron-polyethylene collimator of 30 cm x 20 cm aperture settled in the 280 cm thick concrete wall of 100 cm x 50 cm aperture. The absolute neutron fluence of this field was measured with the proton recoil counter telescope (PRT) and the neutron spectrum was measured with the TOF method. The 22.0 and 32.5 MeV peak neutron fluences were 1.1×10^{3} and 1.7×10^{3} n cm^{-2} μC^{-1} at the collimator exit behind 8.6 m from the target. The neutron fluence during the experiment was monitored simultaneously with the ^{238}U fission chamber fixed closely to the target.

INS Neutron Field

The INS neutron field was used only for neutron irradiation and the irradiation samples were placed 10 cm away from the Li target in the forward direction, in order to get high neutron fluence and to depress the contribution of room-scattered neutrons, since the irradiation room is small in space. The neutron spectra are the same as those in the CYRIC neutron field. This field is now not available.

TIARA Neutron Field

The TIARA neutron field was established in the neutron beam line collimated into 10 cm diameter. The 2 to 5 mm thick ^{7}Li target settled in the cyclotron room was bombarded by the proton beam of 20 to 90 MeV at 0 deg and the protons passed through the target were bent down to the beam dump by a clearing magnet, and the neutrons produced at 0 deg were extracted through the 220 cm thick concrete wall. The absolute fluence of source neutrons was determined with PRT and the neutron fluence during the experiment was monitored simultaneously with the ^{238}U and ^{232}Th fission chambers fixed closely to the target. The FWHM of 40 and 65 MeV monoenergetic peak and the peak neutron yield have the respective values of 2.0 MeV and 2.1×10^{4} n cm^{-2} μC^{-1}, 2.1 MeV and 3.2×10^{4} n cm$^{-2}\mu$C^{-1}, at the collimator exit behind 4 m from the target, for 43 and 67 MeV proton incidence. The neutron spectra measured with the TOF method.

RIKEN Neutron Field

The RIKEN neutron field is now being established at the E4 experimental room of the separate sector ring cyclotron. The proton beam having energies of 80, 90, 100, 110, 120, 135, 150 and 210 MeV were injected on a 10 mm thick ^{7}Li target through the beam swinger. Protons passed through the target were cleared out by the magnet and absorbed in the spectrograph. Neutrons produced at 0 deg were transported through the iron-concrete collimator of 20 cm by 20 cm aperture and 120 cm length. The neutron spectra were measured with the TOF method using BC501A and the absolute neutron fluence with the Li activation method using the ^{7}Be activity from the ^{7}Li(p,n)^{7}Be reaction.

MATERIALS AND METHODS

Bi Spallation Detector

Two sizes of natural bismuth samples were prepared. Thick samples are 80 mm diam by 10 mm thick and thin samples are 30 mm diam by 2 mm thick, which have chemical purities of 99.999 %.

The neutron reaction cross sections of Bi in the energy region from 20 to 210 MeV were measured by irradiating these samples in the p-Li quasi-monoenergetic neutron fields at INS, TIARA and RIKEN. The gamma-ray activities of the irradiated samples were counted by using a Ge detector and the reaction rates of identified radioisotopes were obtained after correction of self absorption and sum-coincidence effects.

By using the neutron energy spectrum $\Phi(E)$ and the reaction rate, A, the activation cross section $\sigma(E)$ can be estimated as follows. The reaction rate, A is divided into two parts; one is induced by the peak energy neutrons and the other by the low energy continuum neutrons, as

$$A = N \int_{Eth}^{Emin} \sigma(E)\,\Phi(E)\,dE + N\,\sigma(Ep)\,\Phi(Ep)$$

where N : number of target atoms relating to the relevant reaction,
E_{th} : threshold energy,
E_{min}: lowest energy of monoenergetic peak neutrons,
$\sigma(Ep)$: cross section at peak neutron energy,
$\Phi(Ep)$: monoenergetic peak neutron flux.

If the threshold energy E_{th} is higher than E_{min}, the first integration term must be zero. Otherwise, this term can be estimated by successive subtraction method using the neutron flux $\Phi(E)$ having lower peak energy. The $\sigma(E)$ values in lower energy region were cited from the evaluated data files, ENDF/B-VI (4), McLane et al. (5) and so on.

Organic Liquid Scintillation Detector

The cylindrical organic liquid scintillator of 12.7 cm diam by 12.7 cm long NE-213 or BC501A is coupled to a R4144 photomultiplier connected to the E1458 base (Hamamatsu Photonics Co. Ltd.) which is specially designed to expand the dynamic range of output pulses for high energy neutron measurements. The detector size which stops the recoil proton up to about 120 MeV was selected in order to to be able to detect as higher energy neutrons as possible with keeping a good n-γ pulse-shape discrimination capability.

The response functions of the scintillator were measured at CYRIC, TIARA and RIKEN (6). At CYRIC, 35-MeV protons and 50- and 65-MeV ^{3}He ions were injected into a 10 mm thick Be target. At TIARA, 67 MeV proton beam was injected into a 7.6 mm thick copper target, and at RIKEN, 135 MeV proton beam was injected into the Be (70 mm thick) + C (20 mm thick) target. These targets produced white spectral neutrons and the response functions down to a few MeV neutron energy were obtained by grouping them into monoenergetic interval with the TOF method coupled with the beam chopping system.

Si Semiconductor Dosimeter

The dosimeter installs two neutron sensors and one gamma-ray sensor, which enables us to give neutron and gamma-ray doses at the same time (1,2). One type, slow neutron sensor, is an n-type silicon crystal on which a p+ layer of elementary boron enriched 94% ^{10}B is deposited in about 1 mm thickness and the other type, fast neutron sensor, is an p-type silicon crystal without boron coating. Both crystals are contacted with 0.08 mm thick polyethylene radiators and in some cases only the slow neutron sensor is covered with thermal neutron filter of 0.5mm thick cadmium to improve its energy response. Figure 1 shows the schematic cross sectional view of two neutron sensors. The gamma-ray sensor is the p-type silicon detector of 3mm x 3mm without any radiator.

These three sensors are encapsulated in a metal package together with the charge sensitive preamplifier and the linear amplifier circuits. The output pulses from the sensors are counted through the pulse height discriminator and fed to the CPU for computing and displaying the dose equivalent values. The external size of the dosimeter is 100mm x 60mm x 20mm and its weight is about 170g.

The neutron detection efficiencies of these two sensors were measured in the monoenergetic neutron field at FNL. Monoenergetic neutrons of 0.2, 0.55, 1, 2, 5 and 15 MeV were produced using the Dynamitron accelerator. The dosimeter was placed in the forward direction to the beam axis. The efficiency measurement of the slow neutron sensor to thermal neutrons was done in the experimental hole of the TRIGA-II type reactor of Rikkyo University and in the thermal neutron field leaked from a graphite pile of the Institute of Radiation Measurements (IRM). The dosimeter was placed in front of a commercially available ellipsoidal water phantom, 45 cm high and 30 cm wide. The output pulses due to alpha particles produced by the ^{10}B(n,α) reaction and protons recoiled from the elastic collision in the polyethylene radiator were measured with a multi-channel analyser, in this measurement.

CR39 Track Dosimeter

The CR39 plastic has higher sensitivity than the NTA film for lower energy neutron, however many background etch-pits appear on the surface of nonirradiated CR39 plastic. In order to depress this background contamination, we diminished it by dyeing the CR39 plastic before etching with a KOH solution. The number of background etch-pits per cm^2 decreased about a factor of 10 after dyeing. As shown in Fig. 2, the CR39 dosimeter is contacted with two kinds of radiators, one is a 0.2 mm thick boron nitride for measuring low energy neutrons and the other is a 1 mm thick polyethylene for measuring fast neutrons.

The energy response of the CR39 etch-pits behind the two radiators were measured with the monoenergetic neutron field in the energy range of 8 keV to 15 MeV at FNL, graphite-moderated thermal neutrion fields at the Electro-Technical Laboratory and IRM, and the quasi-monoenergetic neutron field of 22 and 33 MeV at CYRIC. In these experiments, the dosimeter was also attached on a ellipsoidal water phantom.

RESULTS AND DISCUSSIONS

Bi spalltion detector

From the above experiments, we could identify the radionuclides of ^{207}Bi to ^{196}Bi produced by ^{209}Bi(n,2n) to ^{209}Bi(n,14n) reactions, respectively. Figure 3 indicates the cross section data of ^{209}Bi(n,2n) to ^{209}Bi(n,10n) reactions which have already been analyzed, in comparison with other experimental data (5) and the ENDF/B-VI high energy file data calculated by the ALICE code(4). Our data are generally in good agreement with them, but a large discrepancy can be found for Bi(n,9n) reaction, which might indicate a possibility of the inaccurate data of decay scheme and/or branching ratio of ^{201}Bi . This figure clearly shows that the excitation functions of Bi(n,xn) reactions have simple and similar shapes, and the threhold energies differ at about 8MeV interval, which indicates that these reactions are quite useful for high energy neutron spectrometry.

The Bi detector has been used by our group to measure neutrons leaked through bulk shield of 3m thick iron and 1m thick concrete at ISIS of Rutherford Appleton Laboratory.

Organic Liquid Scintillator

We obtained the neutron response functions of the scintillator by sampling neutron events into neutron energy intervals of 1, 2, 4, 5 MeV for neutron energy range from 0 to 44, 44 to 70, 70 to 90, 90 to 130 MeV, respectively (6). The response matrix of 68 neutron bin x 70 light output bin in the neutron energy range of 0 to 120 MeV was formed by using the measured response functions from 5 to 120 MeV neutrons and the SCINFUL Monte Carlo calculations (7) below 5 MeV neutron.

This detector has being used for neutron shielding experiment at TIARA and for thick-target yield experiment with heavy ions at the heavy ion medical synchrotron facility, National Institute of Radiological Sciences (HIMAC).

Figure 4 shows the cross-sectional view of the shielding experiment at TIARA. Inside the 340-cm-thick concrete shielding wall between the cyclotron room and the experimental room, an empty space of 120 cm x 120 cm x120 cm is equipped for shielding experiments. The concrete shield of 25 to 200 cm thickness and the iron shield of 10 to 130 cm thickness were fixed in contact with the 10.9-cm-diam collimator exit located at 4 m from the neutron target. The neutron energy spectra transmitted through shields were measured with the BC501A scintillator, using 40 and 65 MeV quasi-monoenergetic neutron sources which were produced by 43 and 68 MeV p-^{7}Li reactions. In Fig. 5, neutron spectra penetrated through concrete which were unfolded from the measured light output distributions with the FERDOU code (8) are compared with the MORSE Monte Carlo calculation (9) using the DLC-119/HILO86 group cross section library (10), as examples. This figure revealed in general the good agreement between experiment and calculation.

Figure 6 shows the schematic diagram of the experiment at HIMAC. Neutrons produced from a target bombarded by heavy ion beams were measured with three sets of the 12.7 cm diam by 12. 7cm long NE213 scintillators by the TOF method. A veto counter of 5 mm thick NE102A plastic scintillator was set in front of the NE213 to discriminate the secondary charged particles. A 0.5 mm thick NE102A scintillator fixed upstream to the target was used to produce beam pick-up signals for the TOF starting. The neutron energy spectra produced at 0 degree from 20 mm thick C, Al, and 10 mm thick Cu, Pb targets which were bombarded by 100 MeV/nucleon ^{12}C ions are shown in Fig. 7, as examples.

Si Semiconductor Dosimeter

Figure 8 shows the neutron detection efficiency of the dosimeter as a function of neutron energy. The measured results are the sum of the integrated counts given by the slow neutron sensor and the integrated counts of the fast neutron sensor multiplied by a factor of 20, in order to get the detection efficiency as close as possible to the fluence-to-dose-equivalent conversion factor given by ICRP-51 (11) which is drawn in a dotted line. In Fig. 8, the results calculated with the Monte Carlo method are also shown to compare with the measured results. Very Good agreement between experiment and calculation can be seen in the energy below 5MeV. Above 5MeV, the calculation underestimates the measured results due to the neglection of the contribution of charged particles which are produced in the silicon crystal itself and the surrounding material by various neutron reactions.

This dosimeter which combines two silicon sensors has neutron sensitivity over a wide energy range from thermal to 15 MeV and also has good energy response, excluding a large deviation from the ICRP-51 response curve in the energy range from 50 keV to 1 MeV, as seen in Fig. 8. Considering the energy response of the dosimeter shown in Fig. 8, the neutron dose equivalent H can be given by adding the neutron dose equivalent of energy higher than 1 MeV, H_f and that of energy lower than 1 MeV, H_s. H_f and H_s are given by

$$H_f = K_f C_f \qquad \text{for En} \geq 1 \text{ MeV},$$
$$H_s = K_s C_s \qquad \text{for En} \leq 1 \text{ MeV},$$

where C_f, C_s are the respective counts measured with fast sensor and slow sensor, K_f, K_s are the respective conversion factor in units of μSv/count. The K_f and K_s values were determined as 0.5 and 10 μSv/count, respectively, from the estimation in the fission and 1/E slowing-down spectral fields.

In order to investigate the accuracy of this dose estimation method in a wide variety of actual neutron fields, we have done the field test of the dosimeter calibration in the following typical neutron fields having known neutron energy spectra; 1) moderated ^{252}Cf neutron source calibration field, 2) a beam extraction hole of the fast neutron source reactor of University of Tokyo, 3) labyrinth from the 40 MeV cyclotron room of Tohoku University, 4) MOX (Mixed Oxide) fuel handling room of Power Reactor and Nuclear Fuel Development Corporation, 5) 14MeV d-T neutron field penetrated through concrete shield, and 6) On the outer surface of the concrete shield surrounding several hundreds MeV electron synchrotron. In these field tests, the dosimeter was fixed on the water phantom faced to the neutron beam direction. The measured counts were compared with the dose equivalent values obtained from the dose equivalent counters (rem counters) of Studsvik Co. 2202D and Fuji Electric Co. NSN1 which were used as neutron dose monitors.

Figure 9 summarizes the results of these field tests. The ratio of neutron dose equivalent value measured with this personal dosimeter to that with the rem counter is shown as a function of neutron energy in the test field averaged by weighting with the dose equivalent. The ratio must be equal to 1 for the ideal dosimeter, and our personal dosimeter gives neutron dose equivalent within a factor of 2 margin of accuracy, excluding a special field in which thermal neutron fluence occupies more than 50% of total neutron fluence, such as at some positions in the labyrinth from the cyclotron room. Even in such a field, we can estimate the neutron dose equivalent within a factor of 3 by using a thermal neutron sensor with Cd cover and moreover with much better accuracy by adjusting the conversion factor K_s slightly.

CR39 Track Dosimeter

Figure 10 shows the weighted sum of the energy response of the dosimeter with two radiators, boron nitride (BN) and polyethylene (poly), in order to give a best fit to the ICRP51 response curve. The data at thermal, and 8 keV up to 15 MeV energies are the measured results (shown in white circles and triangles), and the data between thermal and 8 keV energies are the calculated results with the Monte Carlo method (in white squares). Good agreement between experiment and calculation can be seen and the energy response of this dosimeter well fits the ICRP51 response curve in the energy range lower than about 10 MeV. In order to improve the energy response above 10 MeV, the weighting factor was further increased only for the etch-pits having a diameter larger than 20 μm, considering that the diameter of etch-pits increases with neutron energy. The thus-adjusted energy response of the dosimeter is also shown as white square signs in Fig. 10 and indicates much better agreement with the ICRP51 response curve above 10 MeV. The dose equivalent in mSv is then given by the following formula,

$$H\,(\text{mSv}) = \{BN/8 + [poly1 + (poly2 - 100) \times 8] \times 8\} \times 10^{-4}$$

where BN, poly1 and poly2 are the etch-pits per cm^2 of CR39 with BN and those having a diameter smaller and larger than 20 μm with polyethylene radiators, respectively. If poly2 is less than 100, the third term of the above formula is neglected.

CONCLUSION

We have developed two types of high energy neutron spectrometers, and active and passive personal neutron dosimeters. The two spectrometers are now in use for neutron spectrometry at accelerator facilities and these two dosimeters will be commercially available very soon.

ACKNOWLEDGMENTS

The authors wish to thank Dr. Y. Kumamoto and Mr. A. Fukumura for their kindful cooperation during the HIMAC experiment and the machine group members for their four cyclotron operations during our experiments.

RADIATION PROTECTION AT THE LHC, CERN'S LARGE HADRON COLLIDER

K. M. Potter, M. Höfert and G. R. Stevenson

CERN, Geneva, Switzerland

ABSTRACT

After a brief description of the Large Hadron Collider (LHC), which will produce 7 TeV on 7 TeV proton collisions, some of the radiological questions it raises will be discussed. The machine will be built in the 27 km circumference ring-tunnel of an existing collider at CERN. It aims to achieve collision rates of 10^9 per second in two of its high-energy particle detectors. This requires two high-intensity beams of more than 10^{14} protons each. Shielding, access control and activation in addition to the high power in the proton-proton collisions must be taken into account. The detectors and local electronics of the particle physics experiments, which will surround these collisions, will have to be radiation resistant. Some of the environmental issues raised by the project will be discussed.

THE DESIGN CONCEPT OF THE LHC

The Large Hadron Collider (LHC) of CERN will be a synchrotron-collider which accelerates and stores two intense beams of particles circulating in opposite directions and collides them head-on at two or more points where particle physics detectors can study the interactions. While CERN's present collider, LEP, collides electrons and positrons at energies up to 100 GeV, the LHC will collide two beams of protons at energies of up to 7 TeV. The LHC will be installed in the same underground tunnel which at present houses LEP alone (see Figure 1). Since the circumference of the LHC is given by the existing LEP tunnel, the maximum beam energy depends only on the magnetic field which can be reached in the high quality dipole magnets needed to guide the protons around the 27 km of the tunnel. These magnets, which will use superconducting coils of NbTi cooled to 1.9 K are the subject of a vigorous R and D programme as they need to provide a field of 8.4 T, almost 50% higher than that presently foreseen for any other accelerator.

The LHC is designed to study quark-quark interactions whose point-like nature implies that cross-sections decrease as the energy E increases. To maintain a constant detection probability for a given type of event, the luminosity, which is proportional to collision rate, should increase at least as E^2. To explore rare processes such as Higgs$\rightarrow 2Z^0 \rightarrow 4\mu$ the LHC must be able to provide luminosities of the order of $10^{34}\,\mathrm{cm}^{-2}\mathrm{s}^{-1}$ (interaction rates of approximately 10^9 per second). To achieve this, high intensity circulating beams are needed with very small cross-sections at the collision point. The LHC will circulate two opposing proton beams in ingenious "two-in-one" magnets which provide the necessary twin magnetic channels with opposite sign fields in the same yoke and cryostat.

The layout of the LHC, indicated in Figure 2, is given by the form of the LEP ring which consists of eight arcs with a bending radius close to 3.5 km linked together with 550 m long straight sections to form a regular structure. The two beams of the LHC will lie side by side in the horizontal plane in the arcs, 194 mm apart, and will cross over in the centre of each straight section where collisions are required. Two such regions, P1 and P5, will be used for large general purpose LHC detectors, called ATLAS and CMS. The Technical Proposal for each of these has been prepared by collaborations of some 1500 particle physicists from all over the world. Two smaller and more specialised experiments, ALICE which will study lead-ion collisions and LHC-B which will study particles with the fifth "beauty" quark and CP

violation, will be installed at P2 and P8, respectively. The remaining straight sections will be used for LHC machine utilities, one to provide safe external beam dumps for the beams at the end of each run, one for the accelerating system of Radio Frequency cavities and the other two for the beam cleaning systems which will be needed to ensure that halo particles cannot reach the vacuum chamber walls and deposit their energy in the superconducting magnets.

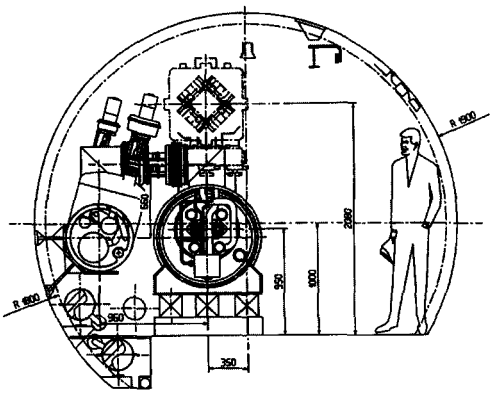

Figure 1: A cross-section of the machine tunnel with the twin aperture super-conducting magnet of the LHC installed below a LEP quadrupole. The separated cryogenic feed-line and connecting valve box can be seen on the left.

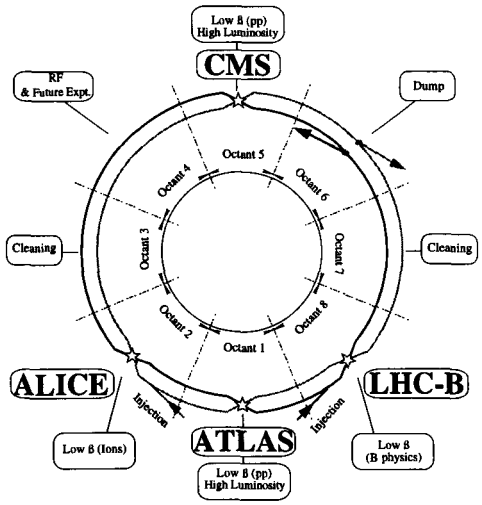

Figure 2: A schematic layout showing the assignment of the eight long straight sections of the LHC to experiments and utilities

The LHC will obtain its protons from the existing CERN accelerator chain of 50 MeV Linac, 1.4 GeV Booster, 26 GeV PS (Proton Synchrotron) and the 450 GeV SPS (Super Proton Synchrotron). The requirements of the LHC, large numbers of high intensity proton bunches with the correct small emittance, are only slightly beyond the routine performance of this injector chain and the necessary development is well underway. As these same injectors frequently operate with other particles, notably heavy ions such as lead, the LHC will also be able to accelerate and collide heavy ions. Luminosities of up to $10^{27}\,\mathrm{cm}^{-2}\mathrm{s}^{-1}$ should be reached with lead ions in the LHC with the total energy of the collisions between these nuclei being about 1150 TeV.

The luminosity, $\mathcal{L}$, per collision point with two equal beams is given by:

$$\mathcal{L} = N^2 k f \gamma / 4\pi\epsilon\beta^*$$

where N is the number of protons in each of k circulating bunches, f is the revolution frequency, β^* is the value of the betatron function at the collision point and ϵ is the emittance corresponding to the 1σ contour of the beam, normalized by multiplying by the Lorentz factor $\gamma = (E/m_0c^2)$.

It is easy to see that high luminosity requires as many high density bunches as possible with the smallest possible transverse cross-section at the collision point (N and k large, $\epsilon\beta^*$ small). The main limit to such a simple approach comes from the so called beam-beam effect which results from the extremely non-linear fields seen by the particles of one beam as they pass through the bunches of the other. The long range

interaction between the bunches of each beam which occurs on either side of the crossing points where the beams pass through a common length of vacuum pipe, about 100 m long, is reduced by introducing a small but finite crossing angle. A careful cost optimization of performance has led to the main parameters of the LHC given in Table 1.

Table 1: Main LHC parameters

	Protons	Pb-Ions
Centre of mass total energy (TeV)	14	1148
Magnetic field in bending magnets (T)	8.4	8.4
Initial luminosity per collision region ($cm^{-2}s^{-1}$)	10^{34}	2×10^{27}
Bunch spacing (m/ns)	7.5/25	37.4/124.8
No. of particles per bunch	10^{11}	9.4×10^{7}
Number of collision regions assumed	2	1
Beta parameter at interaction point (m)	0.5	0.5
r.m.s. beam radius at collision point (mm)	16	15
r.m.s. collision region length (mm)	54	53
r.m.s. energy spread $\delta E/E$	1.1×10^{-4}	1.1×10^{-4}
Beam crossing angle (μrad)	200	100
Luminosity lifetime (h)	10.0	6.7
Stored energy per beam (MJ)	334	4.8
Synchrotron radiation per beam (kW)	3.6	–

For the reasons given above the LHC requires the highest possible magnetic field, which makes the twin aperture superconducting dipoles the most technologically challenging components. The development of these magnets was started in 1985, in close collaboration with European Industry and other Accelerator Laboratories, with the aim of achieving 10 T fields. Progress has been impressive and five 10 m prototypes built in industry have been delivered and tested. Three of these magnets were assembled in a "string-test" during 1995 to verify the cryogenic system needed to bathe the coils of all 1344 dipoles and some 2000 smaller magnets in superfluid helium and maintain them at 1.9 K. As a result of a year's successful testing, the basic concepts of cooling and powering the LHC magnets have been well validated and a number of changes have been incorporated into the latest design report (1).

The massive cryogenic system needed will be based on that already installed to cool the superconducting accelerating cavities of the LEP 200 project. The system will need a considerable upgrade, however, to lower the temperature from the 4.5 K used for the LEP cavities to the 1.9 K needed for the LHC magnets and to provide the increased cooling power needed to cool down 31,000 tons of cold mass in a reasonable time. A total of about 400,000 litres of liquid helium will be needed, but nonetheless the LHC will be extremely energy-efficient, providing twenty times the collision energy and ten thousand times the luminosity of the SPS p-pbar collider which operated in the 1980s, for a similar energy consumption.

During the whole LHC operation cycle of particle injection, acceleration, colliding and finally extracting and dumping the beams, one of the most critical systems will be the beam cleaning system. A series of collimators must intercept the beam halo particles and prevent them from depositing energy in the coils of the magnets and causing the superconducting strands of the coils to become resistive *i.e.* to quench. If this should happen, for whatever reason, the stored energy in the coils of the magnets will be rapidly extracted to avoid destroying them. It is estimated that a point loss of as few as 10^6 protons per second could quench a magnet, while the losses from small angle elastic scattering in the collision regions alone will scatter of the order of 10^9 protons per second into the halo region.

At the end of a colliding beam run, the two beams will be deflected by fast kicker magnets, providing 18 Tm with a 3 μsec rise time, into extraction channels leading to dump blocks about 750 m away. An appropriate gap will be left in the normal bunch structure during injection so that with proper time synchronization the kicker magnet can extract the beam without excessive losses. The extraction channels will have to be equipped with sweeping magnets to spread the beams over the dump blocks. Even so the inner core of the dumps will have to be made of graphite in order to withstand the very high ($\sim$ 2000°C) temperatures generated by the intense proton beams during the dumping operation. By diluting the beam in this way, the 330 MJ of each beam can be safely absorbed without incurring a risk of destroying the absorber block by the thermal shock. The absorbers will be 14 m long blocks of iron with central cores of graphite encased in aluminium. The iron may have to be water-cooled to allow repeated use during setting up and machine studies and the assemblies will be installed in caverns, designed to cope with the induced radioactivity. Like most of the rest of the LHC, these caverns will be some 100 m underground.

A Conceptual Design Study of the Large Hadron Collider (1) was published in October 1995, less than 12 months after the CERN Council approved the project in December 1994. Technical studies suggest that, with adequate funding, the LHC could be built and installed by the year 2004, but the exact time scale will depend on how many non-member countries accept CERN Council's invitation to join the project. If funding is inadequate, a two stage programme with first operation in 2004 at a lower energy and luminosity is envisaged. In that case full performance might not be reached before 2008.

LHC SHIELDING

Shielding requirements for high-energy proton storage rings are normally not been based on the estimates of loss that will occur around the ring under standard operating conditions. As explained above, these losses must be kept to a minimal level for the storage ring with superconducting magnets to work at all. Estimates of shield thicknesses are based more on the potential exposure in the case of an unexpected loss of the circulating beam (or beams) at a single point. The damage caused to the accelerator by such a loss would be dramatic, and every effort will be made to ensure that a full beam loss will not occur. However, although the probability of such an event is extremely small, a full beam loss cannot be excluded from consideration. This shielding philosophy is explored in more detail in (2). The design constraint chosen for the LHC was that the loss of one circulating beam at full intensity should not give rise to an *ambient* dose equivalent of more than 50 mSv at the outer surface of the shield. This is expected in the real exposure situation to lead to an *effective* dose equivalent of less than 20 mSv. This would not then involve any declaration of a radiological incident or accident to a controlling authority and would not jeopardized the future work of the persons involved in radiation areas. Simulation studies suggest that 4 metres of concrete would be needed to shield the accelerator ring to meet this requirement (3). Similar simulation studies have been made for a full beam loss occuring in the ALICE experiment; the results from one of these studies is given in Figure 3 which shows dose equivalent contours in the experimental cavern and in the occupied area in a deep pit above a shield plug. The numbers indicate the dose in mSv from a full loss on one side of the experiment and show that with the shield configuration under study at the time, the dose constraints were not achieved (4). Access to the top of the shield plug must therefore be restricted.

The layout of one of the two high-luminosity experiments, ATLAS, is indicated in Figure 4. In these experiments the main source of radiation to be shielded is given by the inelastic p-p collisions. These provide a source which slowly varies in time according to the luminosity. The experiments themselves provide some shielding around the interaction point. However inside the detector during operation, radiation levels can be high enough to damage the detectors and their associated equipment. Typical fluence levels inside the ATLAS detector are given in Figure 5 for neutrons having energies above 100 keV (5). The shielding provided by the detector is clearly visible, as is the fact that survival of silicon-based semiconductor devices is not at all assured inside the inner detector assemblies. It must be noted that radiation

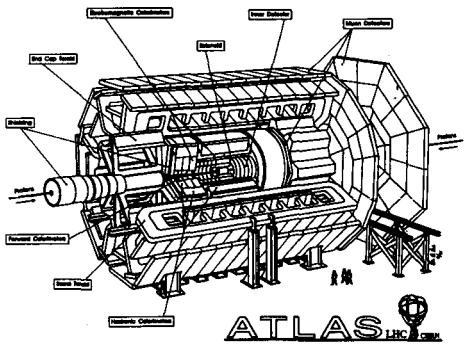

Figure 4: The ATLAS layout.

damage is always of concern to persons concerned with radiological protection at high-energy accelerators since damage goes hand-in-hand with high levels of induced radioactivity. Thus replacement of damaged components can lead to significant exposure of personnel.

In the very-forward regions of the experiment, special shielding-collimators must be placed in front of the first superconducting quandrupoles of the accelerator to avoid excessive energy deposition in the magnets. These collimators act as strong secondary sources of stray radiation and have to be specially shielded to avoid serious background problems in the muon chambers installed around the main detector. The result of the shielding provided around these collimators and by the detectors themselves is that the experimental regions give the false appearance of being only lightly shielded against beam losses in relation to the LHC main ring, with only 2 m as the thickness of the lateral shield around ATLAS and 3 m around CMS.

INDUCED RADIOACTIVITY IN THE ACCELERATOR STRUCTURE

As explained above, a proton accelerator equipped with superconducting bending magnets and quadrupoles such as the LHC has to be protected from beam losses to avoid quenches. The fact that beam losses in the superconducting magnets must be low means that high radiation levels from induced radioactivity cannot occur in the arcs of the LHC. It has been estimated however that the dose rate from induced radioactivity close to the cryostats will be $\lesssim 1\ \mu$Sv/h (6), arising from inelastic interactions of the circulating protons with the residual gases in the vacuum chamber.

It therefore appears to be prudent to expect the need to designate the LHC ring during shut-downs as a Controlled Radiation Area on this consideration alone. This level of dose rate can be considered as a minimum base level. Local areas of high radioactivity will be concentrated in three distinct areas of beam losses, *i.e.* the interaction points of the experiments, the dumps and the collimators.

Figure 6 indicates the dose rates from induced radioactivity that can be expected in the CMS exper-

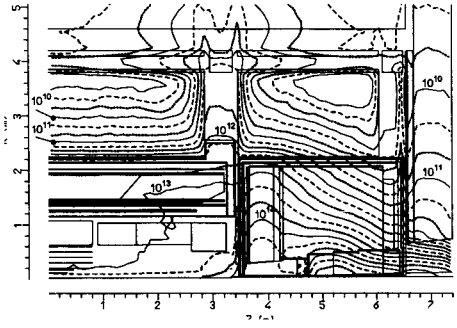

Figure 5: The annual fluence of neutrons (in cm^{-2}) having energies above 100 keV in the inner detector and calorimeter system of ATLAS (reproduced from reference (5)).

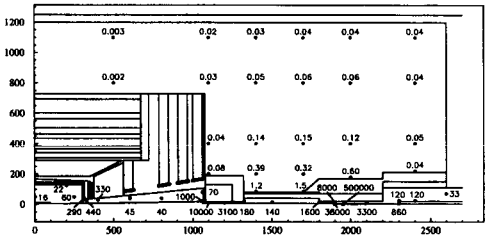

Figure 6: Estimated dose rates from induced radioactivity (in μSv/h) 1 day after the stop of a 60 day operating period for the CMS detector region (reproduced from reference (7)).

imental region (7). It will be seen that the levels outside the detector and the forward shielding are not significant. However maintenance work inside the inner detector region will have to be strictly controlled and special handling procedures will be necessary for work on equipment in the very-forward regions close to the beam-pipe.

The dumps are essential for absorbing the protons when emptying the rings of the circulating beams once these are no longer useful for physics experiments. These dumping operations will take place once or twice a day, and since the dumps will be heavily shielded with iron, the induced activity in the dump caverns will only lead to dose-rates of the order of several tens of μSv/h.

Scraper-collimators are essential for the successful operation of the LHC. They are needed to remove off-momentum protons which otherwise would be lost in sectors of the LHC containing superconducting magnets. A system of well adjusted beam apertures is required around the machine in specific places, limiting the beam size by scraping off the halo that builds up with time due to the proton-proton collisions in the experiments. The cleaning sections installed in octants 3 and 7 will concentrate beam losses and the whole region around these scraper elements will become highly radioactive. Iron shields of approximately 1 metre thickness will be required in some places to reduce dose rates from induced activity to tolerable levels in the passage-way alongside the machine elements.

All items inside the LHC tunnel during operation must be considered as and in most cases are slightly radioactive, and must be treated as such when removed from the machine *e.g.* properly marked. In the case of the LHC, the dispersion of machine and experimental components taken out for repair and maintenance, and moved into non-radioactive areas like normal workshops, must be careful controlled. By no means can such items be eliminated from the site as normal scrap material so long as it has not been shown that the activity contained therein is below the exemptions limits for the specific materials concerned. Due to the sheer number of items that are installed in the machine not all maintenance and repair operations can be closely followed by a radiation protection technician. Maintenance staff for the machine and experiments therefore need careful education in radiation matters.

CONCLUDING REMARKS

It is not possible in such a short review to cover in depth all aspects of the radiological situation of the LHC. These are treated in detail in many laboratory reports which are available to the public. The final design of the accelerator has yet to be determined, but sufficient studies have already been completed to show that it will be possible to operate the LHC well within the limits of radiation exposure for both the personnel of CERN and persons living in the region of the LHC.

ACKNOWLEDGEMENTS

THE ENVIRONMENT

As for other proton accelerators, the topics that are of concern for the environment of the LHC installations are the propagation of prompt radiation (muons and neutron skyshine) and the activation of air, cooling-water, soil/rock and ground-water.

The activation of soil is generally of concern for the environment if some of the radionuclides formed can dissolve in the ground water. Here the particularity of the LHC is that the machine is mostly situated more than 100 m underground in a geological formation of compressed sandstone called molasse that does not contain any mobile water and in particular has no exchange with the groundwater contained in the moraine layers near the surface from which the local drinking water supply is taken.

Thanks to the depth of the implementation of the LHC, radiation levels from prompt radiation will not be observed at the surface. Although strongly directional beams of high-energy muons *e.g.* behind the beam dumps propagate over several kilometers they always remain underground and thus present no radiation hazard for the environment. The underground machine tunnel, the experimental areas and the service galleries are connected to the surface by access shafts of 10–20 metres in diameter. Due to the length of these shafts and the presence of local shielding in the underground areas, or additional top shielding at the top of the shafts, the radiation levels from neutrons at the ground surface-level will always be low and the propagation of these neutrons via skyshine will not lead to radiation levels of any significance.

As far as the release of airborne and liquid radioactivity into the environment is concerned, CERN has fixed annual release limits that have been agreed upon by the Host State authorities. With the advent of new dose factors in the recently published Swiss Ordinance on radiation protection that relate the release of a specific radionuclide to the effective dose of an exposed member of the public the original limits are actually under review at CERN.

The activation of air in high-energy proton accelerators gives rise to short-lived radionuclides such as ^{13}N, ^{15}O and ^{11}C formed by spallation reactions and ^{41}Ar which is formed in air by a thermal neutron reaction, and hence is normally detected only in small quantities at accelerators. In the LHC however particular attention has to be paid to this radionuclide due to the presence of some 100 tonnes of liquid argon in the ATLAS detector where the direct formation of ^{41}Ar is possible. This could escape into the air of the experimental caverns in case of leakage from the argon calorimeters.

Air from the LHC underground areas will be released at four points equally spaced around the ring with distances of about 7 kilometres between them. One of the realistic approaches when calculating the new radionuclide specific release figures will be to assume that the four plumes from the ventilation are not superimposed and thus the hypothetical member of the general public could never receive the dose from the sum of the four releases.

Water that is collected in the drains that run all around under the floor of the LHC tunnel becomes activated due to proton beam losses. There is a particularly abundant water flow in the drains of the part of the machine tunnel which runs through the limestone at the foot of the Jura mountains and which will be activated particularly by the known beam losses in the collimator region of point 3. The water which is pumped to the surface will have an activity that will not allow its immediate release into the environment but requires a delay of several hours to ensure that any activity in this water meets drinking-water standards. The necessary delay is automatically provided by the passage of the water through decantation tanks to remove any suspended solid matter (mainly sand).

Beam-Limiting and Radiation-Limiting Interlocks

Robert J. Macek
AOT-DO
Los Alamos National Laboratory (LANL)
Los Alamos, NM 87545, USA

ABSTRACT

This paper reviews several aspects of beam-limiting and radiation-limiting interlocks used for personnel protection at high-intensity accelerators. It is based heavily on the experience at the Los Alamos Neutron Science Center (LANSCE) where instrumentation-based protection is used extensively. Topics include the need for "active" protection systems, system requirements, design criteria, and means of achieving and assessing acceptable reliability. The experience with several specific devices (ion chamber-based beam loss interlock, beam current limiter interlock, and neutron radiation interlock) designed and/or deployed to these requirements and criteria is evaluated.

INTRODUCTION

The title of this paper refers to active, engineered radiation-safety systems consisting of electronic devices which sense errant beam conditions or excessive prompt radiation and then command other devices to automatically limit or shut off the beam current. Such systems are increasingly used at a number of US accelerator Laboratories to mitigate potential prompt radiation accident scenarios. A number of factors motivate this practice including, most importantly, the cost of additional shielding but also the need to protect accelerator components from beam-induced damage and even to prevent potential failure modes of the fixed shielding. This paper will only be concerned with systems intended for personnel protection.

Common situations where instrumentation-based radiation-safety systems become an important option include:1) changes in radiation safety standards, 2) upgrades that significantly increase beam power to an area, and 3) configurations where certain equipment or procedural failures can send high intensity beam to an area that normally receives low intensity beam.

At one time, it was considered adequate to design shielding to meet regulatory dose management limits for source terms corresponding to the highest beam losses expected to be encountered during normal operating conditions. There was less concern with what could happen under abnormal or accident conditions. Indeed, when the assumed source term was a local loss of the order 0.1 - 1% of the maximum normal operating beam power, then the worst case accident, a full-power spill, would not be life threatening even if the accident lasted as long as hour or so. In this case, the shielding would still limit the radiation fields on the outside of the shielding to less than 10 mSv/h (1 rem/h) for a full power spill (assuming that the shielding was designed to give 10 μSv/h for a 0.1% local spill). While radiation fields at this level are a serious matter, they will not lead to a life-threatening dose if the exposure time is an hour or so.

Modern high-powered accelerators and beam lines, such as those that serve the meson factories or spallation neutron sources, are designed and operated with maximum allowable losses of 10^{-6}/m or less over much of their extent. If shielded only for normal or expected losses, the accelerator has an accident potential that is now a much greater since a full power local spill could produce radiation fields of 10Sv/h (1000 rem/h) or greater outside the shielding. Life-threatening doses could be incurred if the spill lasts an hour or so. In these circumstances, instrumentation-based protection systems offer the promise of accident mitigation.

Even if the shielding for the initial accelerator capability was adequate for full-power spills, improvements and upgrades of accelerator beam power are the norm and create the potential for higher radiation fields under abnormal conditions. Shielding retrofits are frequently much more difficult and costly than the same shielding augmentation at the time of initial construction at a "green field" site. Here as well, active systems offer a possible solution.

From the beginning, LAMPF (now LANSCE) used automatic beam-loss limiting instrumentation to protect the accelerator from damage and keep activation low enough for hands-on-maintenance.

The construction of the proton storage ring (PSR) required a high-intensity H^- ion source which was also used to provide highly chopped beam for a fast-neutron facility, WNR. With these new facilities came the capability for new errant beam situations where high intensity beams could appear in beam lines which normally saw much lower beam intensity. The same instrumentation used at LAMPF to limit activation was also used in these new facilities and was thought to be adequate for limiting loss in accident situations as well. Critical examination of these issues lead to the development of a more reliable system of beam limiting devices suitable for personnel protection. Retrofits to the shielding were still implemented where possible in the areas of greatest concern (1).

Each of the situations enumerated earlier have been encountered at LANSCE. Extensive use has been made of improved beam-limiting and radiation-limiting interlocks to reduce the probability of large doses in severe accident scenarios. The first preference was for shielding or physical barriers rather than instrumentation. However, in some situations we found that shielding retrofits sufficient to deal with the accident potential by shielding alone were very expensive or practically impossible to implement without a major rebuild of the facility. For these situations, there was no acceptable alternative other than greater use of active protection systems.

SYSTEM REQUIREMENTS AND DESIGN CRITERIA

Acceptance of beam-limiting and radiation-limiting interlocks for personnel protection, especially as a substitute for additional shielding, depends upon making the case that the interlocks will reliably prevent **any** unacceptably large beam spills. The system requirements and design criteria that further this goal are discussed below.

A. Ultra-High Reliability

A key issue in the acceptance of active safety systems is the achievement and demonstration of ultra-high reliability or equivalently, ultra-low failure rates for these systems to perform their safety function. Consensus on a single, suitable criterion for the reliability required of "active" protection systems has not been achieved. A frequently sought goal is that failure of the overall protection system leading to death or serious injury should be "incredible", which is often taken to be a failure rate of less than once in a million years. Demonstration of such low failure rates by direct observation is obviously out of the question. Rigorous proof through analysis and computation is also elusive. However, probabilistic analysis and assessment does have value as will be discussed later.

In a graded approach, reliability requirements and potential consequences of a system's failure to mitigate worst-case accident scenarios would be correlated such that higher reliability is required for the more serious consequences. Quantification of the relationship is another elusive goal because it is fundamentally a judgment of acceptable risk. In practice, one is driven to provide the most reliable system possible within a budget.

In lieu of numerical reliability specifications which can not be demonstrated by direct measurement, deterministic features or processes can be specified which are known to make positive contributions to reliability and which can be evaluated without much ambiguity. Included would be such features as redundancy, testability, fail-safe characteristics, and rigorous quality standards.

B. Criterion for "Fail-Safe" Operation

Fail-safe operation of the protection systems is a feature often required or sought after for engineered safety systems. In practice, no system can be shown to be truly fail-safe with respect to all possible failure modes. A definition or criterion that appears feasible in practice is to use the term "fail-safe" for systems which fail safe with respect to any single-point failure. At Los Alamos, this concept was pioneered by Andrew Browman and employed in the design of the both the beam loss interlock and beam current limiter interlock which are now part of the radiation security system (RSS). To be more specific, the criterion used was that any single point hardware failure will have one of three outcomes: the device continues to perform its protection function, or the device shuts off the beam and holds it off until the fault/failure is corrected, or the gain changes by less than some specified tolerance (20% was chosen the beam loss interlock) and the device continues to perform its protection function at the changed sensitivity. This definition of the term fail-safe will be used through out the rest of this paper.

Some techniques used to achieve fail-safe design include:

- Use of redundancy within a module,
- Continuous self-checking,
- Continuous monitoring of power supply voltages or other critical parameters.

To follow the fail-safe concept to its logical conclusion, one should also consider single-point human failures in design, construction, testing, operation and maintenance. However, this is rather difficult to do with completeness. Redundancy in the form of independent verification of construction, modifications, maintenance and testing is often used to minimize "single-point" human/administrative failures.

C. Redundancy

Redundancy is used extensively to improve reliability and avoid single-point failures. It primarily improves reliability and availability with respect to uncorrelated failure modes or events. The main weakness is common cause failures which reduce simultaneous multiple failures to an equivalent single point failure mode or event. Some examples of correlated or common cause failures are aging and wear-out phenomena, common environmental changes (such as temperature, humidity, dust, vibration, radiation damage, etc.), lightening induced failures, mechanical crushing from a single event, and design flaws in redundant systems employing identical units. The use of different physical principles or different technologies in the redundant devices is helpful in reducing common cause failure modes.

D. Complete Coverage by Radiation Detector Interlocks

To be most effective, the interlock system should be capable of detecting any unacceptable beam losses no matter where it occurs. In this context, unacceptable beam losses are those that can lead to unacceptable radiation exposure in areas where occupancy is not prevented by physical barriers. Therefore, sufficient devices are deployed in such a way that unacceptable beam loss at any point in the beam acceleration, transport or beam handling systems is detected at the required or specified minimum sensitivity (or at greater sensitivity). Mere sampling is not sufficient.

E. Required Dynamic Range

To provide protection against the full range of possible accident scenarios it is necessary that the overall system have a dynamic range that covers all possibilities from the minimum required sensitivity in normal operations to the maximum possible dose/dose rate that can be delivered under full- power beam spill accident scenarios.

F. Testability/Verifiability

Frequent testing is a well-known technique for improving device availability and one that the system design should facilitate. It should be possible to easily verify or test for proper functioning all essential safety features of the device while it is in place. Where redundancy is used to achieve fail-safe operation with respect to single-point failure modes, it is crucial to find and correct any single-point failures in redundant components shortly after they occur since such units or sub-systems no longer satisfy the fail-safe criteria (at least in the case of two-fold redundancy).

G. Acceptable False-Alarm Rate

Frequent false alarms discredit a device with operators. At some frequency of false alarms the device will be ignored or taken out of service even if the false alarms are fail-safe. In my experience, false alarms at the rate of one/month of operation are tolerable; once per week is not.

H. Isolation and Tamper Resistance

Safety-critical systems should be made resistant to inadvertent or willful tampering with components that are essential to the safety function. One reason for isolation of safety systems from other interlock or instrumentation systems is to avoid inadvertent compromise of the safety features; another is that isolation makes it easier to lock off the safety system components, and junction boxes and wiring plant.

I. Beam Plugs and Reliable Beam Shut Off

The active protection system is only as reliable as its weakest link. Care must be taken to ensure that the detection of an errant beam or excessive radiation condition results in a command that is reliably transmitted to a sound and reliable beam shut off system. Electronic beam deflectors will

quickly shut off the beam, but, they should be backed up by fail-safe beam plugs. These would be beam stoppers that can take the full power of the beam indefinitely or else create a passive shutdown of the accelerator before the beam burns through the plug. The later feature is implemented for the fusible beam plugs used at LANSCE. The fusible beam plug is an idea picked up from SLAC. The face of the beam plug is a fairly thin metal window (the fuse) covering a cavity filled with air and connected by tubes to the atmosphere. If high power beam strikes the window it causes the window to melt and let air into the accelerator before the body of the plug can melt. The air is sufficient to ruin the vacuum and stop acceleration without destroying the accelerator.

J. Quality Control

Rigorous quality assurance and quality control standards for critical safety systems components, wiring plant, design, construction, installation, testing, maintenance, training, certification and documentation are needed to ensure that the design policies, principles and criteria are properly implemented. Quality standards approaching those used for critical safety systems in the nuclear industry are recommended.

SOME EXAMPLES

The concepts and principles discussed above have been applied to the very challenging situation at LANSCE. The aim was to have a redundant, three-layered, "defense in depth" where each layer employed a different technology so as to minimize common mode failures. The first layer was a system of fail-safe beam loss interlocks based on ion chamber detectors placed in the beam tunnels. The second layer employed fail-safe beam current limiters to prevent excess beam currents in critical areas. The third layer consisted of neutron radiation detector interlocks outside the shielding deployed to enforce limits on the maximum neutron radiation levels in occupied areas. The fail-safe ion chambers and the current limiter were developed specifically to meet these criteria for the Line D facilities at LANSCE and have since been used at other LANSCE facilities. The well known "Albatross" was used as the detector for the third layer. While it was modified to satisfy some of the criteria listed earlier, it proved to be not as robust and reliable as the other two.

A. Beam-Loss Interlocks

Ion-chamber based interlocks are used at several leading US accelerator laboratories. At LANSCE, the ion-chamber based, beam-loss interlock is referred to as the errant beam detector. Errant beams are detected by the radiation generated from beam losses somewhere in the vicinity of the detector. The unique features introduced to make it fail-safe and suitable as a safety interlock are discussed here. For details and other features refer to reference (2).

The ion chamber is filled with nitrogen gas at 1 std. atmosphere, so that if it leaks, the pressure will drop to about 0.75 std. atmosphere. (local atmospheric pressure), and remain mostly nitrogen. After a leak it will still function as a satisfactory ion chamber, albeit with a somewhat lower gain but still within the 20% tolerance.

The signal from the ion chamber is converted to a voltage and presented to two redundant processing channels. Fail-safe operation is achieved by self-checking the common portion and by redundancy in the rest of the unit. Continuous self-testing is implemented using a background current generated by a resistor assembly between the HV and signal electrodes. A fault signal is generated if the ion chamber current is not greater than 80% of the design value for the background current. This checks that the chamber HV has not dropped by more than 20% and checks continuity of the signal cable and HV cable. A fault signal due to excessive beam spill is generated when the ion chamber current (background + signal) is greater than the trip set point (background + threshold).

For those components that are not checked by the self-testing feature, redundancy is used to ensure that no single point failure is unsafe. The device has dual-redundant current sensing circuitry except for the analog input from the chamber (which is checked by the self-testing feature). Redundant fault outputs are supplied to the dual-line interlock system backbone to transmit the shut-off command to accelerator shut-off system. The design has been checked carefully to see that the following types of "single point" failures will be fail-safe: an open, short or significant change in value for resistors and capacitors; an open at any junction between two components; a short between

any two junction points; a short between any junction point and ground; a short between any junction point and the power supply rails; and shorts between any number of pins on a single IC. Additional circuitry monitors power supply voltages and generates a fault signal if these are out of tolerance. On a complete loss of power the system will fault both channels.

A full suite of test functions are available via front panel switches. These are designed to test the full functionality of each leg of the redundant processing circuitry and are performed periodically. An overall test with a source placed on the detector is also perform periodically. Construction, bench testing, installation, repair, maintenance, operation and field testing are covered by documented and approved procedures (3-4).

The final level of redundancy within this layer is achieved by the deployment of extra detectors in the beam tunnel. A spill at any point in the tunnel is viewed by at least two detectors at a specified minimum sensitivity.

The response of this detector has been tested with beam over the full range of dose rates and spill conditions that could be encountered in service at LANSCE (5-6). At the very highest levels (~ 3 rads/pulse) with the short PSR pulse (200 nanosecond width), the response is non-linear but still monotonic. These tests did show the need to keep the threshold setting below the maximum available from the front panel adjustment (administrative control) in order to ensure that the device will always trip for any large spill regardless of pulse width and repetition rate. Administrative control of the threshold settings is also needed because the trip levels required for personnel protection vary with location depending on the configuration of the shielding and distance of the detector from the beam line.

We are convinced that this system now meets the criteria for being fail-safe in the limited sense defined in this paper. It was not easy, as is evidenced by that fact that the present version is Model III. Previous versions were found to have subtle flaws; some found by actual failures in the field, others by additional analysis of the design. Some forty units of Model III have been in service since 1992 with no "unsafe" failures i.e. no failures that were not fail-safe.

B. Beam Current Limiter Interlocks

Some beam facilities are designed or operated to take only a small fraction of the beam current that is possible from the accelerator. For these beam areas, errant beam conditions can include an unintended increase in the beam current directed to the facility. Here, a single device that detects excessive current can protect a large area.

A fail-safe beam current limiter based on a beam current transformer has been developed and implemented at LANSCE. The fail-safe feature is achieved by a combination of self-checking and redundancy. Self-checking is implemented using a test winding on the beam transformer toroid. The signal from the toroid is split and the signals sent to dual-redundant processing channels which present the fault status to the corresponding channels of the dual-redundant RSS "backbone". Faults are generated by failure of the self-checking circuitry or by excess beam current. Loss of power will fault both channels of the unit. The power supply voltages are also checked by the self-check circuitry. A calibrate winding is also installed though the toroid. It permits test signals to be injected to verify proper functioning of all critical features including the proper value of the trip point.

A reliability analysis of this device was performed by an experienced team of safety analysts from LANL in collaboration with the designers of the beam current limiter. It was part of a limited-scope, probabilistic safety analysis of selected safety systems at LAMPF (8).. An analysis of the beam current limiter was performed initially using failure modes and effects analysis and criticality tools to examine the system components and potential failure modes. This was followed by a fault tree analysis. The analysis provide estimates of system unavailability (ratio of average downtime to uptime in the time interval between testing) of 3.7×10^{-3} with an estimated error factor of 2.2. Annual testing and operation for half a year per year were assumed. These imply an estimated failure rate of 1.5×10^{-2}/y for unsafe failures.

Experience with the current limiters has been good. Several units have been in service since 1989 and there have been no unsafe failures. Experience has demonstrated its vulnerability to radiation damage. The electronics are placed near the toroid to minimize electrical noise. In one case

a unit failed that was placed close to a beam stop, however, it failed safe and faulted until replaced. In another case, a unit faulted when exposed to a large radiation pulse produced by beam spill from an occasionally misfiring of the PSR extraction kickers. It always failed safe, but the rate of these false alarms was too high and the unit was withdrawn from service at this location.

There is set of circumstances or accident scenarios where the current limiter interlock will not provide the level of protection usually sought. The limiter operates by sensing the algebraic sum of currents passing through the toroid and does not sense neutral beams or equal mixtures of positive and negatively charged beam. This means it will not function as needed in situations where the beam is partially or totally neutralized. At LANSCE, where H^- beam is used, protection can be lost in accident scenarios where the beam is partially stripped either to H^0 or a neutralized mixture of H^-, H^0 and H^+ before passing through the toroid. Such stripping might be the result of poor vacuum or material that partially covers the beam.

C. Area Radiation Interlocks

An interlocked detector suitable for use outside of the shielding is also a challenging problem, particularly if it is to do double duty i.e. monitor routine levels and serve as an interlock to mitigate any and all prompt radiation accident scenarios. The albatross IV neutron detector was chosen at LANSCE for two reasons; it was designed for use at pulsed accelerators and it was already in routine use at this laboratory (8). It was modified to fail safely on power failures and a self-checking feature was added which required that the detector produce a minimum count rate from an internal gamma-ray source.

For a number of reasons, primarily limited resources and the over confidence that was a result of successful experience with it as a survey instrument, the design of this complex unit was not subjected to the same level of scrutiny as the two other instruments described above. In doing so an important limitation to the dynamic range was overlooked, but one that was pointed out in a subsequent safety review. The Geiger tubes in the unit were used in a counting mode and could "lock up" i.e. cease to count at all at high event rates just when the protection is needed most. The cure was to add current mode detection that is activated at high count rates so that the combination of detection modes covers the required dynamic range.

A radiation detector more suited to safety-interlock requirements is still needed. The Albatross was designed as a survey instrument not as an interlock. It is more complicated than desirable for the interlock function. Reliability has not been as high as with the other instruments. Failure rates in the LANSCE environment have been on the high side and there have been four failures that were not fail-safe. The unsafe failures were investigated and modifications made to prevent future occurrences. Reliability has improved since the last modifications. In the past two years, 40 units were in service and there have been no unsafe failures.

It should be noted that complete coverage outside the shielding is more difficult than in the beam tunnel primarily because the radiation distribution (from a local spill) coming through the shielding is more narrowly concentrated around the direction of the ray with the least number of attenuation lengths. Thus, the spacing of detectors needed for full coverage is reduced and the number required increases.

ASSESSMENT OF RELIABILITY

Demonstration of ultra-low failure rates is difficult. Direct measurement of such rates for a complete system is not practical. One has little choice but to rely on some type of analysis. The techniques of probabilistic risk assessment (PRA) used, for example, in the nuclear reactor industry constitute a well-developed methodology appropriate to this problem. The main thrust of this methodology has been applied to parts of the LANSCE radiation security interlock system (7,9). The reliability analysis of the beam current limiter discussed earlier is a good example. The analysis provides more than just an absolute estimate of failures rates. Once the model has been developed, it can be used to isolate the factors that make the greatest contribution to unreliability. One can also study the effect of changes to the design or to specific input parameters. Relative probabilities are often more accurate than absolute probabilities since common factors drop out of the ratio. Such

analyses help to identify the most cost-effective measures for improving reliability, assuming that the costs of various changes can be estimated readily.

The complexity of probabilistic methods used in PRA is another barrier to acceptance of the conclusions. Those who must act on the results or conclusions often do not have the expertise to adequately judge the results. Peer-review of the study by PRA experts who do not have a vested interest in the outcome can help decision makers.

The operating experience with the 3 specific devices discussed above is reaching the stage where it provides useful data for assessment, perhaps even quantitative estimates, of device reliability. For example, over 100 device-years of service have been logged for the loss monitor device with no failures implying an upper bound on the failure rate in the neighborhood of 10^{-2}/y. Combining the device reliability estimates to produce a reliability estimate for the entire protection system is possible if one assumes statistical independence. The present data is inadequate to test that assumption in a straightforward way.

CONCLUSIONS

The use of instrumentation-driven, beam-limiting and radiation-limiting interlocks for radiation protection is on the increase at US accelerator laboratories. Most would agree that well-conceived and well engineered active protection systems can reduce the risks from prompt radiation accidents. The main debate centers over the extent to which these systems can be used to define the safety envelope for accelerator operations or, expressed in trade jargon, the amount of credit to give to these systems towards meeting safety goals. Acceptance of instrumentation-based radiation safety systems ultimately depends on the confidence that is developed in both the systems' reliability and the systems' "completeness". The latter term refers to the system's ability to deal effectively with all possible prompt radiation accident scenarios.

The set of system requirements and design criteria discussed in this paper are aimed at producing a personnel protection system that is both highly reliable and highly complete in its coverage of accident scenarios. In addition, the requirements and design criteria were formulated to make it possible to objectively determine compliance. The experience, to date, with systems designed to these requirements is encouraging. The problem is challenging but solvable.

ACKNOWLEDGEMENTS

Many people have contributed to the development of the concepts and systems discussed here. I want to acknowledge my many colleagues at LANSCE who made important contributions to development of the concepts and did all of the implementation. They include the LANSCE Radiation Safety Committee, now chaired by Olin van Dyck; Andrew Browman, Floyd Gallegos, Rich Ryder, Mike Plum, David Brown, Martha Zumbro. Mohsen Sharirli played a leading role in our effort to apply the methods of PRA to accelerator safety systems.

An important function was served by a workshop on the subject at Los Alamos chaired by Ralph Thomas. Many of the fundamental concepts discussed here were aired at this workshop and were peer-reviewed by a panel of experts from the field who were in attendance. Proceedings are available as an Los Alamos report (10).

ICRP CONCEPTS AND TASKS IN INTERNAL DOSIMETRY

Alexander Kaul
Bundesamt für Strahlenschutz, D-38201 Salzgitter, Germany

INTRODUCTION

The uptake of a radionuclide and its retention with time in an organ or tissue (source organ or tissue) following its ingestion, inhalation, or systemic administration either by injection or through wounds, is described by biokinetic models, which are sufficiently simple to facilitate estimates of organ equivalent doses for radiation protection purposes. For the assessment of *annual limits for intake of radionuclides by workers* (ALI) and of *dose coefficients for intakes of radionuclides by members of the public* and *patients*, the International Commission on Radiological Protection (ICRP) has developed biokinetic models for the uptake of radionuclides by the gastrointestinal tract and the respiratory system, the latter for different ages. For the *systemic behaviour of radionuclides*, i. e. translocation of radionuclides to and between body organs and tissues, specific biokinetic models were adopted by the ICRP. Considering urinary excretion the ICRP has developed a kidney-bladder model to be applied to all substances used for kidney function tests, and to other radionuclides if urinary excretion results in a significant absorbed dose to the bladder wall.

The fraction of energy absorbed in a target organ or tissue from the transformations of a radionuclide in a source organ or tissue is mathematically described by a dosimetric model.

In the Symposium „Internal Dosimetry" the concepts of the ICRP for the assessment of doses to workers, members of the public and patients from radionuclides are described in detail by K. F. Eckerman and M. Roy considering biokinetic and dosimetric models and dosimetry of the respiratory tract, respectively. In addition application of ICRP concepts of internal dosimetry is presented by J. W. Stather for the special case of estimating the dose to the embryo and fetus following acute and chronic intakes of radionuclides by the mother.

The introductory paper describes present and future activities of the ICRP on internal dose assessments.

PRESENT AND FUTURE TASKS OF THE ICRP IN INTERNAL DOSIMETRY

The 1990 recommendations of the ICRP (1) are based on the most recent information from the epidemilogical studies in the populations of Hiroshima and Nagasaki. These recommendations indicate that the risk of radiation-induced cancer exceeds those assumed in the 1977 recommendations (2) by a factor of 3 to 4. Consequently, the primary dose limits for workers and members of the public were correspondingly reduced, i.e. from 50 mSv per year to 100 mSv during 5 years corresponding to an average of 20 mSv per year, and from 5 to 1 mSv per year, respectively. Consequently the devired or secondary limits, i.e. the ALI and the Derived Air Concentration DAC have to be adapted.

Since Committee 2 of the ICRP is responsible for the development of values of secondary limits and thus for the assessment of those data underlying these limits the major future tasks of the Committee is to adjust internal dose calculations to the new recommandations of the ICRP (1) considering organ/tissue and radiation weighting factors, and taking into account recent knowledge on biokinetic behaviour of radionuclides.

DOSES TO MEMBERS OF THE PUBLIC

As an extension of its work for many years in the field of developing secondary limits for the control of intakes of radionuclides by workers, in March 1987 the ICRP established a Task Group of Committee 2 charged with the assessment of internal dose coefficients as a function of the individual's age. The work of the Task Group has been limited to a consideration of those radioisotopes of elements which are expected to be released into the environment due to human activities, and which may have significance for environmental radiation protection purposes.

Age-dependent ingestion dose coefficients for radioisotopes of 29 elements together with preliminary inhalation dose coefficients for radioisotopes of 11 elements, based on the ICRP 30 lung model and the ICRP 26 tissue weighting factors, were published in Publications 56, 67 and 69 (3, 4, 5). Age-dependent inhalation dose coefficients for radioisotopes of the above 29 elements together with those of curium and calcium were calculated by means of the Human Respiratory Tract Model for Radiological Protection (to be described by M. Roy in this symposium) in ICRP Publication 66 (6) for a median aerodynamic diameter of 1 μm and were published in ICRP Publication 71 (7). Compounds, previously assigned to lung clearance Classes D, W, and Y in Publication 30 (8, 9, 10), have been allocated to lung absorption types F, M and S, with f_1 values for material cleared to the GI tract taken from ICRP publications 56, 67 and 69 (3, 4, 5). If additional information on GI absorption was available, then this was applied and detailed in the datasheets.

In addition, Committee 2 is developing a report on doses to the embryo and fetus following acute or chronic intakes by the mother of radioisotopes of the above 29 elements plus curium and calcium (to be described by J. W. Stather in this symposium).

A further activity of Committee 2 is to estimate the reliability of ICRP's dose coefficients for intakes of radionuclides by ingestion and inhalation. The main aim is to develop an approach which should be quantitative, selective, addressing only health individuals of various ages and a limited number of elements. Reliability refers to

- the GI tract model,
- f_1 values for gastrointestinal absorption,
- the respiratory tract model,
- systemic biokinetic models.

In addition, uncertainty concerns the biokinetics of radioactive progeny produced in the body. Variability of doses will be considered quantitatively for specified examples of elements.

DOSES TO WORKERS

The terms of reference of the Task Group of Committee 2 on Internal Dosimetry was extended in 1993 to include a revision of ICRP Publications 30 (8, 9, 10) on Limits for Intakes of Radionuclides by Workers ALI. In order to permit immediate application of the Commission's 1990 Recommendations (1), revised values of the ALI based on the methodology and biokinetic information from ICRP Publication 30, but which incorporated the new dose limits and radiation and tissue weighting factors, were calculated by the Task Group on Dose Calulations and issued as ICRP Publication 61 in 1991 (11).

Since issuing this Publication, ICRP has published the revised kinetic and dosimetric model of the respiratory tract in Publication 66 (6). To give values of inhalation dose coefficients for workers using this new model, both Task Groups an Internal Dosimetry and Dose Calculations of Committee 2 have recalculated the dose coefficients for workers underlying the ALI in

Publication 61 (11). These revised dose coefficients were published as ICRP Publication 68 (12).

In due time, possibly in about 5 years, a complete revision of ICRP Publication 30 (8, 9, 10) will be issued, taking into account new anatomical and physiological data, and newer biokinetic models. It is intended to publish inhalation and ingestion dose coefficients for radioisotopes of elements being relevant for work places, together with bioassay data for monitoring purposes.
The comprehensive revision of Publication 30 will include:

- a review of the choice of lung absorption parameters and default absorption types for inhalation of different chemical forms of the elements found in the workplace;
- a consideration of data on f_1 values for ingested or swallowed chemical forms after inhalation;
- an update of the biokinetic data and models for systemic activity for the elements not covered in Publications 56, 67, 69, and 71 (3, 4, 5, 7);
- provision of models that can be used both for internal dosimetry and for interpretation of bioassay data.

An interim revision of ICRP Publication 54 (13) on „Individual Monitoring for Intakes of Radionuclides by Workers: Design and Interpretation" is inteded to be published early in 1997 to provide data for monitoring that are consistent with ICRP Publication 68 (12). The report will cover selected radioisotopes of the following elements: ^{3}H, Fe, Sr, Ru, I, Cs, Ra, Th, U, Pu, Am, Cu, and Cf. Tabular data will be provided for the excretion over the first 7 days post intake. Equilibrium levels will be given only for long-lived radionuclides.

The Task Group on Dose Calculations is giving consideration to changes in dosimetric models before the revision of Publication 30 (7, 8, 9) can be issued. These include:

- modifications to absorbed fractions of α and β/γ emitters deposited in the skeleton;
- need to allow for bremsstrahlung in the calculation of the Specific Effective Energy;
- use of phantoms based on medical imaging data for dosimetric modelling;
- taking account of the distribution of blood in different organs and tissues;
- consideration of new Reference Man data for the distribution of red bone marrow;
- consideration of females;
- depth doses in walled organs, e.g. the urinary bladder;
- the possibility of a revised model for the GI tract.

For dosimetric purposes parts of Publication 23 (14) on Reference Man will be revised. The report on skeleton was published recently as Publication (15).

The report on anatomical data and gross body composition is under preparation. Further reports will be on

- elemental composition,
- physiological data, and
- gastrointestinal tract.

DOSES TO PATIENTS

In 1988 a Task Group of ICRP Commitee 2 has published a report as Publication 53 (16) on Absorbed Doses to Patients from Radiopharmaceuticals to give absorbed and effective

doses for 113 radiopharmaceuticals labelled with 74 radioisotopes of 36 elements, including the range of variation to be expected in pathological states, for adults, children, infants and the fetus. This data is continuously updated by a Task Group of Committees 2 and 3 and published as addenda to the Annals of the ICRP (17), and can be used also as a measure for the dose from occupational exposure of personal engaged in the manufacture or use of radiopharmaceuticals.

DOSIMETRY OF THE RESPIRATORY TRACT

Monique Roy

Institut de Protection et de Sûreté Nucléaire, Fontenay aux Roses 92265 France

INTRODUCTION

A new dosimetric model of the human respiratory tract has been recently recommended by the International Commission on Radiological Protection, in ICRP Publication 66 (1). This model was intended to update the previous lung model of the Task Group on Lung Dynamics (2) that was adopted by ICRP in Publication 30 (3). With this aim, extensive reviews of the available knowledge were made for anatomy and physiology of the respiratory tract and for deposition, clearance and biological effects of inhaled radionuclides. Finally, expanded dosimetry requirements resulted in a widely different approach from the former model. The main features of the new model are the followings: instead of calculating the average dose to the total mass of blood filled lung, the model takes account of differences in radiosensitivity of the various respiratory tract tissues. It applies not only to adult workers but also to all members of the population, and provides reference values for children aged 3 months, 1, 5, 10, and 15 years, and adults. Deposition modelling of airborne gases and aerosols associates age dependent breathing rates, airway dimensions and physical activity, to particle size, density and chemical form of inhaled material. Clearance results of competition between mechanical transport clearance and absorption to blood. At each step of the calculation, adjustment guidance is provided to account for use of exact values of particle sizes and specific dissolution rates of inhaled material in order to calculate their own parameter of retention in the airways, and to assess accurately doses to the respiratory tract. Possible influence of smoking, of respiratory tract diseases and of eventual exposure to airborne toxicants is also addressed.

MORPHOMETRY

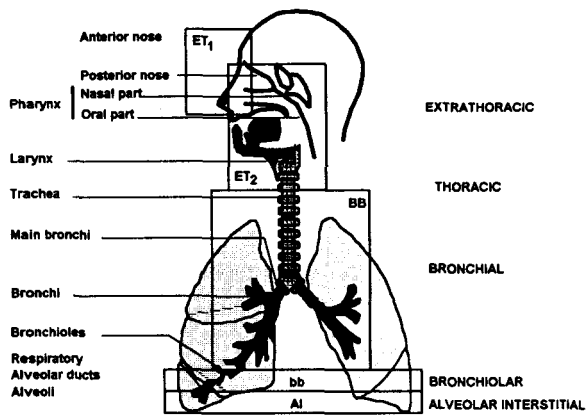

Figure 1: Respiratory tract regions of the model.

The dosimetric model considers the respiratory tract as four anatomical regions (**Figure 1**):

- **ET**, Extrathoracic region comprising the anterior nose, $\mathbf{ET_1}$ and the posterior nasal passages, larynx, pharynx, and mouth, $\mathbf{ET_2}$;
- **BB**, the bronchial region, consisting of the trachea and bronchi from which deposited material is cleared by ciliary action;
- **bb**, the bronchiolar region, consisting of the bronchioles and the terminal bronchioles;
- **AI**, the alveolar-interstitial region, consisting of the respiratory bronchioles, the alveoli and the interstitial connective tissue.

All four regions contain lymphatic tissue and lymph nodes, LN_{ET} that drain the extrathoracic region, and LN_{Th} that drain the thoracic region.

The cytology, histology and morphometric structure are modelled for each region. Reference values for dimensions important to dose calculation are specified, such as airway dimensions, lengths and diameters, and masses of target organs.

TISSUES AND CELLS AT RISK

Information about effects of radiation on the respiratory tract were reviewed from animal studies and data from irradiated human populations. The most sensitive tissues and cells to radiation-induced cancer were identified. The target tissues in each region are located at different depth from the airway surface:

- in ET, the average depth of the target basal cell nuclei is 40-50 micrometers (μm).
- in BB, the average depth of the target secretory and basal cell nuclei are 10-40 and 35-50 μm, respectively.
- in bb, the average depth of the target secretory cell nuclei are 4-12 μm.
- in AI, where the target Clara cells and type II alveolar cells are covering the alveolar surface, the average dose is calculated to the whole region.

To take account of differences in sensitivity between tissues, each region is given a risk apportionment factor that represents the contribution from each region towards the total detriment associated with lung.
Although it is generally accepted that the regions of the respiratory tract differ greatly in radiosensitivity, and in their contribution to the total radiation detriment, precise data on regional sensitivity is lacking. Therefore, the weighting factor of 0.12, given by ICRP 60 (4) is divided equally among the bronchial, bronchiolar and alveolar-interstitial regions. In the extra-thoracic region, clinical observations suggest that the risk is to the posterior nose, larynx and pharynx. **(Table I)**

Table I: Detriment apportionment factors in the airways.

Tissue	Lung W_T ICPR 60	Apportionment factors ICPR 66
Extra-thoracic region	**0,025**	
ET_1 Anterior nose		0,001
ET_2 Posterior nasal passages pharynx, larynx mouth		0,998
LN_{ET} Lymphatics		0,001
Thoracic region	**0,12**	
BB Bronchial		0,333
bb Bronchiolar, G9-G16		0,333
AI Alveolar, interstitial		0,333
LN_{TH} lymphatics		0,001

PHYSIOLOGY

Aerosol inhalability, partitioning of airflow between nose and mouth as well as breathing rates determine the amount of radionuclides inhaled. Therefore comprehensive reference values for volumes and frequencies are recommended for adults of both genders and children aged 3 months, 1, 5, 10, and 15 years, for various levels of activity: resting, sitting, light and heavy exercise. Information is also provided to derive appropriate values for various ethnic groups. Combined with habit data of physical activity, they allow to give reference volumes inhaled per day, for reference age groups of a population.

DEPOSITION

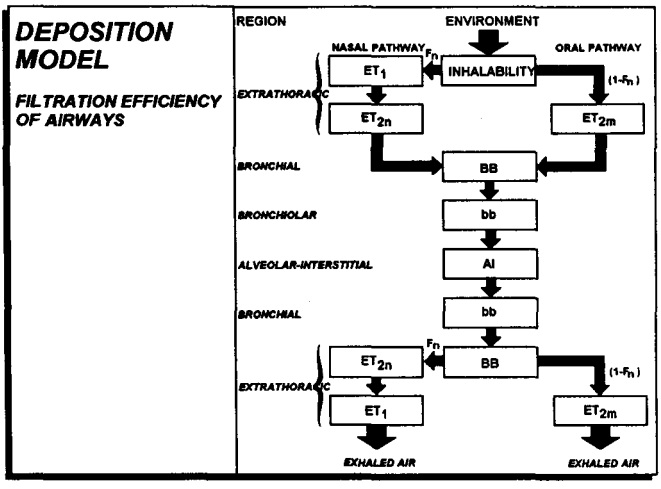

Figure 2: Deposition model: Fn = fractional airflow through nose; 1-Fn = fractional airflow through mouth.

The deposition model describes the initial process that determine the fractions of the inhaled material remaining in the four regions of the airways after expiration. (**Figure 2**). Deposition efficiencies are calculated from human measurements in relationship with particle sizes and airflows. In order to predict deposition in women and children these values are scaled by airway dimensions and breathing rates. The regions are treated as a series of filters. Their efficiencies are assessed on aerodynamic processes such as gravitational settling and inertial impaction, and the thermodynamic process of diffusion, acting during both inspiration and expiration. Deposition fractions are calculated for all possible aerosols (0.0006-100μm) assuming log/normal particle size distributions. Corresponding curves for each population age group are also given as functions of the activity median thermodynamic diameter, **AMTD**, and of the activity median aerodynamic diameter, **AMAD.** Guidance is given to take account of the growth of hygroscopic particles in the airways during the respiratory cycle.

In the absence of information on the particle sizes, deposited fractions are calculated for default values. AMAD of 5μm for workers and 1μm for the public are recommended, with reference to published experimental data in the relevant environments. Whenever particle sizes are readily measured, input of this data is recommended.

A material specific model is derived for gases and vapours. Inhaled gas molecules reaching the airways return to the expired air unless they dissolve in or react with the surface lining. Information on these solubility and reactivity properties are obtained from experimental data.
As default approach the model assigns gases and vapours to three classes:

- **SR-0**. Insoluble and non-reactive: negligible deposition in the respiratory tract. In many cases dose is from the filling air irradiation to the airways.
- **SR-1**. Soluble or reactive: deposition may occur throughout the respiratory tract; in the absence of other information 100% deposition is assumed with the following distribution: 10% ET1, 20% ET2, 10% bb, 20% BB, and 40% AI.
- **SR-2**. Highly soluble or reactive: total deposition and instantaneous translocation to blood in the extrathoracic region.

CLEARANCE

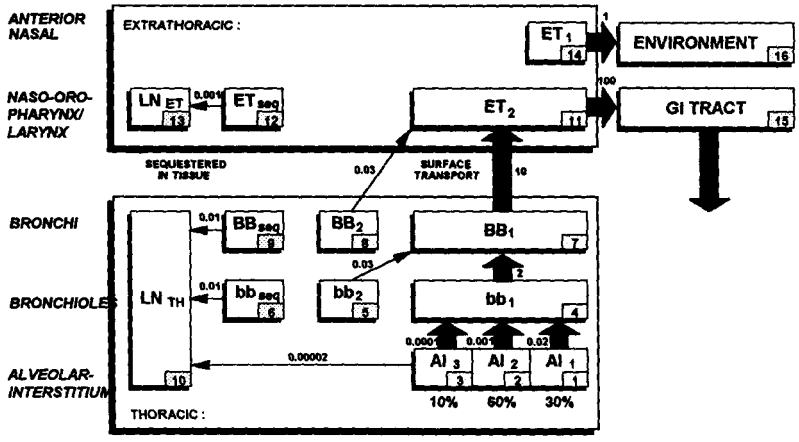

Figure 3: Particle transport model. Rate constants are in d^{-1}.

In each region, after deposition, clearance rates will change with time, and are represented in the model by a combination of compartments. Each one clears at a specific constant rate, independent of age and sex.
Material deposited in ET1 is removed by extrinsic means such as nose blowing but in other regions clearance is competitive between two complementary processes: **particle transport** towards the gastro-intestinal tract and lymph nodes, and **absorption** into body fluids.

Particle transport rates are assumed to be the same for all deposited aerosols and the values of rate constants were derived from experimental studies, so far as possible from human data. An ideally insoluble material deposited in the airways would be cleared according to the model described in **Figure 3.**

Absorption into body fluids depends on the physical and chemical form of the deposited material. It is assumed to occur at the same rate in all regions, except ET1, where none occurs. Absorption into blood is generally a two stage process. (**Figure 4**)

- dissociation of the particles into material that can be absorbed into blood,
- dissolution, then absorption into body fluids of soluble material and of material dissolved from particles.

Rates of absorption observed for compounds for which reliable human or animal data exist are preferably used in the model. Otherwise, default values of absorption rates are specified according to whether the absorption rate is considered to be fast (Type F), moderate (M) or slow (S).

These absorption rates as approximate half-times are:

- 10 minutes for 100% of F material,
- 10 minutes for 10% and 140 days for the remaining 90% of M material, and
- 10 minutes for 0.1% and 7000 days for the remaining 99.9% of S material. (It has been observed that even the most insoluble material show an early absorption of a small fraction of the amount deposited). **(Table II)**

Table II: Default absorption parameters for Type **F, M** and S material

Type of absorption	F (fast)	M (moderate)	S (slow)
Fraction dissolved rapidly, f_r	1	0.1	0.001
Rapid dissolution rate, s_r, d^{-1}	100	100	100
Slow dissolution rate, s_s, d^{-1}		0.005	0.0001

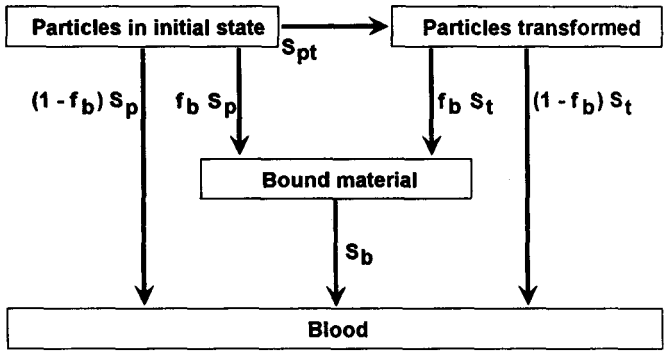

Figure 4: Airway to blood absorption model:

Sp	= rate of dissolution in initial state;
Spt	= rate of transformation;
St	= rate of dissolution in transformed state;
fb	= fraction retained in bound state;
Sb	= rate of dissolution in bound state.

CALCULATION OF TISSUE AVERAGE DOSE

Doses are calculated in accordance with the ICRP 30 approach, in which energy absorbed is averaged over the mass of the target tissue in each organ. The results are then summed up for each region. The committed equivalent dose is calculated over an average working life of 50 years, for workers, and life span of 70 years for persons of the public. These regional equivalent doses are weighted for relative radiation sensitivity using the above defined apportionment factors. The adjusted values are summed separately for the whole extrathoracic and thoracic regions. To these two equivalent tissue doses the ICRP 60 weighting factors are then applied to calculate their contribution to effective dose:

- 0.12 to the thoracic region formerly specified for lungs, and
- 0.025 to the extra-thoracic region, half of the remainders', when it exceeds the highest dose in any of the twelve specified organs.

For inhalation, the age-dependency of dosimetry relates mainly to the smaller sizes of airways and to specific values of deposition. As clearance is not precisely known in children, adult parameters are used as default for particle transport and absorption to blood through airways. Finally, breathing rates being smaller in children, smaller intakes balance higher doses per unit of intake, and the resulting effective doses are close to the adults' for the same exposition.

Effective Doses per Unit of Intake, (Sv. Bq^{-1}) have been calculated with this model for inhaled radionuclides that are most important to Radioprotection. They are now given in Publication 68, (5) for workers and in Publication 71, (6) for members of the public. Compared with doses previously given by ICRP Publication 30, for workers, the data obtained with the new model tend to be:

- lower for soluble alpha and beta emitters,
- similar for moderately soluble material, except for long-lived transuranic isotopes where the recent calculations give twofold lower doses,
- lower for the insoluble forms of most of the radionuclides.

The fact that Publication 68 gives lower doses than those given by Publication 30 is mainly related to deposition that was overestimated by ICRP 30 in the thoracic regions, and in the case of former class D, to slower absorption to blood than in the recently reviewed Type F.

Examples of comparison of Annual Limits of Intakes, calculated for workers according to both publications, are presented in **Table III**. In the case of Publication 30, the primary limit of annual effective dose is 50 mSv,

whereas in Publication 68 it is 20 mSv. Particle size defaults are: 1 μm AMAD, in Publication 30 and 5 μm AMAD in Publication 68, (ALI for 1 μm AMAD are also given to allow for exact comparison).

Table III: Annual Limits for Intakes of some radionuclides inhaled by workers

	CIPR 30		CIPR 68 (1 μm)		CIPR 68 (5 μm)
^{60}Co	W	6×10^6	M	2.1×10^6	2.8×10^8
	Y	1×10^6	S	0.7×10^6	1.2×10^6
^{131}I	D	2×10^6	F	2.6×10^6	1.8×10^6
^{137}Cs	D	6×10^6	F	4.2×10^6	3.0×10^6
^{235}U	D	5×10^4	F	3.9×10^4	3.3×10^4
	W	3×10^4	M	7.1×10^3	1.1×10^4
	Y	2×10^3	S	2.6×10^3	3.3×10^3
^{237}Np	W	200	M	950	1.3×10^3
^{239}Pu	W	200	M	425	625
	Y	500	S	1330	2410
^{241}Am	W	200	M	510	740
E*	**50 mSv**		**20 mSv**		

* = Annual limit of Effective dose

CONCLUSION

The new Human Respiratory Tract Model for Radiological Protection provides flexibility to calculate doses for a wide range of exposure conditions and for specific individuals. This flexibility also allows for revision of reference parameters as new information becomes available without changing the general model characteristics. The wide availability of personal computers allows the user to go into detailed dose calculations and to modify standards values. Recent softwares have been developed for this purpose.

RADIATION DOSES TO THE EMBRYO AND FETUS FOLLOWING INTAKES OF RADIONUCLIDES BY THE MOTHER

J Stather, A Phipps and A Khursheed

National Radiological Protection Board
Chilton, Didcot, Oxon, UK, OX11 ORQ

ABSTRACT

In 1987 the International Commission on Radiological Protection set up a Task Group of Committee 2 charged with the responsibility for calculating radiation doses from incorporated radionuclides for all age groups in the population. This includes the development of models for calculating doses to the embryo and fetus following intakes of radionuclides by the mother.

The development of models for calculating doses to the embryo and fetus is complex. Particular problems that have had to be addressed are the limited amount of human data available and the consequent need to use both the results of animal studies and chemical analogies; the varying rate of tissue and organ development in different species; the lack of detailed information on the distribution and retention of radionuclides in tissues of the embryo and fetus following intakes by the mother, either before or during gestation; and the radiation sensitivity of tissues of the embryo and fetus.

In the development of dosimetric models for specific elements, human data have been used as far as is possible. Where this has not been available a generic modelling approach has been adopted. The models are being used to calculate doses to both mother and offspring for acute and chronic intakes, both before conception and at various times during gestation. Committed doses are being calculated as well as doses to birth. The results of preliminary dose calculations are considered.

RADIATION DOSES TO THE EMBRYO AND FETUS FOLLOWING INTAKES OF RADIONUCLIDES BY THE MOTHER

INTRODUCTION

The need for the assessment of radiation doses to all age groups in the population from both naturally occurring and artificial radionuclides present in the environment is increasingly being recognised by national and international organisations. Whilst dosimetric models for infants and children can generally be based on those developed for adults, with appropriate modifications to biokinetic parameters[1], in the case of exposures *in utero* fundamentally new models need to be developed. Such models are also important for assessing doses to the embryo and fetus for women who may be either occupationally exposed or given radio-labelled drugs for clinical reasons. In the most recent recommendations of the International Commission on Radiological Protection, ICRP[2] particular emphasis is placed on measures to control exposures *in utero* for women who are occupationally exposed. This arises because of the recognition of the greater sensitivity of developing tissues to ionising radiation[3,4] and the need to treat the fetus broadly as a member of the public.

There are at present no generally accepted methods for calculating radiation doses to the developing embryo and fetus following intakes of radionuclides by the mother. A number of laboratories have developed models for a few radionuclides[5-7] and recently the United States Nuclear Regulatory Commission issued a report describing approaches to calculating doses to the embryo and fetus from internally incorporated radionuclides[8]. Ideally, dosimetric models should be based on human data but information is available for radioisotopes of only a few elements and for most the results of animal experiments must be used, although even here data are frequently very limited. Models may also be based on chemical analogies.

An ICRP Task Group on Internal Dosimetry (INDOS) is developing models that can be used for calculating doses to the embryo and fetus following intakes of radionuclides by the mother. Specific information will be used, as far as is possible. When appropriate data are not available, a generic modelling approach has been adopted.

STAGES OF DEVELOPMENT

When calculating doses from incorporated radionuclides the different stages in development of the conceptus need to be taken into account.

Pre-implantation

In most mammalian species, the ovum passes from the oviduct into the uterine lumen a few days after fertilization and implants in the mucosa about 2 to 3 days later, ie at about 6 to 7 days after fertilization. At implantation the developing conceptus (blastocyst) weighs less than 10 μg and consists of an outer layer of trophectoderm cells, which will give rise to the bulk of the placenta and the inner cell mass from which the embryo and the fetal membranes will form. It is thought to be nourished by the transfer of low molecular weight substances in uterine secretions through the zona pellucida[9]. The timing of this initial period is very similar in most mammalian species (Table 1).

The Embryo

After embedding in the epithelial lining of the uterus the implanted cell mass becomes closely surrounded by maternal tissue, the progressive erosion of this tissue constituting a source of nourishment. The period of organ formation may be considered to last up to about the end of the second month, at which time the developing embryo

still weighs less than 10 g[10]. Because of the close apposition between the embryo and the uterus wall, it has been commonly assumed, in the absence of more specific information, that the dose to the embryo up to the end of the second month of gestation can be approximated by the dose to the uterus. While this may be a reasonable approximation for many ß/γ emitters it is not necessarily the case for alpha emitters which have a short path length (a few tens of μm) in tissue.

The Fetus

From the end of organogenesis (taken to be 60 days post conception in man, Table 1) progressive formation of new tissue (histogenesis) and growth are the characteristic processes that take place during the fetal period. There are, however, significant differences between species in this latter stage of pregnancy. The human fetus, as with most other mammalian species, is contained in the amniotic fluid where it is surrounded by fetal membranes and nourished via the placenta through the umbilical cord. The newborn child at birth weighs about 3.5 kg. The mass of the conceptus has thus increased about five-hundred fold from the end of the embryonic period to birth and by more than a factor of 10^7 since conception.

The Newborn Child

The amount of radionuclide present in the newborn child also needs to be estimated. The calculated body content at birth may then be used to calculate the committed dose to age 70 years using biokinetic models for infants and children given in ICRP Publications 56, 67 and 69[1,11,12].

DEVELOPMENT OF BIOKINETIC AND DOSIMETRIC MODELS

Transfer of Radionuclides to the Fetus

Radioactive materials have to cross a number of membrane barriers to reach the tissues of the embryo and fetus from the maternal circulation. The processes involved in this transfer include simple diffusion, facilitated transport, active transport, movement through pores and channels, and pinocytosis[13-16]. Radionuclides which are isotopes of stable elements that are required by the developing embryo and fetus will follow the normal pathways for that element (eg, Na, K, Ca). Isotopes of elements that have similar chemical properties to essential elements are likely to follow similar pathways, although the rates of transfer may differ (eg, Cs behaves similarly to K, Sr like Ca). For other radionuclides the rates of transfer to the embryo and fetus will depend upon their chemical affinity for different transport systems in the body and, as a result, the extent of uptake is unpredictable.

Human data: Most available human data on placental transfer of radionuclides are available from studies with labelled metabolites or pharmaceuticals although some data are available for radionuclides in weapons fallout (eg, Sr, I, Cs). Analyses of autopsy samples have given information on both naturally occurring and artificially produced radionuclides and some comparative information has been obtained through *in vitro* perfusion studies using human placentas.

The rather limited amount of human data makes it essential to use the results of animal studies in the development of dosimetric models for man, although even here information is frequently very limited.

Animal data: In the extrapolation of animal data to man, care is needed; particular problems in the development of dosimetric models for the embryo and fetus include: the varying progress of organ development in different species; the presence of several types of placenta in different species, all of which provide a selective but potentially different barrier between maternal and fetal blood; the rapidity of growth; the complex pattern of growth and differentiation with the potential for quite different distributions of radionuclides in the embryo and fetus from that in the mother; and uncertainty about the location of sensitive cells at various stages of development. The pattern of results obtained experimentally for most radionuclides is similar, although overall transfer to the newborn is very variable. In general, concentrations of radionuclides at birth are highest following intakes towards the end of pregnancy although the concentrations are less than in normal tissues. For some bone-seeking radionuclides (eg, Sr) administered at the end of gestation, however, the concentration may be higher in the newborn than the mother, reflecting the demand of the rapidly developing skeleton for calcium.

Dosimetric models: In the development of dosimetric models information is ideally needed on the initial uptake of the radionuclide by the fetal and maternal tissues following its entry into maternal blood and on its subsequent distribution and retention. Data are required on the extent to which activity deposited in maternal tissues is subsequently translocated to the fetus[7] and doses to the fetus from maternal deposits of radionuclides also need to be assessed.

Where sufficient information is available on the uptake and distribution of radionuclides in the embryo and fetus then elemental specific models are being developed. This applies for example to tritiated water and to isotopes of Fe, Sr, I and Cs. For most other elements animal studies provide the basis for the models. In practice, for many elements studies with experimental animals may only give data on relative concentration ratios in the fetal and maternal tissues (C_F/C_M) and details of the distribution of radionuclide in fetal tissues are often not given. In these circumstances, a general approach has been adopted for calculating the dose to the developing embryo and fetus.

For the embryo (to 60 days after conception), the dose is taken to be the same as that to the uterus; on this basis all tissues of the embryo will receive the same dose. For calculating the dose to the tissues of the fetus for non-penetrating radiation (alpha and beta emissions and photons with E <10 keV), experimentally determined C_F/C_M ratios obtained shortly after administration of radionuclides to the mother are used. Multiplying this ratio by the dose to maternal tissues gives an estimated dose to the fetal tissue, on the assumption that the distribution of activity in the fetus is the same as that in the mother. This approach is expected to be conservative in most instances as rapid growth of the fetus will reduce the concentration of radionuclides in fetal tissue, although this dilution effect may be to some extent offset by transfer to the fetus from radionuclide deposits in the maternal tissues. A number of radionuclides would be expected to equilibrate rapidly between maternal and fetal tissues. These include isotopes of the alkali metals, which are predominantly ionic in body fluids and have a rapid turnover in tissues, as well as many tritium and ^{14}C labelled compounds.

For the majority of radionuclides, penetrating radiation from activity deposited in maternal tissues will also contribute to the dose to the fetus. This dose is presently taken to be the same as the dose to the uterus. It is expected that in final calculations doses will be based on models for a pregnant woman.

As indicated above, for many animal studies the distribution of radionuclide in fetal tissues is not reported and the assumption has therefore to be made for calculating doses that the distribution in the fetus is the same as that in the mother. Recent autoradiographic studies have, however, shown that following administration to the mother early in gestation there can be a significant uptake of some radionuclides in the yolk sac membranes (eg, ^{95}Nb, ^{106}Ru, ^{210}Po and ^{239}Pu). This may be important as haemopoietic development involves the migration of stem cells and it appears likely that the primitive stem cell population may arise in the yolk sac, or even at the earlier egg cylinder stage. These stem cells may subsequently migrate to the liver once the extra embryonic and embryonic circulations become connected. Ultimately haemopoietic stem cells pass to the bone marrow. It has therefore been proposed that for calculating doses to the haemopoietic stem cells in the developing fetus, the calculated dose should reflect this migration and the potential of these cells to receive a radiation dose at different sites in the body (yolk sac, liver and bone marrow), taking into account the appropriate period of gestation in the human.

DOSE COEFFICIENTS FOR THE EMBRYO AND FETUS

For the calculation of dose coefficients a range of intake regimens by the mother have been adopted that should allow doses to the embryo and fetus to be determined for any pattern of exposure of the mother. For acute exposures, intakes of radionuclides by ingestion or inhalation (for aerosols with activity median aerodynamic diameters of 1 μm and 5 μm) are taken to occur at the start of weeks 1, 5, 10, 15, 25 and 35 of pregnancy and at 6 months and 2½ years before conception. For chronic exposures, intakes are taken to occur during the year of pregnancy starting from the time of conception, and for 1 year and 5 years before conception. It is proposed that in the final report equivalent doses to the date of birth will be given for the embryo and fetus for all tissues with a specific tissue weighting factor in adults as well as the average dose to remainder tissues (calculated as the mass weighted average). The effective dose will also be given using the w_Ts recommended by ICRP in Publication 60[2]. Whilst these values are not strictly appropriate for exposures *in utero*, they have been used as no alternative tissue weighting factors are presently available. The effective dose provides a useful quantity for assessing the consequences of different patterns of intake of radionuclides and for comparison with maternal doses. Effective doses (to age 70 years) received after birth will also be calculated, together with the total effective dose (before and after birth) received by the offspring and its ratio to the total committed effective dose received by the mother. It

is intended that the dose coefficients will be given for all elements and radionuclides in Publications 56, 67, 69 and 71[1,11,12,17]. The results of some preliminary calculations are given in Tables 2 and 3.

In general, the results of preliminary calculations indicate that for many radionuclides doses to the offspring will be less than those to the mother. For isotopes of caesium and other radionuclides that equilibrate rapidly in the body, the dose to the newborn child is expected to be similar to that of the mother, although the total committed dose may be much less (Table 1). For acute intakes of ^{131}I late in pregnancy the dose to the newborn child may approach twice that of the mother. Similarly, intakes of alkaline earth radionuclides towards the end of pregnancy can result in higher doses to fetal tissues at birth than to maternal tissues, although the total committed dose to the offspring will be less. There is little suggestion that doses to the child will be appreciably higher than maternal doses, particularly for chronic intakes by the mother either before or during pregnancy.

It is expected that the report will be ready for publication in about 18 months time.

RADIATION DOSES TO THE EMBRYO AND FETUS FOLLOWING INTAKES OF RADIONUCLIDES BY THE MOTHER

National Radiological Protection Board
Chilton, Didcot, Oxon, UK, OX11 ORQ

INTRODUCTION

The need for the assessment of radiation doses to all age groups in the population from both naturally occurring and artificial radionuclides present in the environment is increasingly being recognised by national and international organisations. Whilst dosimetric models for infants and children can generally be based on those developed for adults, with appropriate modifications to biokinetic parameters[1], in the case of exposures *in utero* fundamentally new models need to be developed. Such models are also important for assessing doses to the embryo and fetus for women who may be either occupationally exposed or given radio-labelled drugs for clinical reasons. In the most recent recommendations of the International Commission on Radiological Protection, ICRP[2] particular emphasis is placed on measures to control exposures *in utero* for women who are occupationally exposed. This arises because of the recognition of the greater sensitivity of developing tissues to ionising radiation[3,4] and the need to treat the fetus broadly as a member of the public.

There are at present no generally accepted methods for calculating radiation doses to the developing embryo and fetus following intakes of radionuclides by the mother. A number of laboratories have developed models for a few radionuclides[5-7] and recently the United States Nuclear Regulatory Commission issued a report describing approaches to calculating doses to the embryo and fetus from internally incorporated radionuclides[8]. Ideally, dosimetric models should be based on human data but information is available for radioisotopes of only a few elements and for most the results of animal experiments must be used, although even here data are frequently very limited. Models may also be based on chemical analogies.

An ICRP Task Group on Internal Dosimetry (INDOS) is developing models that can be used for calculating doses to the embryo and fetus following intakes of radionuclides by the mother. Specific information will be used, as far as is possible. When appropriate data are not available, a generic modelling approach has been adopted.

STAGES OF DEVELOPMENT

When calculating doses from incorporated radionuclides the different stages in development of the conceptus need to be taken into account.

Pre-implantation

In most mammalian species, the ovum passes from the oviduct into the uterine lumen a few days after fertilization and implants in the mucosa about 2 to 3 days later, ie at about 6 to 7 days after fertilization. At implantation the developing conceptus (blastocyst) weighs less than 10 μg and consists of an outer layer of trophectoderm cells, which will give rise to the bulk of the placenta and the inner cell mass from which the embryo and the fetal membranes will form. It is thought to be nourished by the transfer of low molecular weight substances in uterine secretions through the zona pellucida[9]. The timing of this initial period is very similar in most mammalian species (Table 1).

The Embryo

After embedding in the epithelial lining of the uterus the implanted cell mass becomes closely surrounded by maternal tissue, the progressive erosion of this tissue constituting a source of nourishment. The period of organ formation may be considered to last up to about the end of the second month, at which time the developing embryo

still weighs less than 10 g[10]. Because of the close apposition between the embryo and the uterus wall, it has been commonly assumed, in the absence of more specific information, that the dose to the embryo up to the end of the second month of gestation can be approximated by the dose to the uterus. While this may be a reasonable approximation for many ß/γ emitters it is not necessarily the case for alpha emitters which have a short path length (a few tens of μm) in tissue.

The Fetus

From the end of organogenesis (taken to be 60 days post conception in man, Table 1) progressive formation of new tissue (histogenesis) and growth are the characteristic processes that take place during the fetal period. There are, however, significant differences between species in this latter stage of pregnancy. The human fetus, as with most other mammalian species, is contained in the amniotic fluid where it is surrounded by fetal membranes and nourished via the placenta through the umbilical cord. The newborn child at birth weighs about 3.5 kg. The mass of the conceptus has thus increased about five-hundred fold from the end of the embryonic period to birth and by more than a factor of 10^7 since conception.

The Newborn Child

The amount of radionuclide present in the newborn child also needs to be estimated. The calculated body content at birth may then be used to calculate the committed dose to age 70 years using biokinetic models for infants and children given in ICRP Publications 56, 67 and 69[1,11,12].

DEVELOPMENT OF BIOKINETIC AND DOSIMETRIC MODELS

Transfer of Radionuclides to the Fetus

Radioactive materials have to cross a number of membrane barriers to reach the tissues of the embryo and fetus from the maternal circulation. The processes involved in this transfer include simple diffusion, facilitated transport, active transport, movement through pores and channels, and pinocytosis[13-16]. Radionuclides which are isotopes of stable elements that are required by the developing embryo and fetus will follow the normal pathways for that element (eg, Na, K, Ca). Isotopes of elements that have similar chemical properties to essential elements are likely to follow similar pathways, although the rates of transfer may differ (eg, Cs behaves similarly to K, Sr like Ca). For other radionuclides the rates of transfer to the embryo and fetus will depend upon their chemical affinity for different transport systems in the body and, as a result, the extent of uptake is unpredictable.

Human data: Most available human data on placental transfer of radionuclides are available from studies with labelled metabolites or pharmaceuticals although some data are available for radionuclides in weapons fallout (eg, Sr, I, Cs). Analyses of autopsy samples have given information on both naturally occurring and artificially produced radionuclides and some comparative information has been obtained through *in vitro* perfusion studies using human placentas.

The rather limited amount of human data makes it essential to use the results of animal studies in the development of dosimetric models for man, although even here information is frequently very limited.

Animal data: In the extrapolation of animal data to man, care is needed; particular problems in the development of dosimetric models for the embryo and fetus include: the varying progress of organ development in different species; the presence of several types of placenta in different species, all of which provide a selective but potentially different barrier between maternal and fetal blood; the rapidity of growth; the complex pattern of growth and differentiation with the potential for quite different distributions of radionuclides in the embryo and fetus from that in the mother; and uncertainty about the location of sensitive cells at various stages of development. The pattern of results obtained experimentally for most radionuclides is similar, although overall transfer to the newborn is very variable. In general, concentrations of radionuclides at birth are highest following intakes towards the end of pregnancy although the concentrations are less than in normal tissues. For some bone-seeking radionuclides (eg, Sr) administered at the end of gestation, however, the concentration may be higher in the newborn than the mother, reflecting the demand of the rapidly developing skeleton for calcium.

Dosimetric models: In the development of dosimetric models information is ideally needed on the initial uptake of the radionuclide by the fetal and maternal tissues following its entry into maternal blood and on its subsequent distribution and retention. Data are required on the extent to which activity deposited in maternal tissues is subsequently translocated to the fetus[7] and doses to the fetus from maternal deposits of radionuclides also need to be assessed.

Where sufficient information is available on the uptake and distribution of radionuclides in the embryo and fetus then elemental specific models are being developed. This applies for example to tritiated water and to isotopes of Fe, Sr, I and Cs. For most other elements animal studies provide the basis for the models. In practice, for many elements studies with experimental animals may only give data on relative concentration ratios in the fetal and maternal tissues (C_F/C_M) and details of the distribution of radionuclide in fetal tissues are often not given. In these circumstances, a general approach has been adopted for calculating the dose to the developing embryo and fetus.

For the embryo (to 60 days after conception), the dose is taken to be the same as that to the uterus; on this basis all tissues of the embryo will receive the same dose. For calculating the dose to the tissues of the fetus for non-penetrating radiation (alpha and beta emissions and photons with E <10 keV), experimentally determined C_F/C_M ratios obtained shortly after administration of radionuclides to the mother are used. Multiplying this ratio by the dose to maternal tissues gives an estimated dose to the fetal tissue, on the assumption that the distribution of activity in the fetus is the same as that in the mother. This approach is expected to be conservative in most instances as rapid growth of the fetus will reduce the concentration of radionuclides in fetal tissue, although this dilution effect may be to some extent offset by transfer to the fetus from radionuclide deposits in the maternal tissues. A number of radionuclides would be expected to equilibrate rapidly between maternal and fetal tissues. These include isotopes of the alkali metals, which are predominantly ionic in body fluids and have a rapid turnover in tissues, as well as many tritium and ^{14}C labelled compounds.

For the majority of radionuclides, penetrating radiation from activity deposited in maternal tissues will also contribute to the dose to the fetus. This dose is presently taken to be the same as the dose to the uterus. It is expected that in final calculations doses will be based on models for a pregnant woman.

As indicated above, for many animal studies the distribution of radionuclide in fetal tissues is not reported and the assumption has therefore to be made for calculating doses that the distribution in the fetus is the same as that in the mother. Recent autoradiographic studies have, however, shown that following administration to the mother early in gestation there can be a significant uptake of some radionuclides in the yolk sac membranes (eg, ^{95}Nb, ^{106}Ru, ^{210}Po and ^{239}Pu). This may be important as haemopoietic development involves the migration of stem cells and it appears likely that the primitive stem cell population may arise in the yolk sac, or even at the earlier egg cylinder stage. These stem cells may subsequently migrate to the liver once the extra embryonic and embryonic circulations become connected. Ultimately haemopoietic stem cells pass to the bone marrow. It has therefore been proposed that for calculating doses to the haemopoietic stem cells in the developing fetus, the calculated dose should reflect this migration and the potential of these cells to receive a radiation dose at different sites in the body (yolk sac, liver and bone marrow), taking into account the appropriate period of gestation in the human.

DOSE COEFFICIENTS FOR THE EMBRYO AND FETUS

For the calculation of dose coefficients a range of intake regimens by the mother have been adopted that should allow doses to the embryo and fetus to be determined for any pattern of exposure of the mother. For acute exposures, intakes of radionuclides by ingestion or inhalation (for aerosols with activity median aerodynamic diameters of 1 μm and 5 μm) are taken to occur at the start of weeks 1, 5, 10, 15, 25 and 35 of pregnancy and at 6 months and 2½ years before conception. For chronic exposures, intakes are taken to occur during the year of pregnancy starting from the time of conception, and for 1 year and 5 years before conception. It is proposed that in the final report equivalent doses to the date of birth will be given for the embryo and fetus for all tissues with a specific tissue weighting factor in adults as well as the average dose to remainder tissues (calculated as the mass weighted average). The effective dose will also be given using the w_Ts recommended by ICRP in Publication 60[2]. Whilst these values are not strictly appropriate for exposures *in utero*, they have been used as no alternative tissue weighting factors are presently available. The effective dose provides a useful quantity for assessing the consequences of different patterns of intake of radionuclides and for comparison with maternal doses. Effective doses (to age 70 years) received after birth will also be calculated, together with the total effective dose (before and after birth) received by the offspring and its ratio to the total committed effective dose received by the mother. It

is intended that the dose coefficients will be given for all elements and radionuclides in Publications 56, 67, 69 and 71[1,11,12,17]. The results of some preliminary calculations are given in Tables 2 and 3.

In general, the results of preliminary calculations indicate that for many radionuclides doses to the offspring will be less than those to the mother. For isotopes of caesium and other radionuclides that equilibrate rapidly in the body, the dose to the newborn child is expected to be similar to that of the mother, although the total committed dose may be much less (Table 1). For acute intakes of ^{131}I late in pregnancy the dose to the newborn child may approach twice that of the mother. Similarly, intakes of alkaline earth radionuclides towards the end of pregnancy can result in higher doses to fetal tissues at birth than to maternal tissues, although the total committed dose to the offspring will be less. There is little suggestion that doses to the child will be appreciably higher than maternal doses, particularly for chronic intakes by the mother either before or during pregnancy.

It is expected that the report will be ready for publication in about 18 months time.

CANCER RISK AMONG ATOMIC BOMB SURVIVORS

Kiyohiko Mabuchi,[1] D.A. Pierce,[1] D.L. Preston,[1] Y. Shimizu,[1] and M. Vaeth[2]

[1]Radiation Effects Research Foundation Hiroshima, Japan
[2]University of Arhus, Arhus, Denmark

The Radiation Effects Research Foundation (RERF) and its predecessor, the Atomic Bomb Casualty Commission (ABCC), has been conducting a long-term follow-up of a cohort of the atomic bomb survivors in Hiroshima and Nagasaki. The continuing follow-up of this population, known as the Life Span Study (LSS) cohort, has been a major source of epidemiological data for radiation risk assessment (1, 2). Periodic analyses of the LSS mortality data have resulted in a series of reports that describe and quantify radiation effects on cancer mortality (3). More recently, a series of comprehensive reports of cancer incidence for this cohort has also been published (4-7). The latest report on the LSS cancer mortality data through 1990 will soon be published. The purpose of this presentation is to provide an updated overview of the LSS cancer and leukemia data.

LIFE SPAN STUDY

Population

The LSS cohort includes most survivors within 2.5 km of the bombings who lived in Hiroshima or Nagasaki in 1950 and who met certain conditions that were considered favorable for follow-up. The cohort also includes a sample of survivors who were within 2.5 - 10 km of the hypocenter; this group was chosen to be of the same size and to have the same age and sex distribution as the original group of more proximally exposed survivors. The portion of the LSS cohort used in the latest analysis includes about 86,500 survivors for whom DS86 radiation dose estimates are currently available (8, 9). This represents 93% of all the survivors in the cohort, and consists of 34,300 survivors with estimated doses less than 0.005 Gy kerma and 52,200 with estimated doses of 0.005 Gy or higher (a mean dose of 0.26 Gy). The LSS data are characterized primarily by acute exposure to low LET gamma radiation, with a non-negligible neutron component in Hiroshima. However, the 37,000 subjects in the dose range of .005 - .20 Gy can also provide useful information on low-dose effects.

Follow-up

Mortality follow-up for the period from 1950 onward has been undertaken using regular checks on the vital status of all cohort members based on the Japanese family registration system known; causes of death are obtained from information recorded on death certificates. This method of follow-up provides virtually complete ascertainment of vital status and mortality data. The LSS cancer incidence data that have recently become available from the Hiroshima and Nagasaki tumor registries provide better diagnostic information and improve ascertainment of relatively non-fatal cancers; these are an important complement to the mortality data. A subset of the LSS cohort has been followed by biennial health examinations under the Adult Health Study program, providing longitudinal data on disease morbidity and health status. These mortality and morbidity follow-up data enable comprehensive analyses of a wide spectrum of health outcome associated with radiation exposure from the atomic bombings.

RESULTS TO DATE

At the end of 1990, 56% of the LSS cohort members were alive while most of those exposed at middle ages or later in life had died (Table 1). However, it is particularly important to note that some 85% of those exposed at ages less than 30 years are still alive

Table 1
Cohort survival by age at exposure

Age at exposure	People in 1950	Percent alive in 1990
0-9	17,824	94
10-19	17,557	86
20-29	10,882	77
30-39	12,270	51
40-49	13,489	16
50 +	14,550	1
Total	86,572	56

Excess cancer deaths

Excess leukemia deaths among the atomic bomb survivors became apparent a few years after the bombings, reaching a peak 5-10 years after the exposure, followed by a gradual decline. Since 1950, a total of 249 leukemia deaths occurred in 86,500 survivors in the LSS cohort. Of these, 86 leukemia deaths are considered as excess deaths due to radiation, and these account for 49 % of 176 leukemia deaths in the 52,200 subjects with significant exposures (Table 2).

Table 2
Cancer deaths among 52,200 A-bomb survivors with significant exposures
1950-1990

	Total number of deaths	Estimated number of deaths due to radiation exposure	% attributable to radiation exposure
Leukemia	176	86	49%
Other types of cancer	4,687	341	7%
Total	4,863	427	9%

Excess deaths from cancers other than leukemia emerged 5-10 years after the exposure. To date, a total of 4,687 deaths from cancers other than leukemia have occurred in 52,200 survivors with significant exposures in the LSS cohort (Table 2). Of these, 341 or 7 %, are considered to be associated with radiation exposure. Thus, for cancers other than leukemia, or solid cancers, the proportion of deaths due to radiation is much smaller than for leukemia but the absolute number of excess deaths is much larger.

Temporal patterns of cancer risk

The long-term follow-up of the LSS provides a unique opportunity to examine the temporal patterns of cancer and leukemia risk as they are affected by age at exposure and sex. As evident from the discussion below, understanding of such temporal patterns is essential in risk assessment. The age-dependent temporal patterns are strikingly different for solid cancers and leukemia. Figure 1 depicts the age and sex dependent temporal patterns of solid cancer risk. One of the most important findings here is that, for those exposed as adults, the excess relative risk per unit radiation dose (ERR) of solid cancers has been remarkably constant over the follow-up period. This means that the excess absolute risk has increased over the entire follow-up period roughly in proportion to the rapid age-specific increase of the background risk. For those exposed as children, the ERR of solid cancers, which was especially high in the early years of follow-up, has been found to be decreasing over time. Since the very high ERR for this group early in the follow-up is based on a very small background risk at young ages, the absolute risks for the young survivors are still relatively small. Because of the large number of the young subjects who are yet to be followed, how the solid cancer risk will behave for the young survivors in the future is one of the main remaining questions.

The ERR for solid cancer is also higher for women than men. However, in interpreting the sex difference in ERR, one must keep in mind that the background rates for men are at least twice as high as for women. The absolute risk for cancers other than leukemia is quite similar for men and women.

In sharp contrast to the solid cancer deaths, most of the excess leukemia deaths occurred early in the follow-up. Patterns of risk for leukemia are shown in Figure 2. Generally the excess relative risk decreases with time (or with aging), but the rate of decrease in the risk is lower (or the decrease is less rapid) for those exposed at older ages. Particularly among those exposed as children, essentially all of the excess deaths occurred during the several years after the exposures. On the other hand, among those exposed as adults, the excess risk persists at low levels throughout the entire follow-up period.

Dose response curves

Another important finding from the LSS follow-up data is a striking difference in the shape of a dose response curve for solid cancers and leukemia. The dose response curve for solid cancers is unequivocally linear whereas there is a statistically significant upward curvature in the leukemia dose response curve up to about 3 Gy. The difference in dose response curve for solid cancers and leukemia may reflect different underlying mechanisms for carcinogenesis and leukemogenesis, as the former is known to involve multi-step processes and multiple factors whereas for the latter chromosomal rearrangements are of primary importance.

The low dose extrapolation factor (LDEF) is the adjustment factor to be applied to linear risk estimates in extrapolating the excess risk to low doses. The shape of the dose response curve for solid cancers and leukemia has been analyzed using the LSS data (10,11). Based on the LSS incidence data, LDEF values for solid cancers were in a narrow interval around 1, with a value of 1.4 or greater being inconsistent with the data. For leukemia, the best fitting LDEF value was 2.5 with but a value as high as 10-15 could not be ruled out.

Lifetime risk projection

The LSS cancer data are used by various national and international organizations concerned with radiological protection. In setting up safety standards, considerations are given to projected life time risk estimates and other measures of health detriment attributable to radiation exposure. At the present time, one of the most important sources of uncertainty in lifetime risk estimates is the projection that must be made from the incomplete follow-up. This is especially true for those exposed at young ages.

To examine the effect of different assumptions about the future course of the solid cancer risk, the UNSCEAR 1994 Report used three different models in projecting the lifetime risk that an individual would die from cancer (or leukemia) as a result of exposure to radiation (Table 3). In one model, the ERR for solid cancer is assumed constant throughout the lifetime of the survivors. This is a commonly used method but seems somewhat unreasonable since it is now clear that the solid cancer ERR among young survivors has been decreasing over the follow-up. In two alternative models, the solid cancer ERR for the survivors who were less than 45 years old at exposure is assumed to decrease linearly starting 45 years after exposure but at different rates of decrease. The excess leukemia risk in the LSS occurred mostly in the early years of follow-up and appears to be decreasing for the youngest survivors. Therefore, there is no need to consider different projection models.

Table 3
Comparison of estimates of lifetime risk of mortality form solid cancers and leukemia following acute whole-body exposure to 1 Sv
(from UNSCEAR 1994 Report)

Projection method	Lifetime risk in percent	Years lost per case
Solid cancers		
Constant relative risk [a]	10.9	11.6
Decline to risk for age at exposure 50 [b]	9.2	12.3
Declines to zero risk at age 90 years [c]	7.5	13.3
Constant relative risk (UNSCEAR 1988)	9.7	11.4
Leukemia		
Linear-quadratic dose response model	1.1	31
Constant relative risk (UNSCEAR 1988)	1.0	26

[a] ERR constant from 10 years after exposure

[b] ERR constant for first 45 years after exposure; risk then decreases linearly with age. At attained age 90 years, the risk is equal to that for a person aged 50 years at exposure

[c] ERR constant for first 45 years after exposure; risk then decreases linearly with age. At attained age 90, the risk is equal to that for a person aged 50 years at exposure.

COMMENT

The LSS cohort data have provided unique opportunities for elucidating the nature and magnitude of risk associated with radiation exposure as it is affected by sex, age and time. With only about 50% of the subjects for whom the follow-up has been completed, there clearly is still much to be learned from the future follow-up. The most important uncertainty at the present time relates to the temporal pattern of solid cancer risk of those survivors who were exposed early in life. How the risk for this group of young survivors will behave in the future is one of the most important remaining questions. Although the patterns of leukemia risk are much more complex than those for solid cancers, most of the excess deaths occurred in the early years of follow-up. There appears much less uncertainty with respect to risk estimates for leukemia, although continued work is also important to obtain a complete picture on the temporal distribution of leukemia risk.

METHODOLOGY OF ENVIRONMENTAL DOSE ASSESSMENT

John E. Till, Ph.D.

***Radiological Assessments Corporation*, 417 Till Rd, Neeses, SC 29107, USA**

INTRODUCTION

It has often been said that risk assessment is more an art than a science. In the early days of risk assessment, this may have been a true statement. Indeed, the components that comprise a risk assessment evolved as individual sciences, considering transport of radionuclides in the environment, dosimetry, and risk, once exposure has occurred. These individual sciences gradually and more frequently were merged together into comprehensive dose and risk assessment models. Risk assessment is a process that is rapidly becoming very sophisticated in its techniques, and through extensive efforts in validation of models, it is gaining credibility as a reliable scientific approach to understanding risk and making decisions about risk. Today, risk assessment is indeed a science that will become more important in the future of radiological health.

Risk assessment can be either prospective or retrospective. Risks can be estimated for possible future releases of materials (prospective), or they can be estimated for releases that occurred in the past (retrospective). Prospective risk assessments are carried out in conjunction with new facilities that are being constructed or perhaps to demonstrate that compliance will be met for an operating facility. An excellent example of retrospective risk assessments are the dose reconstruction studies being conducted on the weapons complex facilities in the US and studies of populations exposed following the Chernobyl reactor accident. Although the two types of risk assessment may be undertaken somewhat differently in their methods, there are many similarities in the techniques applied to both.

In explaining the process of risk assessment to my colleagues and to the public, I have often used this illustrative equation to express the interdisciplinary nature of this research and how these disciplines are inherently linked together.

$$\text{Risk} = (S \bullet T \bullet U \bullet D \bullet R)_{uvcp}$$

where,

S = source term (characterization of the quantity and type of material released),
T = environmental transport and fate of the material released,
U = usage factors (characteristics of individuals exposed),
D = conversion to dose,
R = conversion to risk,
u = uncertainty analysis,
v = validation,
c = communication of results, and
p = public participation.

This presentation will briefly review the state-of-the-art of each of these basic elements of risk assessment and describe what, in my judgment, the future holds and where the focus of our efforts should be for improving this science. Since our research has recently focused on dose reconstruction in the US, I will use examples from these studies throughout this paper.

SOURCE TERM (S)

The source term is the characterization and quantification of the material released to the environment. It is the heart of a risk assessment. We frequently give too little attention to the derivation of the source term, and yet this step of risk assessment is where the greatest potential lies for losing scientific and public credibility. Therefore, it is important that development of the source term be given highest priority and that the source term be carefully checked before making risk calculations.

Two key points are offered about how source terms should be derived for risk assessments. First, uncertainties must be included with the estimates of releases. This aspect of the source term has frequently been overlooked in the past, with release estimates being reported as single values, when in reality we know there is a range of possible values that exist. The uncertainty estimates should account for all possible sources of uncertainty in the calculation.

Second, the source term should be derived from as many different independent approaches as possible. The Fernald Feed Materials Production Center (FMPC), near Cincinnati, Ohio in the US is a part of the US nuclear weapons complex that processed uranium ore. We estimated the release of uranium from the FMPC using two

methods. The first method considered the amounts of material being processed at the site and estimated the fractional release of uranium to atmosphere through the various offgas treatment systems (primarily scrubbers and dust collectors). Using this approach, it was determined that the "best estimate" of uranium released to atmosphere was 170,000 kg with the 5th and 95th percentiles ranging between 270,000 kg and 360,000 kg (Table 1). An alternative calculation was performed (1), looking at the amount of uranium deposited on soil within 7.5 km of the site based on soil samples that had been collected over time. Taking into account environmental removal of some of the uranium, and the amount of uranium that would have been deposited from the atmosphere, it was estimated that the source term for uranium released from the site to the atmosphere would lie between 78,000—90,000 kg with a median value of 212,000 kg. This alternative calculation, although the uncertainties are large, gives us additional confidence that our estimate of the source term for uranium is reasonable.

The Fernald site included several concrete silos in which ore containing high concentrations of radium was stored. Between 1952 and 1979 these silos (known as K-65 silos because of the radium bearing material stored inside) were vented to the atmosphere, thus creating a strong source of radon and radon daughter products, that exposed nearby residents (Figure 1). After 1979 several remedial measures were taken to reduce the emissions of radon, and in more recent years, a number of measurements were made to estimate radon releases. Unfortunately during the period prior to 1979, few measurements were made to quantify the release of radon, at a time when the releases would have been the greatest.

Table 1. Uranium and Radon Source Terms for the FMPC for 1951-1988[a] (1)

Source	Median release estimate	5th percentile	95th percentile
U to Atmosphere			
Primary estimate	310,000	270,000	360,000
(Alternative calculation)	212,000	78,000	390,000
U to Surface Water	99,000	85,000	120,000
Radon to Atmosphere			
Primary estimate	6,300 TBq	4,100 TBq	8,500 TBq
(Alternative calculation)	3,200 TBq	540 TBq	11,000 TBq
Radon-222 daughters[b]	4,800 TBq	3,200 TBq	7,000 TBq

[a] Values are in kg of uranium, except releases from the K-65 silos which are reported in TBq.

[b] The release quantities for decay products are quantities of each of the short-lived decay products, polonium-218, lead-214, bismuth-214, and polonium-214.

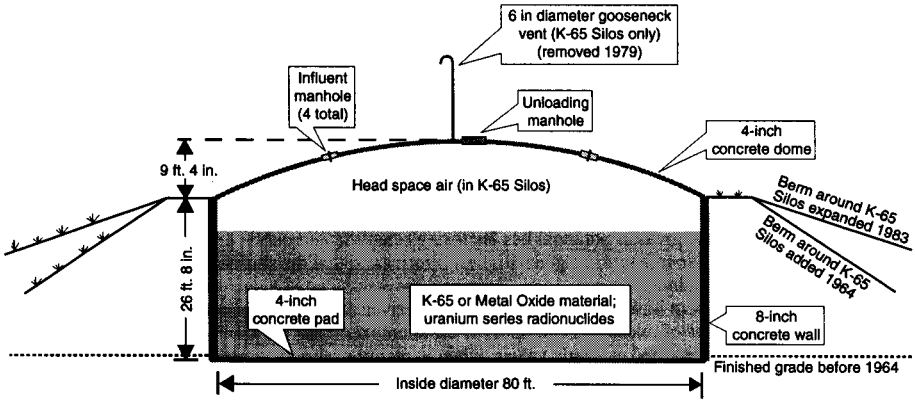

Figure 1. Schematic diagram of the K-65 silos located on the Fernald site.

The radon source term for Fernald was particularly challenging to derive. As with uranium, we estimated radon emissions and uncertainties for the silos using two different techniques. One method used measurements that were made prior to and after the sealing of the silos in 1979, along with information we had about the history of the silos and characteristics of the material stored. The second technique was a strictly theoretical approach that calculated the amount of radium in the silos, estimated the radon production and diffusion into the head space and out of the silo vents. The theoretical technique resulted in a greater uncertainty because more parameters with wide distributions were involved in the calculation. However, as can be seen in Table 1, there is overlap in the two estimated source terms, giving us confidence that our estimates for radon are plausible.

Environmental Transport (T)

With regard to environmental transport, one important recommendation stands out — always apply site specific data when they are available. The more data that exist characterizing the environment around a site, the more defensible the risk assessment. In fact, where measurements of environmental concentrations can be used in place of models, this is always preferable.

One example of a case where we have applied environmental measurements to assist in risk assessment is for the dispersion of releases to the atmosphere at the Fernald site. As with many dose reconstruction studies, detailed information on atmospheric conditions (wind speed and direction, stability categories, precipitation) at the site were not available until the late 1980s. In our search of the historical records, we located two sets of measurements of radon at different distances downwind from the silos, collected during the 1980s. A diffusion coefficient was developed based on a Gaussian area source model for a circular area of radius 50 m (representing the area of the two silos from which the radon emerged). The curve was fit to the radon measurement data. The uncertainties account for factors such as parameters used in converting concentrations to diffusion values and uncertainties in release rates of radon from the silos as well as measurement error.

We applied this empirical dispersion model to the releases of both uranium and radon released to the atmosphere at Fernald (Figure 2). Obviously, many other factors had to be accounted for in the overall model such multiple release points at the site, different chemical forms of uranium, particle size, deposition and resuspension among others. However, the air concentration as a function of distance downwind was based on measurements taken near the site. This approach resulted in less overall uncertainty in the environmental transport calculations. Therefore, it is always a smart investment in resources to carefully characterize environmental properties at the site for which the risk assessment will be performed. In the end, a more defensible calculation can be made and in addition, less uncertainty is likely to be introduced into the calculation.

USAGE FACTORS (U)

The importance of usage factors is often overlooked in risk assessment. The term, usage factor, refers to diet, lifestyle, and residence history data for individuals who live near the site, and other information that characterize the region around the facility being studied such as land use and agricultural practices. Typically we put little effort into developing usage factors in risk assessment and opt instead to insert values taken from the literature which often have little relevance to the particular region being studied. Although this tactic may not introduce large uncertainty into the overall estimation of risk, it can result in a loss of credibility with the public who are the object of the study.

In almost every risk assessment there are special population groups who do not fit the usage factors for the general public. One example of this occurred in the dose reconstruction project for the Hanford Site, another facility within the US nuclear weapons complex, located in south-central Washington state in the US. The Hanford facility released large amounts of radionuclides, and I-131 in particular to the atmosphere (3), however significant quantities of materials were also released directly into the Columbia River which was used for cooling the production reactors at the site (4). Pathways of exposure from the river were investigated thoroughly. Members of the general public who lived near the river received relatively small doses (estimated to be 15 mSv over about 40 years) from consumption of river water, consumption of fish from the river (150 kg of fish per year), and activities in and around the river. However, special attention had to be given to Native Americans who relied on the river for a major component of their food, fish. Therefore, the types of fish consumed, the quantities of fish eaten, and other uses of the river had to be determined specifically for Native American tribes near the site. Such information is not available in the literature and had to be collected by surveying elders of the tribes to develop a typical diet and to determine where the principal fishing locations existed. These data are currently being collected and analyzed, however, it is evident that the Native Americans who lived near and downstream of the site are likely to have received significantly higher doses from this pathway than the general public. Such an analysis could not be made without the cooperation of the Native American tribes in the Hanford study.

Surveys of individuals being studied to obtain person-specific usage factors were also carried out in the Utah Thyroid Cohort Study (5). In that research, surveys were conducted on the parents (or another living relative) of approximately 3,500 individuals who were children at the time of exposure to iodine from fallout resulting from the

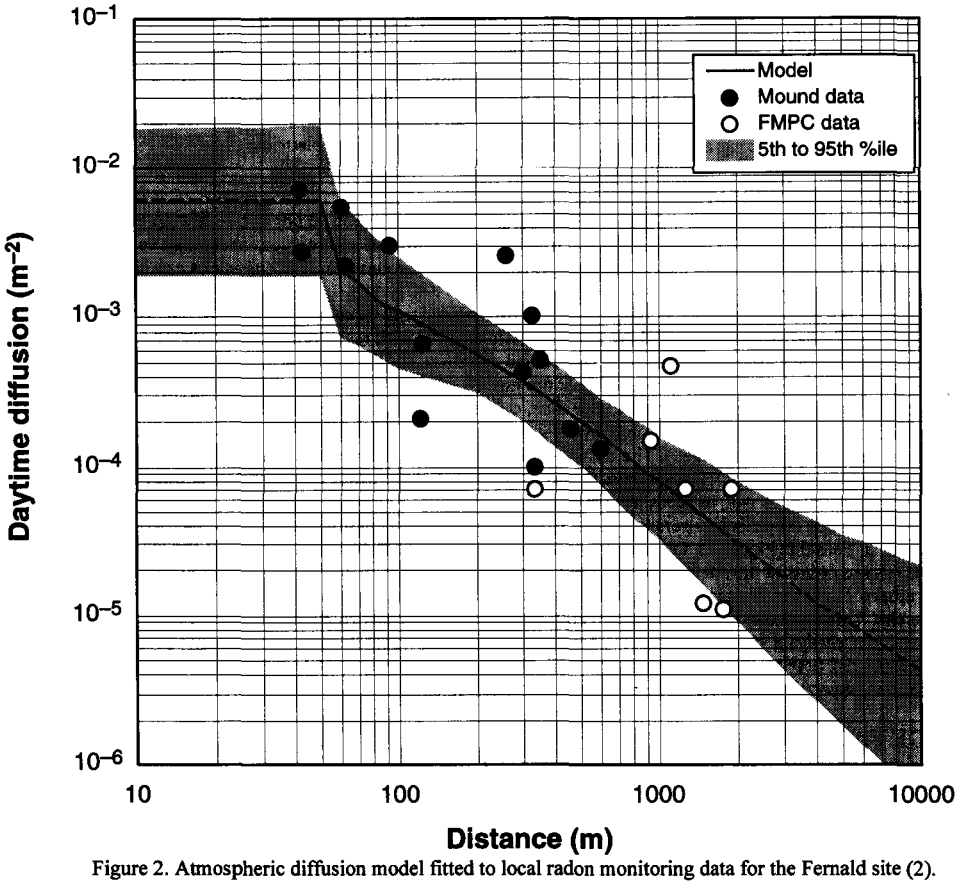

Figure 2. Atmospheric diffusion model fitted to local radon monitoring data for the Fernald site (2).

atmospheric nuclear weapons tests in the US. These data allowed individual doses and uncertainties to be estimated for each member of the cohort. The doses and uncertainties were used to determine if a higher incidence of thyroid disease existed in the group and could it be attributed to the fallout.

These two examples illustrate the importance of usage factors in risk assessment and the fact that the collection of such site-specific data cannot be underestimated.

DOSE CONVERSION FACTORS (D)

The conversion of intake of radionuclides or external exposure to dose has become a simple process because of effort put into deriving and publishing dose conversion factors using metabolic models. However, these factors typically do not include uncertainties and therefore a key component in the overall risk calculation is often not addressed.

In the Hanford Environmental Dose Reconstruction project (3-4), it was determined that one of the two most important contributors to overall uncertainty was the dose conversion factor for I-131 (the other key component of uncertainty was the feed-to-milk transfer coefficient.) In this analysis, it was pointed out that the uncertainty in the iodine dose conversion factor was due primarily to variability in the mass of the thyroid, uptake of iodine in the gastrointestinal tract, transfer of iodine to the thyroid, and the biological half-time of iodine.

Estimating uncertainties for dose conversion factors is a fertile and important area for research in the future. Although work in this area is underway, it will be a considerable time before dose conversion factors and their

uncertainties can be established for all radionuclides. Indeed, this is an area where priorities must be set, in order to establish the methods to be used and to be sure we are focusing first on radionuclides of greatest importance in risk assessment.

CONVERSION TO RISK (R)

Two key issues are important to note with regard to risk conversion. The first issue deals with inclusion of uncertainties in estimates of dose in epidemiological studies to analyze incidence of disease and resulting risk. Kerber et al. (5) incorporated individual doses and uncertainties (6) into their analysis of thyroid disease in a cohort exposed to fallout from the Nevada test site. They concluded that there was a statistically significant excess of thyroid neoplasms, with an increase in excess relative risk of 0.7% per mGy. This approach to incorporating uncertainties associated with doses into the epidemiological analysis will be used more commonly in the future and is a relatively new technique for deriving estimates of risk in studies of large populations where individual doses have been assigned.

The second issue related to conversion to risk is that of quantifying uncertainty in the risk factors being applied. As with conversion of intake or external exposure to dose, conversion of dose to risk is a straight forward process with the publication of risk factors by a number of different groups (7-9). Little is known about uncertainties associated with the risk factors in use today. The current risk estimates of cancer following exposure to ionizing radiation are based primarily upon analyses of Japanese survivors of the atomic bombings at Hiroshima and Nagasaki. These risk estimates essentially relate to uniform whole-body low LET radiation exposures to doses ranging from 0.01 Gy to 4 Gy delivered at high dose rate.

Uncertainty in the risk factors for radiation was described by Sinclair (10) as having five primary components: (1) epidemiological uncertainties; (2) dosimetrical uncertainties (3) projection to lifetime; (4) transfer between populations; and, (5) extrapolation to low dose and dose rate. Epidemiological uncertainties include statistical uncertainties associated with quantifying the relatively small number of excess cancers attributable to ionizing radiation from the background cancers resulting from all causes. Also included in epidemiological uncertainties are uncertainties from underreporting of cancers per unit population and non-representativeness of populations used to determine risk. Dosimetrical uncertainties include those from random errors in individual dose estimates arising from errors in the input parameters used to compute doses and systematic errors due to the presence of more thermal neutrons at Hiroshima than originally estimated. Risk projection includes uncertainties associated with extrapolating beyond the time period covered by the observed population. Transfer of estimates of risk from one population (Japanese) to another introduces an additional source of uncertainty that must be considered. Finally, since the exposures for the A-bomb population was at relatively high dose rate, uncertainty is introduced when we extrapolate estimates of risk to low dose, low dose rate situations, common in most risk assessments. This area of risk assessment research is very important for the future and the ideas introduced by Sinclair (10) must be pursued. Indeed, it is very possible we may find that the risk factors themselves introduce more uncertainty into the overall estimate of risk than any other single component.

UNCERTAINTY ANALYSIS (u)

Uncertainty analysis is an essential element of risk assessment. Methods for quantification of uncertainty have been well established. Today, it is expected that when one carries out a risk assessment, the best estimate of risk is reported along with associated uncertainties. Although we commonly see uncertainties associated with doses, it is not likely to see uncertainties calculated in overall risk, primarily because as mentioned above, uncertainties in the risk factors are still being developed.

The most common method for uncertainty analysis uses Monte Carlo statistical techniques incorporating a random sampling of distributions of the various models and parameters involved (Figure 3). In this simplified illustration, A is an input parameter to the model, and Y is the result, or output, corresponding to A. For each specific value of A, the model produces a unique output Y. Such an application of the model is deterministic, because A determines Y. But A may not be known with certainty. If uncertainty about A is represented by a distribution, such as the triangular one in the figure, repeatedly sampling the distribution at random and applying the model to each of the sample input values A_1, A_2... gives a set of outputs Y_1, Y_2,..., which can be arranged into a distribution for Y. The distribution of Y is then the estimate of the uncertainty in Y that is attributable to uncertainty in A. This is a stochastic, or Monte Carlo application of the model.

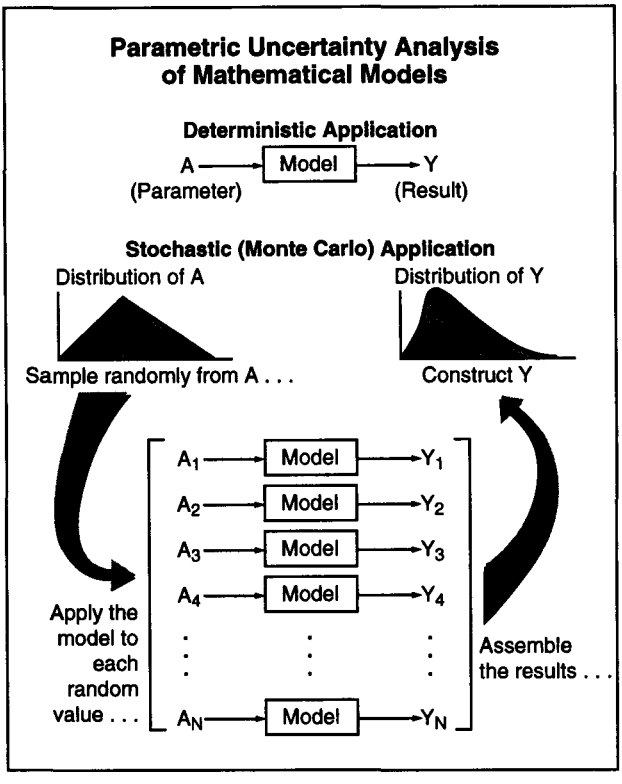

Figure 3. Schematic presentation of Monte Carlo methods for propagating a parametric uncertainty distribution through a model to its results.

The goal to estimate uncertainties in risk assessment demands that powerful computers be available for such a calculation. Until recently, limitations in computer hardware were the primary reason why uncertainties were not propagated throughout the entire calculation. Today, however, computer memory and speed of calculations have advanced to the point where relative inexpensive computers are required to undertake such a complex calculation.

VALIDATION (v)

Retrospective risk assessments in dose reconstruction are providing a unique opportunity to validate environmental transport models. The historical records contain a vast resource of measurement data, much of it collected many years ago, that can be used as the basis for comparisons between estimated environmental concentrations and values that were measured. These comparisons are providing us with some of the best indicators of reliability to date for the mathematical models being developed and applied by scientists in risk assessment.

In the Fernald Dosimetry Reconstruction Project, we have examined all available monitoring data from several different sources, and calculated predicted to observed ratios for a number of different pathways. As expected, it is rare that perfect agreement exists; however, overall confidence in our methodology is boosted by the strong agreement between historical data and estimated concentrations, suggesting that neither the source term nor the environmental transport calculations are seriously off the mark.

For example, Killough et al. (11) have made extensive use of historical monitoring data to confirm that estimates of releases of uranium in air and surface water are reasonable. Figure 4 shows one example of comparisons of predicted uranium concentrations in the Great Miami River near Fernald to those measured for the same period. Good agreement exists between predicted to observed values (mean P/O value of 1.3), enhancing

confidence that the source term and environmental concentrations predicted reasonably reflect conditions that actually existed at the time.

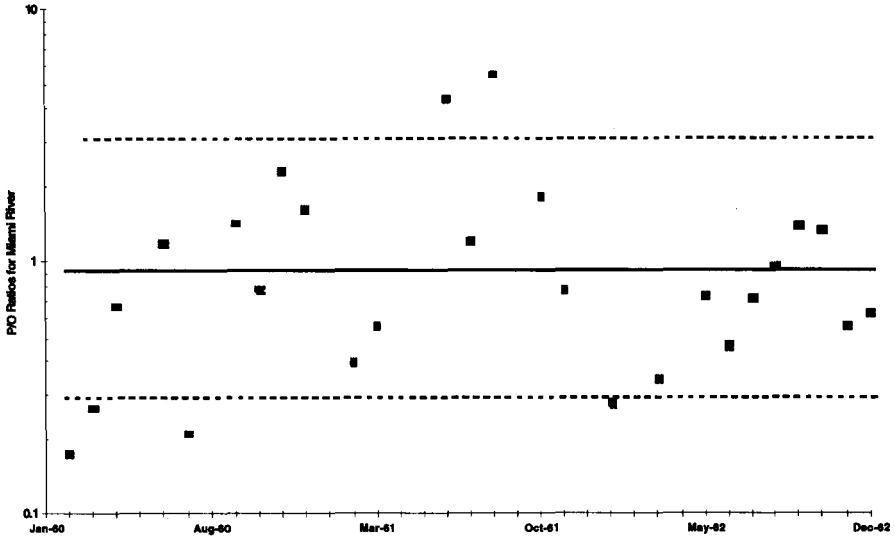

Figure 4. Comparison of predicted to observed concentrations of uranium in the Great Miami River downstream of the Fernald site (11).

Validation of our methods must continue to receive strong attention in the future. We must be certain that every opportunity is taken to make comparisons between predicted and observed estimates of concentrations in the environment.

COMMUNICATION OF RESULTS AND PUBLIC PARTICIPATION (*c,p*)

I include the remaining two elements of risk assessment into this final section because they are inherently linked together. Risk assessment is a public process. In almost all situations, we are required to estimate risk to members of the public who have been or who may be exposed to releases of contaminants to the environment. In the end, we must achieve both public and scientific credibility (12). As scientists we have come a long way in establishing the technical methods described in the sections above. On the whole, however, we are quite inept in communicating our results with the public and working with the public in conducting risk assessments. This is an area where the most progress could be made with the least investment of resources.

Risk communication has become a branch of risk assessment in itself. Many techniques have been devised to explain to the public the meaning risks resulting estimated doses. Many comparisons have been proposed between risks from exposure to radiation and risks from other sources common in life. We may be able to help people understand the potential importance of risks by referring to the overall risks posed by natural background, fallout, and other involuntary exposures and comparing these to our own estimates of risk for the particular situation. Although these comparisons help, there is no replacement for scientists personally conveying the results of their calculations to the public who are at risk. We would all like to think that society is ready to agree on a common set of risk levels for decision-making. Indeed it would make life simpler, but we are not at that point with either the technology to compute risks or the public's understanding and acceptance of risk. Trying to impose a level of risk as being "significant" or "insignificant" leads to a serious loss of credibility. During my past decade of work on dose reconstruction projects, I have learned that the best way to respond in communicating the significance of a level of risk is to respond personally. What I mean by this is that we as scientists can tell people how we feel about the significance of a level of risk, but we cannot tell the public what they should feel or think.

Public involvement in risk assessment is not common to us. I have found, however, that including the public in as many ways as possible in the risk assessment process builds credibility. Further, including the public

who are being addressed in the risk assessment can lead to the inclusion of valuable site-specific information as described in the discussions above about usage factors.

CONCLUSIONS

Risk assessment is a science that will gain momentum and recognition in the future. It began as many individual sciences addressing the release of radionuclides to the environment, their transport in environmental media, their ingestion by humans, the resulting dose to organs of the body, and the correlation between these doses and the incidence of disease in the population exposed. Slowly and methodically, the individual sciences were melded into the discipline we call risk assessment. Today, this science is rapidly advancing on both the radiological and chemical fronts. There is no question that in the future, risk assessment will be the major tool for making decisions about building new facilities that are yet to release contaminants, and for understanding the importance of contaminants that have been released in the past.

To say we have come a long way in the advance of this science is an understatement. To say we have much work yet to do is a fact.

GAMMA-RAY SPECTROMETRY IN THE ENVIRONMENT AND MODELLING OF EXTERNAL EXPOSURES

Peter Jacob,[1] Vladislav Golikov,[2] and Florian Gering[1]

[1]GSF Institut für Strahlenschutz, Postfach 1129, D-85758 Oberschleißheim, Deutschland
[2]Institute of Radiation Hygiene, Mira Street 8, 197101 St. Petersburg, Russia

INTRODUCTION

Atmospheric releases of gamma emitting radionuclides lead to external radiation exposures of the population. As a rule, the external radiation contributes a significant part to the total exposure of the population that is caused by such a release (1). The importance of the external radiation pathway was demonstrated, *e.g.*, after the Chernobyl accident, especially for longer periods after the accident (2-5). In the aftermath of the Chernobyl accident, the data base for estimating external population exposures has been considerably extended and this paper is devoted to describe a few of the recent developments.

A powerful tool for determining external exposures is gamma-ray spectrometry in the environment (6), since it is fast and allows to determine radionuclide activities per unit area and radionuclide specific absorbed dose rates in air, which in turn is the basis for any solid prediction of the doses to be expected. Due to the pioneering work of Lowder *et al.* (7) and of Beck *et al.* (8,9), a widely accepted procedure of so called *in-situ* gamma-ray spectrometry has been developed (10,11). In this approach, an assumption on the distribution of the radionuclides in the soil has to be made, and this is the main source of uncertainty (6,12). A number of attempts were undertaken to reduce this source of uncertainty by using additional information contained in the measured spectrum. The approaches have been summarized in (6), and more recent approaches are (13,14). Due to large statistical uncertainties, most of these papers were not able to demonstrate the range of applicability of the proposed method. However, Rybaçek *et al.* (15) showed the suitability of a simultaneous evaluation of the 662 keV gamma peak and of the 32 keV Roentgen peak of ^{137}Cs for an improved activity determination during the first years after the deposition of the radionuclide. In this paper, a combined approach based on the peak-to-valley method (16) and on the multi-line approach (17) is demonstrated to improve *in-situ* gamma-ray spectrometry for longer times after a ^{137}Cs deposition.

Since the reactor accident of Chernobyl, the knowledge on three basic parameters in the modelling of external population exposures after radionuclide depositions has been considerably improved. The first parameter is the gamma dose rate absorbed in air per ^{137}Cs activity per unit area deposited on an open undisturbed site. In this paper, a phenomenological approach parameterizing the different values of this parameters for fuel particles, condensation particles and ^{137}Cs attached to the background aerosol by the distance from the release point is described. Further, recent results on the other two parameters, location factors (18,19) and group factors, here defined as the ratio of the effective dose of a population group relative to the effective dose of an adult anthropomorphic phantom standing on an open undisturbed site with a representative ^{137}Cs activity per unit area, are shortly summarized.

GAMMA-RAY SPECTROMETRY IN THE ENVIRONMENT

In this section a new approach is described for determining several years after a ^{137}Cs deposition the activity per unit area and the gamma dose rate absorbed in air by gamma-ray spectrometry. This new method is based on four ideas:

i) the distribution of cesium in the soil is approximated by the Lorentz function as proposed by Hillmann *et al.* (20);
ii) the peak-to-valley method proposed by Zombori *et al.* (16) is applied to the 661.6 keV peak of ^{137}Cs;
iii) valley corrections are obtained by photon transport simulation calculations as proposed by Hillmann (21); and
ii) the Q-value method proposed by Karlberg (17) is applied to four lines of the uranium decay chain and three lines of the thorium decay chain.

In the peak-to-valley method the difference of the counts in an spectral area below the peak and of background peaks is attributed to the photons which were emitted with the same energy as those in the peak and which were scattered under a small angle. Thus, together with the peak counts, two parameters derived from the spectrum are used to obtain information on the distribution of the radionuclide under consideration in the ground.

The *in situ* measurements were performed with a n-type high purity germanium detector with an efficiency of 25%. The detector was posed at a height of 1 m above ground. Spectra were recorded for exposure times of four hours at six open lawns in Southern Bavaria during measurement campaigns in 1993 (21) and in 1995 (22). ^{137}Cs and ^{134}Cs distributions in the ground of the six sites were measured in 1993 (20). Figure 1 shows an example of a recorded spectrum with an identification of the dominant peaks. The peaks used in the analysis are marked by an arrow, the areas used as valley and background are indicated by shaded regions.

The area around the peak is shown in more detail in Fig.2 with an indication of the valley (620-650 keV), the peak (657-666 keV), and the background area (670-700 keV). In the valley area, A represents the

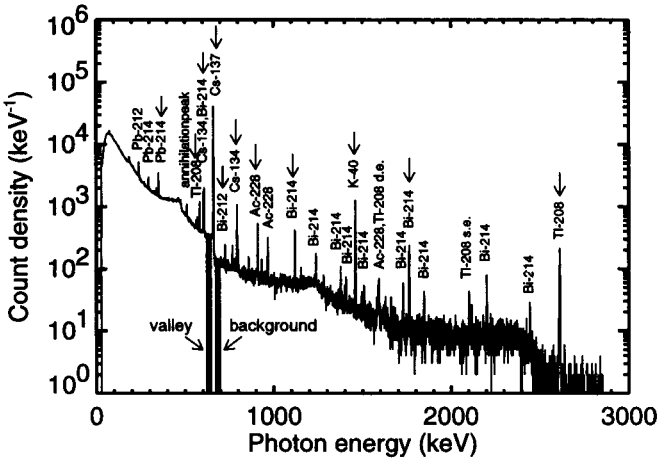

Figure 1. Gamma spectrum recorded in 1995 during four hours at a height of 1 m above ground at a open flat meadow close to Graben in Southern Bavaria. The arrows indicate the lines that were used in the spectrum analysis, the regions the valley and the background for the application of the peak-to-valley method to ^{137}Cs.

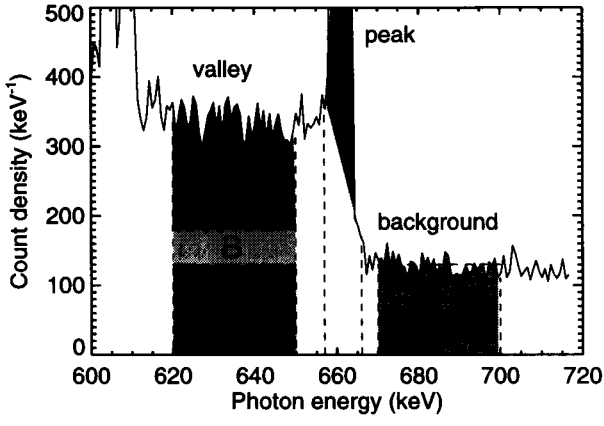

Figure 2. Valley, peak and background counts in the spectrum of Fig. 1 are indicated here by shaded areas. In the valley area, A represents the background component as above the peak, B the additional background due to the inhomogeneous spectrum of the scattered radiation of photons with higher energies, and C scattered photons with an initial energy of 662 keV.

background above the peak, B the addional background counts due to the nonconstant spectrum of scattered radiation from photons with originally higher energies than 700 keV, and C the scattered radiation of photons with an initial energy of 661.6 keV. In the first step of the spectrum evaluation, contributions to the valley, peak and background area by unscattered photons emitted from ^{214}Bi (626.9 keV, 630.8 keV, 633.1 keV, 639.6 keV, 649.2 keV, 661.4 keV, 665.5 keV) and from ^{228}Ac (620.3 keV, 629.2 keV, 640.2 keV, 648.8 keV, 660.4 keV, 666.3 keV, 674.6 keV, 677.3 keV). The magnitude of these contributions is derived from the more expressed peaks of ^{214}Bi and of ^{228}Ac in the spectrum.

The second step in the analysis is the determination of the additional background counts B (22). The distribution of radionuclides in the uranium and thorium decay chains in the ground are approximated by a two layer model. The radionuclides are assumed to be in radioactive equilibrium. Photon transport simulations have been used to calculate the fluences of unscattered photons, and contributions to the background area(670-700 keV) and the valley area (620-650 keV), at a height of 1 m above ground for various of such two layer distributions of each of the two decay chains. As indicated in Fig. 1, four measured lines for the thorium decay chain and three measured lines for the uranium decay chain are than used to determine the effective two layer

distributions of the radionuclides by the Q-value method (17). The corresponding contributions to background and valley area are obtained from the photon transport calculations. For ^{40}K the assumption of a homogeneous distribution was tested with the peak-to-valley method for the 1460.8 keV peak and no significant inconsistency could be found.. Again corresponding contributions to background and valley were obtained from photon transport simulations. A similar procedur was adapted for ^{134}Cs, the distribution of which was approximated by a representative Lorentz distribution. Finally, to take into account cosmic radiation and smaller lines not simulated, the additional background counts B were multiplied by the ratio of measured and simulated background counts. Results are summarized in Tables 1 and 2.

Table 3. ^{137}Cs activity per unit area in 1993, as derived in two measurement campaigns by the proposed method of *in situ* gamma-ray spectrometry and by laboratory measurements of soil samples.

From the measured peak-to-valley ratios given in Table 1, effective Lorentz distributions are derived for ^{137}Cs. For this purpose, peak-to-valley ratios for various Lorentz distributions have been derived by photon transport calculations (21) and a correlation between the depth and the width of the maximum of the Lorentz distribution has been assumed (20). From the effective Lorentz distributions, the ^{137}Cs activity per unit area was derived. A thorough analysis of uncertainties was performed (22). Results are summarized in Table 3 and compared with results obtained by soil sampling (20). The dose absorbed in air due to the radiation from ^{137}Cs is determined with a higher accuracy than the activitiy per unit area.

MODELLING OF EXTERNAL EXPOSURES

In the framework of the project 'JSP 5-Pathway analysis and dose distributions*' a model was developed to describe external dose distributions among the Russian population in areas contaminated after the Chernobyl accident (23). The developed model is assumed to be applicable from the year 1990 to the end of the lifetime of people being born before the reactor accident of Chernobyl.

At the time t after a deposition of a cesium isotope, the effective dose rate $E_i(t)$ of a member of a population group i may be calculated by

$$\dot{E}_i(t) = A \cdot \dot{g} \cdot \exp(-\lambda \cdot t) \cdot r(t) \cdot \sum_j f_j(t) \cdot p_{ij}(t) \cdot k_{ij}(t), \qquad (1)$$

where A is the activity deposited per unit area on a reference site, $\dot{g}$ the gamma dose rate in air per activity per unit area with a reference distribution of the cesium in the ground, λ the decay constant, and r(t) the gamma dose rate in air at the reference site divided by the gamma dose rate in air for the reference distribution. The summation index j indicates types of locations, f_j the gamma dose rate in air at a location j relative to the gamma dose in air at the reference site, $p_{ij}(t)$ the relative frequency of stay for members of population group i at location j and $k_{ij}(t)$ the conversion factor from the gamma dose in air to effective dose.

In this report, reference sites are considered to be open fields with undisturbed soil, normally lawns or meadows. A plane source below a soil slab with a mass per unit area of 0.5 g cm^{-2} has been chosen as a reference distribution to approximate the energy and angular distributions of the radiation field in air over an undisturbed field during the first years after the deposition. For this geometry, a value for $\dot{g}$ of 1.7 nGy h^{-1}per kBq•m^{-2} has been obtained for ^{137}Cs and of 4.7 nGy h^{-1}per kBq•m^{-2} for ^{134}Cs (24).

Gamma dose rates in air over open fields

A data base on the attenuation of the gamma dose rate in air due to the migration of cesium into the soil has been established. Main sources of information were (25,26) and new results obtained in the framework of the projects JSP 5* and ECP 5**. The data base has about 450 data sets, each containing besides other information the time of measurement, the value of r(t), and the distance from the Chernobyl nuclear power reactor plant.

The data set indicates the factor r(t) to decrease with increasing distance from the release point. Two factors may be responsible for this observation. First, cesium bound to fuel and condensation particles is known to be less available for migration than cesium that has been evaporated and then attached to the background aerosol. Second, in the data base for short distances, observation points with dry deposition dominate, whereas for long distances observation points with wet deposition dominate. Data grouped in three distance groups are given in Table 4.

Time after deposition (years)	Distance category		
	D ≤ 100 km	100 km < D ≤ 1000 km	D>1000 km
	a_1=0.48; a_2=0.81	a_1=0.60; a_2=0.63	a_1=0.53; a_2=0.51
0.75	1.17 (1.15)	0.98 (1.05)	0.87 (0.88)
2.75	0.88 (0.93)	0.84 (0.78)	0.67 (0.64)
4.75	0.87 (0.82)	0.68 (0.66)	0.55 (0.53)
6.75	0.79 (0.77)	0.60 (0.60)	0.46 (0.48)
24	— (0.59)	— (0.45)	0.39 (0.36)
30	— (0.54)	— (0.42)	0.33 (0.33)

Table 4. Average values for r(t) of entries in data base for the first seven years after Chernobyl and derived from measurements of the atomic weapons tests fallout. The values in parentheses give the results of Eq. (2) with the parameters indicated in the heading of the table.

* Supported by the EC under contract COSU-CT94-0091
** Supported by the EC under contract COSU-CT94-0081

Prediction of the future behaviour of r(t) may be based on observations of the fallout from nuclear weapons tests. An analytical approximation of the data for measurement sites at large distances from the release point and for the nuclear weapons tests in the form

$$r(t) = a_1 \cdot \exp(-\ln 2 \cdot t/T_1) + a_2 \cdot \exp(-\ln 2 \cdot t/T_2), \quad (2)$$

yielded half lifes to be T_1 = 1.5 years and T_2 = 50 years. Based on the observation that fuel particles tend to dissolve over a period of several years in the environment, the same half lifes were assumed for the other distance categories and obtained values for a_1 and a_2 are indicated in Table 4.

The weapons fallout was deposited over long periods and column experiments have shown that under these conditions the initial penetration of the cesium into the soil is negligeable (27). However, the sites in the far field from Chernobyl studied here had different meteorological conditions and an initial migration of the cesium during the wet deposition. It may be assumed that this initial difference retains and that the Chernobyl cesium will have migrated more deeply than corresponding profiles for the weapons fallout at the same time after deposition. Nevertheless both data sets are pooled here, since no better information is available for long times after deposition.

Location factors

In settlements of urban and rural type, the characteristics of the radiation field differ from those over an open plot of virgin land due to shielding and to varying source distributions on the surfaces as a result of different deposition velocities, run-off and weathering. Gamma-ray spectrometry has been used in urban and rural environments in Denmark, Germany and Sweden to obtain extensive results on location factors for ^{131}I, ^{103}Ru, ^{137}Cs, ^{134}Cs, ^{140}La, (28,29). In Russia, location factors have been measured with thermoluminescence detectors in the higher contaminated areas of Ukraine ($A^{Cs137} > 185$ kBq • m^{-2}) in the period 1987-1989 (19). In Russia, first measurements were performed in summer 1989 (30) in three large villages of the Bryansk region with Cs-137 activities per unit area above 1000 kBq/m^2 (Nikolayevka, Yalovka and Svyatsk). During this campaign, several thousand gamma dose rate measurements were performed in different points in the settlements and in their vicinity. The analysis included only data obtained in villages before decontamination actions were taken. Similar measurements were performed in the period 1992 to 1994 in ten villages in the contaminated area of Russia. The results obtained in the two countries were found to be consistent. Location factors measured after 1987 in rural environments were found to be independent of time. Values are given in Table 5.

The presence of a snow cover during the time period November-March reduces according to experimental measurements performed in the Brjansk region in the average the value of the dose rate in air over virgin plots by a factor of 0.76. Since the average reduction over streets may be assumed to be less, location factors during winter time might be a little higher than during summer time. This is confirmed by TLD-measurements of individual doses performed in the same settlements in winter and in summer time. According to these

Location	f_j	p_{ij} (anual)				
		Indoor workers	Outdoor workers	Pensioners	School children	Preschool children
Living areas						
house (wooden)	0.13					
house (brick)	0.07	0.50	0.48	0.68	0.60	0.52
multi storey house	0.02					
outside of houses	0.55	0.21	0.15	0.30	0.24	0.14
Work areas						
buildings	0.07	0.25	0.07	0.0	0.0	0.0
multi storey house	0.02	0.0	0.0	0.0	0.15	0.25
work yard	0.30	0.03	0.07	0.0	0.0	0.09
ploughed field	0.50	0.0	0.15	0.0	0.0	0.0
virgin land	1	0.0	0.04	0.0	0.0	0.0
Rest areas						
forest, meadow	1	0.01	0.01	0.02	0.01	0.0
Group factor	—	0.22/0.19/ 0.17	0.30/0.27/ 0.24	0.27/0.23/ 0.20	0.22/0.19/ 0.16	0.18/0.14/ 0.12

* The first number is for residents in wooden houses, the second in brick houses and the third in multistorey houses

Table 5. Location factors f_j, relative frequencies of stay p_{ij} and group factors $\sum p_{ij} \cdot f_j$ for rural population groups.

measurements, the mean reduction of the annual external dose to snow cover of 0.94 was derived. This small effect is not considered in the following.

Relative frequencies of stay

Information about relative frequencies of stay of the adult rural population at various locations were obtained in Ukraine from 8984 responses of evacuees from the 30 km zone to a questionnaire (19). In Russia, in 1989, 1992, and 1993 corresponding responses of the rural population to questionnaires were obtained and results are summarized in Table 5.

Effective dose per gamma dose in air

The migration of the radionuclides into the soil changes the spectral-angular distribution of the photon fluence exposing the human body. In principle, the value of k_{ij} will change as well. To estimate experimentally conversion factors for a real vertical radionuclide distribution in soil, in summer 1991 and 1992 a series of phantom experiments was carried out. In the experiments three antropomorphical phantoms were used, the Alderson Rando phantom presenting adults and two phantoms of children of 5 and 1 year of age (produced by ATOM Ltd, Riga, Latvian Republic). As experimental sites, two open sites of virgin land, one open ploughed site, and a location inside a wooden house in contaminated areas were chosen.

The experimental results for the three outdoor locations agreed within the limits of only 10% for each of the phantoms. Results of Monte Carlo calculations (31) for the reference distribution (plane source at 0.5 g/cm^2) of radionuclides were found to be intermediate between the experimental results for outdoor and indoor locations. In the present model a value of 0.9 Sv•Gy^{-1} for preschool children (0-7 years), of 0.8 Sv•Gy^{-1} for school children (8-17 years) and of 0.75 Sv•Gy^{-1} for adults is assumed for all locations.

Model results

Annual effective doses of rural indoor workers living in woodframe houses are shown in Fig. 3. For comparison results of the UNSCEAR model (32) are given approximating the attenuation due to the cesium migration into the soil by a constant factor. Dose estimates for Russian settlements in 1991 (2) agree within 10 % with the current model. In the present model for the period 1990-2056, annual effective doses of different population groups differ by a constant factor. The factors for rural population groups are given in Table 6. Urban population groups have lower external exposures due to the Chernobyl accident (33). According to Table 6 rural outdoor workers living in woodframe houses are the critical group for external exposures. Among them, forestry workers and herdsmen receive the highest dose (33).

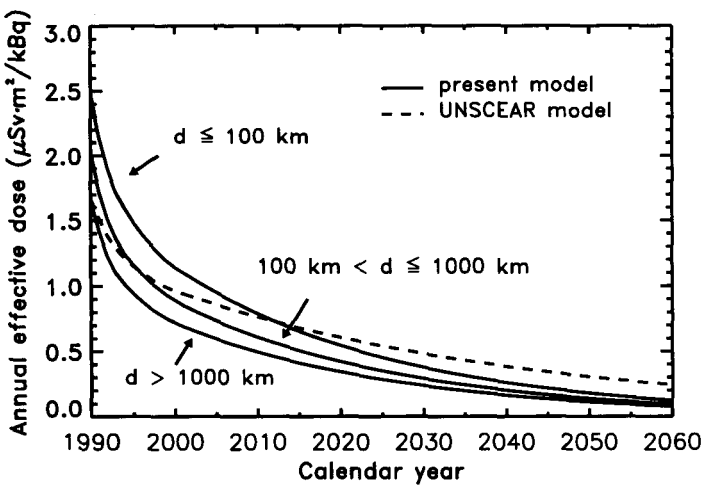

Figure 3. Annual effective doses due to external exposures of rural indoor workers living in woodframe houses. Results are normalized to the ^{137}Cs activity initially deposited per unit area, a ratio of the ^{137}Cs activity to the ^{134}Cs activity of 1.8 has been assumed. The dotted line represents the UNSCEAR model (32).

Population group	Wooden houses	Brick houses	Multi storey houses
Indoor	1.00	0.86	0.77
Outdoor	1.36	1.23	1.09
Pensioners	1.23	1.05	0.91
Schoolchildren	1.07	0.92	0.78
Preschoolchildren	0.98	0.76	0.65

Table 6. Annual effective doses due to external exposures of rural population groups, normalized to the annual effective dose due to external exposures of rural indoor workers living in woodframe houses.

Comparison with measurements of individual external doses

Monthly external doses were measured with TLDs during the spring-summer periods of 1990-1993 in 21 settlements of the Bryansk region with average ^{137}Cs activities above 0.4 MBq/m^2 (34). The conversion factor from readings of an individual dosimeter to the value of the effective dose was determined on the basis of the results of phantom experiments, and it was 0.9 Sv/Gy for adults, 0.95 Sv/Gy for schoolchildren and 1 Sv/Gy for preschoolchildren. Table 7 shows a good agreement between the average doses in the population groups obtained by the model and by measurements. A comparison with measured individual doses showed some of those to be larger than the largest of the average doses in the population groups. Doses to individuals are not the scope of the present model.

Year	Monthly effective dose (μSv)					
	Wood houses			Brick houses		
	Model	Measurement	Ratio	Model	Measurement	Ratio
1990	290	285(174)	1.02	271	230(100)	1.18
1991	246	235(414)	1.05	230	205(103)	1.12
1992	216	200 (95)	1.08	202	200 (49)	1.01
1993	195	150(195)	1.30	182	115 (84)	1.58
Average			1.11			1.22

Table 7. Monthly effective doses (μSv) of outdoor workers in the Bryansk region in the periods (April-November) of the years 1990 to 1993. Results of the present model and of TLD measurements (34) are given, the figures in parentheses give the number of measurements.

EVALUATION OF THYROID DOSES FROM RADIOIODINE RELEASES

André Bouville
National Cancer Institute, Bethesda, MD 20892

INTRODUCTION

Iodine is a volatile element which is very mobile in the environment. Iodine enters the metabolism of living organisms and is selectively taken up and concentrated in the thyroid gland; it plays a major role in the synthesis of the thyroid hormone and is partly secreted in milk.

There are at least 25 iodine isotopes with mass numbers ranging from 117 to 141. All except ^{127}I are radioactive. Omitting the very short-lived ^{140}I and ^{141}I, thirteen isotopes are produced by fission: ^{127}I (stable), ^{128}I (25 min), ^{129}I (1.57×10^7 a), ^{130}I (12.4 h), ^{131}I (8.06 d), ^{132}I (2.3 h), ^{133}I (21 h), ^{134}I (52.8 min), ^{135}I (6.7 h), ^{136}I (83 s), ^{137}I (23 s), ^{138}I (5.9 s), and ^{139}I (2 s). From the point of view of environmental contamination and resulting doses to man, the most important isotope of iodine is ^{131}I, with minor roles occasionally played by the short-lived ^{132}I and ^{133}I, and by the long-lived ^{129}I. Because of its half-life of approximately 8 d, ^{131}I is a short-term problem: within two months after its environmental release, ^{131}I will have decayed to insignificant levels.

Iodine-131 is mainly found in the environment as a result of nuclear explosions and of airborne releases from nuclear reactors and fuel reprocessing plants. Thyroid doses are, in most cases, mainly due to the consumption of ^{131}I-contaminated fresh cows' milk, with minor contributions resulting essentially from the consumption of leafy vegetables and other foodstuffs with short shelf life, and from inhalation. Because of the smaller mass of their thyroid gland, children receive higher doses than adults for a given intake of ^{131}I. Atmospheric releases of, and thyroid doses from, ^{131}I from the nuclear industry are relatively well documented (1-2):

- Testing of nuclear weapons in the atmosphere, which took place essentially in the early 1960s, caused the release of about 650 000 PBq of ^{131}I (2). The major part of this activity was produced in high-yield tests, and was carried upwards into the stratosphere, from which it descended to ground level in a matter of months or years. Consequently, little ^{131}I was available to deliver doses to man. Collective thyroid doses from global fallout of ^{131}I are estimated to have been about 3.3×10^6 man Gy, corresponding to a per caput thyroid dose to the world population of about 1 mGy. These figures, however, do not take into account the local and regional collective thyroid doses from the early, low-yield, tests that were conducted in the 1950s. Some of these low-yield tests were carried out at the Nevada Test Site in the United States, mainly from 1951 to 1957; they caused a release of about 5 500 PBq of ^{131}I in the atmosphere. Because the explosive energy of those tests was relatively small, most of the ^{131}I produced remained in the troposphere and was rapidly available to contaminate human foodstuffs. A preliminary estimate of the collective thyroid dose to the population of the contiguous United States from the tests conducted at the Nevada Test Site is about 4×10^6 man Gy, corresponding to an average thyroid dose of about 20 mGy for that population (3). The thyroid doses received by the populations living in the vicinity of the Nevada Test Site have been studied in detail (4-6). Individual thyroid doses to children were estimated to range up to 4 600 mGy (5). It should also be noted that the test Bravo, which consisted in the detonation in March 1954 of a high-yield device mounted on a barge over the reef of Bikini Atoll in the mid-Pacific Ocean, resulted in intense local and regional fallout and in the evacuation of about 300 people within 3 days after the detonation as well as the exposure of Japanese fishermen on board the Lucky Dragon (7-8). The estimated thyroid doses which, in this case, were mostly due to short-lived radioiodines, ranged up to 20 000 mGy (9).

- The operation of nuclear reactors leads to relatively small releases of ^{131}I under normal conditions; it is estimated that the total release of ^{131}I from reactors used worldwide for the production of electrical energy up to 1989 was 0.045 PBq and that the corresponding collective thyroid dose to the local and regional populations residing around the reactors is 460 man Gy (2). However, much greater atmospheric releases and doses resulted from the Windscale accident of 1957 and from the Chernobyl accident of 1986. About 0.7 PBq of ^{131}I was released during the Windscale accident (10); the collective thyroid dose was approximately 20 000 man Gy (11), with individual thyroid doses ranging up to 100 mGy (12). During the Chernobyl accident, about 330 PBq of ^{131}I were released into the atmosphere (13); a preliminary estimate of the total collective thyroid dose received by the populations

residing in the contaminated areas of the former Soviet Union is about 1.2×10^6 man Gy (14); individual thyroid doses up to 10 000 mGy and more are estimated for children in the most affected areas (15). In comparison to those reactor accidents, the reactor accident of Three Mile Island in 1980 was minor with an estimated atmospheric release of ^{131}I of 0.00055 PBq (16-17).

- The operation of plants that reprocess nuclear fuel for civilian purposes results in small releases of ^{131}I because the nuclear fuel originating from the reactor is stored before reprocessing for a time long enough to ensure that ^{131}I has decayed to low levels. It is estimated that the total release of ^{131}I from worldwide civilian fuel reprocessing plants was 0.004 PBq up to 1989 and that the corresponding collective thyroid dose to the local and regional populations residing around the fuel reprocessing plants is 30 man Gy (2). However, much greater atmospheric releases and doses resulted from the operation of plants reprocessing nuclear fuel for military purposes during the early days of the nuclear age when only a short storage time was allowed before reprocessing. Releases of ^{131}I at Hanford from 1947 to 1949 amounted to approximately 25 PBq (18) and a similar figure has been advanced for the releases at Chelyabinsk (19). Assuming a collective thyroid dose of 10^{-11} man Gy per Bq of ^{131}I activity released (2), the collective thyroid doses resulting from the releases from each plant would be about 2×10^5 man Gy.

The evaluation of the thyroid doses from radioiodine releases depends on the type of monitoring data that is available. The preferred types of data are, in order of decreasing usefulness: (a) direct thyroid measurements, (b) concentrations in air, milk, and leafy vegetables, (c) depositions per unit area of ground, and (d) atmospheric releases. The use of each type of data will be illustrated in turn.

EVALUATION OF THYROID DOSES BASED ON DIRECT THYROID MEASUREMENTS.

In the case of the nuclear reactor accident that occurred at Chernobyl in April 1986, the content of ^{131}I in the thyroid of people living in the highly contaminated areas of the former Soviet Union was large enough that the gamma radiation emitted by the thyroid as a result of the radioactive decay of ^{131}I could be readily measured with a radiation detector held in the vicinity of the neck. Several hundred thousands people were monitored in this way in Ukraine, Belarus, and Russia within a few weeks after the accident (15; 20-21). The measured exposure rates were then converted into thyroid doses using appropriate assumptions on the dynamics of intake of ^{131}I both before and after the direct thyroid measurement. Since few measurements of ^{131}I in air and foodstuffs were made after the accident in former Republics of the Soviet Union, the dynamics of intake of ^{131}I was largely based on environmental transfer models. Because the ingestion of ^{131}I-contaminated milk was for the majority of individuals exposed the main contributor to the ^{131}I intake (22), the intake function was in most cases represented by the time dependence of the milk contamination following a single deposition.

In the three Republics of the former Soviet Union with highly contaminated areas (Ukraine, Belarus, and Russia), the databases on thyroid doses derived from direct thyroid measurements were used to infer the thyroid doses in areas with few, or no, direct thyroid measurements. In each of the three countries, relationships were sought between the thyroid dose and the ^{137}Cs deposition, which has been extensively measured throughout the contaminated areas:

- in the Chernigov region of Ukraine, the following empirical relationships were obtained (15):

  $D(T) = K \times a^{\exp(-b \times T)}$ [1]

  where: D(T), in cGy, is the thyroid dose for age T (y),
  a (unitless) is a parameter representing the thyroid dose at age 0
  b (y^{-1}) is a parameter describing the age dependence of the thyroid dose
  K (cGy) is a scaling parameter characterizing the radioiodine intake, calculated according to:

  $\log(K) = 640 \times (\log(\sigma(^{137}Cs)) / \rho^2) + 2.7 \times \cos(\phi) + 0.013 \times \rho \times \sin(\phi) - 1.6$ [2]

  where: $\sigma(^{137}Cs)$ is the ^{137}Cs deposition at the location considered,
  ρ (km) and ϕ are the polar coordinates of that location with respect to the Chernobyl site.

- in Belarus, a relationship has been established between the average thyroid dose received by people in rural settlements and the ground-deposition density of radionuclides (^{137}Cs or ^{131}I) in this settlement and in the area around the settlement (20). For the settlements in Hoiniki in Gomel oblast, and Kostukovichi and Krasnopolye in Mogilev oblast:

D_{jx} (adult) = $3.5 \times 10^{-8} \times \sigma_x(^{131}I) + 1.4 \times 10^{-8} \times \sigma_{jx}(^{131}I)$ [3]

$= 3.5 \times 10^{-8} \times R_x \times \sigma_x(^{137}Cs) + 1.4 \times 10^{-8} \times R_{jx} \times \sigma_{jx}(^{137}Cs)$ [4]

where: D_{jx} (adult) is the arithmetic mean thyroid dose, in Gy, for adult population in settlement, j, in area, x, in the absence of any countermeasures in the settlement and for typical lifestyle and dietary habits,

$\sigma_x(^{131}I)$, $\sigma_x(^{137}Cs)$ is the average ground-deposition density, in Bq m^{-2}, of ^{131}I (^{137}Cs), in area, x,

$\sigma_{jx}(^{131}I)$, $\sigma_{jx}(^{137}Cs)$ is the average ground-deposition density, in Bq m^{-2}, of ^{131}I (^{137}Cs), in the settlement, j, in area, x,

R_x, R_{jx} is the average ratio of the ^{131}I to ^{137}Cs ground-deposition densities in area, x, or in the settlement, j, in area, x.

It can be expected that, on average in an area, $\sigma_{jx}(^{131}I) = \sigma_x(^{131}I)$, so that the average relationship between ^{131}I deposition density and the average adult thyroid dose is:

$D_x(adult) = 4.9 \times 10^{-8} \times \sigma_x(^{131}I)$ [5]

Ongoing research may clarify whether equations 3 and 4 are generally applicable to all contaminated areas of Belarus. It is likely that correction coefficients taking into account the role of fuel particles, and parameters such as the standing crop biomass, the fraction of cow's intake from pasture grass, and the date of the beginning of cow's pasture will need to be factored in (20).

- in Russia, Zvonova and Balonov (21) analyzed the thyroid measurements and radiation survey data for the Bryansk and Tula oblasts. The thyroid doses derived from direct thyroid measurements for 3 to 6 years old children were found to be correlated with the ^{137}Cs ground-deposition density, the kerma rate in air on May 10-12, 1986 (i.e, 14 to 16 days after the beginning of the accident), the mean ^{131}I concentration in milk in the period May 5-12, 1986, and the average radiocesium content in adults in July-August, 1986. With respect to the ^{137}Cs ground-deposition density, the following relationship was obtained:

  $D(3\text{-}6) = (76 \times 10^{-8}) \times \sigma(^{137}Cs)$ [6]

  where: D(3-6) is the average thyroid dose for 3 to 6 years old children (Gy), and
  $\sigma(^{137}Cs)$ is the ^{137}Cs ground-deposition density (Bq m^{-2}).

  According to Zvonova and Balonov (21), the average ratio of the deposition densities of ^{131}I and ^{137}Cs was approximately 8 immediately after the period of intense deposition, so that:

  $D(3\text{-}6) = (9.5 \times 10^{-8}) \times \sigma(^{131}I)$ [7]

It should be noted that the measurement of the gamma radiation emitted by the thyroid with a radiation detector held in the vicinity of the neck is not the only method available to derive the thyroid dose from a direct measurement on man. Measurements of ^{131}I in urine also have been used for that purpose, notably to estimate the thyroid doses received by the Marshallese as a result of the test Bravo, in 1954 (9).

EVALUATION OF THYROID DOSES BASED ON MEASUREMENTS IN FOODSTUFFS AND IN AIR.

For regions other than the most contaminated areas of the former Soviet Union, the evaluation of the thyroid doses resulting from the Chernobyl accident was based on measurements in foodstuffs and in air. In Russia, Kryshev (22) made use of the detailed data of radioecological monitoring that were available for Sosnovy Bor near Leningrad to infer that the thyroid doses from inhalation were much lower than those due to ingestion and that the main contributors to the thyroid dose received by children were the consumption of milk, followed by the consumption of water, vegetables, bread, and home-baked goods. The following empirical relationship was derived (22):

$D(T) = K(T) \times R(T) \times \sigma(^{131}I)$ [8]

where: D(T) is the thyroid dose, in Gy, for age, T, in years,
R(T) is the thyroid dose coefficient, in Gy Bq^{-1},
$\sigma(^{131}I)$ is the ^{131}I deposition density, in Bq m^{-2}, derived from the ^{137}Cs ground-deposition density, and calculated for 15 May 1986 (about 17 days after the likely time of highest deposition),
K(T) is the ^{131}I transfer coefficient from ground deposition to intake by people of age, T, in Bq per Bq m^{-2}.

The following values of K(T) were obtained by Kryshev (22):

T (y)	1	5	10	15	adult
K (Bq per Bq m^{-2})	0.28	0.32	0.36	0.36	0.47

When recalculated to reflect the transfer coefficient related to the total ground deposition of ^{131}I, assumed to have occurred on 28 April 1986, the values of K(T) become:

T (y)	1	5	10	15	adult
K (Bq per Bq m^{-2})	0.065	0.074	0.083	0.083	0.11

On the basis of the variation of K with age shown above, using the thyroid dose coefficients recommended by ICRP (23), and population fractions of 0.02, 0.16, 0.20, and 0.62 for the age groups around 1 y, 5 y, 10 y, 15 y, and for adults, respectively, a transfer coefficient from ^{131}I deposition density to per caput thyroid dose of 7×10^{-8} Gy per Bq m^{-2} is obtained.

The same parameter values can also be used to derive the per caput transfer coefficients from the adult values for Belarus (equation 5) and from the 3 to 6 years old children for Russia (equation 7; data from Zvonova and Balonov). The per caput transfer coefficients obtained in that way are 7×10^{-8} Gy per Bq m^{-2} for Belarus and 5×10^{-8} Gy per Bq m^{-2} for Russia (data from Zvonova and Balonov).

The ^{131}I concentrations in milk and in leafy vegetables that were measured in most countries of the Northern hemisphere after the Chernobyl accident were used by the UNSCEAR Committee to estimate in a consistent manner the thyroid doses received by the populations of those countries (13). The ^{131}I concentrations in leafy vegetables were found to be, on average, 1.5 times greater than those in milk. However, when the relative consumption rates of milk and leafy vegetables are taken into account, the ^{131}I intakes from milk were, on average, much greater than those from leafy vegetables, especially in the countries of Northern, Central, and Eastern Europe that were most affected by the Chernobyl accident.

Measurements of ^{131}I concentration in milk were also used by the UNSCEAR Committee to estimate the thyroid doses due to global fallout from the nuclear weapons tests conducted in the atmosphere, mainly in the 1960s (2; 17). On the basis of measurements in Argentina (24), the relationship between ^{131}I ground-deposition density, $\sigma(^{131}I)$ in Bq m^{-2}, and time-integrated milk concentration, C_m in Bq a L^{-1}, was estimated to be:

$$C_m = 6.3 \times 10^{-4} \ \sigma(^{131}I) \qquad [9]$$

A transfer coefficient from ^{131}I deposition density to per caput thyroid dose of 8×10^{-8} Gy per Bq m^{-2} is derived from equation 9 using the values adopted by UNSCEAR (2) of 0.3 L d^{-1} for the average milk consumption rate and 1.2×10^{-6} Gy Bq^{-1} for the age and milk consumption weighted thyroid dose coefficient.

EVALUATION OF THYROID DOSES BASED ON MEASUREMENTS OF GROUND DEPOSITION.

The importance of the deposition - pasture grass - cow's milk pathway to man as a major dose contributor in the case of an atmospheric release of ^{131}I was not fully recognized until 1957. Therefore, the dose reconstruction efforts related to radioiodine releases prior to 1957 are largely based on measurements of radionuclides other than ^{131}I (or of total beta measurements or exposure rates) as well as on environmental transfer models.

Atmospheric testing of nuclear-weapons-related devices at the Nevada Test Site (NTS) began in 1951; most of the atmospheric releases of radioactive materials, including ^{131}I, took place in test series conducted in 1951, 1953, 1955, and 1957. In the Off-Site Radiation Exposure Review Project of the U.S. Department of Energy, doses were estimated for the "local" populations (less than 800 km from the NTS); the key data used to reconstruct thyroid doses from ^{131}I releases were estimates of ground-deposition densities of ^{131}I from each location of interest and each important test, which were derived either from the available exposure rates or from contemporary measurements of ^{137}Cs and $^{239,240}Pu$ in soil, combined with data on the relative abundance of radionuclides produced in each test (25-27). The transfer coefficients representing the ^{131}I intakes per unit deposition density were estimated to vary according to the fallout date and to the age and sex of the person considered (28). Examples of results, averaged over both sexes, for a date with low transfer coefficient (17 March) and for

a date with high transfer coefficient (24 July) are (28):

Age (y)	<1	1-11	12-18	Adult
Transfer coefficient (Bq per Bq m^{-2}): fallout on 17 March	0.0044	0.0092	0.013	0.016
Transfer coefficient (Bq per Bq m^{-2}): fallout on 24 July	0.17	0.14	0.13	0.08

The per caput thyroid doses per unit deposition density, calculated using the thyroid dose coefficients recommended by ICRP (23), are found to vary from 9×10^{-9} to 9×10^{-8} Gy per Bq m^{-2} according to the date of fallout.

The U.S. National Cancer Institute also is carrying out a study related to ^{131}I releases from the NTS; that study includes the estimation of thyroid doses received by populations across the continental United States (29). According to preliminary estimates, the amount of ^{131}I that was deposited throughout the continental United States as a result of the weapons tests conducted at the NTS is 1.5 EBq (over an area of 7.7×10^6 km^2) and the per caput thyroid dose was about 20 mGy, corresponding to an average thyroid dose per unit deposition density of about 10^{-7} Gy per Bq m^{-2} (3).

EVALUATION OF THYROID DOSES BASED ON MEASUREMENTS OF AIRBORNE RELEASES.

There are cases where human or environmental radiation monitoring data are not available, either because the radioiodine releases, although important, occurred during the early days of the nuclear age, when environmental monitoring was not a priority, or because the radioiodine releases are so low that they cannot be readily detected in the environment. In the absence of human or environmental monitoring data, the evaluation of the thyroid doses is based on estimates of radioiodine releases.

For example, the ^{131}I releases from the Hanford Site in the United States for the years 1945 to 1951 were estimated on the basis of the operating histories of facilities on the site and on the knowledge of the effluent control technologies in use at the time of release (18). Detailed thyroid dose estimates were then prepared for 1102 locations around the site, 12 different representative individuals, distinguished by age and gender, and a series of food source scenarios, by means of environmental transfer models and data on milk production, distribution and consumption, among other factors (30).

Routine reactor releases have been usually so low in recent years that the environmental concentrations are not detectable and the resulting thyroid doses can only be calculated by means of environmental transfer models. The UNSCEAR Committee, which compiles every few years the data available on routine releases from nuclear power plants and other nuclear facilities (2; 13; 17), uses a model site and model calculations to evaluate the collective doses resulting from routine releases of radionuclides; the collective thyroid dose per unit of ^{131}I activity released is estimated by the UNSCEAR Committee to be about 10^{-11} man Gy per Bq (2; 13; 17).

DISCUSSION.

General information on the major sources of radioiodine releases into the atmosphere from the nuclear industry is summarized on Table 1. Most of those releases occurred more than 30 years ago. The nuclear weapons tests that were conducted in the atmosphere account for most of the ^{131}I that was released into the environment and for most of the resulting collective thyroid dose.

The thyroid doses were evaluated using different methods according to the types of radiation data that were available. Table 2 presents values of collective thyroid doses normalized per unit of activity released and of average thyroid dose normalized per unit deposition density. As expected, the normalized collective doses are much greater for ground-level releases than for the nuclear weapons tests, which carried the radioactive materials that they produced to high altitudes. The average thyroid doses per unit deposition density are remarkably similar, given the variety of methods and models that were used to estimate that quantity. It should be kept in mind, however, that for a given deposition density, the individual thyroid doses vary by orders of magnitude according to the date of fallout, agricultural practices, the age of the person considered and dietary habits.

THE INFLUENCE OF ICRP ON EUROPEAN LEGISLATION CONCERNING MEDICAL RADIATION EXPOSURE

Penelope J Allisy-Roberts
BIPM, Pavillon de Breteuil, 92312 Sèvres Cedex, France

INTRODUCTION

There are two fundamental Directives in force in Europe concerning radiation protection. Staff and public protection is covered by a Basic Safety Standards Directive, the current version of which was enacted in 1980 (1,2), following the recommendations of the International Commission on Radiological Protection (ICRP) published as ICRP 26 (3). In 1984, a European Directive specifically covering patient protection was enacted for the first time (4) and is still in force.

In 1991, the ICRP published general recommendations as reported in ICRP 60 (5) updating their previous general recommendations (3) of 1977. Since its publication, ICRP 60 has been considered within the European frame and new Directives have been negotiated to include the latest concepts. These two Directives, which will replace the present ones, are at different stages of adoption but the process should be complete for both within eighteen months.

The aim of this paper is to describe the input of the Article 31 Group of the European Commission to the process of amending European radiation protection legislation and to detail the changes which have been incorporated, which should improve patient protection in the medical diagnostic and therapeutic environment in accordance with ICRP recommendations.

THE LEGISLATION AMENDMENT PROCEDURE

The group of scientific experts in public health referred to in Article 31 of the Euratom Treaty (Article 31 Group) and appointed by the Member States of the European Union (EU), advises the European Commission on matters concerning radiation protection within the European Union. In 1993, the Article 31 Group proposed revisions to the Basic Safety Standards Directive to take into account the recommendations of ICRP 60. Their proposal has been amended on its journey through the European legal process and is currently in the final stages of approval (6).

In 1994, the Article 31 Group set up a working party on Medical Exposures which had as its members, radiation physicists and medical practitioners from radiotherapy, nuclear medicine and radiology. They were asked to review the present Directive on patient protection and the experience gained in its implementation in the Member States. The working party considered the developments in the medical uses of ionizing radiation, the progress in radiation protection epitomized by the recommendations of ICRP and relevant aspects of the proposed Basic Safety Standards Directive. The outcome of this work was a revised patient protection Directive which was then discussed and revised by the Article 31 Group.

The final opinion of the Article 31 Group supporting this revision of the current patient protection Directive was reached at a meeting on 31 May 1995. This revised Directive on "health protection of individuals against the dangers of ionizing radiation in relation to medical exposures" (hereinafter referred to as the Patient Protection Directive or PPD) was submitted last Autumn to the European Commission for adoption. The schedule now is that the PPD goes to the Economic and Social Committee of the EU (which is the procedure laid down by Article 31) in April 1996. In the Summer it will then be introduced to the European Council who will seek the opinion of the European Parliament this Winter. If all goes well, the new Directive will be adopted by the European Council next Summer, that is July 1997.

Each Member State in the European Union will then have a period, probably up to 1999, to produce enacting legislation to implement the Directive. In the UK for example, this will take the form of revision to the Regulations on patient protection [7,8].

The protection of workers, including medical and paramedical staff, and of members of the public such as visitors to medical centres, is not affected by the Directive on medical exposures but is ensured by the Basic Safety Standards Directive (6).

THE INFLUENCE OF ICRP RECOMMENDATIONS

It is perhaps not surprising that the recommendations of the ICRP are incorporated into European legislation comparatively quickly. On the Article 31 Group, there are three members of ICRP Committee 3 (all of whom are members of the Medical Exposures working party), members of the three other ICRP Committees and, indeed, the Chairman of the Main Commission. All the members of the Article 31 Group either work directly with radiation (necessarily not just in the medical field), or have a role in radiation protection in their Member State.

Although the general recommendations of ICRP 60, where they relate to medical exposures, have been taken into account during the discussions on the Article 31 Group, other ICRP publications relating to medical exposures have obviously influenced the outcome of the proposals for revision which produced the new PPD. One consequence of which is that the proposed Patient Protection Directive has been enlarged in scope, to include both volunteers in research and, individuals, such as close family or friends, helping voluntarily in the support and comfort of patients (often referred to as comforters and carers).

The 1984 Directive had already incorporated the principles of justification and optimisation as they relate to medical exposures. The new PPD has several specific requirements which reinforce these concepts such as referral criteria and the use of reference levels for medical diagnostic exposures. There is published evidence that by applying the principles of justification and optimization, exposures can be reduced in a cost-effective manner without losing the efficacy of the related practice [9,10].

The concept of potential exposures to patients, together with the requirement of keeping their probability and magnitude as low as reasonably achievable, is specifically included in the PPD.

An important requirement of the current Directive is that any use of ionizing radiation in medical procedures is effected under the responsibility of a practitioner (this term being clearly defined within the Directive as relating to medical, dental of other health professional entitled to take clinical responsibility within their Member State). The new PPD requires that the overall responsibility remains with the practitioner but to provide support, practical aspects of the medical procedure could be delegated to other individuals as authorized by the competent national authorities. The requirements for the training of practitioners and these other individuals are now explicit, including continuing education and training, which should lead to improvements in practice.

The PPD expands the existing requirements on quality control of radiological installations and supplements them by requiring the establishment of quality assurance programmes which also include assessment of doses received by patients. Such programmes (10) have been demonstrated to reduce individual exposures (11). Health and safety requirements including radiation protection aspects regarding the design, manufacture, placing on the market of the medical devices used are actually covered by another Council Directive 93/42/EEC concerning Medical Devices (12).

Special requirements are included for sub-sets of individuals who are deemed to be at particular risk from radiation exposure. These include paediatric patients, asymptomatic individuals entering health screening programs, patients undergoing interventional radiology or high exposure studies such as computed tomography, pregnant patients, breast feeding patients and comforters and carers.

In the last part of the PPD, to monitor progress, Member States are requested to ensure the establishment of processes for auditing the implementation of the requirements of the Directive, and to make estimates of individual and collective doses from the various medical practices.

ICRP Committee 3 (Medical radiation) is currently producing reports on the practical aspects of implementing the ICRP recommendations. These are being designed to help, not just the legislators

and practitioners within European Member States but those in every country, to apply the principles of radiation protection every day as a natural extension of their medical radiation practices.

CONCLUSION

The objective of the 1984 Euratom Directive on patient protection was to reduce medical radiation exposures to the population without jeopardizing the benefits, whether these were early recognition of disease, diagnosis or therapy. With the continuing expansion of medical practices using ionizing radiation, measures need to be taken to reduce individual exposures so that collective effective dose is limited.

The revised Patient Protection Directive maintains the previous objective and provides further detail, founded on practical experience and ICRP reports, as a base for European Member States to develop their own legislation. This should result in improved use of radiological practices so that the population can continue to receive the benefits of medical exposures while the collective effective dose is better controlled.

THE ROLE AND DETERMINATION OF PATIENT DOSE IN X-RAY DIAGNOSIS

M. Zankl, N. Petoussi-Henß, W. Panzer

GSF - Forschungszentrum für Umwelt und Gesundheit
Institut für Strahlenschutz
Postfach 1129

ABSTRACT

In radiation protection of the patient in x-ray diagnosis all three principles of radiation protection should be applied. So-called dose constraints which limit entrance surface doses ensure implicitly that patient doses should not exceed certain levels. With respect to justification, it is believed that there is a large potential for patient dose reduction by avoiding both clinically unjustified examinations and unnecessary repetition of diagnostic procedures. While this appears to be quite straightforward, the strategy for optimisation is more complicated. Here, a reasonable compromise between high image quality and low patient dose has to be found, as often measures aimed at improved image quality lead to an increase of patient dose, and, vice versa, measures aimed at a reduction of patient dose result also in reduced image quality.

Whereas the problem to quantitatively assess the quality of a given image is still not solved satisfactorily, the determination of patient doses has become increasingly feasible in recent years. For this purpose, computer codes, often based on Monte Carlo techniques, simulating the radiation transport in material are commonly used together with computational models of the human body. Most of the computational body models in use are so-called mathematical models, that means, mathematical expressions representing simple geometrical bodies are used to describe idealised arrangements of body organs. Additionally, tomographic models were developed in recent years which use computed tomographic data of real persons to provide three-dimensional representations of the body.

Using these computational models of the human body, numerous studies concerning organ and tissue doses from diagnostic radiology were performed. Although it is not recommended to apply the calculated doses to assess individual patient doses, the influence of single exposure conditions as, e.g., tube voltage, filtration, field size and location, focus-to-skin distance, on organ and tissue doses can be studied readily, thus resulting in information prerequisite for optimisation in x-ray diagnosis. Additionally, the tomographic models enable to assess the influence of moderate variations of the patient size on organ doses and, therefore, improve to a certain extent the applicability of literature data on patient doses to individuals.

INTRODUCTION

Because most procedures causing medical radiation exposures are clearly justified and because the procedures are usually for the direct benefit of the exposed individuals, less attention has been given to the optimisation of protection in medical exposures than in most other applications of radiation sources (1). On the other hand, it is a well-known fact that the radiation doses from diagnostic radiology are the largest contribution to the collective dose from all man-made sources of radiation (2). From this, it is obvious that diagnostic radiology should be of major concern for radiation protection and that, consequently, the guidelines established by

the ICRP for occupational radiation protection should be applied also to diagnostic radiology as far as possible.

(1) Justification:
In relation to the justification of examinations in diagnostic radiology it is accepted that most examinations result in information beneficial to the patient and that, consequently, the benefit of these examinations will, in general, by far outweigh the radiation detriment. It is, nevertheless, believed that there is a large potential for patient dose reduction by avoiding both clinically unjustified examinations and unnecessary repetition of diagnostic procedures. Furthermore, it should also be considered whether imaging techniques not involving ionising radiation could be applied if they result in the same diagnostic benefit.

(2) Optimisation:
Optimisation in diagnostic radiology commonly involves two aspects: the first is to establish quality assurance and quality control programmes to ensure a proper performance of the x-ray equipment; the second is the necessity to find a reasonable compromise between high image quality and low patient dose, as often measures aimed at improved image quality lead to an increase of patient dose, and, vice versa, measures aimed at a reduction of patient dose result also in reduced image quality.

(3) Limitation:
It is generally accepted that there is little use of dose limits in diagnostic radiology, as there are large ranges of doses due to the different complexity of the situations considered. It is, however, of concern that dose differences of up to two orders of magnitude for the same type of examination have been reported in diagnostic radiology (1). Therefore, more and more consideration is given to dose constraints for application in some common diagnostic procedures (3-5). These should be applied with sufficient flexibility to allow higher patient doses where indicated by sound clinical judgement.

Whereas for the justification of diagnostic radiological procedures patient doses do not play an important role, they are of major consequence for optimisation and limitation. Furthermore, the necessity to determine patient doses may arise routinely due to legal regulations (as, e.g. the German X-ray Ordinance) or in special cases, e.g. due to possible legal consequences of an individual examination. The various dose quantities considered for these specialities will be characterised in the following, and methods to determine these dose quantities will be described.

THE ROLE OF PATIENT DOSES IN X-RAY DIAGNOSIS

There are several aspects in x-ray diagnosis where patient doses are considered:

(1) Dose constraints:
A strict limitation of doses to patients comparable to the practice in other fields of radiation protection is unthinkable in x-ray diagnosis as this would adversely affect the care for the patient in special situations. On the other hand, it seems unnecessary that dose differences of orders of magnitude should occur for routine examinations. Therefore, dose constraints can be established in a sense that recommended dose values normally should not be exceeded for a certain examination of an average patient. These recommended values are based on the results of extended field studies where good radiographic technique and equipment were to be used. The dose constraints for each specific examination usually were then derived as the third quartile of all doses reported for this examination (3-5). It is important both for carrying out

such a field study and for testing of compliance with the recommended values in routine that the reference doses are of a simple nature and accessible to routine practice. Therefore, usually easily measurable dose quantities are used for this purpose as, e.g., entrance dose (free in air), entrance surface dose or dose-area product.

In this context, the demand for measuring the dose-area product in specified has recently arisen (6). The fields considered are extremely dose-intensive x-ray examinations, paediatric examinations (especially frequent examinations of premature babies), examinations in connection with surgical measures or in interventional radiology with extended fluoroscopy times. Furthermore, it was recommended to measure the dose-area product during the training of medical staff and at facilities equipped to switch to a performance involving high dose-rates. Although no attempt was made to establish dose constraints for these fields, the necessity was recognised to increase the awareness of the magnitude of doses involved; with this increased awareness it is hoped that also the sense of responsibility for the doses applied to patients would increase.

(2) Optimisation of examinations:
Optimisation in x-ray diagnosis means achieving a reasonable compromise between high image quality and low dose to the patient. For this purpose, special quality criteria characterising a good radiographic technique for different types of examinations were evaluated by CEC study groups (3,4). These include detailed requirements for the image as well as a set of technical parameters for the performance of the examination. As the recommended technical parameters are accepted to result in sufficient image quality, optimisation considerations can be based on the resulting patient doses. Here easily accessible doses as, e.g., entrance surface dose, are insufficient because the dependence of doses within the patient on the technical parameters varies with depth in the body and distance from the x-ray field. This is demonstrated by an example in Table 1. The increase of tube voltage from 90 to 125 kV for a chest examination of a female phantom reduces the entrance surface dose markedly, whereas organ doses decrease by much less or even not at all, depending on the position of the organ within the body.

Table 1: *Organ doses, entrance surface dose and effective dose from a postero-anterior chest examination for two different tube voltages, calculated for a female mathematical phantom (7). Focus-to-skin distance: 150 cm; field size: 35 cm · 35 cm; anti-scatter grid: 12/40; dose at image receptor: 5 µGy (Data from (8)).*

	Organ doses (µSv)			Organ doses (µSv)	
Tube voltage	90 kV	125 kV		90 kV	125 kV
Thyroid	22.6	22.8	Adrenals	146.6	116.5
Thymus	37.6	36.6	Kidneys	15.0	11.4
Breast	48.9	43.4	Red bone marrow	45.1	38.4
Oesophagus	79.0	59.4	Skeleton	120.3	86.6
Lungs	214.3	164.5	Skin	37.6	27.4
Liver	52.6	45.7	Muscle	37.6	27.4
Spleen	67.7	54.8			
Pancreas	45.1	38.8	Entrance surface	466.2	301.6
Stomach wall	22.6	22.8	Effective dose	47.5	38.2

Consequently, in a first step, a set of organ doses seems to be a more appropriate descriptor of patient exposure. On the other hand, a whole set of doses is rather unpractical, since single

organ doses are influenced by the altered exposure parameter to a different extent. There may occur situations where a change of one or more technical exposure parameters may result in the decrease of some organ doses and in the increase of some others. Then a list of organ doses does not allow an unequivocal decision which of the techniques considered is preferred with respect to patient dose. In these situations, a more condensed form of the information, preferably in one single number, is of advantage. For this purpose, the effective dose is of benefit, the sum of the weighted equivalent doses in selected organs and tissues of the body as introduced by the ICRP (1). Although this quantity should be used with caution in the field of x-ray diagnosis (8), it allows the ranking of various examination techniques with respect to patient dose in a rather simple and unequivocal way.

(3) Determination of doses to individual patients:
There are very few cases in X-ray diagnosis where a determination of doses to an individual becomes necessary. These are mainly: examinations in the pelvic region of pregnant patients; frequent examinations in the course of occupational diseases after which cancer occurs and the question arises with which probability this was caused by the examinations; unnecessary or inadequately conducted examinations entailing litigation; examinations leading to extremely high doses which might be followed by deterministic effects. In these rare situations, the determination of single organ doses is indispensable. In any situation where the probability has to be determined that a specific disease having occurred in an individual could have been caused by a certain exposure, the dose to the diseased organ is of major importance. In the case of deterministic effects, the knowledge of single organ doses can support further patient care.

(4) Determination of collective doses:
Doses of the whole or of groups of a population are determined to provide data for the following purposes: justification of examinations and risk-benefit analysis as, e.g., in the case of screening programmes; evaluation of the contributions from different examinations to decide where optimisation measures would be most necessary and effective; balancing of exposures due to statistical reasons and comparison with exposures from other sources. Here again, effective dose is of major importance, although the derivation and use of a slightly different quantity employing risk factors more appropriate to a patient population than those specified by the ICRP for a population representative of all ages and both sexes (1) would be highly desirable.

THE DETERMINATION OF PATIENT DOSES IN X-RAY DIAGNOSIS

In those cases where measurable dose quantities can be used, their determination is quite straightforward. Devices for the measurement of dose-area product are becoming more and more frequently available in common x-ray practice; if the field size applied during an examination is known, the entrance dose free in air can be easily deduced. The entrance surface dose can be measured directly on the patient using appropriate dosimeters without hindering the examination.

As soon as organ and tissue doses or effective dose have to be used, the situation is more complicated, as these doses are, in principle, unmeasurable. There is some indication that effective dose could be deduced from measured values of the dose-area product to within approximately 30% accuracy using a single conversion coefficient for groups of projections, field positions and beam qualities (9). Further investigations showed, however, that the numerical uncertainties of converting dose-area product to effective dose exceed 30% in many cases, when generally valid conversion coefficients are used (10). To refine this approach, it becomes

necessary to consider additional exposure parameters like tube voltage and field size, shape and position. Furthermore, this approach is not feasible for single organ doses.

A convenient method for the determination of organ and tissue doses are calculations using radiation transport codes together with computational models of the human body. The calculations are mostly based on the Monte Carlo method; that means that single particle histories are simulated whose exact course is sampled from known probability distributions of the influencing parameters; the dose quantities of interest are finally evaluated by averaging over millions of these single histories.

Types of computational models

The models of the human body used for this type of simulations are mostly so-called mathematical models, that means, mathematical expressions representing planes, cylindrical, conical, elliptical or spherical surfaces are used to describe idealised arrangements of body organs. This type of models was introduced by Fisher and Snyder (11) and further refined and extended by various authors. At the GSF, male and female adult mathematical models have been introduced (7). The best known representative of the mathematical models is that by Snyder et al. (12,13) which has been commonly called the "MIRD-5 phantom" due to being published in the MIRD Pamphlet No. 5. Referring to this, mathematical models are sometimes also called MIRD-type models.

More recently, tomographic models were developed, which use computed tomographic (CT) data of real persons to provide three-dimensional representations of the body. The first step for the construction of these models is to obtain a whole-body CT scan consisting of contiguous slices. The data are then processed using appropriate image processing software. Each organ or tissue is represented by those volume elements (voxels) which were identified as belonging to it from the CT slice images. The tomographic type of models (also called "voxel models") was introduced by two groups independently, approximately ten years ago (14,15). More recently, voxel models were constructed by various workers (16,17). At the GSF, five models of this type were constructed so far, two paediatric, two adult and a model of an Alderson-Rando physical phantom (18-20).

Comparison of mathematical and tomographic models

In mathematical models, organ shapes are reduced to a very simple form to limit the software and computational requirements. Consequently, the mathematical models are not designed to describe any individual in detail but rather to represent whole populations. On the other hand, tomographic models are constructed from CT data of real persons who might deviate significantly from reference data. The shapes of the body organs are determined by identifying all the voxels belonging to each organ. Thus, the shape of each organ is more realistic than for the mathematical models, although, being reconstructed from a specific individual, it might not be representative of large populations.

Mathematical models are usually rigid in size, whereas the external dimensions of tomographic models can be adapted to any size, for each of the three dimensions independently. All internal dimensions of the resulting scaled-down or scaled-up version of the original model are also changed with the same scaling factors. It is, however, important to keep the scaling factors within rational magnitudes; otherwise, considerable errors in the body proportions might be introduced.

In mathematical models, all skeletal components are homogeneously distributed in the skeleton, and there is no geometric representation of spongiosa. Usually, for estimating the dose to

the red bone marrow, the variation of the red bone marrow distribution among different bones and at various ages is considered (21,22), whereas the variation within single bones is not. In tomographic models, the amount of bone marrow and hard bone in each single skeletal voxel can be estimated, based on the CT data. Although it is not possible to identify functional bone marrow by this method or to model the complicated trabecular bone structure exactly, the distribution of bone marrow can be determined with the resolution of the CT scan, i.e. normally a few cubic millimetres.

Apart from these differences which should be kept in mind, the two types of models, mathematical and tomographic, are, in principle, equally suitable for the calculation of organ and tissue doses in x-ray diagnosis.

Studies performed

The mathematical models, primarily designed for use in internal dosimetry, were soon applied for external exposure conditions also. The first of the studies for diagnostic radiology was performed by Rosenstein (23), presenting organ doses for frequent x-ray examinations of adult patients. This was followed by work related to paediatric radiology (24,25) and fluoroscopic examinations of the upper gastrointestinal tract (26). The exposure parameters in these studies refer to the situation in the USA and are different from those considered for organ dose calculations due to examinations in Western European countries. The latter were represented mainly by studies performed at GSF and NRPB for conventional x-ray diagnosis (27-29), computed tomographic examinations (30-33) and, more recently, for paediatric radiology (34). Organ doses for fluoroscopic examination of the coronary arteries were evaluated in a co-operation of the Center of Devices and Radiological Health and GSF (35).

Adult tomographic models were used for the calculation of organ doses from dental radiography (14,36-38). The tomographic paediatric models constructed at GSF were used for organ dose calculations in paediatric conventional x-ray diagnosis (18,39) and CT examinations (40,41). Furthermore, work was performed to study the influence of patient size on organ doses in x-ray diagnosis (42,43). Table 2 shows, as an example, some selected organ dose conversion coefficients for CT examinations of paediatric patients.

Table 2: *Summed organ dose conversion factors for head and thorax scans of an eight week old baby and a seven year old child. The tube voltage is 125 kV, the angle of rotation is 360°. An asterisk as table entry means that the conversion factor is less than 0.005 (Data from (41)).*

	Organ dose per air kerma free in air

Thyroid	0.59	0.60	0.58	0.41

CONCLUSIONS

In radiation protection of the patient in x-ray diagnosis, the three principles introduced by the ICRP for occupational radiation protection should be applied also; it should be recognised, however, that in applying these principles a higher flexibility, compared to occupational radiation protection, is needed in order not to adversely affect the care for the patient in special situations. Whereas for the justification of diagnostic radiological procedures patient doses do not play a significant role, they are of major consequence for optimisation and limitation. Dose limitation is, to a certain extent, achieved by the observation of dose constraints which are defined in form of easily measurable quantities, e.g. entrance surface dose, entrance dose free in air or dose-area product. Optimisation in x-ray diagnosis means to achieve a reasonable compromise between high image quality and low patient dose. For optimisation purposes, the above mentioned easily accessible quantities are of limited value; in this context, organ and tissue doses as well as effective dose are the quantities of interest.

Calculations using Monte Carlo techniques together with computational human models are a very suitable method for the determination of organ and tissue doses from various radiation exposures in diagnostic radiology. The calculated dose values apply, strictly speaking, only to patients with the same body characteristics as the models used and to an exact replication of the exposure parameters simulated. Individual doses are strongly influenced by the body dimensions as well as by the irradiation conditions, such as field size, field position, focus-to-film distance, photon spectrum, etc. Accordingly, organ doses derived from the literature may deviate from the doses in real patients and should, therefore, be applied to individual situations with appropriate caution. An evaluation of the influence of patient size, as included in some of the above mentioned studies, improves the applicability of literature data to individual patients to a certain extent. One of the most powerful applications of organ dose calculations is to quantify the effects of changes in the exposure conditions on the doses to single organs, as these effects are largely independent of individual patient anatomy. Knowledge of the relationships between organ doses and certain technical exposure parameters allow to select an examination set-up, among several possibilities known to result in acceptable image quality, which minimises the dose to certain organs. Thus, dose calculations can play an effective role within optimisation in x-ray diagnosis.

PRACTICAL APPROACHES TO DOSIMETRY FOR THE PATIENT AND STAFF FOR FLUOROSCOPIC PROCEDURES

Marvin Rosenstein

Center for Devices and Radiological Health, Rockville, MD 20850

INTRODUCTION

Three recent developments that provide practical information on radiation dosimetry for patients or clinical staff for diagnostic or interventional fluoroscopy are presented. They are: (i) a Handbook for determining absorbed doses in tissues (for patients) from coronary artery procedures; (ii) recommendations on avoiding radiation-induced skin injuries (to patients) during fluoroscopically-guided interventional procedures: and (iii) a method for determining effective dose (to staff wearing protective aprons) from fluoroscopic procedures, using the results of personal monitors.

HANDBOOK OF SELECTED TISSUE DOSES FOR FLUOROSCOPIC AND CINEANGIOGRAPHIC EXAMINATION OF THE CORONARY ARTERIES

The Monte Carlo procedure and anthropomorphic phantoms (i.e., ADAM and EVA) used to produce the Handbook for examinations of the coronary arteries is the adaptation of the BRHGAM code (1) by the Gesellschaft für Strahlen-und Umweltforschung (2). The mathematical phantom for the reference male patient (ADAM) is a modification of the original MIRD-5 phantom (3), with the addition of an esophagus (4) and the addition of a supporting tabletop at the back of the phantoms (5). The reference female patient (EVA) is the ADAM phantom reduced uniformly to 83 percent of its original size, with the unique female tissues instead of the unique male tissues (2).

The simulated examinations of the coronary arteries are based on a series of distinct x-ray fields commonly used in coronary interventional radiology, derived from analyses of practice at the Institut de Cardiologie de Montréal (6,7). The views and arterial projections represented are generally applicable to a broad range of examinations following a variety of clinical protocols. For each arterial projection, a separate Monte Carlo calculation was made with ADAM and EVA for the relevant complex oblique x-ray field in divergent-beam geometry, with specific x-ray spectra representative of clinical practice (5).

The Handbook presents twelve tabulations, one tabulation for each of eleven arterial projections, and one tabulation that provides nominal data that can be used for an examination consisting of several views, in lieu of the individual tabulations. The nominal approach is acceptable for coronary artery examinations because all the views share the heart as a relatively small, common region intercepted by the central ray of each different x-ray field. The arterial projections are specified by view (e.g., RAO, right anterior oblique), angulation of image receptor (if different than 0 degrees) in the transverse and saggital planes, and location of the field center (left or right ventricle). Descriptions of the standard nomenclature used in the anatomy of the coronary arteries and to identify the arterial projections, the specifications for the irradiation geometry and complex oblique views, and the coefficients of variation for the Monte Carlo calculations are provided in the Handbook (5). Data are tabulated for the entrance skin in the primary field and 20 internal tissues or organs. The tabulated values (conversion coefficients) are tissue dose (mGy) per 1-Gy air kerma (free-in-air) at the skin-entrance plane.

In extended coronary artery examinations, cumulative absorbed doses to that portion of skin lying directly in the path of the incident primary field may approach or exceed the thresholds for deterministic injury. The entrance skin in the primary field is only a small fraction of the entire skin tissue; the extent is delimited and the location is determined by the collimation and irradiation geometry of the anatomical projections.

Except for the heart, the internal organs and tissues listed are those with which cancer, genetic effects or in utero effects have been associated (8). The heart surrounds the ventricle field centers and always lies within the field of view. It receives the highest absorbed doses per unit air kerma of the internal organs. The data for the heart are provided for reference purposes; there is no health effect yet established for absorbed doses in the heart for the ranges that occur in coronary artery examinations.

The data are presented for three beam qualities for each reference patient (i.e., ADAM, 2.5, 4.0 and 5.5 mm Al HVL; EVA, 2.0, 3.5 and 5.0 mm Al HVL). The range of beam qualities corresponds to that observed

in the study conducted at the Institut de Cardiologie de Montréal (7) and that observed in a nationwide survey of fluoroscopy practice in the United States (9). The beam qualities are without the presence of a supporting tabletop. For the usual ranges of kVp and aluminum filtration combinations used in fluoroscopy and cineangiography of the coronary arteries, the results should have uncertainties of less than 10 percent when half-value-layer (HVL) alone is used to describe beam quality (5).

When the actual diameter of field of view (FOV) at the image receptor plane differs from that used in the reference simulation by more than 20 percent, the following correction is recommended (5):

$$[\text{FOV(actual)}/\text{FOV(tabulated)}]^2.$$

The correction is not applicable to the entrance skin in the primary field, since the absorbed dose in that portion of skin is not dependent on the size of the area irradiated.

The tabulation for the nominal conversion coefficients is given in Table 1.

Table 1. Nominal Conversion Coefficients for Fluoroscopic and Cineangiographic Examinations of the Coronary Arteries (from reference 5): SSD = 60 cm; SID = 90 cm; FOV diameter at image receptor = 14 cm

	Tissue dose (mGy) per 1-Gy air kerma (free-in-air at the skin-entrance plane)

Testes	+	0.002	0.004			

+ less than 0.001 mGy absorbed dose per 1-Gy air kerma.

The Handbook can be used to perform a view-by-view or a nominal analysis of an examination. To use the nominal approach, the coronary artery examination is characterized in an overall sense. This permits a quick, but somewhat less accurate way to estimate nominal tissue doses for a complete examination without detailed specifications for the particular views applied clinically.

The complete examination is characterized with nominal values for four parameters:

(a) the beam quality (i.e., mm Al HVL);

(b) the total air kerma (free-in-air at skin-entrance plane) summed for all the fluoroscopic plus cineangiographic segments and for all skin-entrance planes;

(c) the field-of-view diameter at the image receptor plane; and

(d) the highest cumulative entrance air kerma (i.e., fluoroscopic plus cineangiographic) for any single skin location. Such a skin region may be irradiated in only one view or in multiple views that share a common locus of irradiation.

The example given below is for a left-heart study of an adult male entailing a left ventriculogram in biplanar mode followed by left and right coronary angiography. In a typical application of the nominal approach, the user will rely on estimated values of the parameters for the entire examination that may be truly nominal, developed at the level of detail and with the degree of accuracy available to the user.

Nominal Parameters for the Entire Examination (Example)
Half-value-layer: 3.6 mm Al
Total air kerma (free-in-air) for all skin-entrance planes: 1.6 Gy
Field-of-view (FOV) diameter at image-receptor plane: 20 cm
Highest cumulative entrance air kerma for any single skin location: 0.80 Gy

Notes: a correction factor of 2.0 is needed for the actual FOV (20 cm rather than the 14 cm in the reference tabulation); and linear interpolation is made between reference HVLs

Tissue	mGy per 1-Gy Air Kerma	Relevant Air Kerma (Gy)	FOV Correction	Tissue Dose (mGy)
Entrance skin in primary field (maximum)	1090	0.80	none	870
Active bone marrow (entire examination)	10	1.6	2.0	32
Lungs (entire examination)	48	1.6	2.0	150

The Handbook presents this same example evaluated by a method in which detailed specifications for the particular views applied clinically were obtained for the examination. The absorbed doses were:

Entrance skin in primary field (maximum), 830 mGy;
Active bone marrow (entire examination), 37 mGy;
Lungs (entire examination), 170 mGy;

which are close to the values obtained above by the nominal approach.

The following general observations for absorbed doses can be made for examinations of the coronary arteries:

(a) Since a variety of different views are used in any specific examination, no single area of entrance skin is uniquely irradiated throughout the examination. Therefore, the cumulative air kerma for all the views will be a significant overestimate of the maximum dose to any portion of the entrance skin. The largest single cumulative dose in a portion of the entrance skin occurs where a common region of skin is irradiated in multiple views. The maximum absorbed dose to a portion of entrance skin will need to be evaluated for each examination.

(b) For the fields used in coronary artery examinations, larger fractions of the heart, lung, esophageal and adrenal tissues are in the radiation fields than other internal tissues, although the heart is not subject to radiation risk at the doses involved. The magnitude of the absorbed dose in these tissues is much lower than the maximum absorbed dose in the entrance skin in the primary field (see value for the lungs in the example). The absorbed doses in other internal tissues are less than the absorbed doses in heart, lung, esophageal and adrenal tissues, some being an order of magnitude or more lower per 1-Gy air kerma (see Table 1).

RECOMMENDATIONS FOR AVOIDANCE OF SERIOUS X-RAY-INDUCED SKIN INJURIES TO PATIENTS DURING FLUOROSCOPICALLY-GUIDED PROCEDURES

An increasing number of invasive procedures, primarily therapeutic in nature and involving use of devices under fluoroscopic guidance, are becoming accepted medical practice. These procedures are performed by a variety of medical specialists and may provide significant advantages over alternate therapies in terms of improved clinical outcome and reduced patient risk. However, physicians performing these procedures should be aware of the potential for serious radiation-induced skin injury caused by long periods of fluoroscopy occurring with some of these procedures. Such injuries have been reported as a result of radiation exposure due to long fluoroscopic exposure times, high dose rates or both (10).

The types of injury to skin and adjacent tissues which result from x-ray irradiation are summarized in Table 2 along with the typical absorbed dose in the skin required to produce the injury. Appearance of the injury is dependent on variables other than cumulative absorbed dose in the skin, such as: the rate of delivery of the radiation; the fractionation of the absorbed dose; the age and characteristics of the exposed person; and the site on the skin of the exposure.

Table 2. Typical Threshold Doses for Radiation-induced Skin Injuries (adapted from reference 11)

Effect	Typical Threshold Absorbed Dose (Gy)	Fluoroscopic On Time (a) to reach Threshold (hours) at 0.02 Gy min^{-1}	at 0.20 Gy min^{-1}	Time (b) to Onset of Effect
Early transient erythema	2	1.7	0.17	hours
Temporary epilation	3	2.5	0.25	~3 weeks
Main erythema	6	5.0	0.50	~10 days
Permanent epilation	7	5.8	0.58	~3 weeks
Dry desquamation	10	8.3	0.83	~4 weeks
Invasive fibrosis	10	8.3	0.83	- - -
Dermal atrophy	11	9.2	0.92	>14 weeks
Telangiectasia	12	10.0	1.00	>52 weeks
Moist desquamation	15	12.5	1.25	~ 4 weeks
Late erythema	15	12.5	1.25	~6-10 weeks
Dermal necrosis	18	15.0	1.50	>10 weeks
Secondary ulceration	20	16.7	1.67	>6 weeks

(a) Time required to deliver the typical threshold absorbed dose to skin at the specified rate.
(b) Time after single irradiation to observation of effect.

The absorbed dose rate in the skin from the direct beam of a fluoroscopic x-ray system is typically between 0.02 and 0.05 Gy min^{-1}, but may range from 0.01 to more than 0.50 Gy min^{-1}, depending on the mode in which the fluoroscopic equipment is operated and the size of the patient. The times required to deliver the typical threshold dose shown in Table 2 are for fluoroscopic dose rates of 0.02 Gy min^{-1} (the usual dose rate for normal fluoroscopy for an average-sized patient) and 0.20 Gy min^{-1} (a dose rate near the maximum permitted for the high-level control mode of operation in the United States) (12). The times listed are for irradiation to a single skin area by a stationary, continuous fluoroscopic x-ray beam.

Other than the mildest symptoms, such as transient erythema, the injuries from the irradiation may not appear until weeks following the exposure. Physicians performing these procedures may not be in direct contact with the patients following the procedure and may not observe the symptoms when they occur. For this reason, it is recommended that information be placed in the patient's record which permits estimation of the absorbed dose to the skin, especially for patients who may receive a significant fraction of the threshold dose from single or multiple procedures. Physicians should counsel such patients on the possible symptoms and risks from these procedures.

Table 3 presents examples of the x-ray-induced skin injuries reported to the Food and Drug Adminstration in the United States that illustrate the range of procedures and the severity of the injuries. Details that would permit quantitative estimates of the absorbed doses to the skin were generally not available, since records were not maintained on the extent of fluoroscopic exposure times and other technical factors or the facility was unwilling to share additional information.

Table 3. Examples of Skin Injuries from Fluoroscopy Reported to the Food and Drug Administration (from reference 10)

Patient Sex and Age	Procedure	Nature of Injury	Fluoroscopic Exposure Time
male, 40	coronary angiography and PTCA followed by second coronary angiography	skin necrosis requiring 12 cm x 10 cm skin graft	unknown; estimated to exceed 120 min
female, ?	RF cardiac catheter ablation	7.5 cm x 12.5 cm second degree burn	unknown
female, 25	RF cardiac catheter ablation	skin breakdown 3 weeks post procedure	unknown; procedure time of 325 min
female, 34	RF cardiac catheter ablation	draining skin lesion on back 5 weeks post procedure	unknown; procedure time of 190 min
female, 62	balloon dilation of bile duct anastomosis	burn-like injury on back requiring skin graft	unknown
female, 61	renal angioplasty	skin necrosis requiring skin graft	unknown, procedure time of 165 min

PTCA is percutaneous transluminal coronary angioplasty; RF is radiofrequency

The Food and Drug Administration has issued a Public Health Advisory (13) with recommendations for avoiding such x-ray-induced skin injuries and additional advice (14) on recording information in the patient's record that identifies the potential for such injuries.

Recommendations to avoid serious x-ray-induced skin injuries during fluoroscopically-guided procedures

(a) Establish standard operating procedures and clinical protocols for each specific type of procedure performed. The protocols should address all aspects of the procedure, such as patient selection, normal conduct of the procedure, actions in response to complications and consideration of limits on fluoroscopy exposure times.

(b) Know the radiation dose rates for the specific fluoroscopic system and for each mode of operation used during the clinical protocol. These dose rates should be derived from measurements performed at the facility.

(c) Assess the impact of each procedure's protocol on the potential for radiation injury to the patient.

(d) Modify the protocol, as appropriate, to limit the cumulative absorbed dose to any irradiated area of the skin to the minimum necessary for the clinical tasks, and particularly to avoid approaching cumulative doses that would induce unacceptable adverse effects. Use equipment which aids in minimizing absorbed dose.

(e) Enlist a qualified medical physicist to assist in implementing these principles in such a manner so as not to adversely affect the clinical objectives of the procedure.

Additional advice on recording information in the patient's record that identifies the potential for skin injuries

(a) Each facility should establish a threshold dose for recording information. The Food and Drug Administration suggested a threshold absorbed dose in the skin of 1 Gy, but the facility may select another value (such as 2 Gy) based on its experience.

(b) Determine the fluoroscopically-guided procedures that will approach or exceed the selected threshold. The Food and Drug Administration stated that the list should include the following procedures:

Radiofrequency cardiac catheter ablation
Vascular embolization
Transjugular interhepatic portosystemic shunt
Percutaneous endovascular reconstruction

and any others that professional and medical specialty organizations suggest or the facility determines will approach or exceed the selected threshold.

(c) For these procedures, record an unambiguous identification of those areas of the patient's skin that received an absorbed dose that may approach or exceed the selected threshold. The facility may also wish to include in the patient or supplemental record an estimate of the cumulative absorbed dose (and an estimate of its uncertainty) to each irradiated area of the skin noted in the patient record, or sufficient data to permit estimating the absorbed dose to those areas of skin. Cumulative absorbed dose in skin refers to the dose accrued by any specific area of skin over the course of a single or possibly multiple procedures.

No consensus currently exists as to the most effective method for estimating skin dose. Absorbed dose in the skin from fluoroscopy may be estimated through: (i) direct measurements, such as placing radiation dosimeters on the patient during the procedure; or (ii) indirect means, such as collection of specific information for a patient on equipment technique factors combined with patient and procedure characteristics, or such as use of supplementary information obtained with measurement and recording devices attached to the x-ray equipment. Note, however, that the sum of all exposures (i.e., the cumulative value for air kerma) occurring in an entire procedure is likely to be a significant overestimate of the cumulative absorbed dose to a specific area of skin, except in the event that the x-ray beam is stationary during most of the procedure.

Each approach to dose estimation has advantages and disadvantages, and all of the approaches involve practical complexities. Fortunately, clinical decisions and patient management do not require highly accurate estimates of the cumulative absorbed dose to the skin. It is more important that the potential for approaching or exceeding the threshold for injury be recognized and avoided, if possible.

A METHOD FOR DETERMINING EFFECTIVE DOSE TO STAFF WEARING PROTECTIVE APRONS DURING FLUOROSCOPY AND INTERVENTIONAL RADIOLOGY

Clinical staff taking part in diagnostic and interventional procedures using fluoroscopy wear protective aprons to shield internal tissues and organs in the torso from scattered x rays. Use of the measurements from monitoring devices worn outside and above protective aprons as the record of effective dose (E) for these individuals results in significant overestimates of their actual risk (15).

Experimental determinations of E have been reported for simulated irradiation of clinical staff for conditions commonly encountered in fluoroscopy and interventional radiology (16). In that work, x-ray scatter radiation was produced at various x-ray tube potentials in the range of 70 to 110 kVp, with the x-ray tube in overtable or undertable position. The operational quantity, personal dose equivalent for strongly-penetrating radiation, $H_p(10)$, can be obtained from the film badge dosimeters that were placed on the neck and waist of a Rando phantom that simulated a clinical staff member. Absorbed doses to tissues and organs, when a protective apron was not present, were determined using numerous thermoluminescent dosimeters in the phantom. Absorbed doses to the tissues, when a protective apron was present, were estimated from the absorbed doses without a protective apron, as modified by transmission data for the appropriate x-ray tube potential and equivalent lead thickness of the apron. E was computed as described by the ICRP (8) for the noted range of x-ray tube potentials without an apron and with aprons having equivalent lead thicknesses from 0.1 to 0.5 mm.

The relationships between E and the $H_p(10)$ values obtained from the film badges are quite variable over the conditions studied. For example, for aprons of 0.3 and 0.5 mm lead equivalence, $H_p(10)$ for the neck film badge ranges from 21 to 72 times higher than the corresponding E, and $H_p(10)$ for the waist film badge ranges from 1.7 times higher (multiply by 0.60) to 67 times lower than the corresponding E (15). The fluctuations in kVp used during various fluoroscopy procedures render a direct use of the conversions for individual staff impractical. However, when a single personal monitor is worn at the neck outside and above a protective apron, dividing the $H_p(10)$ value for this personal monitor value by 21 (the minimum value in the range) will provide a conservatively high estimate of E. This modification gives appropriate credit for the protection afforded by the apron and does not overestimate the value of E by more than a factor of 3.4.

From the experimental results, one can produce an empirical formula for E (that uses the results of two personal monitors) of the form:

$$\text{estimate of } E = aH_1 + bH_2;$$

which is a weighted sum of the $H_p(10)$ values obtained with personal monitors worn under a protective apron at the waist (H_1) and at the neck above and outside a protective apron (H_2).

The procedure was to iterate values of the weighting factors a and b by trial and error until a desired approximation of E for radiation protection purposes is achieved for the clinical range of x-ray tube voltages, the two x-ray tube locations, and for aprons with 0.5 and 0.3-mm lead equivalent thicknesses.

The criteria for a desired formula for radiation protection purposes were: (i) minimize the underestimates of E, even at the expense of larger overestimates of E for some conditions, and (ii) obtain a close estimate of E at the combination most frequently encountered in clinical practice (i.e., 90 kVp, 0.5 mm lead equivalent apron and undertable x-ray tube).

The resulting formula, using the experimental conversion factors, is:

$$\text{estimate of } E = 0.5\ H_1 + 0.025\ H_2.$$

The estimates of E resulting from the formula are presented in Table 4. Over the stated range of conditions, the estimates range from 1.06 E to 2.03 E. The criteria for a desired formula are met. There are no underestimates and the largest overestimate is 2.03 E. The estimate for the most frequently encountered combination is 1.06 E. Use of the formula would be a simple and practical way to monitor E when both personal monitors are worn.

Table 4. Estimates for E Using Empirical Formula for Two Personal Monitors, Aprons Present, Over and Undertable X-ray Tubes (Derived from references 16 and 17)

Apron Thickness (mm lead equivalent)	Tube Voltage (kVp)	Estimate of E Relative to a Value of 1.0
0.5, overtable	70	1.49
	90	1.96
	110	1.13
0.5, undertable	70	1.10
	90	1.06
	110	1.34
0.3, overtable	70	1.56
	90	2.03
	110	1.26
0.3, undertable	70	1.27
	90	1.21
	110	1.44

Molecular and Cellular Mechanisms in Radiation Carcinogenesis

Simon D. Bouffler
Biomedical Effects Department, National Radiological Protection Board,
Chilton, Didcot, Oxon, OX11 ORQ, UK

Substantial epidemiological data exist which implicate ionising radiation as a causative agent for a broad range of human cancers (1). To date, epidemiology has been able to provide good evidence of increased cancer risk for single acute radiation doses greater than 100 mGy. Understanding and estimation of radiation cancer risks below this level remain problematic and controversial. Developing an in depth knowledge of the mechanisms by which ionising radiation causes cancer should help to strengthen low dose risk estimates.

In recent years there have been significant advances in the understanding of many basic cellular processes including the regulation of cell proliferation. Unrestrained cellular proliferation is the key characteristic of cancer. The causes of this unrestrained proliferation lie in alteration of the normal patterns of expression of genes involved in proliferative control. Powerful tools for molecular genetic analysis are now available to help elucidate the genetic alterations in cancers. Cell biological and biochemical methods can be used to define the cellular consequences of these genetic alterations.

The basis for much of the understanding of genetic mechanisms in carcinogenesis has its origins in the study of chromosomes. Two broad categories of chromosomal rearrangement have been identified in human and animal tumours: translocations and deletions. Chromosome deletion events lead to the loss of genetic information while translocations cause the rearrangement of genes but not gene loss. Translocations are largely, but not exclusively associated with, haematological malignancies (see reviews 2,3). Deletions are more commonly associated with solid tumours (see 2,4) although deletions have also been observed in some human haematological malignancies such as acute myeloid leukaemias (AMLs, eg. 5,6). The consistent association of a particular chromosomal rearrangement with a specific tumour is indicative of the importance of genes on the involved chromosomes in the development of the tumour.

There is now a very large number of consistent chromosomal translocations associated with specific tumours (eg. 2,3). Among those identified are the t(8;14) in Burkitts lymphoma (BL), t(10;14) in T cell acute lymphocytic leukaemia (T-ALL), t(9;22) in chronic myelogenous leukaemia (CML) and t(15;17) in acute promyelocytic leukaemia (APML). Molecular analysis of these translocations has led to the identification of the genes involved and given some indications of the consequences of the translocations. Essentially two classes of translocation have been identified, those that lead to the over expression of one of the partner genes and those in which a novel fusion gene is formed from which a fusion oncoprotein is produced. Translocations of the over expression type are common in lymphocytic leukaemias. In T-cell leukaemias one of the genes is commonly a T-cell receptor (*TCR*) gene while in B cell leukaemias immunoglobulin (*Ig*) loci are frequently involved. These genes are actively expressed in the corresponding normal cell type. Genes which are otherwise silent (ie. not expressed) can become active when translocated into the vicinity of one of the highly expressed genes. Thus in Burkitts lymphoma the *MYC* gene is over expressed due to its translocation close to an *Ig* gene locus and in the t(10;14) in T-ALL the expression of the *HOX11* gene is driven by a *TCR* gene. Examples of gene fusions include *BCR-ABL*, involved in the t(9;22) in CML and *PML-RARA* in APML. These fusions lead to the production of proteins with abnormal functions.

Both the over expression and gene fusion translocations can be considered 'gain of function' mutations, ie. normal genes are expressed inappropriately or novel fusion genes are expressed. These events are in general genetically dominant, that is only one such change is sufficient to give an effect. The products from this group of proto-oncogenes are frequently involved in the processes of signal reception and transduction from the cell membrane to the nucleus (signal transduction pathway genes) or more directly in the regulation of gene activity (transcription factor genes). Gain of function mutations can also be on a smaller scale as in the *RAS* gene base pair mutations associated with rodent skin, breast and liver tumours (7,8,9).

Deletion events involve a class of genes known as tumour suppressor genes. Frequently, these genes are involved in the control of cell proliferation, differentiation or transcription. Consequently, upon the loss or mutation of such genes, proliferation may be enhanced of differentiation blocked. The classic examples of deletions in cancers are the del(13) involving the *RB1* gene in retinoblastoma and the del(11) in Wilms tumours in which the *WT1* gene is lost. In general these events are genetically recessive and so loss or mutation of both copies of the gene is necessary for a phenotypic effect. The gene which has been found to be most commonly lost or mutated in human cancers, *p53* (10,11), also acts as a tumour suppressor although some dominant negative mutations exist.

A single genetic alteration is rarely, if ever, sufficient to give rise to a malignant tumour. In solid cancers it is likely that 5-10 genetic or epigenetic alterations are required. In haemopoietic system cancers it is probable that fewer events are necessary. Where a very consistent genetic alteration is associated with a specific cancer, it is a good candidate for an initiating event. However, many of the genetic changes in tumours have a less strong and specific association. A gene very consistently altered in one tumour may also be involved in other tumour types but in a less specific fashion. One of the best studied human cancers is colorectal cancer in which consistent and early changes to tumour suppressor genes is followed by an accumulation of secondary events (12).

These basic principles of carcinogenesis have in the main been derived from the analysis of human tumour material. The identification of human tumours which are known to be associated with radiation exposure is very difficult. Therefore much of the current research on radiation carcinogenesis exploits animal models. At NRPB there is a strong interest in mechanisms of radiation-induced AML in the mouse. This system will be described to give a flavour of how molecular and cytogenetic methods can be exploited to understand mechanisms of radiation carcinogenesis.

AML can be induced to a maximum frequency of ~25% of CBA/H mice following a single acute x-ray exposure (13,14). Radiations of other qualities such as α-particles and neutrons can also induce AMLs in this inbred mouse strain (16,17). Cytogenetic analysis of radiation-induced AMLs by G-banding revealed a consistent chromosomal aberration, deletion or translocation of one chromosome 2 homologue (18). Similar aberrations have been found in AMLs induced in other mouse strains (19-21). Chromosmoe 2 aberrations can also be detected at 5 days - 1 month post irradiation in bone marrow cells (18), well before the average 18 month latent period required for full tumour development. Not only do chromosome 2 aberrations form early but they form in excess by comparison with other chromosomes - an approximately 2.5 fold excess of chromosome 2 events was noted at sample times between 1 and 6 months post-irradiation (22). In this study (22) it was found that all irradiated animals carried chromosome 2 aberrations, so while these aberrations are very early and possibly initiating events, they do not determine which individuals will develop AML. Similarly this experiment indicated that secondary events, undetectable at the cytogenetic level, contribute to leukaemogenesis.

Further resolution of the DNA sequences involved in mouse leukaemogenesis has required the development of a system for molecular mapping. By exploiting differences in allele sizes between inbred strains for certain abundant and widely distributed molecular markers known as microsatellites, mapping of deletions in AMLs developing in irradiated F1 mice has been possible (23). Chromosome 2 deletions

were detected in about 65% of AMLs arising in x-irradiated F1 CBA/H x C57Bl Lia mice. While the breakpoints involved in the deletions were not entirely consistent, clustering was observed and it has been possible to define 5 deletion types (23). In addition to defining breakpoints at the molecular level it has been possible to identify a minimally deleted region of about 30 cM in size. In the absence of strong breakpoint specificity, a mechanism of tumorigenesis involving abnormalities in gene expression seems unlikely, gene losses are probably of greater importance.

The microsatellite markers associated with breakpoints and the minimal deleted region can be used to isolate larger DNA clones in these areas. Such clones can then be exploited for further molecular and cytogenetic resolution of the AML associated genetic alterations. Using the technique of fluorescence *in situ* hybridisation (FISH) with these clones, it is possible to quantitate more accurately the frequency of these AML associated aberrations at very early post irradiation times. Thus, the size of the pool of radiation-initiated cells can be defined in individual animals. Through further genomic-wide screening of AMLs by microsatellite analysis, additional target genes for acute myeloid leukaemogenesis may be identified. FISH experiments as described above should enable the assignment of a temporal position for such changes in the leukaemogenic process.

One further issue in radiation carcinogenesis which can now be addressed is that of genetic predisposition. Within human populations certain rare cancer prone individuals and families exist. Some of these cancer prone syndromes are associated with the inheritance of genes which encode elements of DNA damage processing systems. Examples of this category are xeroderma pigmentosum (24), hereditary non-polyposis colon cancer (25) and ataxia telangiectasia (26). Inheritance of classic tumour suppressors such as *RB1* and *WT1* underlie familial retinoblastoma and Wilms tumour respectively (see review, 4). Proto-oncogenes at present seem rarely to be associated with cancer predisposition. The only clear example here is the *RET* proto-oncogene involvement in multiple endocrine neoplasia type 2A (27). As yet there are no clear cases of a human gene or genes predisposing to radiation-induced cancer. However, with the recent identification of a gene mutated in ataxia telangiectasia (28) this situation may change. The differences in tumour incidence between strains of mice have been exploited to map tumour susceptibility loci (eg. 29). Such strategies can also be applied to radiation-induced cancers. It has proven possible to generate artificial mouse mutants susceptible to radiation carcinogenesis (30).

To summarise, the advances in the understanding of the process of carcinogenesis in general and radiation carcinogenesis in particular can benefit mechanistic modelling of radiation cancer risk. A knowledge of radiation cancer associated genetic alterations and their temporal sequence allow the construction of valid models which can be exploited in risk estimation. Furthermore, the target gene alterations identified can be used for screening of individuals for preneoplastic lesions and in some case suggest rational bases for therapy.

IONIZING RADIATION-INDUCED DNA DAMAGE AND ITS REPAIR

Malgorzata Z. Zdzienicka

Department of Radiation Genetics and Chemical Mutagenesis, MGC, Leiden University, 2333 AL Leiden, Wassenaarseweg 72, and J.A. Cohen Institute, Interuniversity Research Institute for Radiopathology and Radiation Protection, Leiden The Netherlands.

The deposition of energy in the cell by ionizing radiation results in damage to DNA, both directly and indirectly, as a effect of free radical formation. As a consequence, a variety of DNA lesion are induced, including single- and double-strand breaks (SSB and DSB, respectively), and base damages. All organisms have highly efficient mechanisms for the recognition and repair of DNA damage. The cellular response to ionizing radiation, in addition to DNA repair, includes other safeguards such as cell cycle regulation and mechanisms involved in scavenging of free radicals which are produced by ionizing radiation. Therefore, a tremendous complexity of the cellular defense mechanisms against ionizing radiation can be expected.

To dissect and elucidate these mechanisms, X-ray-sensitive mutants have been investigated in a wide variety of organisms. In humans only two hereditary disorders are shown to have clearly an increased sensitivity to ionizing radiation: ataxia telangiectasia (AT) and Nijmegen Breakage Syndrome (NBS) (reviewed in ref. 1 and 2). The recent isolation of the *ATM* (*AT Mutated*) gene for several previously established complementation groups indicate that one gene is responsible for AT (3). The existence of patients with characteristics of both, AT and NBS indicate that these two disorders are closely related, although recent studies suggest that they are distinct, since the gene(s) defective in NBS is not located at the site of the *ATM* gene (4 and 5).

As a genetic approach to analyze the mammalian cellular response to ionizing radiation, in addition to the human mutants, many X-ray-sensitive mutants have been isolated in cultured rodent cells, and at least eleven complementation groups have been identified (reviewed in ref. 6). Amongst these groups, one group has been suggested to be defective in the gene homologous to the AT gene (7).

Recently, a fruitful interaction between researchers working in different fields, such as radiobiology, biochemistry, immunology and somatic cell genetics has led to the discovery that V(D)J recombination, the process responsible for the formation of the immunoglobulin and T-receptor genes, utilize elements of the DSB repair machinery. Studies with four groups of X-ray-sensitive rodent cell mutants (groups 4, 5, 6, and 7), have led to the identification of the *XRCC4* (8), *Ku86, Ku70*, and *DNA-PK*$_{cs}$ genes (reviewed in ref. 9 and 10). Recently, mutations in XRCC4 and Ku86, have been identified in the hamster mutants of group 4 and 5, respectively, providing the direct evidence that the *XRCC4* (8) and *Ku86* (11) genes, are responsible for the observed phenotype of these groups of mutants. Sofar, mutations in DNA-PK$_{cs}$ which are responsible for the defect in *scid* mouse cells, have not been identified.

Rodent mutants have served as a tool for the isolation of the *XRCC1* and *XRCC3* genes (12 and 13) which are involved in DNA single-strand break repair. The *XRCC1* gene product is required for normal activity of DNA ligase III (14), and the *XRCC3* gene function remains unknown.

In addition to the defective repair of DNA lesions induced by ionizing radiation, defects in cell cycle progression might lead to the increased X-ray sensitivity. The phenomenon of radioresistant DNA synthesis (RDS) after γ-irradiation was the first sign of a defect in cell cycle control in AT cells. A major insight into the nature of the product of the *ATM* gene is indicated by the observation that the carboxyl terminus of this protein is similar to the catalytic subunit of phosphoinositide 3-kinase (PI 3-kinase) (3). This protein is implicated in the response to DNA damage. The ATM protein shows the functional homology to the products of several genes such as, MEC1, rad3, mei-41, TEL1 and DNA-PK$_{cs}$ which play a role in cell-cycle control in the presence of DNA damage (reviewed in ref. 15 and 16).

A recent finding that a gene located on human chromosome 4q enhances the level of inhibition of DNA synthesis after gamma-irradiation (17), indicates that the rate of DNA synthesis is regulated by numerous genes, including *ATM, NBS*, and the gene localized on chromosome 4q. The identification of hamster mutants showing RDS (18) should be helpful in the identification of these genes. Since the gene on chromosome 4q inhibits DNA synthesis after ionizing radiation without correcting the X-ray sensitivity, in terms of cell killing or chromosomal aberrations, it is indicated that RDS is not responsible for these biological consequences of RDS (19).

The isolation of the genes involved in NBS, as well as in the remaining complementation groups of rodent X-ray-sensitive mutants, and the recognition of their precise role, should further elucidate the mechanism of the cellular response to ionizing radiation and its involvement in cancer.

Biological indicators for radiation exposures

Christian Streffer, Institute for Medical Radiobiology, University Clinics, Essen, D-45122 Essen, Germany

The experience with accidental radiation exposures has frequently shown that the physical dosimetry does not give sufficiently good results for dose estimations. Therefore the determination of biological effects is necessary in order to get some additional information about the absorbed radiation dose. Several biological systems have been studied under these circumstances and interest for biological indicators for radiation damage has increased appreciably. There are two main reasons for this interest:

1. Biological indicator can be used in addition or even in substitution to physical dosimetry. It is an advantage that biological indicators can be determined for biological dosimetry after a radiation exposure has taken place which is in contrast to physical dosimetry.

2. Biological dosimetry gives not only information about the range of the absorbed (radiation dose) but it is also possible to get information about the individual radiosensitivity which can vary considerably from person to person. Therefore biological indicators are also a measure of the biological-medical radiation damage. By determination of such indicators it is possible to give a prognosis about possible radiation damage. It is further possible to start therapeutical procedures under these conditions earlier.

A number of methodologies have been studied for these purposes:

1. Electronspin resonance,
2. Biochemical indicators,
3. Chromosomal aberrations,
4. Hematopoetic changes,
5. Studies of spermiogenesis.

The most efficient and widely used techniques are those which measure chromosomal aberrations. Several methodologies are used in this connection: The evaluation of structural chromosomal aberrations in metaphases,

premature chromose condensation, the determination of micronuclei and recently the use of molecular biological techniques like fluorescence in situ hybridization (FISH).

A useful biological indicator should fulfil the following features:

1. The measured radiation effect should be dose dependent in a certain dose range. It would be desirable that this dose range covers radiation doses of occupational exposures at working places (20 - 50 mSv) up to accidental exposures of several sievert.

2. A certain specificity should exist for the changes by ionizing radiation.

3. It should be possible to get some information about dose rate effects.

4. The results should be available within a few days after radiation exposure.

5. The radiation damage should be measurable over a certain time period.

6. It should be possible to determine a partial body irradiation and to measure the localization of radiation exposure.

7. The biological material which is needed for the determination should be easily obtained.

These demands are maximal and cannot be fulfilled by any indicator up to now. Ionizing radiation induces free radicals in many biological materials. These free radicals can be quantitatively determined by electronspin resonance. The measurements can only be performed with materials with a low water content. Several studies have shown that teeth are very well suited for such studies. But also in hair and bone free radicals can be measured. After the nuclear accident in Tschernobyl this technique has been used for dose estimation in several cases. It is also possible by this technique to measure radicals in bricks, stones and other material in order to estimate local radiation doses.

A number of studies have been performed in order to use biochemical systems for dose estimation. In this connection the excretion of metabolites after the

break down of proteins and nucleic acids has been mainly investigated. It was observed that in a dose range between 0.5 to 2.5 Gy a good dose response can be obtained for taurine and other amino acids as well as with metabolites of DNA. However, there is a very high individual variability with respect to these parameters and therefore it is difficult to obtain a reasonable dose estimation with the biological systems which have been used up to now.

Most experience for biological dosimetry has been obtained with cytogenetic techniques through which chromosomal changes can be measured. Most widely the determination of the socalled dicentric chromosomes has been used. These chromosomes are formed after chromosome breakages and subsequent connection of these breaks in such a way that a chromosome with two centromeres results. The formation of dicentrics shows a certain specificity for ionizing radiation. The conventional technique has been found useful for dose ranges between 0.1 to several sieverts. The dependence on radiation quality and dose rate has been studied. Again the spontaneous rate of dicentrics can differ individually considerably. This has to be taken into consideration and complicates dose evaluation in the low dose range. Usually chromosomal aberrations are determined in metaphases of proliferating lymphocytes from blood after cell proliferation has been stimulated. Dicentric chromosomal aberrations have to be measured within a few weeks after a radiation exposure. Otherwise the cells with such chromosomal aberrations get lost and an estimate is no longer possible.

For these disadvantageous reasons a new technique has been introduced: The fluorescence in situ hybridization (FISH). With this technique it is possible to paint specific chromosomes by the corresponding DNA probes and to study not only instable chromosomal aberrations like dicentrics or chromosome breaks but also to determine stable chromosomal aberrations like translocation, deletious etc. As DNA probes for all human chromosomes are available today this technique can be widely used. With this technique it is possible to determine chromosomal aberrations even are several years after a radiation exposure. Thus chromosome aberrations could be measured in survivors after the atomic bombing in Japan even today. Further the potential of this technique allows to study a number of fundamental radiobiological questions.

Besides these techniques for which a lot of experience and expertise is necessary an easier method has been developed: The determination of

micronuclei. With this technique it is not necessary to push the cells into the metaphase but micronuclei can be determined also in interphase cells. However, the cells have to go through mitosis before micronuclei are expressed. Micronuclei originate also from chromosome breaks with acentric fragments and from whole chromosomes which are located in the cytoplasm.

During last years a technique has been developed which includes a proliferation control. Cytochalasin B has been used in concentrations which allow the division of the cell nucleus but not the division of the cell itself. Under these conditions cells with two cell nuclei develop. The micronuclei which consist of chromatin particles in the cytoplasm are only determined in such bionucleated cells. The specificity of the expression of micronuclei is less than with dicentrics. Cells with micronuclei get lost with in a few weeks like cells with dicentrics. Therefore an exact measurement can only performed within a few weeks after radiation exposure. Although the sensitivity for the micronucleus determination is less than for other cytogenetic techniques it has been found very useful that the results are obtained quickly and comparatively easily. Further the micronucleus test can be used with an automated cell system.

With all these cytogenetic techniques it has been shown that besides estimates of radiation dose it is also possible to get a measure of the individual radiosensitivity. For instance in a number of persons with genetic syndromes like ataxia telangiectasia, Franconi anaemia and others which show a high degree of radiosensitivity it has been found that the expression of chromosomal aberrations including micronuclei is increased. Most of these genetic syndromes are expressed only in persons who have the mutation in both genes (homozygotes), the genetic mechanism is recessive and not dominant. However, it has been found that an increased radiation effect can also be seen in heterozygotes (mutation only in one gene) although the increase of the radiation effect is less in these individuals than in the homozygotes. This variability of individual radiosensitivity certainly will play a significantly larger role for radioprotective measures in the future. Therefore it is desirable to have such techniques available which give an information about the extent of radiation damage and to use this information for the decision whether therapeutic measures have to be applied or can be excluded.

It can be suggested from these experimental experiences that the comparative simple micronucleus assay is used for screening if many persons have been exposed by an accident. Under these circumstances quite a number of results can be obtained in a very few days after blood samples have been taken from the exposed individuals. The micronucleus assay can be used again in a dose range of 0.1 to several sieverts. As with chromosomes evaluations of micronuclei have been described for fast neutrons, also dose rate effects have been studied. After such a screening the blood of the exposed people can be investigated by looking for conventional chromosomal aberrations or using the FISH technique. Especially in the low dose range these methodologies certainly can give more exact data. In one accident it was possible to measure the radiation effect by the micronucleus test and the formation of dicentrics. Comparable results were obtained.

With these techniques it is certainly possible to get an information about a radiation exposure including the individual radiosensitivity which will be very useful for judgements of accidental situations.

HEALTH ASPECTS OF CELLULAR MOBILE TELEPHONES

Heinrich Garn
Austrian Research Centre Seibersdorf, A-2444 Seibersdorf, Austria

INTRODUCTION

Cellular mobile telephones are one of the main topics among health aspects of electromagnetic fields. In many countries, the number of people opposing communication towers is on the rise. Lawsuits against telecommunication and power line companies have been filed. All this makes people doubt the safety of electromagnetic fields.

With respect to cellular phones, there are two scenarios:

☆ Exposure of the operators of hand-held terminals (HHT).

☆ Exposure of the general public from base stations (BS).

In the first case, the transmit antenna of the HHT is very close to the human body. For normal operation, the distance will roughly be 2 - 3 cm. The transmitter power of the HHT is comparatively low, but there is a considerable fraction of the radiated electromagnetic energy penetrating the tissue. Considering the second case, BS transmitter powers are by a factor of 100 - 1000 higher, but the distance between antenna and the human body is by a factor of 1000 - 100000 greater, as far as areas of unrestricted public access are concerned. As the power density of an electromagnetic wave decreases inversely proportional to the square of the distance, exposure of the public is always significantly (by many orders of magnitude) lower than exposure of operators of HHTs.

Some well-known interaction mechanisms of microwave radiation with the human body have been very well-established today. In some other areas, there is still a need for further research. This paper summarizes present knowledge on human safety with mobile telephone systems.

TECHNICAL CHARACTERISTICS OF CELLULAR MOBILE TELEPHONE SYSTEMS

Cellular mobile telephone systems can be categorized with respect to several parameters: Digital or analogue modulation, carrier frequencies, transmitter power, etc. Table 1 shows a survey about the technical characteristics of some selected, important systems used around the world today. We find that

- both analogue and digital systems are used today, but the trend clearly goes towards digital systems. With respect to biological effects, the key difference between the two kinds of modulation is that analogue systems use continuous transmission, while digital systems use pulsed transmission.
- Transmitter frequencies of HHTs are in the ranges of 441-456 MHz, 810-849 MHz, 872-915 MHz, 1.429-1.453 GHz, and 1.710-1.785 GHz. With respect to biological effects, a different carrier frequency makes a difference in the amount of energy absorbed in the tissue (see chapter about the heating effect below).
- Mean transmitter powers of HHTs never exceed 1 W, for most digital systems it is below 0.6 W. Moreover, most systems operate at even reduced power when the transmission channel is sufficiently good.

The data given in Table 1 summarizes the key characteristics of cellular telephones with respect to health aspects.

RELEVANT BIOLOGICAL EFFECTS

Based on present knowledge, the following biological effects can be considered relevant for human exposure to electromagnetic radiation from mobile telephone systems:

Local heating of tissue due to absorption of electromagnetic energy:

This effect occurs while using hand-held terminals. Results of scientific investigations will be discussed below. The effect does not occur with exposure of the general public by the electromagnetic radiation from base stations, as far as areas of unrestricted public access are concerned.

Interference of the electromagnetic field from hand-held terminals with electronic medical implants such as cardiac pacemakers or defibrillators:

The results of scientific investigations will be discussed below. Interference caused by the electromagnetic radiation from base stations does not occur, as far as areas of unrestricted public access are concerned.

Other effects that are known from in-vivo or from in-vitro experiments seem not to be relevant or have not been sufficiently well established yet to allow a conclusion to be made.

Changes in human EEG:

One researcher (1) reported a five-fold increase in the power density of the 10.7 Hz (α) - spectrum of the human EEG. Changes were observed during and after exposure with 217 Hz - modulated radiofrequency fields of a power density of less than 0.1 $\mu W/cm^2$. The carrier frequency was 150 MHz, the duration of the square-wave pulses were 100 μs. We have repeated the experiments described in (1), the same was done at several other research

Table 1. Selected public cellular mobile telephone systems that use HHTs

System	Countries	Mobile transmitter frequencies [MHz]	Mobile transm. mean rms output power [W] [1]	Modulation	Multiple Access	Analogue / Digital
NMT 450	Scandinavia, Denmark, France, Austria, Switzerl.	441-456 [2]	1	PM speech FSK contr. sign.		A
ETACS	U. K., Italy, Austria, Spain, Malta, Ireland	872-905	0.45 [3]	PM speech FSK contr. sign.	SCPC/ FDMA	A
NTT	Japan	915-940 [2]	1			A
NMT 900	Scandinavia, Denmark, Switzerland	890-915	1	PM speech FSK contr. sign.	FDMA/ TDMA	A
GSM	Europe, Asia, Pacific	880-915	0.25 [4]	GMSK	TDMA	D
CDMA	North America	824-849	0.6	QPSK	DS/CDMA	D
NADC	North America, Asia, Pacific	824-849	0.2	/4 DQPSK	FDMA/ TDMA	D
JDC (PDC)	Japan	810-826	0.3	/4 DQPSK	FDMA/ TDMA	D
JDC (PDC)	Japan	1429-1453	0.3	/4 DQPSK	FDMA/ TDMA	D
DCS 1800	Europe	1710-1785	0.125	GMSK	TDMA	D

[1]) All systems except NMT 450 use mobile power control. Example: GSM in Austria: Power reduction in 2 dB-steps as soon as -94 dBm (÷ 0,4 pW) is reached at the mobile receiver input.

[2]) Summary of frequencies used in different countries or regions, values rounded.

[3]) 0,6 W ERP = standard, approximately 1,5 dB antenna gain assumed.

[4]) Units with 2 W peak power. The standard would allow 5 W for HHTs, but there are no 5 W terminals on the market.

PM ..... phase modulation
FSK ..... frequency shift keying
GMSK ..... gaussian minimum shift keying
QPSK ..... quadrature phase shift keying
DQPSK ... differential quadrature phase shift keying
FDMA ..... frequency division multiple access
TDMA ..... time division multiple access
DS/CDMA direct sequence code division multiple access
SCPC ..... single channel per carrier

laboratories throughout the world. All results were negative, the findings of (1) were not confirmed, e. g. (2). Thus, at present, reactions to the observations reported in (1) would not be justified.

Influences on cell membrane permeability:

The transport of the cations potassium (K^+), sodium (Na^+) and calcium (Ca^{++}) from the interior of the cell to the intercellular space can be increased by amplitude modulated fields (1 - 100 Hz) in the frequency range of 50 MHz - 3 GHz (3, 4, 5). This has overall significance for the general cell function. The effect seems to be restricted to certain „windows" of power density and frequency. It seems to be a true non-thermal effect, as the results have been obtained even at specific absorption rates below 1 mW/kg. So far there has not been any mechanism demonstrated that could explain the phenomenon. Furthermore, the relevance of the effect for human health is totally unclear. Thus, the preliminary results about influences on cell membrane permeability cannot be used to derive conclusions regarding the use of mobile telephone systems at present.

Influences on nerve tissue:

The electrochemical potential of brain- and peripheral nerve cells can be affected by radiofrequency radiation (4, 5). It seems to be impossible to distinguish between thermal and non-thermal effects. The literature available today does not permit any conclusions regarding exposure with mobile telephone systems.

Influences on the immune system:

Several studies show that it has been possible to increase the level of macrophage activity or to inhibit the activity of natural killer cells by exposure to radiofrequency radiation. Effects seem to be mainly due to thermally induced stress when the whole-body temperature is increased by 1 degree Celsius or more. A chain reaction is then initiated from the hypothalamus. Results are not conclusive. At present it is not possible to derive any conclusions regarding mobile telephone systems.

Mutagenic and carcinogenic effects:

It has not been possible to demonstrate independent mutagenic effects (genetic damage) at cellular levels, even under weak hyperthermic conditions. An independent initiation effect on the DNA level with direct DNA damage has not been positively demonstrated after exposure to radiofrequency fields. The activity of the enzyme ornithine decarboxylase and the activity of nonspecific protein kinases can be affected by strong radiofrequency fields. Therefore, such fields cannot be regarded as an initiator of a carciogenic process on the cellular level. A possible promotion has not been proven, but, according to some published, preliminary results of investigations, it cannot be excluded (6). These studies are very controversial. The majority of the studies was done using specific absorption rates higher than those occuring with normal use of mobile telephones. On the basis of data available today it is not possible to derive conclusions regarding mobile telephones.

Most of the data regarding the effects mentioned above are inadequate for drawing any conclusions about possible health effects of cellular telephones. Further investigations will be necessary before judging the relevance of the above mentioned effects.

EXPOSURE OF OPERATORS OF HAND-HELD TERMINALS

Heating effect

Hand-held terminals are operated at distances between antenna and biological tissue of approximately 5 - 30 mm. The parts of the tissue (head) that are located close to the antenna absorb a significant amount of electromagnetic energy. This absorption of energy leads to a temperature rise in the tissue. Supply of energy and cooling by blood flow can compensate, if a certain amount of power per mass (specific absorption rate, in watts per kilogram) is not exceeded, and if the rate of blood flow (volume per time, in liters per minute) is sufficiently high. This criterion will be fulfilled for very low power transmitters (numerical values will be given below) and tissue with a high rate of blood flow. An example for this is the brain, which has a metabolism that is eight times the body average. The criterion might not be fulfilled for tissue with a low rate of blood flow such as the eye. Another relevant criterion is the sensitivity of the organ that is irradiated. Critical organs could be

- the eye (located at the body surface; high absorption due to protein; no blood flow);
- the inner ear (located very close to the antenna of the hand-held terminal; no absorbing tissue (only bone) between antenna and cochlear; high absorption in the liquid of the cochlear, which contains the hair cells; thermally isolated location in bone with only minimal blood flow);
- the hypothalamus (well-cooled by blood flow, surrounded by brain tissue with a high rate of blood flow; possibly critical organ because it controls a variety of functions in the body, e. g. circulation of blood, breathing, etc.);
- pineal gland (well-cooled by blood flow; possibly critical organ because it produces the tumor-inhibiting hormone melatonin).

Due to the heterogenity of the human head, the field distribution in the tissue is very complex. Today, complicated numerical techniques are used to calculate local specific absorption rate (SAR) and local temperature rise. Furthermore, results of measurements of electric field-strength and temperature rise in homogeneous and heterogeneous phantoms are available. The following, simple equations are used to determine SAR, once the field-strength has been calculated:

$$SAR = \frac{\sigma |E|^2}{\rho} = c \frac{dT}{dt}$$

where

$|E|$ ..... absolute value of electric field-strength in the tissue

σ ..... conductivity of the tissue; typical values of σ at 900 MHz are between 0.2 S/m (cortical bone) and 2 S/m (aqueous humour)

ρ ..... density of the tissue; for tissue with high water content, $\rho \approx 1$

c ..... heat capacity of the exposed part of the body; for tissue with high water content, $c \approx 4.0\text{-}4.2$ $J.kg^{-1}.°C^{-1}$

dT/dt .. time derivative of tissue temperature.

Published *results about SAR* are sufficiently consistent to draw reliable conclusions: The SARs in various kinds of tissue have been experimentally determined in phantom materials (7), see Figure 1. There is a strong frequency-dependence. The values in Figure 1 are valid for a typical separation distance of 2,5 cm between antenna and body (normal operation of a HHT) and irradiation from a half-wave dipole.

Tissues:

- ● muscle
- ■ brain
- ○ fat
- □ eye

Irradiation with half-wave dipole,
25 mm from phantom surface
7 W transmitter power

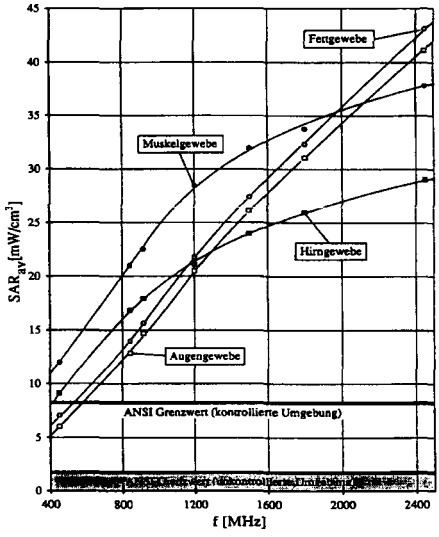

Figure 1: Specific absorption rates in various kinds of tissue, averaged over 1 g (7)

The *distribution of SAR in the head* has been studied by several authors. Figure 2 shows histograms of the SAR-distribution in a horizontal plane through the eyes at 800 MHz (8). The calculation was done using the finite-difference time-domain (FDTD) method. The model of the head consisted of 126.000 cubic cells with a side length of 3,2 mm each. The head is irradiated by a plane wave from the front. Maximum absorption occurs in the eyes. Another local maximum occurs in the center of the head. For the adult (Fig. 2a), the SAR in the center of the head is lower than the SAR in the eyes. For the child (Fig. 2b), the SAR in the center of the head is approximately the same as the SAR in the eyes. When the dipole is located in front of one eye, maximum absorption also occurs in this eye. The maximum in the center of the head disappeares at this near-field exposure. At higher frequencies, the fraction of power penetrating the head is less than at lower frequencies, absorption primarily occurs at the surface and within the first few centimeters of tissue.

Figure 3 shows the maximum values of SAR, averaged over 10 g of tissue, as a function of distance between antenna feed-point and the body (10). At a distance of 2 cm (realistic worst-case for normal operation) and a position of the HHT at the side of the head, the maximum is about 3 W/kg per W for 900 MHz and 4 W/kg at 1.8 GHz. A larger averaging volume results in lower SAR-values, a smaller volume results in higher SAR-values. According to another study, averaging over the eye in an exposure situation where the transmitter is held in front of this eye results in a maximum of approximately 6 W/kg/W at 900 MHz and 11 W/kg/W (adult) to 18 W/kg/W (child) at 1,8 GHz (9). From Table 1 we can see, that transmitter power is less than 1 W for all systems except NMT and NTT. Therefore, in particular for the digital systems, SAR will be lower than the values mentioned above. For, e. g., a GSM handy with 0.25 W average power, worst-case SAR in the eye will be 1,5 W/kg for 2 cm distance. If the antenna is brought even closer to the head, SARs will be higher: For a distance of 3,2 mm and averaging over 1 g of tissue, a local SAR as high as 30.4 W/kg per W has been calculated (9). Such a position of the HHT at the head anyway does not correspond to normal operation.

A more difficult task than the calculation of local SAR is the *calculation of local temperature rise*. Only very few results are available at present. In a recent study (11), the basic relation between SAR, temperature change and transmitter power has been shown, see Figure 4. The graph is valid after 30 seconds of exposure. For such short exposure time, temperature rises linearly with energy deposited in the tissue. Later, thermal equilibrium will be reached. The final amount of temperature rise will depend on a variety of parameters such as the kind of tissue, environmental temperature, cooling by blood flow, etc. In another study (12), the spatial SARs, averaged over one cm^3, were calculated for the human eye, and then the heat conduction equation was solved using the implicit alternating-direction (IAD) algorithm. Irradiation from a half-wave dipole at frequencies of 840 MHz, 915 MHz, 1500 MHz and 1800 MHz led to temperature rises as shown in Figure 5a. For a continuous transmitter power of approximately 0,7 W and a distance of 2 cm between antenna and surface of the eye, maximum temperature differentials reach approximately 0.2° C at 840 MHz, 0.25° C at 915 MHz, 0.6° C at 1500 MHz and 0.65° C at 1800 MHz. For a distance of 6.5 mm and a CW transmitter power of approximately 0.8 W, maximum temperature elevation reaches approximately 1° C at 840 and 915 MHz and approximately 2.2° C at 1500 and 1800 MHz. A maximum absolute temperature of 39° C at 1500 MHz was calculated in the posterior region of

the eye for 6.25 mm distance. Lower transmitter power will result in lower temperature rise and lower absolute temperature, see Fig. 5b: For 2 cm distance and 1500 MHz, temperature rise for a peak transmitter power of 0.7 W and a duty cycle of 1:8 (GSM) is only about 0.04 °C, where it has been about 0,6 °C for 0.8 W CW. Thus we can estimate that the maximum temperature rise in the eye for, e. g., a 2 W - GSM handy with 0.25 W average power at 2 cm distance will not exceed 0.1 to 0.2 °C.

Induction of cataracts in the eye has been shown to occur at temperatures of 41° C or more. Considering the worst-case data given above (12), there seems to be a sufficient safety factor between temperatures occuring with the use of HHTs and temperatures that must be regarded hazardous for the eye.

Temperature elevations in other, possibly critical organs, such as the inner ear, the hypothalamus, etc., have not yet been precisely calculated. This is an important, remaining task that should be carried through, before final judgements about thermal effects, exposure limits, or restrictions on transmitter power can be made.

Interference to Medical Implants

Electromagnetic fields can interfere with electronic apparatus. We have studied 9 scientific publications and symposium contributions about experiments with cardiac pacemakers and defibrillators, e. g. (13, 14, 15, 16). In these studies, a total of 363 tests have been carried out using actual implants in phantoms. In 116 cases interferences occured, this corresponds to 32 %. Among these, 40 (11 %) caused inhibition, 33 (9 %) caused asynchronous pacing, 36 (10 %) caused synchronization, and 7 (2 %) caused combinations of the three effects. All tests were done at very small distances between HHT and surface of the phantom, i. e. representing a HHT held close

to the chest. The above mentioned statistics do not mean that one third of all pacemaker patients have to expect interferences when using a mobile telephone. Most of the tests were carried out in-vitro, and worst-case configurations were used. Enlargement of the separation between HHT and the pacemaker eliminated the interference in all cases. Recommendations for the safety distance range between 10 cm and 40 cm.

Interference to a pacemaker can mean a severe health hazard to the patient:

- Switching to the asynchroneous mode during normal heart activity can trigger vertricular fibrillation, if the impulses appear within the vulnerable phase of the heart. This certainly indicates serious danger.
- Synchronization can lead to wrong stimulation of ventricles. This can make patients feel unwell and effects of weakness and fainting can be expected.
- Inhibition would also result in weakness and fainting.

A major reason for the interferences is the amplitude-modulation of the mobile telephone signals. Therefore, the majority of interferences were found with digital systems. The most dangerous pulse repetition rates are 2 - 8 Hz. Pacemakers can interprete such signals as signals from the heart, whereas they usually filter out components at, e. g., 217 Hz, the normal pulse repetition rate of GSM. Frequency components at 2 - 8 Hz occur during signaling or for instance in the DTX-mode of GSM (discontinuous transmission). In this mode, the number of frames is reduced as long as the user is silent. Also the ringing phase poses a risk to the pacemaker patient. As analogue systems also use digital signaling, interferences are not restricted to digital systems. For analogue systems, the dialing phase appeared to be most critical.

Different kinds of pacemakers show very different reactions to exposure to mobile telephone signals. It is very important that pacemaker patients receive detailed information about possible interferences. Keeping the HHT away from the chest and not carrying it in the breast pocket could be a general safety recommendation for pacemaker patients. Moreover, doctors responsible for implantations should give recommendations for measures to be taken in case of undesired exposure.

EXPOSURE OF THE GENERAL PUBLIC

Cellular nets use cell sizes of typically 1 - 10 km in diameter. The trend goes towards smaller size cells, a higher number of base stations, and consequently lower transmitter powers at both HHT and BS. Antennas of BSs are located on masts on the top of high buildings in order to ensure good transmission. Antennas are constructed

so that their directivity enables maximum radiation in the horizontal plane and minimum radiation towards the ground. The surrounding of such an antenna must be an obstruction-free space for at least several tens of meters. Thus, exposure in areas with public access can never be in the main beam of the antenna.

General public exposure to radiation from BSs is very comparable to exposure from television (TV) stations. The highest-frequency TV channels in Europe are at 860 MHz, which is within the frequency range used for cellular phones as well. Figure 6 shows electric field-strengths measured in a typical urban environment (Vienna, 4th district). FM radio stations, TV stations and cellular telephone signals typically range between 60 and 100 dBμV/m, corresponding to 0,01 - 0,1 V/m. Local maximum values can reach 1 V/m. The public has been exposed to such signals for decades. Looking at the ambient frequency spectrum shown in Figure 6 we can see that signals from cellular telephones are an additional contribution to the total exposure, but they appearently add just a very small percentage.

Let us try to evaluate the SAR for this exposure situation. For far-field exposure at 900 MHz, a field-strength of 0,1 V/m causes a whole-body averaged SAR of approximately 10^{-7} W/kg. In the frequency range of 30 MHz to approximately 300 MHz, a field-strength of 0,1 V/m causes approximately 10^{-6} W/kg. If we were to add up 1000 radiofrequency signals, total SAR would still be below 1 mW/kg, whereas the present, well-agreed limit value for the general public is 80 mW/kg. Thus it is evident, that there is a large safety factor between actual signal levels and recommended safety limits.

Also, TV transmitters have been well-accepted through the years and there were no diseases or health hazards reported.

Entering the near-zone of a BS antenna by, e. g., climbing an antenna mast, requires seperate safety considerations. Here, field-strengths can exceed the safety limits. Careful operation is required as is the case at any radio transmitter or at any industrial location where electromagnetic fields are applied. In areas of unrestricted public access, such situations should not occur.

From the above considerations we can conclude that, based on present knowledge, exposure of the public to the electromagnetic radiation from base stations appears to be no health risk.

SUMMARY AND CONCLUSIONS

The maximum, localized specific absorption rate in the head of a user of a modern cellular telephone reaches 6 W/kg per W transmitter power with normal use (hand-held terminal in a position at the head, where one can speak into the microphone and listen to the loudspeaker; distance between antenna and body surface not less than 2 cm). The strongest hand-held terminals available on the market today use 1 W average transmitter power, most types use less. For a typical GSM handy, e. g., maximum specific absorption rate is 1.5 W/kg in such an exposure situation. The maximum local temperature rise in possibly critical organs in the head, such as the inner ear, the hypothalamus, etc, associated with a certain specific absorption rate cannot be precisely specified yet. Results of scientific investigations are available for the eye. Here, for a distance of 6.25 mm (worst-case), a maximum absolute temperature of 39 °C has been numerically calculated for a continuous transmitter power of 0.7 W at the highest frequencies used in cellular mobile communications today (calculation for 1500 MHz, data at 1800 MHz are almost identical). This maximum occured in the posterior region of the lens. Cataracts are known to occur at temperatures of 41 °C or more, thus there seems to be a sufficient safety factor. The temperature actually occuring with normal use of cellular telephones is well within a range that the human body is frequently exposed to. A

healthy body is able to properly react by thermoregulation. Based on today's knowledge, there is no indication of hazard when hand-held terminals are used in a normal way.

As a precaution, a warning should be expressed regarding a possible exposure situation such as the antenna of a hand-held terminal being pressed against the eye or another part of the head for several minutes or longer. In this case, specific absorption rates can reach 30 W/kg per W or more, which could mean a hazard due to excessive, local heating. This should anyway be treated as a special case of misuse.

A number of further biological effects of microwave radiation has been observed during in-vitro and in-vivo experiments. The relevance of these effects for human safety is totally unclear at present, thus these effects cannot be used to derive safety criteria. The studies are very controversial, clear indications of hazards have not been demonstrated. As a precaution, such effects should however be investigated further. If reliable results become available and they have an impact on human health, they must be accounted for in relevant safety guidelines and standards.

An explicit warning must be expressed to any person with electronic, medical implants. For switched-on hand held terminals a safety distance between antenna and implant should always be kept, as long as immunity of the device has not been clearly demonstrated. The required safety distance should be specified for each type of pacemaker, defibrillator, etc. Typically, it is of the order of 10 - 40 cm. Patients should avoid carrying a hand-held terminal in their breast pocket. Operation at the ear (normal use of the telephone) has been demonstrated to be safe for most types of pacemakers.

Public exposure to radiation from base stations does not cause any hazard. The level of exposure is far below the threshold for well-established effects. Moreover, the public has been exposed to very similar electromagnetic fields (broadcast radio and television) for decades and no adverse effects have been reported.

ESTABLISHED BIOLOGICAL EFFECTS OF EXTREMELY LOW FREQUENCY (ELF) FIELDS, CURRENT PROTECTION CONCEPTS AND RESEARCH NEEDS

J.H. Bernhardt, J. Brix, and E. Vogel
Institute of Radiation Hygiene, Federal Office for Radiation Protection
D-85764 MUNICH-OBERSCHLEISSHEIM

INTRODUCTION

Public concern about possible health hazards from exposure to electromagnetic fields is growing. However, although several epidemiological studies suggest a weak association between the exposure to extremely low-frequency (ELF) fields and an increase in various kinds of cancer, a final risk assessment of long-term continuous exposure to ELF fields is not possible so far. There has not been a definite proof yet that the electric and especially magnetic ELF fields occurring at working places or in every-day life are mutagenic or carcinogenic. Questionable points are those concerning statistical evaluation, insufficient determination of the field strength during exposure, dose-effect relationship, inadequate demarcation of concomitant factors, and - most important - the absence of known interaction mechanisms (for further details see contribution of J. Stolwijk in this book). A final clarification of the question of possible late effects requires further elucidation. The non-stochastic ELF field effects, therefore, are of major importance for the derivation of standards (7).

INTERACTION MECHANISMS

Direct coupling mechanisms: Electric fields

Biological material is a much better conductor than air, therefore an electric field is distorted by the presence of a living being in the field.

Due to polarisation effects electric fields act on the outer surface of the body and lead to hair movements and sensory effects. In addition, time varying electric fields induce surface charges on an exposed body which result in currents inside the body, the magnitudes of which are related to the surface charge density. Depending on the exposure conditions, the surface charge density can vary greatly resulting in a non-uniform distribution of currents inside the body. For sinusoidal electric fields the magnitude of the currents inside the body increases proportionally with frequency. The induced current density distribution varies inversely with the body cross-section and may be relatively high in the neck and ankles of people.

In a wide variety of materials the current density $\underline{J}$ is directly proportional to the field strength $\underline{E}$, $\underline{\mathbf{J}} = \sigma \underline{\mathbf{E}}$, σ is the frequency dependent electrical conductivity of the medium.

Direct coupling mechanisms: Magnetic fields

The permittivity of biological material and air is about the same, therefore magnetic fields, unlike electric fields, penetrate biomaterial without any loss. Time varying magnetic fields induce electric fields and those cause currents inside the body. The internal tissue current density $\underline{J}$ is related to the external magnetic induction $\underline{B}$, using the Maxwell equations, its absolute value can be approximated by : $\mathbf{J = 0.5\ R\ \sigma\ dB/dt}$, where R is the radius of the inductive loop perpendicular to the direction of the magnetic induction.

The appropriate inductive loop radius depends on the orientation of the magnetic field relative to the body. Theoretically, the largest current densities will be induced in the peripheral tissues and will decrease linearly towards the center of the body as the inductive loop radius decreases.

Indirect coupling mechanisms

ELF electric fields interact with biological bodies through electric charges induced on ungrounded metallic objects, such as cars, trucks, cranes, wires and fences. Two types of interaction may occur:

- a spark discharge between the object and the person touching the object;
- the passage of current to ground through a person coming into contact with such an object; the magnitude of the current depends on the total charge on the object and on the person's impedance to ground. This charge, in turn, depends on the frequency, the electric field strength, the object geometry and its capacitance.

Interferences with medical devices

In addition to direct and indirect coupling mechanisms of low frequency fields, interference with active and passive medical devices has to be taken into account. For persons with implanted electronic devices, such as pacemakers, insulin pumps or cochlea implants and for persons with ferromagnetic implants, e.g aneurysm clips or protheses, magnetic fields may pose potential health risks. For example pacemakers in demand-mode may be activated; if the pacemaker rhythm then is asynchronos to the heart activity, this may pose a certain risk. For worst case situations the interference field strengths for 50 Hz fields were determined to be 1.7-6.8 kV m^{-1} resp.13.8-55 μT (8). Very slow fields may also inhibit continuously working pacemakers, especially for frequencies of some Hz, which is close to the heart activity.

BIOLOGICAL EFFECTS

Cellular Studies

Extremely low frequency electromagnetic fields induce time varying distributions of electric charges in tissues and electrical currents. The local electrical field strength respectively the local current density are responsible for any possible effects. Basically all organisms can be influenced by charges, because all molecules contain charged groups and the change of electric potentials plays an important role during chemical and biochemical reactions. In order to examine the interaction of electromagnetic fields and biological systems, the cell, the cell membrane or molecules are possible sites to be inspected.

The cell membrane is a barrier between the cytoplasm with a specific composition of ions and the extracellular medium. The lipid bilayer therefore shields chemical substances and charges. The cell has a negative potential with respect to the extracellular side, in most cases the potential difference is about -70 mV. Consequently there is an electric field strength of about 10 V m^{-1} across the 8 nm of the membrane. Natural biogenic electrical fields result from potential differences at cell membranes e.g. action potentials of nerves and muscle cells. Close to such cells, field strengths up to 200 V m^{-1} can be measured. In the periphery of the heart or brain even a field strength of 50 mV m^{-1} or current densities of 10 mA m^{-2} are possible. It is speculated that these relatively large natural fields are part of an extracellular communication between electrically excitable cells (10).

If the current densities in tissue, induced by electromagnetic fields, are large enough to depolarize the membrane potential up to the excitation threshold, a well defined biological reaction will follow. The mechanisms and thresholds of nerves and muscles are well known in classical electrophysiology. At levels of induced current density exceeding 100 to several hundred mA m^{-2} for frequencies between about 10 Hz and 1 kHz, thresholds for neuronal and neuromuscular stimulation are surpassed. The stimulation for single nerve- and cardiac muscle cells are well above 1 A m^{-2} (11). The threshold current densities increase progressively at frequencies below several Hz and above 1 kHz.

In contrast there is little known about the consequences and the possible mechanisms of interactions between induced, weak electrical fields and biological systems. The induced fields are permanent present and often possess higher frequencies than endogenous fields do (4).

At the moment the hypothesis is that the extracellular surface of the membrane is the target for interaction, it is based on the results of numerous cellular studies using weak magnetic field exposures. It is agreed that receptors in the membrane will be influenced and highly specialized transduction pathways can transform information into the cell. The primary process of the field - protein - coupling mechanism in not understood.

The membrane receptors are specified to transduce one single input signal (e.g. enzyme molecule) to a dominant output message. This unique biological amplification of small signals, lead to the development of many different specific receptor types. Therefore field induced modulation of this transduction pathway leads to different types of reactions without systematical relation.

In experiments, with current densities above 10 mA m^{-2} the following basic effects were produced

- influence of regulation and messenger systems of the cells,
- interference with protein synthesis,
- influence on cell growth and differentiation,
- complex physiological phenomena.

But also exposure with weak magnetic fields below 100 μT (inducing current densities less than 2 mA m^{-2}) may modulate some biological reactions. An evaluation of the various studies with weak fields, is difficult as the results of other labs were not reproduced and the effect found do not differ clearly enough from normal biological variations. Additionally, other experimental parameter proofed to be more effective stimulants.

Animal studies

Many biological endpoints have been examined using exposed rodents or other mammals. There is little evidence to suggest that low level exposure causes any consistent effect on the heart, lungs or immune system.

Various investigations have shown that power frequency fields may affect circadian rhythms via the hormone melatonin (12, 18).

There is some concern about the possible adverse effects of exposure to fields on reproduction and development of embryos and fetuses of chickens but not of mammals (9).

It has been suggested that magnetic fields may increase the risk of cancer incidence by reducing the oncostatic potential of melatonin (14, 18). Studies on carcinogenesis excluded the possibility of initialising cancer by electromagnetic fields, however fields may have a promoting or a co-promotor capacity leading to increased cellular proliferation (9).

Electric Fields - Studies On Volunteers

ELF electric fields can be perceived because of the field-induced vibration of body hair, or the occurrence of spark discharges on contact with clothes or grounded objects. The threshold for perception by hair vibration shows wide individual variation: Only 5% of exposed subjects are able to detect fields as low as 3-5 kV m^{-1} (2, 16). The threshold depends on the relative positions of the head, trunk and limbs, simply as a consequence of the different perturbations of the incident field.

Above a certain threshold, the current to ground is perceived by the person as a tingling or prickling sensation in the finger or hand touching the charged object, for frequencies below about 100 kHz, and as heat at higher frequencies. Although these effects are not considered to be a hazard, hair vibration and tingling if sustained can become an annoyance (5).

A severe shock can be experienced at levels much higher than threshold. The threshold current depend on frequency and on surface of contact area. The thresholds for women are about one third lower and the thresholds for children about 50% lower than the equivalent thresholds of men (3).

Of greater biological significance may be the occurrence of capacitive spark discharges (microshocks) which are generated when two objects of different potential come into close proximity and the electric breakdown field strength of the air is exceeded. These spark discharges will continue as long as the air gap and the potential difference is maintained. The current flows across a very small area of skin and results in a high current density which may be perceptible, irritating or painful. Exposed people may demonstrate stress reactions in the presence of repeated spark discharges with increased nervousness and inability to continue to work.

The threshold for the perception of spark discharges by 10 % of a group of volunteers close to an earthed object has been reported to be 0.6 to 1.5 kV m^{-1} at 50 to 60 Hz, with a similarly defined threshold for annoyance of 2 to 3.5 kV m^{-1} (2). Sensitivity appears to depend on such factors as skin hydration, body location and skin temperature.

There are also extensive laboratory tests on volunteers with better defined exposure conditions, but limited exposure time. The laboratory tests include field exposure times from 3 h to 1 week and field strengths of up to 20 kV m^{-1}. The variables examined were reaction time to optic and acoustic stimulation, physiological factors, EEG, ECG, blood pressure, pulse frequency, body temperature, blood status, biochemical parameters of blood and urine, enzymes and metabolic factors. No significant changes were found.

Magnetic Fields - Studies On Volunteers

At frequencies below approximately 100 kHz, interactions of time varying magnetic fields with biological systems and potential hazards can be considered in terms of induced currents and current densities. The use of induced current densities, is appropriate for the assessment of acute, immediate effects, while it may have some limitations for the complete evaluation of long-term effects. The waveform of the electromagnetic field and peak instantaneous field strengths are important factors to be considered in the response of biological systems. Generally, for frequencies above 100 to 1000 Hz, the thresholds for stimulation effects increase with frequency, up to frequencies where thermal effects dominate (> 100 kHz).

The ability of people to perceive 50 or 60 Hz magnetic fields has been studied by several groups. Visual phenomena (magnetophosphenes) caused by magnetic fields depend not only on the frequency and flux density of the magnetic field, but - with eyes open - also on adaption condition or background illumination. The sensitivity thresholds were found to be frequency dependent with a minimum threshold (maximum sensitivity) of approximately 5 mT at 20 Hz, although threshold values as low as 2 mT have been quoted, rising at lower and higher frequencies. The threshold current density at 20 Hz is estimated to be 10 mA m^{-2}. The investigations indicate that visual phenomena are not released by the magnetic field, but rather by the induced currents influencing the bipolar ganglion cells of the retina. This also explains the agreement between magneto- and electrophosphenes which may result from alternating currents produced by electrodes (5).

Following the development of clinical magnetic resonance imaging (MRI) diagnostic techniques, patients are routinely exposed during examination to intense (up to several mT), time-varying longitudinal and transverse gradient magnetic fields, pulsed at frequencies below about 10 kHz. Experiments have been carried out using volunteers in order to identify thresholds for peripheral nerve stimulation. Small, involuntary muscular twitches of the nose, and sometimes of the lower back and thigh, were reported. Threshold values depend on the orientation of the magnetic field relative to the body and have been estimated to range between

about 25 and 60 T s^{-1}, the lower values corresponding to transverse magnetic field orientation and to current densities exceeding 500 mA m^{-2} (5).

The exposure of volunteers for several hours to 50 or 60 Hz fields of up to 5 mT had no effect on a number of clinical and physiological tests, including haematology and blood biochemistry, ECG, heart rate, blood pressure and body temperature; elevated triglyceride levels were ascribed to other, confounding factors (5, 17).

It may be assumed on the basis of all known effects that man is influenced by low-frequency magnetic fields (50/60 Hz) of more than 5 mT. Volunteers exposed to intense ELF magnetic fields (up to 100 mT) at frequencies between 5 and 50 Hz have reported „indisposition and headaches" during exposure above 60 mT. Changes were also recorded in the visually evoked potential response at this magentic flux density (corresponding current densities of 100 mA m^{-2}, although visual acuity itself was apparently unaffected. Reversal of VEP's were observed that are reported not to be immediately reversible.

CURRENT PROTECTION CONCEPTS

Health implications and basic restrictions

Any discussion on the restriction of exposure has to be built on a certain protection concept. For non-ionizing electromagnetic fields usually the health threshold based system is applied: that is adverse health effects are identified together with the type and magnitude of the fields which cause this effect.

Given the inadequacy of the available data on carcinogenicity, exposure limits for electric and magnetic fields are currently based on well established mechanisms and experimental findings related to acute effects. The published guidelines are based on the limitation of electric fields or current densities induced in the body by exposure to electric or magnetic fields. Nevertheless, by considering the merits of the induced current approach for risk assessment, one should not mistakenly conclude that alternative explanations for other phenomena are impossible.

The following observations can be made for induced current density ranges and magnetic flux densities induced by sinusoidal homogeneous fields (17):

- Below 10 mA m^{-2} are the naturally occurring endogeneous currents of the body.
- Between 10 mA m^{-2} and 100 mA m^{-2} there are well established effects on the visual and nervous system.
- Between 100 mA m^{-2} and 1000 mA m^{-2} changes in the excitability of nerveous tissue is observed and there are possible health hazards.
- Above 1000 mA m^{-2} nerve stimulation and stimulation of the heart including extrasystoles and ventricular fibrillation can occur (acute health hazards).

Based on these data, levels of exposure are recommended which lie well below the levels of nerve excitation. In order to chose an approriate safety margin for such a recommendation, the following factors have to be considered:

- It is difficult to correlate precisely tissue current densities with external fields.
- There is a wide difference in perception thresholds, e.g. between children and grown-ups.
- Extrapolation from acute short term effects to long term exposure.
- Combined effects of exposure to fields and other chemical or physical agents of the environment.
- Medicated persons may have different responses.

Furthermore, experiments are conducted for specific frequencies only so that the whole frequency range and especially all possible modulations cannot be covered with sufficient data. The available set of data mostly is not obtained from experiments with human beings.

In the frequency range between 10 Hz and 10 kHz, for levels of induced current densities above 100 mA m^{-2} the thresholds for possible acute health hazards are surpassed. Given the

considerations above a safety factor of 10 was chosen and it was decided, that for human exposure only current densities below 10 mA m^{-2} should be allowed.

This basic restriction is a factor of 10 below serious acute effects like reversal of VEP and below the lowest threshold of changes in central nervous system excitability. Furthermore this basic restriction is a factor of 100 below the threshold of definite health hazards (ventricular fibrillation).

Then there are additional reasons to adopt lower exposure limits for the exposure of the population than for the ocupationally exposed persons. The main reason are the following: the general public comprises individual persons of all ages and different health status, individuals or groups with particular health susceptibility may be included in the general population. Exposure of the general public may last all day long, where as occupational exposure is restriced, usually to 8 hours a day for 5 days a week. Finally the public cannot be expected to take any risks or to accept any annoyances e.g. from contact currents. Thus for the exposure of the general public another factor of 5 was chosen, which leads to maxium current densities of 2 mA m^{-2}, corresponding to the current densities naturally occurring in the tissues and organs of the body.

The current densities should be averaged over a cross-section of 1 cm^2 perpendicular to the current direction. This averaging seems to be sufficient to include spatial peak values due to differences in the conductivity and in view of the fact that the effects of current densities are occuring at the cellular levels and that the safety zone from stimulating effects is sufficiently large.

Derived exposure levels

In practice, values of „field" quantities are required since the basic quantities cannot be measured directly in the human body. The derived exposure levels is the permissible value for the electric or magnetic field strength which is derived from basic restrictions. Derived exposure levels are given to provide a method of assessment for the effect of electromagnetic fields and to demonstrate compliance with the basic restrictions of exposure. Said exposure levels have been specified in such a manner that the basic restrictions are not exceeded even if the most unfavourable conditions of field exposure are taken as a basis.

Since the first attempt to relate external exposure to internal current densities (1) several numerical and measuring methods were developed for the derivation of field strength exposure limits from the basic restriction. For both methods considerable simplifications have been used up to now that did not account for phenomena such as the inhomogeneous distribution and anisotropy of the electric conductivity and other factors.

Magnetic field models assume that the body has a homogeneous and isotropic conductivity and apply simple circular conductive loop models to estimate induced currents in organs and body regions, i.e., for the head by using the relation $\mathbf{J} = \pi \mathbf{R} \sigma \mathbf{f} \mathbf{B}_0$ (amplitude of the field $\mathbf{B}_0 = \sqrt{2} \cdot \mathbf{B}_{rms}$). More complex models use an ellipsoidal-shaped model (11) to represent the trunk or the whole body for the estimation of induced currents resulting in higher current densities which occur at the periphery of a body. Results are summarized in table 1 for 50 Hz. The exposure level of 0.5 mT for occupational exposure or 100 µT for general public exposure recommended by (7) corresponds to maximum current densities of about 8 mA m^{-2} or 1.6 mA m^{-2}, respectively, in peripheral regions of the trunk. Referring to more realistic calculations based on an anatomically and electrically enhanced model (15) result in higher current densities (i.e., 0.5 mT induce 12 mA m^{-2} at 60 Hz).

Electric field models have to take into account that depending on the exposure conditions, size, shape and position of the exposed body in the field, the surface charge density can vary greatly resulting in a variable and non-uniform distribution of currents inside the body. Thus for sinusoidal electric fields below about 10 MHz the factor of proportionality σ between the

current density and the external field strength should be replaced, so that, $\underline{J}=A\ f\ \underline{E}_{ext}$, where $\underline{E}_{ext}$ is the external unperturbed electric field strength and A is a „shape factor" for human body parts of specific shape and a specific orientation.

The factor A can be determined by model calculation (including measurements) for different parts of the body: for the trunk (average) about $6.7 \cdot 10^{-9}$ S Hz^{-1} m^{-1}, for the ankle about $40 \cdot 10^{-9}$ S Hz^{-1} m^{-1} for the neck about $10 \cdot 10^{-9}$ S Hz^{-1} m^{-1} and for the head $2 \cdot 10^{-9}$S Hz^{-1} m^{-1}. These numbers show that the induced current density distribution varies with the body cross-section and may be relatively high in the neck and ankles of people. The electric field strengths which approximately procuce current densities of 10 or 2 mA m^{-2}, respectively, in different body parts are listed in Table 1. The exposure level of 5 kV m^{-1} for continuous general public exposure recommended by (7) corresponds to a current density of about 2.5 mA m^{-2} in the neck and about 1.7 mA m^{-2} in the trunk (average) if the E-field vector is parallel to the body axis.

Table 1: 50-Hz-electric field strengths and magnetic flux densities producing approximately current densities of 10 mA m^{-2} or 2 mA m^{-2}, respectively, in different body parts (6)

	Trunk (average)	Head	Neck	Ankles, when both feet are grounded	Whole Body (ellipsoidal model)	Head	Wrist/ Ankle
	Shape factor in 10^{-9} S $Hz^{-1}m^{-1}$				$\sigma = 0.2$ S m^{-1}		
Parameters for calculation	A = 6.7	A = 2	A = 10	A = 40	a =0.2 m b =0.85 m c =0.1 m	R=0.075m	R=0.03m
Current density	Electric field strength (kV m^{-1})				Magnetic flux density (mT)		
10 mA m^{-2}	30	100	20	5	0.6	2.5	6
2 mA m^{-2}	6	20	4	1	0.12	0.5	1.2

RESEARCH NEEDS

Recently research on interaction mechanisms of electromagnetic fields has increased enormously. In spite of the large amount of publications there still is no convincing answer, how weak electromagnetic fields in the body can lead to an interaction even below electric stimulation thresholds.

Based on numerous studies with exposure to weak magnetic fields it is hypothesized by now that the induced currents and voltages in the extracellular medium interact with electrochemical processes at the cell surface.

Some biological effects can only be evoked by fields with a narrow set of parameters therefore reaction windows were postulated. Experimental data then have to be used to test the existence of nonlinear intensity-reaction-relations. Only after the proof of this hypothesis a transfer to other biological systems is possible.

The weak fields obviously do have a very differential interaction with the metabolism of organisms. Various effects only lead to a minor temporal modulation of biological reactions. The measurement of different physiological, parameters showed heterogeneous and contradictory results.

Therefore there still is a need for fundamental research to find and to define one or more primary mechanisms. For example it should be found out, if it is the magnetic field or the induced electric field which is responsible for a reaction.

Only with the knowledge of the primary reactions, a systematic concept of research projects can be established for examining the pathway of the biological signal to the manifested effect and for testing the possibility of transduction with subsequent amplification cascades. It has to be elucidated for example which physiological functions are involved and if cells have different sensibilities.

Studies on immune and nervous systems then have to show if those single cells effects can influence the circulation system or the embryonic development or the whole organism have to be tested with exposure conditions.

Central nervous system responses to induced electric current should be further investigated including, for example, *in vitro* brain slice studies of weak electric current effects.

There is a particular need for studies on the possible carcinogenicity of electromagnetic fields. The experimental work should include co-carcinogenesis experiments, particularly looking at co-promotion in animal and cellular models, studies of effects on cell signalling and proliferation, Ca^{2+} uptake and gene expression, and further study of effects on melatonin and its possible role in the suppression of mammary tumour growth.

Further investigations of possible weak ELF field interaction mechanisms particularly of experimentally testable hypotheses such as magnetic field effects on radical pair interactions have merit as well as studies of weak electromagnetic fields interactions with the optical system, in relation to effects on the production of melatonin by the pineal gland.

After the field induced changes or modulations of biological systems are scientifically established, it has to be found out, whether these evoked effects are potentially pathogenic.

BIOLOGICAL EFFECTS OF ELECTROMAGNETIC FIELDS

Camelia Gabriel
King's College London, Strand, London WC2R 2LS, UK.

INTRODUCTION

The effects of electromagnetic (em) fields on biological systems were first observed and exploited well over a century ago. Concern over the possible health hazards of human exposure to such fields developed much later. It is now well known that excessive exposure to em fields may have in undesirable biological consequences. Standards were introduced to determine what constitute an excessive exposure and how to avoid it. Current concern over the issue of hazards stems mainly from recent epidemiological studies of exposed populations and also from the results of laboratory experiments in which whole animals are exposed in vivo or tissue and cell cultures exposed in vitro to low levels of irradiation. The underlying fear is the possibility of a causal relationship between chronic exposure to low field levels and some forms of cancer. So far the evidence does not add up to a firm statement on the matter. At present it is not known how and at what level, if at all, can these exposure be harmful to human health. This state of affair does not provide a basis for incorporating the outcome of such research in exposure standards.

This paper will give a brief overview of the research in this field and how it is evaluated for the purpose of producing scientifically based standards. The emphasis will be on the physical, biophysical and biological mechanisms implicated in the interaction between em fields and biological systems. Understanding such mechanisms leads not only to a more accurate evaluation of their health implications but also to their optimal utilisation, under controlled conditions, in biomedical applications.

INTERACTION OF EM FIELDS WITH PEOPLE

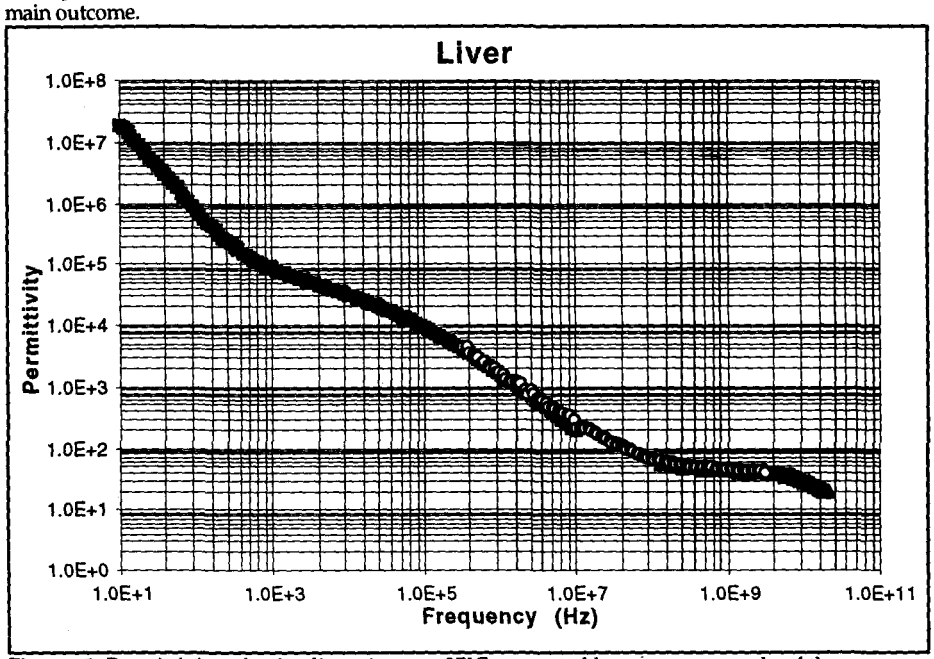
Interactions between em fields and people occur at all levels of organisation. The coupling of external fields with the body is the first step leading to further interactions at the cellular and molecular level. The initial coupling is a function of numerous parameters including field characteristics as well as the size and shape of the body and its electrical properties. The coupling is most efficient when the size of the body is of the same order of magnitude as the wavelength of the field and when the long axis of the body is in the direction of the field. This statement is based numerous dosimetric exercises in which the shape of the body was approximated to a geometric form such as a homogeneous ellipsoid to facilitate calculations and on later verifications using more realistic models (1). A consequence of the primary interaction is that internal fields are induced inside the body. The quantification of these fields and their spatial distribution is the concern of dosimetry.

The internal fields will, in turn, induce local fields at the level of the cells, in the extracellular space, within cells and across cell membranes (2). The quantification of these fields and the determination of local current pathways is termed microdosimetry (3). Microdosimetry can be extended to include interactions at the molecular level using concepts of em energy absorption and the establishment of internal thermal gradients (4).

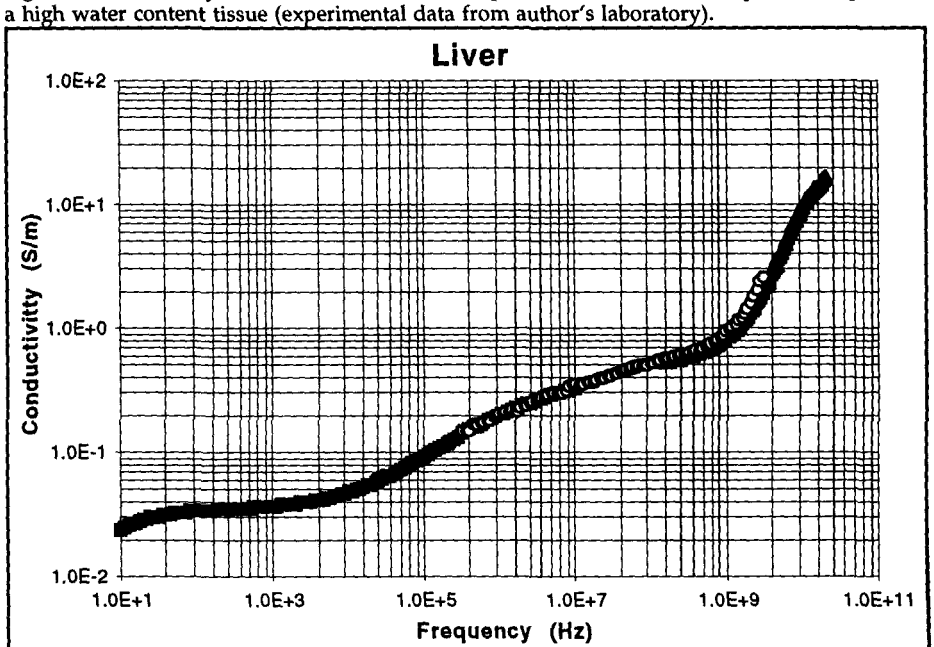
Electromagnetic fields interact with matter through forces generated on charges. Internal electric fields act on bound and free charges in the body tissue causing polarisation, molecular orientation and the establishment of ionic currents. There is little, if any, direct interaction with a magnetic field, instead, time varying magnetic field generate electric fields with the usual consequences.

The electrical properties of tissues (relative permittivity ε' and total conductivity σ) can be considered a measure of the interaction of the tissue with an electric field. For most tissues, the relative permittivity is highly frequency dependent from hertz to gigaherts with values reaching 10^7 below 100 Hz decreasing to less than 50 above 1 GHz (Fig. 1). The corresponding conductivity

values (Fig. 2) increase with frequency is steps that mirror the fall in permittivity. Implicit in this qualitative analysis is that strong direct interactions are likely at low frequencies (high permittivity and low conductivity) while at high frequencies, the interactions are dominated by the high conductivity of tissues making energy absorption from ionic and polarisation currents the main outcome.



Figures 1: Permittivity of ovine liver tissue at 37°C presented here as an example of the spectrum of a high water content tissue (experimental data from author's laboratory).



Figures 2: Conductivity of ovine liver tissue at 37°C presented here as an example of the spectrum of a high water content tissue (experimental data from author's laboratory).

BIOLOGICAL EFFECTS

Cells and tissues exist in a background of bioelectric fields. For example, some electrically active cells sustain a transmembrane potential of up to 0.1 V (inside negative), cell communications initiate action potentials which are pulse like signals lasting a few milliseconds. Currents induced by external fields add to and interfere with these ambient fields. At frequencies below 1 kHz, induced currents flow mainly through the extracellular fluid, they affect the electrical environment of cells, may cause changes in the transmembrane potential, and, if sufficiently intense, stimulate electrically excitable cells. Current densities of the order of 0.1 Am^{-2} are capable of stimulating nerve and muscle cells (5) while higher currents have more serious consequences, this compares with endogenous current densities of between 1 and 10 mAm^{-2}. Interactions at or below the threshold for stimulation are not isothermal, energy is absorbed but the resulting thermal load is negligible by comparison to the thermal fluctuation of the body. The threshold for stimulation increases proportionally with frequency, the energy dissipated by that currents increases at a faster rate. At about 1 MHz, thermal damage to the cells may occur at current densities below the stimulation threshold. Interactions resulting in thermal effects are described in terms of the power absorbed per unit body mass or specific absorption rate (SAR). People are accustomed to receiving thermal stimulation and, provided that these are not too large, the body can deal with them by invoking thermoregulatory responses. The threshold SAR for the onset of thermally induced biological effects is about 4 Wkg^{-1}. This level of SAR may give rise to a temperature elevation of about 1 or 2 degrees and may cause behavioural changes or result in a reduction of performance of learned tasks in experimental animals. These effects are consistent with the rise in temperature. The biological effects associated with higher levels of SAR are well documented and have been extensively reviewed (6, 7) they include modification of the action of drugs, changes in the secretion of hormones, developmental abnormalities as well as transient effects on heat sensitive systems such as spern cells and blood forming tissues. The batabase of biological effects is consistent with a strong correlation between the SAR and the severity of the resulting biological effect.

There is a growing body of evidence describing subtle biological responses to specific low intensity fields below the threshold for thermal manifestations. . A common feature to most of the experimental studies is the lack of dose-response relationship. The concept of low level interactions leading to significant biological effects has been challenged on theoretical grounds (8). The main argument is that such fields are likely to be masked by thermally generated electrical noise. Several non linear interaction mechanisms have been proposed to describe some of the experimental results in terms of signal amplification from resonant or cooperative interactions at the site of the cellular membrane. The absence of dose response relationship together with the lack of well defined mechanism makes it difficult to plan new experiments and even to repeat old ones in different laboratories under identical exposure conditions.

Two examples of well conducted studies will be briefly reported to illustrate the type of research that needs to be replicated in different laboratories. Degenerative changes caused by low level microwave irradiation in the retina, iris and corneal endothelium of primates were first reported in 1985 (9) followed by several studies by the same research group over a number of years (10). The effects were observed with continuous irradiation but pulsed microwaves were found to be as effective at lower power levels. Pre-treatment of the eye with the glaucoma drug timolol maleate further lowered the threshold for damage to an average SAR of 0.26 Wkg^{-1}. Although the authors did not measure intra ocular temperatures in the animals, the results suggest that a mechanism other than significant heating of the eye is involved. Another example of biological effects arising from acute low-level exposure to microwaves involves single-strand breaks in DNA in brain cells from rats (11). No significant effect is observed immediately after irradiation with pulsed microwaves but a dose related effect was observed 4 hours post exposure equivalent to 0.6 and 1.2 Wkg^{-1} whole body SAR. With continuous irradiation increase in DNA single strand breaks were observed immediately as well as 4 hours post exposure. The study suggests that microwave irradiation may increase the rate of DNA breaking or inhibit the repair processes in the cells.

A study by Chou et al (12) illustrates investigations of the effect of chronic exposure to low levels of microwave . The aim of the study was to investigate the effects of long-term exposure to pulsed

microwave radiation. An interesting and important feature of the study was the exposure of a large sample of experimental animals (rats) throughout their lifetimes in order to monitor them for effects on general health and longevity. Statistically the results were negative overall for effects on general health, longevity, cause of death, and lesions associated with ageing and the incidence of benign tumours. Some positive results on hormone levels and changes in the immune system were transient. A statistically significant increase of primary malignancies in exposed rats compared to controls was reported but tumour incidence was lower than historically expected in both groups. The authors state that, in the light of other parameters in the study, it is conjectural whether the excess reflects a true biological influence. Moreover, in the absence of reduced longevity, the biological significance of this effect is questionable. Overall, the results indicate that there were no definitive biological effects in rats chronically exposed to microwaves. The cost of repeating lifetime animal studies is not trivial in many respects, nevertheless, such studies need independent verification. A number of long term exposure studies are currently underway, it will be interesting to see if they have sufficient similarities in the experimental design to enable a meaningful comparison of the data output.

Understanding and eventually predicting the biophysical responses to low levels fields is a challenging task. Below 100 kHz, a prerequisite is the quantification of induced currents at the site of interaction. Such currents are different from those calculated in the primary interaction of external fields with the body assuming tissues to be uniform media of known dielectric properties. In principle it should be possible to extend the same dosimetric techniques to the cellular and molecular levels, in practice, it is very difficult to model with accuracy complex biological tissues including cells and their associated bioelectric fields. The theoretical considerations are not trivial even for random non biological systems (13). The answer may well rest with the development of experimental microdosimetric field measurement techniques (2,14) or indeed with a dual approach of experimental and computational methods.

The estimation of induced current density is important in the frequency range where direct action of the field on cells is anticipated. A different approach to microdosimetry should be adopted at higher frequencies where energy absorption is the prime consideration. For example, dielectric studies can yield relevant information on the polarisation of cells and molecules and help predict the distribution of energy absorptions at the molecular level (4,15). Experimental techniques include the use of molecular probes to provide spatial and temporal estimation of temperature and specific energy absorption at the cellular and subcellular levels (16). Progress rests with a multidiciplinary approach including experimental and theoretical investigations.

IMPLICATIONS FOR STANDARDS

Standards should, ideally, be based on rigorous scientific evidence that a physical agent is capable of causing harm under identifiable conditions. Standards, by their very nature, introduce controls and are bound to have an economic impact. However, when the science is clear cut, all other considerations are forsaken in favour of scientific data of health hazards and their corresponding thresholds. The scientific base underpinning em exposure standards is well established with respect to acute effects, but the issue is clouded by uncertainties provided by the growing database of low levels effects. It is important that such studies be continued and that their health implications, if any, be determined before their incorporation into standards. Equally important is to resist using the prevailing uncertainties as an excuse to adopt policies of 'prudent avoidance' and the like. Prudent avoidance measures may be, and indeed mostly are, harmless in their own right, their incorporation into guidance documents is however tantamount to the rejection of science as basis for protection.

CONCLUSIONS

The importance of microdosimetry has been highlighted to help elucidate the mechanisms of interaction responsible for low level effects. At low frequencies, the emphasis is on estimating the current at the cellular, at microwave frequencies energy absorption should be understood at the

molecular level. The argument points to the importance and the relevance of extending dosimetric studies to include thermal modelling for both human and animal exposures. Because the biological effects are related to the temperature rise, thermal modelling would enable better extrapolation to human from animal experiment and also help our understanding of the mechanisms involved in the interaction.

BASIS OF CONCERN: THE POSSIBLE LUNG CANCER RISK FROM RESIDENTIAL RADON

W. Jacobi
GSF - Research Center for Environment and Health, Institut for Radiation Protection, Neuherberg, D-85758 Oberschleißheim, Germany

INTRODUCTION

Our concern about the lung cancer risk from indoor radon arises from three issues. (1) The measured large variation range of the radon concentration in the indoor air of dwellings; (2) the rather high alpha dose to the critical bronchial cells from inhaled short-lived radon progeny; and (3) the clear evidence of an excess lung cancer risk, increasing with the exposure to radon progeny, which follows from epidemiological studies of Rn-exposed underground miners as well as from animal experiments. - On the basis of the latter findings, the International Agency for Research on Cancer has classified radon with its progeny as a carcinogenic agent to humans.

To quantify the possible lung cancer risk from indoor radon three different types of approaches can be taken into consideration: (1) Direct, well-designed epidemiological studies in population groups exposed residentially; (2) the transfer of exposure-risk models which follow from Rn-exposed miner's data, to the residential radon exposure of the general population; and finally (3) the so-called "dosimetrie approach" which proceeds from the observed excess risk of lung cancer among the atomic bomb survivors (Life Span Study), following a single, short-term dose to the lung by external radiation.

Starting with a summary of the population exposure to residential radon and its progeny, in the following the results and uncertainties of these risk approaches are outlined.

EXPOSURE TO RESIDENTIAL RADON

Survey measurements of the radon concentration in dwellings have been carried out in many countries. The results which are summarized in the UNSCEAR 1993 Report, yield a variation range from a few up to 200 000 Bq m^{-3}. The observed variation can be approximated by a log-normal distribution function with geometric standard variation in the range of 2-3. The cumulative distribution of the national mean values is shown in figure 1. The national arithmetic mean values cover a range from 10 to 110 Bq m^{-3}, compared with a mean value in outdoor air of about 10 Bq m^{-3}.

On the basis of these data UNSCEAR adopts for the world population a population - weighted, arithmetic mean value of the radon concentration in dwellings of 40 Bq m^{-3} (geometric mean 26 Bq m^{-3}). Taking into account a mean equilibrium factor F=0.4 for Rn progenies in indoor air this corresponds to a mean equilibrium - equivalent concentration c_{eq} of 16 Bq m^{-3}. Assuming a mean occupancy factor indoors of 0.8, it follows for the world

population a mean annual exposure indoors (exposure=concentration x residence time) to radon progeny of about $1.13 \cdot 10^5$ Bq h m^{-3}, expressed in terms of the equilibrium-equivalent exposure, or $6.28 \cdot 10^{-4}$ J h m^{-3}=0,177 WLM in terms of potential alpha energy exposure P_p. With a life expectancy of 65-85 years follows a lifetime exposure of 12-15 WLM.

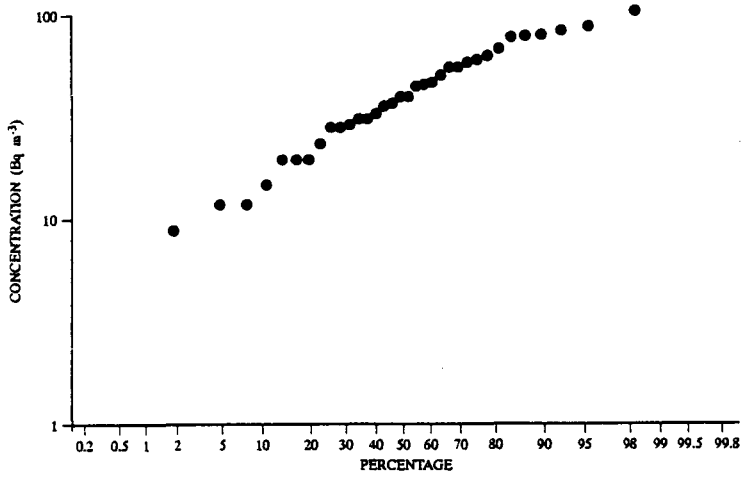

Fig.1. Population-weighted cumulative distribution of the mean radon concentration indoors which results from national surveys in 34 countries (UNSCEAR 1993).

From the observed variation of indoor radon it can be estimated that worldwide in about 2 % of dwellings the annual exposure might be more than a factor 5, and in about 0,2 % more than a factor 20 higher than the worldwide mean annual exposure value. - In this context it seems important to note that the epidemiological studies of Rn-exposed miners yield a statistical significant excess of lung cancer at cumulative occupational exposures above 50 WLM.

EPIDEMIOLOGICAL APPROACH FROM MINER'S DATA

Epidemiological studies of Rn-exposed miners in the USA, Canada, Europe, China and Australia give strong evidence for an the induction of lung cancer by inhaled radon progeny. Recently a joint analysis of the data from 11 cohort studies of male underground miners has been conducted (Lubin et al. 1994a). Figure 2 shows the excess relative risk (ERR) of lung cancer as function of the cumulative exposure P_p (in WLM units) to radon progeny which follows from the combined data of these studies. The analysis yields as best fit a linear relationship up to exposure levels of about 400 WLM with a slope ERR/P_p=0,005 WLM^{-1} (95 % confidence interval 0,002 - 0,010 WLM^{-1}). This relative risk coefficient is modified, however, by various factors. It decreases with attained age and declined with increasing time since exposure. Furthermore the data indicate an increase of the relative risk coefficient with decreasing exposure rate or with long duration of exposure (see figure 3). This inverse exposure-rate effect has been sometimes interpreted in terms of a reciprocal correlation. From an extended analysis of the data it has been recently concluded, however, that this effect decreases with decreasing cumulative exposure and obviously disappears at exposure levels below about 50 WLM which are of relevance for the population exposure (Lubin et al. 1995a).

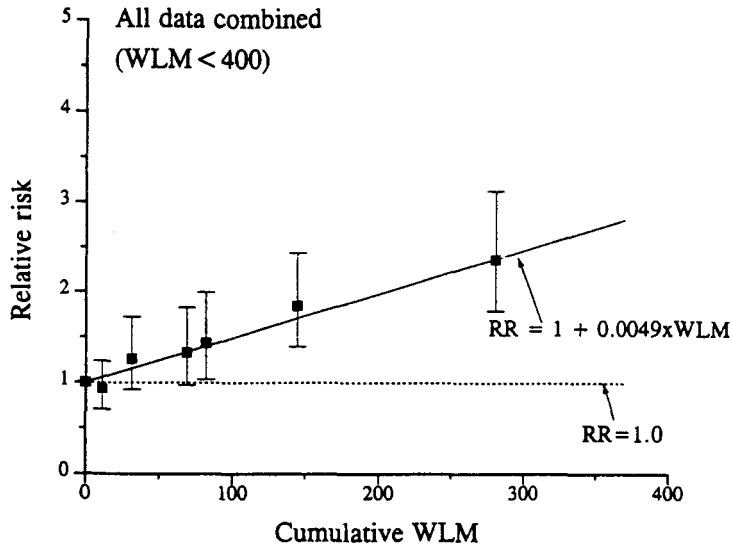

Fig.2. Relative lung cancer risk (RR) as function of the cumulative exposure (in WLM) to radon progeny which follows from the combined data of 11 cohort studies of underground miners. The mean values and their 95 % confidence interval are plotted at the mean exposure in each exposure category. The closed line indicates the best linear fit to the data (from Lubin et al. 1994a).

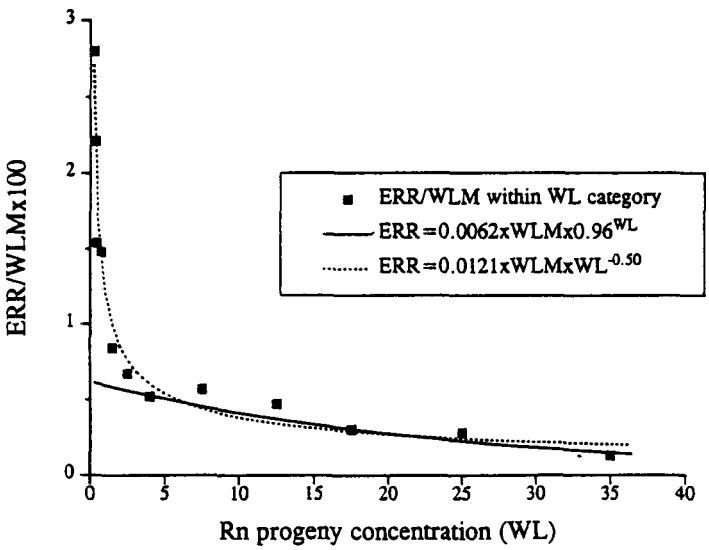

Fig.3. Estimated mean values of the relative risk coefficient ERR/P_p (WLM) within Working-Level (WL) categories as it follows from the joint analysis of 11 cohort studies of underground miners. The curves give the results of different models (from Lubin et al. 1994a).

A further uncertainty concerns the influence of tobacco smoking. The available few data from miners give little quantitative information on this subject. In previous studies (ICRP 1987, BEIR IV-NRC 1988) a multiplicative model was assumed. This means that the relative risk coefficient ERR/P_p, would be equal for nonsmokers and smokers. The now available data from some groups of Rn-exposed miners indicate that the interaction between smoking and radon is somewhat less than multiplicative but more than additive. Lubin et al. (1994a) assumed in their smoking-adjusted model an ERR/P_p-value which is a factor 0,9 lower for smokers and a factor 3,0 higher for nonsmokers, compared with the average value derived from the miner's data. The uncertainty of this adjustment factor for nonsmokers is, however, quite large. A reanalyses of the data of the Colorado uranium miners yields an ERR/P_p-ratio between nonsmokers and smokers (20 cigarettes/day) of somewhat less than 2 (Moolgavkar et al. 1993).

In table 1 the central lifetime risk estimates of the attributable relative lung cancer risk (ARR) from residential radon exposure, averaged over males and females, are listed which should be expected on the basis of the approach from miner's data. In addition to the model of Lubin et al. (1994a) the results of previous estimates (ICRP 1987, BEIR IV-NRC 1988) are given. The ARR-values refer to a lifetime exposure to radon progeny at a constant rate of 0,18 WLM/year as it follows for a mean Rn-concentration indoors of 40 Bq m^{-3} like it was assumed by UNSCEAR.

Table 1. Attributable relative risk (ARR) of lung cancer from residential exposure to radon progeny at a constant mean level of 0.18 WLM per year; central estimates of different risk models derived from miner's data with dosimetric adjustment for indoor exposure.[a]

Relative risk model	Smoking influence	Population	ARR, in percent	
			nonsmokers	smokers
ICRP 50 (1987) const.RR-model	multi-plicative	Reference population[b]	6.8	6.4
BEIR IV (NRC 1988) TSE model	multi-plicative	USA	7.0	6.5
		Germany	6.0	5.7
Lubin et al. (1994a) TSE/AGE/WL-cat model	multi-plicative	USA	12.0	11.3
		Germany[c]	7.3	7.0
	submulti-plicative	USA	28.5	10.3
		Germany[c]	18.8	6.5

a) Dosimetric adjustment factor K for indoor exposure:
0.8 for age < 10 y; 0.7 for age ≥10 y (NRC 1991);
b) refering to a population with a life expectancy of 70 y for males and 75 y for females.
c) estimate for the population in West-Germany, taking into account mortality data 1985-89 Steindorf et al., 1995).

The ARR-values given in table 1 are averaged over females and males. Assuming a multiplicative influence of smoking the attributable risk which follows from the new joint analysis of 11 miner's studies (Lubin et al. 1994), is about a factor 1.7 (US population) or 1.2 (German population), respectively, higher than the values resulting from the BEIR IV-model (NRC 1988). As it should be expected the values, adjusted for a submultiplicative influence of smokers, lead to considerably higher ARR-values for nonsmokers. It must be kept in mind, however, that this risk approach from miner's data involves large uncertainties. The statistical 95 % confidence interval of the input data covers a range given by a factor from about 0.3 to 2.5. Additional systematic uncertainties concern mainly the assessment of miner's exposure, the exposure-rate effect, the influence of smoking, and, last not least, the simplifying assumptions made for the transfer of the risk models from underground miners to the residential exposure of the general population, particularly to females and children.

DIRECT RESIDENTIAL RADON STUDIES

Direct well-designed, epidemiological studies on the carcinogenie effect of radon progeny in indoor air are desirable. Two different types of studies have been conducted: (1) So-called "geographie" or "ecological" studies which look for a correlation between the lung cancer rate in certain geographical areas and the mean radon exposure in these areas; and (2) case-control or cohort studies in which individual radon exposures of lung cancer cases are estimated and compared with those of appropriate controls.

The available results of geographic studies are summarised and reviewed in reports of Stidley and Samet (1993) and of UNSCEAR (1994). A further comprehensive study in which data from 1601 US counties are compared, has been published recently (Cohen 1995). - Summarising, 9 of these studies indicate a positive correlation, 6 studies show no correlation and 5 studies yield a negative association between lung cancer frequency and estimated radon exposure. Taking into regard the general methodological problems and limitations of these studies, the value of such geographical studies is questionable (Stidley et al. 1993, IARC 1995). An exception might be studies which compare the lung cancer frequency in areas with strongly different concentrations of indoor radon, like the study in Umhausen/Tirol in Austria (Ennemoser et al. 1994).

Case-control studies are more appropriate than geographical studies. The results of 12 published case-control studies are summarized and reviewed in the UNSCEAR 1994 Report and in papers of Lubin et al. (1994b; 1996 in press). Most of these studies involve, however, only a relative small number of lung cancer cases, which leads to large statistical uncertainties. This is demonstrated in figure 4 (from Lubin et al. 1994b) where for 7 of these studies the observed relative lung cancer risk is plotted as function of the radon concentration indoors. The three larger studies are the nationwide Swedish study (Pershagen et al. 1994), the study in Winnipeg/Canada (Letournean et al. 1994) and the study in New Jersey/USA (Schoenberg et al. 1990). The Swedish study (1360 cases, 2847 controls) yields for the concentration cohort from 140-400 Bq m^{-3} a mean excess relative risk of 0.3 (95 % CI: 0.1-0.6), compared with the cohort below 140 Bq m^{-3}. The study in Winnipeg (750 cases, 750 controls) shows no significant correlation between lung cancer and indoor radon exposure. The New Jersey-Study (433 cases, 402 controls) indicates a poitive trend after adjusting for smoking and age, but there are only a few cases with higher radon exposure in this study.

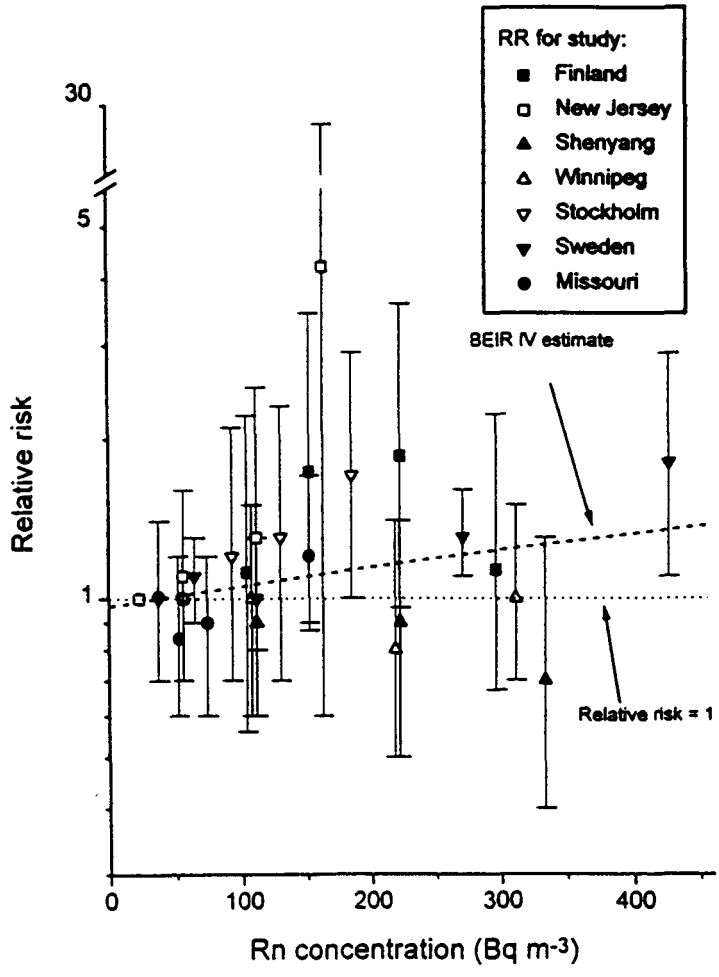

Fig.4. Relative lung cancer risk in different intervals of indoor radon concentration (mean values and 95 % conficence intervals) resulting from 7 residential case-control studies (from Lubin 1994b, 1996). The dashed line shows the increase which should be expected on the basis of the BEIR IV-model derived from miner's data, refering to a residential exposure from age 35-65.

However, all of the available case-control studies have limitations that hinder a clear interpretation of their results. This concerns particularly the assessment of the individual lifetime exposure, taking into regard the residential mobility, and the assessment of the individual smoking habits. It should be kept in mind that in these studies the radon exposure of most lung cancer cases was relatively low and therefore the attributable risk from radon will be small compared with the lung cancer risk from smoking. To illustrate the influence of errors in exposure assessment, Lubin et al. (1995b, 1996 in press) have simulated case-control studies. The results reveal the substantial contribution of these errors in explaining the inconsisteney of the present case-control studies. Lubin concludes: "These simulations imply that it is unlikely that case-control studies alone will be able to determine precise estimates of risk from indoor radon. Also implied is that even future efforts at pooling epidemiological studies may not adequately adress issues of risk from residential radon exposure" (Lubin 1995b).

FINAL CONCLUSIONS

Without doubt ionizing radiation is a carcinogenic agent for humans. This general statement is also valid for the induction of lung cancer from inhaled radon with its progeny. The problem is to quantify the risk from residential radon exposure. The available direct geographical and case-control studies are inconsistent and enable no conclusion. Like in the past risk estimates for residential radon must therefore continue to be based on the approach from epidemiological data of Rn-exposed miners. In spite all uncertainties this approach indicates that, apart from smoking, inhalation of radon with its progeny in dwellings seems to be the most important cause of lung cancer in the general population.

PRIORITY AND PROGRESS

Gun Astri Swedjemark
Swedish Radiation Protection Institute, 17116 Stockholm, Sweden

INTRODUCTION

Since 1980, Sweden has a system for limiting radon in dwellings. Before that, the Swedish Radiation Protection Institute (SSI) had informed about the hazard for about ten years (1,2) without any attention from the mass media. This information was based partly on the results of the measurements carried out by Hultqvist in 1955 (3) and my measurements in the early 1970s (4), which both showed rather high radon concentrations. The risk estimation was based on the experiences from miners especially in non-uranium mines.

Before 1978

Hultqvist measured gamma radiation in 986 dwellings in central Sweden built before 1946. Of these dwellings 287 were studied with regard to radon using ionisation chambers. The resulting radon levels are shown in Table 1. He found high levels in some of the alum shale concrete dwellings but also in a few dwellings built of other materials with very poor air exchange rates and in basements. Limits were discussed but not introduced because a good air exchange rate was judged to be necessary for other hygienic reasons and the ventilation rate was important for the concentration of radon. Another reason was that natural radiation was excluded in the recommendations from ICRP (the International Commission on Radiological Protection) and also in the Swedish radiation protection Act.

Table 1. The radon concentrations in air in four towns in central Sweden in the early 1950s, in houses built before 1946 (3). Both single-family houses and apartments in multi-family houses are included.

	Radon concentration[a], Bq m^{-3}			
	Unaired houses[b]	Aired houses[c]	Weighted average	Highest value
All dwellings	77	36	62	592 (1740[d])
Wood	15.2	15.5	15.2	63
Brick	47	26	40	303
Alum shale concrete	133	67	116	592 (1740[d])

a) 1 Bq m^{-3} = 0.027 pCi/liter
b) No thorough airing was carried out since the day before the sampling of air for measurement.
c) Dwellings were aired the morning before the sampling of air for measurement.
d) This value was not included in the original sample of dwellings. The ventilation rate was extremely poor.

In the 1970s we tried to interest the Swedish national boards responsible for indoor health in the radon problem, but with little success. We saw the radon concentration increase when residents saved energy by decreasing the ventilation rates. At that time we could not use the

idiation protection Act to specify limits or recommendations for natural radiation. We issued booklet for the public and presented it through a press release. One journalist, whom we ontacted said that it was not ethical to inform the Swedish people about such a problem efore Christmas. We also tried to bring up the radon problem internationally but the answer vas "Maybe you in the Nordic countries have a problem with your cold climate, alum shale concrete, and with inhabitants who never open windows, but we don't have that problem." Bo Lindell said at that time: "if you measure houses in your country you will find some houses with high radon levels. Even in a tent you will find levels higher than outdoors". We informed the company which produced the alum shale concrete that the material would not be permitted when limits for radium and thorium concentrations in building materials would be introduced. Subsequently, in 1974, they stopped the production. The material had then been produced since 1929.

1978-1989

However, after we had found several thousands of Bq m^{-3} in houses in 1978 (Table 2), the government granted Bo Lindell's request for a government commission to work with a limitation system for radiation exposure in dwellings. The Commission received a fund for

Table 2. The average concentrations are given for six houses built on abandoned waste from alum shale mining in past centuries in Sweden and for five reference houses. The average for each house of concentrations of radon and radon progeny together with air exchange rates and gamma radiation are given. The measurements were made in October 1978 (5).

Ground	Radon Bq m^{-3}	Radon progeny Bq m^{-3} EER	Air exchange rate h^{-1}	Gamma radiation μSv h^{-1}
6 houses on alum shale waste	400 - 1600	260 - 1030	0.33 - 0.47	0.0.06 - 0.09
5 reference houses	37 - 93	25 - 52	0.14 - 0.35	0.03 - 0.05

Table 3. Radon concentrations in single-family houses and apartments in multi-family houses in the 1976 Swedish housing stock (6). The measurements were made 1980-82.

Type of dwelling	Arithmetic mean, Bq m^{-3}	Geometric mean, Bq m^{-3}	>800 Bq m^{-3}	Highest value, Bq m^{-3} Average in a dwelling
Single-family	122	69	2 %	3310
Multi-family	85	53	1 %	920

targeted research. As one result, a random sampling was carried out in 1980-82 in the 1976 housing stock (6), Table 3, mitigation methods were investigated, a calibration room for testing radon detectors used for searching radon houses was built at our institute (7). This research also implied that the knowledge about radon, earlier concentrated to our institute, was undergoing a rapid growth in other organisations. Much effort was put into informing

health inspectors, builders, residents etc. The recommendations of the Swedish Radon Commission were used by the responsible national boards to set requirements on less than 400 Bq m^{-3} of EER[a)] for existing dwellings and 70 Bq m^{-3} EER for newly built dwellings. It was also recommended that the level should be decreased in the range 70 - 400 Bq m^{-3} EER when this could be done with simple methods.

The Swedish Radon Commission also issued recommendations on the distribution of responsibility between the authorities. The National Board of Health and Welfare is responsible for existing buildings, the National Board of Housing and Planning is responsible for future building and SSI is responsible for correct measurements and for giving advice to the other national boards. The local health and building boards are responsible for health in their region, which means that they are responsible for finding buildings with high levels and for radon risk mapping.

1990 - 1995

The limit (action level) for existing buildings was decreased to 200 Bq m^{-3} EER in 1990 and workplaces were included with the exception of mines etc.. In 1993, the limit was changed to 400 Bq m^{-3} of radon gas as a consequence of an interim report to the government (8) together with a proposal for more efforts to decrease the indoor levels. When the radon concentration is higher than the limit, the owners of single-family houses can receive a grant to cover 50% of the cost up to SEK 15 000 (about $ 2000) for measures to decrease the level. It is recommended to decrease the levels when they are higher than 200 Bq m^{-3} of radon gas. That level is now also the limit for newly-built buildings. The 1990 random sample study of the 1988 housing stock (9) found that about 4% of the dwellings had radon concentrations above the limit for existing buildings, 400 Bq m^{-3}, and about 14% had levels above 200 Bq m^{-3}, the limit for newly-built buildings.

MEASUREMENT PROTOCOLS AND CALIBRATIONS

The first measurement protocols were issued in 1980. New protocols were established in 1988 and another version was published in 1994. We now have two separate protocols: one for legal purposes and one recommendation for short-term advisory measurements e.g. in connection with real-estate transactions. The measurement companies can become accredited on a voluntary basis. We are discussing the certification of radon measurements for consultants and how to put more pressure on the nuclear track film laboratories to become accredited. The protocols require one annual calibration at our institute or another about which we provide information.

We have a radon and a radon progeny standard which is the basis for our radon calibration rooms with a known concentration of radon and radon progeny. The results compare well in international comparisons.

BUILDINGS INVESTIGATED

Measurements are ordered from measuring companies by the local health and building authorities and by private persons. Therefore, we have no statistics of the number of dwellings and workplaces measured unless we ask the local health and building authorities. The last time the municipalities were asked was for the period up to 1992, when 151,600 dwellings and workplaces had been measured. Together with measurements by others, about 240,000 cases had been measured. A further 50,000-100,000 dwellings and workplaces have been measured between 1992 and June 1995 (10).

DWELLINGS MITIGATED

Approximately half of the dwellings, about 15,000, which up to 1992 were found to have levels higher than 400 Bq m^{-3}, had been mitigated at that time. A further 10,000 dwellings are estimated to have been mitigated since then (10). The mitigation methods are described in a handbook (11). The mitigation methods mostly work very well, in a few cases various attempts have to be made to decrease the concentration. New mitigation methods have been developed to decrease the concentration in houses when the building material is the major radon source. One is a wallpaper containing charcoal (12). In a research study it gave very good results, but when used on full scale to mitigate whole homes the results have been less encouraging.

It has been found that the low radon concentrations after different types of mitigation are not always sustained according to the first part of a follow up study (13). A few years after the mitigation the radon concentration had risen by more than 30% in about 25% of the cases. Fifteen dwellings showed at least double as high radon concentration as immediately after the mitigation. This change was not specific to any given method. The second part of the study three years after the first part gave the same resulting pattern, but not for the same dwellings.

The limit (action level) for existing buildings is in principle compulsory. In a building with more than 400 Bq m^{-3} the radon exposure is deemed insanitary. For buildings with rented dwellings, the practice is that the local public health boards can impose penalty if nothing is done in buildings with levels exceeding the limit. For detached houses where the owner lives with his/her family the practice has been only to inform about the risks when the level is above the limit. However, one municipality required measures when children lived in such houses and one house owner has appealed against the decision. The case has been tried in court several times and has not yet been finally decided. Hitherto, the local health board has been found to be right.

NEW BUILDINGS

A decrease in the average radon concentration in dwellings built since 1981 to half of the average before that time can be seen from the random sample study of Swedish dwellings, see Fig. 1. This is partly because the radium rich alum shale-based concrete has not been produced since 1975, but half of the decrease depends on the improvement of ground constructions to decrease the inflow of radon in soil as a result of the 1980 Swedish Building Code together with information and training. The limits given in the Building Code are compulsory but are

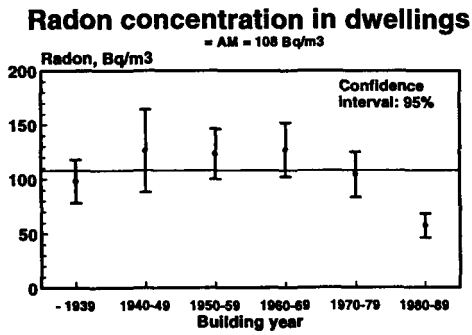

Figure 1. The radon concentrations in the 1988 housing stock (9). The measurements were made in 1990 in a random sampling of Swedish dwellings in single-family and multi-family houses.

applied in different ways. One way of interpretation is that when buildings are finished they are existing houses. Another is that all buildings built after the limitation system came into force should have concentrations below the limit.

WORKPLACES

Systematic investigations of workplaces (other than mines, etc.) have been started by the National Board of Occupational Safety and Health. Earlier, schools and nurseries were investigated by the local public health boards and, when needed, usually mitigated. Few other workplaces above ground level have been mitigated. The limit for workplaces is the same as for dwellings, 400 Bq m^{-3} radon gas. For miners and other underground workers the limit for radon progeny concentrations is 2 MBq h y^{-1} (equivalent to 2 200 Bq m^{-3} of radon gas for 2000 working hours per year and F=0.5[b]). Revision of the limit is being pursued.

WATER

Over the past few years there has been great interest in radon in drinking water. Already in the beginning of the 1960s von Döbeln and Lindell (14) studied the retention in the body for radon following ingestion. On this basis, they calculated the absorbed dose to various organs in the body and found about the same values for adults as were later found based on more experimental work. They also measured the radon concentration in tap water in some towns etc. in central Sweden. The maximum value found was 1200 Bq/l. Most levels were less than 100 Bq/l.

About 10 000 private wells are estimated to have radon concentrations exceeding 1000 Bq/l, based on a study in the 1980s of random sampling of private wells and public water plants (15). Also some public water plants have high concentrations. It has been recommended since 1984 that reduction of radon levels should be considered when the concentrations are between 100 and 1000 Bq/l. It is recommended that radon levels exceeding 1000 Bq/l should be decreased. The National Food Administration has proposed limits for radon in drinking water in 1995. More than 100 Bq l^{-1} would be a compulsory action level for public water plants. 500 Bq l^{-1} would be a voluntarily action level for private wells. Water with more than 1000 Bq l^{-1} would not be suitable for drinking. The interest in decreasing the radon concentration in drinking water seems to be much higher than that for decreasing the radon concentration in the air of the dwellings.

Over the past few years several companies have developed different types of radon removal equipment for private wells. Some of the companies guarantee that the radon concentration in the water after installation will not be higher than 100 Bq l^{-1}. Investigations of conventional water cleaners have shown that the influence on the radon concentration is small (16,17). If limits are established, measurement protocols will be given and accreditation of the measuring companies will be required.

GENERAL EXPERIENCES

The scope of the information problem is illustrated by the fact that around 1000 official persons in 284 municipalities, around 100 000 building professionals, and a large portion of the more than 8 million population, had to be informed about finding on this issue.

One Swedish report deals with the growth, dissemination and implementation of knowledge regarding radon in buildings (18). The project was initiated by the Scientific Advisory Board of Swedish Council for Building Research because the work with radon was

seen as a success compared with other problems. The experiences of the radon work was generalised to general health problems obtained from buildings.

Risk perception and communication about radon have been studied by Lennart Sjöberg at the Center for Risk Research, Stockholm (19). He found among other things that the health risk seemed to be underestimated and that the possibility of decreasing the risk by one's own handling was also underestimated.

TRAINING AND INFORMATION

What are we doing in Sweden on basis of all this experience? Radon issues are now dealt with in most upper secondary schools and at universities. Further training of employed professionals has taken place via external courses of 1-3 days. A radon campaign started in the autumn of 1995. Our booklets have been rewritten, articles for the daily press are written, and the local health and building authorities have received updated information. The main message has focused on the health hazard, on where to order a test, and on mitigation. The demand for training courses has increased and our institute gives courses in measurements (one basic course, and one for accreditation), a course for radon risk mapping, one for mitigation, and one for testing and mitigation of drinking water. Seminars in different parts of the country are planned. A training course on radon given by the European Radiation Protection Education and Training (ERPET) and SSI was held in Stockholm 11 - 15 September 1995.

During the last years our institute has given the high schools the possibility to order nuclear track films, which the pupils themselves place in yoghurt mugs with a sheet of plastic. This is based on an idea from Bristol University. We etch the films chemically after exposure and give a calibration factor, so that the pupils can count the marks on the film and calculate the radon concentration.

CONCLUSIONS

The interim report to the government in 1993 and the suggestions for future work stimulated an interest in the mass media, an interest which has remained. This interest has increased the number of measurements and also the number of mitigated buildings. Most Swedes know something about radon indoors today. Our experience is that it takes a ten year period to disseminate knowledge to health inspectors, builders, inhabitants etc. However, after 15 years with a radon limitation system only about 10-20% of the expected number of dwellings with levels higher than the limit have been mitigated.

---

[a] EER stands for the Equilibrium Equivalent concentration of Radon. EER is derived by multiplying the radon gas concentration by the equilibrium factor F, which in most countries is around 0.3-0.5.

[b] F stands for the equilibrium factor.

IRPA 9
1996 International Congress on Radiation Protection
14-19 April 1996, Vienna

SYMPOSIUM «RADIATION PROTECTION AT NUCLEAR FACILITIES»
Wednesday, April 17, 1996 from 11.00 to 12.30 hours

INTRODUCTION

Laurent STRICKER
Senior Vice President, Safety and Technology Issues
Electricité de France, Paris

Operation and maintenance of nuclear installations imply the exposure of workers, and to a lesser extend of the public, to ionizing radiation. This exposure is by far the smallest contribution to the collective dose received by the population compared with other sources. However, because this contribution can be potentially important from the point of view of the radiation protection of individuals, since the beginning of the practice in the 1950s, it always deserved a particular attention by those in charge of its operation. It is of course beyond the capability of this short symposium to cover all aspects related to radiation protection at nuclear facilities and the session has been deliberately prepared having in mind occupational exposures.

In spite of the general increase in electricity generated, the most striking feature, as far as occupational radiological protection is concerned, is the ongoing improvement of performances over the last two decades. The 1993 UNSCEAR report [1] estimates that during the last 15 years the average annual collective dose has not substantially varied, but the reduction of the effective collective dose per unit electrical energy generated was about 50% and the estimated average individual dose by 30%. These remarkable performances can be observed in almost all types of installation of the nuclear fuel cycle. Figures 1 and 2 below illustrate the evolution of collective exposure in the case of nuclear reactors. Since the early eighties there is a continuous and significative reduction of the collective dose per unit even with the progressing number of reactors put into operation. This trend is even older and more important when using the collective dose per unit of electricity produced as performance indicator.

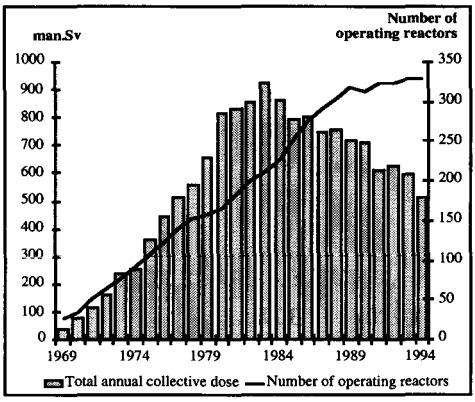

Figure 1 : Number of operating reactors and total collective dose per reactor in OECD countries [2].

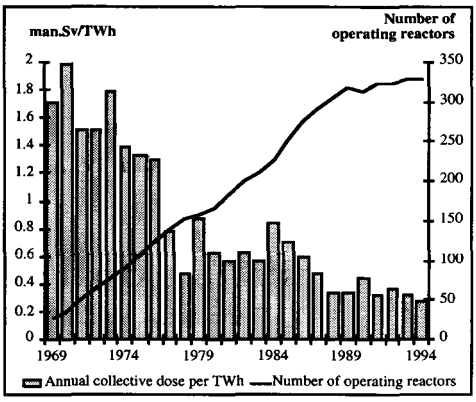

Figure 2 : Number of operating reactors and total collective dose per TWh in OECD countries [2]

As far as individual exposures are concerned, the picture is less clear. The global improvement of the situation over the last decades is not questionable, however the difficulty to follow accurately all transient workers operating in several installations, who are forming in certain countries a significative part of the work force in the nuclear industry, does not allow to present reliable statistics. Some utilities and countries have developed systems to overcome this difficulty and it is possible to present particular situations to illustrate the evolution with individual exposures. As an example Figures 3 and 4 present the performances in terms of annual individual doses for workers in French nuclear power plants since an operational dosimetry network connecting all plants (the so-called DOSINAT system [3]) has been put into operation.

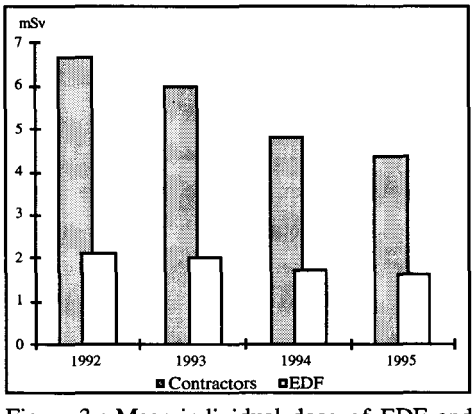

Figure 3 : Mean individual dose of EDF and contractor workers from 1992 to 1995

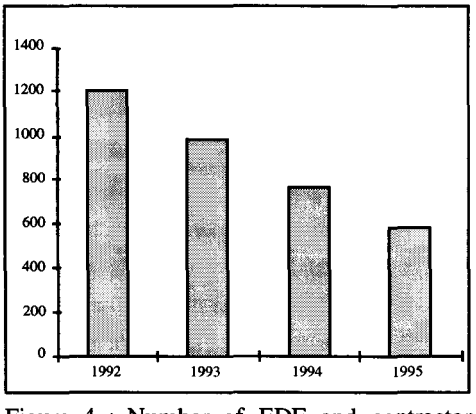

Figure 4 : Number of EDF and contractor workers with annual individual doses higher than 20 mSv

The general evolution of occupational exposure at nuclear installations is of course resulting from a combination of many different factors either of technical or organisational nature. As an introduction to this symposium, I would like to briefly delineate some of these factors that will be presented in a more analytical and detailed manner by the three invited speakers.

The emphasize put since the seventies on the ALARA principle is certainly the driving force to explain the general reduction of occupational exposures observed over the last two decades. The willingness to maintain or to reduce doses as low as reasonably achievable taking into account economical and social considerations has progressively transformed the radiation protection organisation and culture. The rationale in applying ALARA in nuclear installations is to achieve a level of exposure low enough to guarantee a sufficient protection of the workers but preserving at the same time the economical viability of the installations.

The role of regulation in this evolution was certainly important to initiate the process and maintain a high level of commitment of all parties involved. Different views exist in the various countries about how the ALARA principle can be practically implemented. In some countries regulators have clearly played a key role for the spreading of the ALARA approach, in some others, utilities have been the initiators. Whatever the national context, it is now recognized that a large flexibility should be left to operators to develop their ALARA programmes according the specificity of the technical, economical and social context. The role of regulation and regulators with regard to the practical implementation of ALARA will be developed by Mr Thommy Godås and Mr Lars Malmquist from Sweden.

The collective exposure in installations is dependent of ambient dose rates at working places, the duration of the work to be performed in these ambient dose rates and the number of workers involved. Any attempt to better control the doses that the personnel finally received involves to intervene either at the level of the sources or the management of the work. The control of sources has always received much attention in all types of installations and considerable efforts have been done to reduce the radiation field build-up. In light water reactors for example, different techniques have been developed to reduce or replace cobalt in structural materials, to control water chemistry, to decontaminate systems and or to install shieldings for particular components. In recent years, progress has been also made in the field of work management. ALARA programmes are giving more and more importance to non-technical factors that can influence the duration of work in radiation fields. Selection of maintenance options, planning and co-ordination of operations, training of workers, have proven to be efficient ways for reducing the number of manhours in radiological environment [4]. This last aspect will be presented in more details by Mr. David Miller from the United-States.

All together, the various actions developed year after year to either reduce sources or the duration of exposed work combined with the evolution of materials and techniques have resulted in most installations in a significative decrease of individual and collective exposures. The evolution of the collective dose associated with the replacement of steam generators at nuclear power plants, as shown on Figure 5, is certainly one of the most significative example to illustrate the global impact of all the above mentioned actions implemented to control exposures.

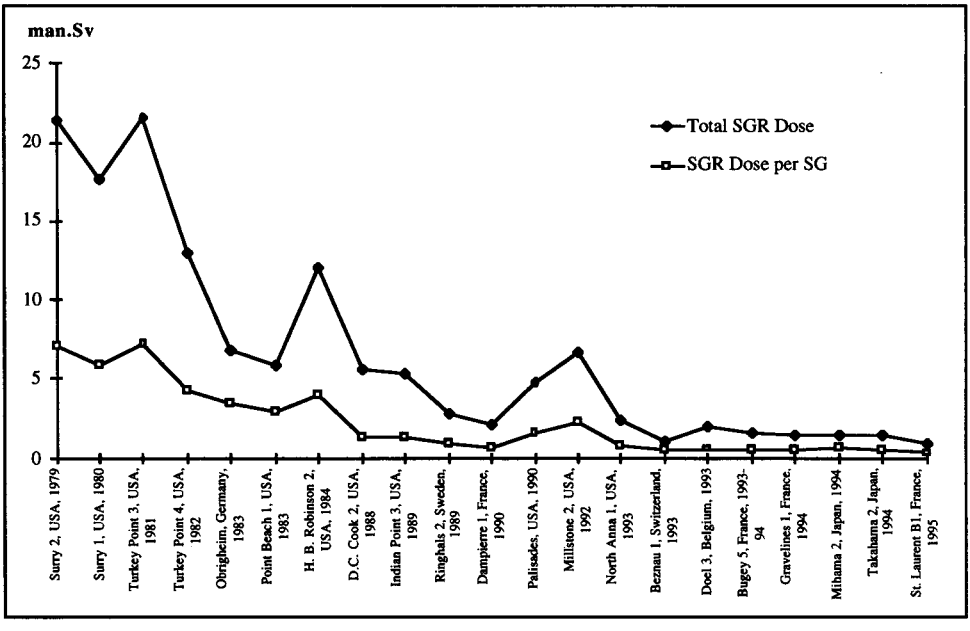

Figure 5 : Evolution of the total collective dose associated with the replacement of steam generators at nuclear power reactors from 1979 to 1995 [2]

The ALARA approach, by putting forward the a priori estimation of exposures, the follow-up of doses and the analysis of past experience with radiation protection, calls for the implementation of systematic and coherent dosimetric systems in order to monitor ambient dose rates and to track personnel doses at the operation and even task levels. Important improvements have been made over the last decade in the field of electronic dosimetry which now allow to obtain a detailed picture of where, when and how doses are received by the various categories of workers during the operation and maintenance phases of installations. It seems now indispensable to fully develop the operational dosimetry to complement the older generation of personal dosimetry which is not in position to provide the adequate and necessary data for the

preparation, follow-up and past experience analysis of operations that are needed in an ALARA perspective.

This last aspect is of prime importance. Large efforts have been deployed over the last recent years to improve at all levels (utilities, national or international organisations) the establishment of past-experience data bases. The International System on Occupational Exposure (ISOE) developed by the Nuclear Energy Agency from OECD is a good example of such effort [2]. Beyond the collection and analysis of the data of most operating reactors in the world, the merit of such a system, like some others, is to give the opportunity to professionals to regularly meet and exchange information and experiences.

Beyond the implementation of appropriate technical and organisational measures, the success of the ALARA approach in nuclear installations is closely related to the spreading of a «radiological protection culture» aiming at promoting the commitment of all those involved, from the top management down to operators through a clear delineation of their respective responsibilities [5]. The motivation of operators during all phases of the work, from planning to past experience analysis, and their sensibilisation through education and training to their individual and collective responsibilities as far as exposures are concerned is of prime importance for maintaining doses as low as reasonable. It is possible here to draw a parallel with the «safety culture» as defined and promoted by the International Atomic Energy Agency in its INSAG-4 document [6]. Mr Sollet from Spain will developed this last point in more details in its presentation but I will say a few words about another important aspect related to the involvement of contractors for improving radiological protection in installations. Because of their important role at the maintenance level, especially in nuclear power plants, contractors must be closely associated to the radiation protection programmes to establish common goals through an ongoing dialogue. In this perspective Electricité de France has introduced a partnership with its contractors within the framework of professional organisations.

To conclude these short introductory remarks I would like to emphasise some of the challenges the nuclear industry is now facing as far as occupational radiation protection is concerned. First, the decreasing trend for collective and individual exposures per unit of energy produced have certainly not reached their asymptote and further progress should be possible at reasonable costs. For the next future, one of the main objectives will be for operators to maintain individual exposures below the 20 mSv range for the personnel being exposed for periods longer than 5 years.

The contribution of dismantling of older installations will progressively become more important in the total exposure of workers. The experience with dismantling is still limited and efforts need to be made to prepare this future activity with the same level of protection for the

workers that will be involved as the one reached with the workers in operating installations. New installations will be designed and constructed in the future and this must be done based on the lessons of the past. The future reactor now in preparation at the European level in cooperation between Germany and France (The so-called European Pressurised Water Reactor (EPR)) is a good example of how ambitious radiation protection objectives can be set at the early phase of a project based on past experience and a careful evaluation of alternative options.

Reduction in occupational exposures at nuclear installations is not only desirable because it directly contributes to the health and safety of the personnel but also because it enhance the safety and the reliability of installations by making their operation more efficient and economical. As a responsible for the safety and the technical operation of the French reactors I am strongly convinced that maintaining a good level of protection of workers at nuclear facilities and, when feasible, improving it, is a guarantee of the quality of operations and therefore of the general safety of the installations. The long-term production of nuclear-powered electricity requires from all operators of the nuclear fuel cycle a solid relationship with their environment mainly based on trust. The demonstration that it is possible to operate the fuel cycle while maintaining individual and collective exposures as low as reasonable achievable plays certainly an important role for meriting this confidence.

Finally, I would like to emphasize that the IRPA-9 Conference, with the participation of so many colleagues from all over the world is an excellent opportunity to exchange experience and views about the various facets of the issues that will be raised during this short symposium, and I hope that fruitful contacts will be made during the course of the Conferences.

INTRODUCTION

The term "safety culture" first came into use after the Chernobyl accident, and in the course of its brief 10-year existence, the expression has been the source of inspiration for a very large number of texts, procedures and plans which, in many cases, have given rise to specific activities and objectives.

In the field of radiation protection, a monumental effort has been made to implement optimization criteria or ALARA in nuclear installations, and such endeavors have managed to bring about a considerable reduction in the collective doses associated with the operation of nuclear power plants throughout the world.

These programs for designing radiation protection on the basis of optimization criteria and of applying concepts such as efficiency, costs, benefits, rationalization, etc., must be the foundations upon which to create an effective overall radiation protection culture that should covers the whole organization, and which at the same time succeeds in ensuring that the concept of radiation protection transcends the basic framework of activity in the installations, and enters other spheres of the organization until it reaches top level management and its aims are considered to be as important as economic or productivity goals.

BACKGROUND

The primary aim of radiation protection is to prevent the occurrence of harmful health effects in individuals being exposed to ionizing radiation, without unduly limiting the beneficial effects that the activities which give rise to such exposure have upon individuals and society.

The conceptual framework of radiation protection is established in the recommendations set out by the International Commission on Radiation Protection (I.C.R.P.), adopted in national regulations, this in turn being based upon the E.U. Directives, in the case of the countries which are members of the European Union, and the publications issued by the International Atomic Energy Agency (I.A.E.A.) in Vienna.

The radiation protection model for nuclear installations is based on the basic principles of safety and protection announced by I.N.S.A.G. and I.C.R.P., which are outlined below:

- To reinforce "Safety Culture" in order to enhance positive attitudes and bring about an improvement in the behavior of both individuals and the organization.

- Nuclear safety, radiation protection for the workers and the general public and the preservation of the environment are fundamental basic principles which govern the operation of the nuclear installations.

- All activities that involve exposure to ionizing radiation, must yield sufficient benefit to society and to the exposed individuals to outweigh the radiation health

detriment it causes or could cause.

- Radiation sources and installations should be provided with the best available protection and safety measures under the prevailing circumstances.

- The design of the installation and the operating procedures, shall be in accordance with the principle of defense in-depth, so that any potential failures can be compensated by the safety and prevention measures.

- The safety of an installation and protection of the workers and the population, must be ensured by sound management and engineering, quality assurance, training and qualification of personnel, comprehensive safety assessments and attention to lessons learned from experience and research.

- The principle which governs interventions undertaken in the event of an emergency must be justifiable.

These basic principles were later formulated by the I.A.E.A. in a draft of a Safety Fundamentals of the Safety Series collection in two (2) main objectives of radiation protection and safety and eleven (11) basic principles that are derived from those two, concerning practices and actions to which we will be making reference.

- **Objective of Protection**

  To prevent the occurrence of determinist effects in the individuals by keeping the doses below the relevant thresholds and to ensure that all reasonable steps are taken to reduce the occurrence of stochastic in the population at present and in the future.

- **Objective of Safety**

  To protect individuals, society and the environment from harm by establishing and maintaining effective defenses against radiological hazards from sources.

The radiation protection system for practices, is based on four (4) principles:

- Justification of practices
- Dose limits
- Optimization of protection
- Prevention and mitigation

The interventions are governed by two (2) basic principles:

- Justification of intervention

- Optimization of intervention

Three (3) principles of implementation are drawn up from the above, concerning the following:

- Location of sources
- Design and construction
- Operation and use of sources

Finally, details are given of two principles regarding the organization and management of radiation protection and safety:

- Legal framework
- Responsibilities

These basic principles of radiation protection are not new, they were all drawn up, either in identical or similar form, many years ago and form part of the manuals and operating procedures for the installations. Workers are already familiar with them but, and this is the paradox, they have not been able to create a radiation protection culture among the organizations that perform or develop them.

Although it has been in existence for a much shorter period of time, the "nuclear safety culture" has well managed to create, or is managing to weave an effective culture tissue among both organizations and individuals, so that safety can proceed with the ongoing process of improvement. One of the reasons of the success has been its novelty in the formulations and the wish of not lag behind. Whatever the reasons are for the success of the implementation of the "nuclear safety culture", the fact is that it must serve as an example to be followed, and that such a safety culture should likewise be extended to the concepts of radiation protection in such a way that it is no longer possible to distinguish one concept from the other, or at least, that the organization develops ongoing ways of improving radiation protection.

CULTURE OF RADIATION PROTECTION

Without attempting to define culture, it is worth mentioning certain characteristics that are common to any definition thereof, and which can be summarized as follows: a set of principles, values and beliefs jointly shared by all members of an organization, together with standards and expectations that influence the behavior and attitudes of the members of such an organization.

Applied to radiation protection, this concept could then be defined as the entire set of technical and social standards, together with the behavior and attitudes of the individuals concerned with a reduction in the exposure of workers and the general public to ionising radiation.

The element that distinguishes this definition from other general definitions of the radiation protection concept, and that which gives it its cultural nature, is the part that includes the attitudes and the behavior of the individual.

If this definition is correct and the initial thesis that no effective radiation protection culture yet exists, it is also true to say - or at least the conclusion to be drawn is - that either the basic principles are not shared by all levels on the hierarchical scale, a possibility which would have to be ruled out on grounds which are self-evident, or that the behavior and attitudes of the constituents of the organization are not sufficiently active where radiation protection is concerned.

In the light of the above - What are the factors that might exert a positive influence on the behavior of individuals in the field of radiation protection? Without fear of error but without wishing to provide an exhaustive account, the following factors influence such behavior:

- The perception of risk
- Attitudes towards work
- Work group dynamics
- Attitude towards technology
- Attitude towards the organization, hierarchy, leadership, procedures and working habits
- Personal motivation and expectations of improvement

We will now go on to analyze these factors as a whole, together with other conditioning elements regarding radiation protection, with a view to specifying all that is necessary for the creation of a radiation protection culture.

REGULATORY ASPECTS

It is the case in nearly all countries, that the practical application of the principle of optimization of radiation protection ALARA (As Low As Reasonably Achievable) is developed within the organizations, at the same time as the safety culture is being developed.

The driving force behind the application of the principle of optimization has not been equally applied in all countries and organizations, sometimes this being due to the regulatory bodies and at other times because of factors inherent to the organization itself.

In countries where standards are more clearly defined, the initiative generally corresponds to the regulatory bodies, but acceptance and implementation have been

brought about more through imposition than a general consensus that has been convinced of its necessity and, as a whole, the process tends to be rather laborious and time-consuming, probably due to the lack of flexibility of the regulatory practices to be applied to all circumstances. One single and valid implementation pattern does not appear to exist for all organizations.

However, what is relevant in this case, is that all the effort made in implementation must be used and situated in a more general radiation protection framework, in which optimization will naturally be the most important current criterion, but without excluding the attitudes and behavior of individuals.

Other countries, which have less prescriptive controls and a more performance based, the application of the optimization criterion, are allowing the utilities, in a more flexible climate, to find the tools needed for using their specific cultural elements and to create an effective and efficient "ALARA culture" in the organization, and they have a more suitable shape from which to expand upon the objectives already achieved, thereby establishing a genuine radiation protection culture.

STRATEGIC FORMULATIONS

A first step towards ensuring a successful radiation protection culture is to expand its scope of activity. Radiation protection must not only exist within a nuclear power plant framework, but should also operate at the highest decision-making levels of the company.

The current scenario in which nuclear activity takes place, makes the safe operation of nuclear power plants and radiation protection for the workers, the general public and the environment, an ever-increasing necessity. The obligations that those responsible for the operation of nuclear installations have to the workers and to society in general, based upon essential values and quality management attributes, require a clearly defined professional code of conduct, that not only guarantees the responsibility of the professionals to society in such a way that nuclear safety and radiation protection are constantly being perfected, but also by participating in society at the same time, having a role that is clearly subordinate to the latter where service is concerned. In this way, radiation protection becomes a requirement regarding the strategic outlines and company policy, as an ongoing attempt is made to modernize and improve management.

The maximum body for company representation and decision-making, which we shall refer to as the General Management, is a key element for initiating, implementing and maintaining a radiation protection culture, because jurisdiction as regards the allocation of resources, falls upon this body, which is likewise responsible for defining the culture of the entire organization.

The General Management must also include the permanent objective of protecting the workers health, the prevention of accidents, occupational illnesses and diseases and the protection of the environment, as an integral part of its strategic plans. This ongoing preoccupation of nuclear power plants must materialize itself in paying

attention to the constant improvement of radiation protection in nuclear installations.

Such corporate undertakings must take the form of a few clearly defined and easily definable aims, well known to all the organization members, and sufficient resources must be allocated to guarantee their fulfillment. In short, radiation protection should also become part of the management and decision elements of the General Management.

These main company strategies and obligations must bear the following in mind:

- Economic and social factors that affect the protection of the workers and the general public alike, given that the purpose of radiation protection is to provide an acceptable level of protection, without limiting the benefits that nuclear installations give to society and without forgetting their social dimension.

- The integration of radiation protection criteria into the general production, quality and continuous improvement targets, by means of a radiation protection policy based on predictions and goals, the measurement of the results and an analysis of experiences. It has to be possible to measure these goals by establishing performance indicators that must reflect the results of the company's policies.

- This integration of the elements of radiation protection at top level management, ought not to be interpreted as implying a modification to the existing organizational structures, but rather that a natural integration process should take place. This would require that the General Management be provided with an advisor in radiation protection so that the latter could provide the former with constant and continually updated information as regards the achievement of the objectives and a monitoring of all relevant activities.

PLAN MANAGEMENT POLICY AND ORGANIZATION RESPONSIBILITIES

The second step in a commitment towards radiation protection culture concerns the management of the installation.

The Management of the installation must promote the initiatives that lead to the establishing of a radiation protection network involving all the workers. The principle that the workers themselves must be the beneficiaries from radiation protection as well as being those responsible for it, must no longer be a mere maxim, and has to become a reality.

It has been proved that a nuclear power plant operating with a small collective dose has better indicators and performances, as well as being more economical and safer than other plant with the same power but with a higher dose. The dose is, in itself, indicative of the quality of the operation in a nuclear installation. The lower the dose the greater the quality.

A lower dose means less time spent in the radiation zones, more reliable equipment, a greater availability of personnel, lower maintenance and operating costs, more time devoted to training and, in all probability, shorter outages times and thus greater revenues.

Therefore, from a power plant perspective, the plant management provides the main impetus for radiation protection culture, and is also its most enthusiastic adherent, and defines the radiation protection policy as an integral part of its operational goals, allocating the resources required for successfully carrying out this policy and involving all management levels to this end. So, by way of example, the use of tools for cost-benefit analysis can make it possible for a decision to be taken to reduce power, with a view to making an urgent maintenance intervention in operation.

There are a variety of ways in which other managerial levels can be involved. One of the most effective ways is to make an associate between the specific objectives and the dose. The dose is also converted into an additional goal for each department.

Each department has a maximum annual limit that must be efficiently and effectively managed, and reported to Management for their activities and achievements, in the same way as with a budget.

Therefore, the radiation protection service (R.P.S.) for the installation is not alone in its responsibility for this, because the duties must be shared among all those involved in the organization of the plant. This is a natural way for the principles of radiation protection to filter through and throughout the entire installation, and to bring about an integration in the existing organization, operation procedures and radiation protection maintenance criteria, as well as enhancing the creation of interdisciplinary groups for the purpose of programming, planning, carrying out and reviewing/revising all the work.

Of course, this process of change cannot take effect without the involvement of the radiation protection service on the site. If it is the workers who are the protagonists when it comes to radiation protection, they must be offered every assistance in making their tasks easier. The term customer-oriented service must be the aim of the service and has to play an active role to make the work easier for others at all the stages involved in those plant activities in which the worker dose is a common element.

The all too well known mentality of acting as a sort of police force within the controlled zone must be abandoned, and such activities should be replaced by systems of surveillance, advice and support for the tasks. The bureaucratic concept of passing through a control point for the radiation protection service to authorize the work must also be abandon. The Radiation Work Permit must cease to be a Permit, and to form part of the Work Order, thereby enhancing the smooth-running of the radiation protection measures. Furthermore, the R.P.S. ought to provide the executing services with all radiological information concerning the plant, so that these services can plan their tasks well in advance and succeed in obtaining a more efficient management of the personnel in their charge. The use of radiation and dosimetric data bases at the disposal of all personnel, together with the presence, in the controlled zone, of all mimics updated in

real time plus radiological information for the premises will help well-trained foremen to manage both their own radiation protection and that of those in their charge.

WORKER ATTITUDE

If the controlling bodies act in such a way as to enhance the natural integration of the radiation protection criteria into the management of nuclear installation in the widest sense of the term, so that the radiation protection culture becomes an undeniable fact, only worker involvement will remain to be achieved.

The worker thus becomes a basic element in the framework of the radiation protection culture. If active worker participation does not become a reality, the whole process is doomed to failure. Therefore, it is essential to modify the behavior and attitudes of the workers, so that they themselves not only carry out the company's radiation protection policy, but also feel themselves to be fully integrated in the plans and their developments.

Nevertheless, worker involvement is a complex process that is still at the blueprint stage, and a wide range of factors come into play, such as: economic, cultural, social, technical, interpersonal relationships, etc.

In the light of the above, no attempt is being made to establish universal recipes for actions to be taken in order to bring about active worker involvement in the setting up and development of the cultural process. However, the following list of conditions and pre-requisites have to form part of management activities if the workers are to be involved:

- Risk Perception and Attitude towards Technology

  The non-tangible nature of ionising radiation risk, even the expression to define them - stochastic and determinist risks -, the social pressure that tends to magnify such risks, an unawareness of the technology, the possible existence of an inherent yet subconscious tendency to reject, etc., may well have caused the workers to fail to understand the reasons for radiation protection standards and thus not take part in defining them, leading them to a situation in which they complacently accept such rules without really knowing why. Therefore, it would appear obvious that the initial training and any later re-training, must always place emphasis on these basic concepts and explain the risks of ionising radiation in a clear and unambiguous way, by way of analogies involving other more easily recognizable risks. All positive experience obtained in the prevention of professional risks, must be put at the disposal of the radiation protection service and the radiological risks must be included in a more global management of professional risks, given that the activities involved in radiation protection are not exclusive to the technicians, but also require the participation of all those involved in nuclear activities and are of equal importance at all organizational levels.

- Behavior of Management and Senior Staff

  If the workers are to be involved in the culture of radiation protection, management must be able to imbue them with a perception of its own desire to promote the principles, not only of willingness to have such a policy, but also that management itself sees it as being necessary. The existence of Committees at the highest level which deal with radiation protection questions on a routine basis, the frequent presence of senior staff in radiation zones verifying the conduct of the workers and showing an interest in the development of the work being carried out in the radiation zones, making sure that radiation protection matters are as important as safety, economic and operational objectives, etc., must be activities that are conducive to an improvement in worker participation where radiation protection is concerned.

- Education and Training

  Reference has already been made to some aspects of worker training. Recipes that cannot be justified must be abandon, and training activities must be focused upon the general philosophies of protection and correct practice in radiation protection for the personnel and the general public. Familiarity with the codes of conduct in radiation zones and the carrying out of high quality work, are the logical consequences of training programs that have properly assimilated.

- Worker Participation in Management

  The existence of work-outs and improvement groups that integrate the active participation of the workers and in which new lines of action are proposed that, once approved, receive the whole support of management, should help to achieve worker involvement when it comes to developing radiation protection. Seeing that these initiatives are finding an increasingly prominent place in the annual plans of the units, provides a climate that is favorable to achieving more active worker participation in the implementation of a radiation protection culture.

- Information and Communication

  Regular worker participation of the monitoring of the goals of radiation protection in a clearly visible and manifest way, the preparation of information sheets, posters, awareness campaigns, a prompt reply from management to the suggestions made by workers, etc., will mean that the information and communication will flow from management to the workers and vice versa, again creating an atmosphere which is conducive to motivating the workers and gaining their support, when it comes to consolidating and crystallizing radiation protection culture.

CONCLUSIONS

From the above, some conclusions can be drawn in order to establish an efficient radiation protection culture among organizations for the operation of nuclear power plants.

- The organization ought to practice a realistic and open-minded sense of self-criticism, when analyzing the specific weight and scope of the radiation protection in the structures of the company, as well as ensuring that Management really is involved in the radiation protection culture, and in the process of deciding how to extend this discipline beyond the strict confines of the Plant itself; these should be the pre-requisites to defining the starting point from which to achieve a radiation protection culture.

- Experience in the management of professional risks must serve as a reference point for incorporating radiation risks into the overall management of risks in nuclear installations.

- An endeavor must be made to generate transparent information concerning the operations and risks that exist at nuclear installations both in the direction of the workers and of society in general, so that the former with their behavior can help to reduce risks and the latter can be convinced that this technology should be accepted. The image the company conveys to the outside world must be improve through the achievement of goals that are more and more demanding in matters regarding radiation protection.

- Both the behavior of the regulatory bodies and that of the organization itself, in the field of radiation protection, must progress towards being based more on performance targets with rational criteria concerning costs, benefits, economics, clients, etc.

- Programs and techniques must be developed that serve to motivate the workers and get them to participate in all the activities whose purpose it is to improve radiation protection, until such time as radiation questions form a natural part of everyday working life.

ALARA IN PRACTICE: A REGULATORY PERSPECTIVE

Thommy Godås, Lars A Malmqvist
Swedish Radiation Protection Institute

"Radiation Protection at Nuclear Facilities"
Wednesday, April 17, 1996
Vienna, Austria

ABSTRACT:

The paper will start with a presentation of how ALARA programmes fit into the operation management of nuclear power plants. This will be illustrated with the practices adopted in Swedish power plants in recent years. A particular attention will be given on how regulatory requirements related to ALARA have been formulated and implemented in a systematic way by utilities.

The paper will also address all aspects related to inspection and controls of ALARA programmes. The experience gained so far in Sweden allows for some general recommendations about the way to establish an effective framework for the implementation of ALARA programmes and a positive co-operation between regulators and utilities.

INTRODUCTION

Occupational dose reduction is important not only for the health and safety of the workforce but also because the associated requirement for a good management system enhances safety, quality and reliability of the installation and thus the economy of the plant. Indeed, during the eighties and beginning of the nineties progress has been made and occupational doses have decreased in most countries but unfortunately this is not the situation in Sweden. We have learned that there is no time for complacency because as plants become older there is a general tendency of increased maintenance and repair requirements. Moreover, the ICRP Publication 60, which recommends more stringent dose limits, further draws the attention to the exposure of workers and consequently to ways of reducing such exposure.

BACKGROUND

In 1975 the Swedish Radiation Protection Institute started the work with a new regulation on limitation of releases of radioactive substance from nuclear power stations.
Because of the limit 5 manSv/ GW installed electric effect (global collective dose) for the releases from the power station, we had to say something about the occupational collective dose.

In the above regulation we can read the following:

"In the assessment as to whether the practice is justified, the contribution made by occupational exposures must also be taken into account. This also applies when assessing the scale of the radiation protection measures which should be taken ("protection optimisation"). In order to limit the future *per caput* dose it is found to be more suitable from an administrative point of view to limit the occupational exposure by means of special rules which are not associated with the releases of radioactive substances into the environment. The rules for occupational
exposures should nevertheless include a limitation of the collective dose commitment from this exposure per unit of the practice. Until further notice it is recommended that measures be taken with the purpose of keeping the contribution from occupational exposure within the power stations below 2 mansieverts per GW installed electric effect and year."

:, one of the most important reason to give the utilities a guidance value for the collective dose from onal exposures was our knowledge about the dose situation in other countries. During the early s there was a trend to higher doses. This was a situation we tried to avoid (figures 1 and 2).

1

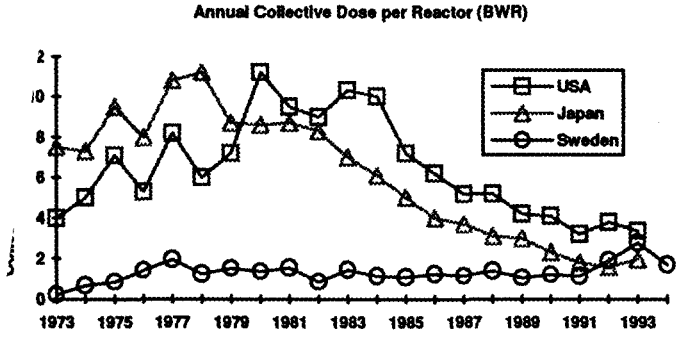

Figure 2

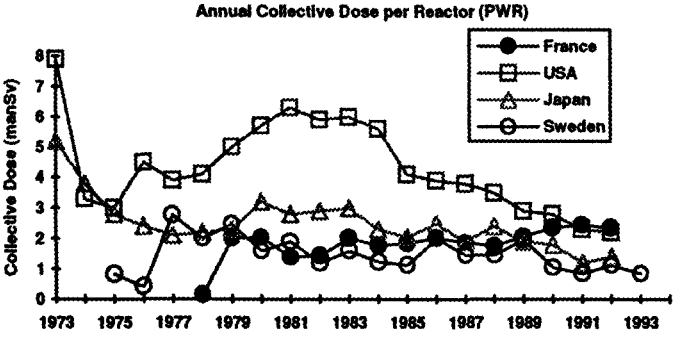
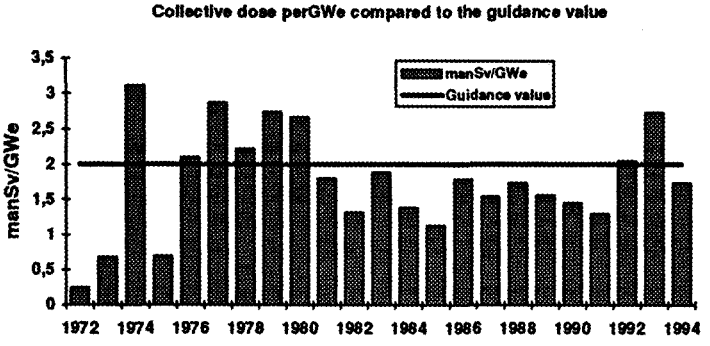


The decrease in doses we saw in the end of the eighties and in the beginning of the nineties (figure 3), didn't give any motivation for implementing new ideas with regard to lower the doses.

Figure 3

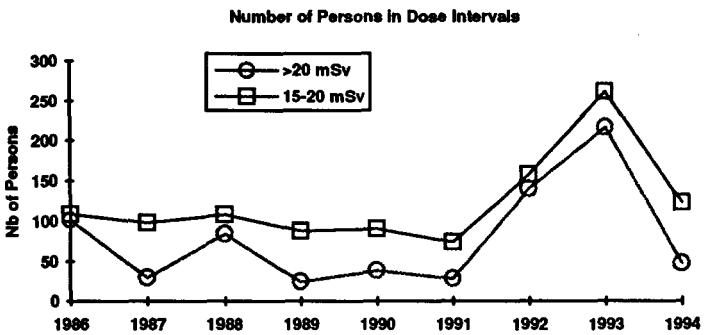


As can be seen from Figure 1, the collective doses in Swedish BWRs have been low, but started to increase in 1992 and continued to do so also in 1993. In 1993 the total collective dose (PWRs included) reached the level

of about 28 manSv, i.e. 2.8 manSv per installed GWe, which in fact exceeds the planning level of 2 manSv per GWe.

Also, the annual individual doses have increased during the same years but are still well below the dose limits (50 mSv for any one single year and 100 mSv as a total for five consecutive years). Moreover, the annual average for all the work force are below the ambition level of the SSI of 5 mSv per year. However, for some groups the average individual doses have exceeded that level. The number of persons with annual doses of more than 20 mSv was in 1993 about 200 but the number decreased to less than 50 for 1994 (figure 4).

Figure 4



REASONS FOR INCREASING DOSES

Due to significant amounts of work, the doses have increased considerably during 1992 and 1993. The increasing doses can partly be explained by the fact that some of the reactors are ageing thus requiring significant maintenance and repair works. Increasing safety requirements resulting in extending inspection programs are also contributing to this. In particular, a significant safety related event happened in 1992, when some insulation material was fed into the inlets of the safety injection systems causing risk of clogging. This event led to repair and modification works at all the BWRs of similar design leading to collective doses of about 7 manSv for the five reactors concerned.

ACTION TO TURN THE TREND

The changed situation with high collective doses has called for the establishment of more fundamental ALARA-programs (ALARA an acronym for As Low As Reasonably Achievable) especially for the BWRs. Using the research funds, the SSI started in April 1993 a significant development program in the field of dose reduction. The Swedish "reactor maker" ABB-Atom was asked to examine the reasons for the increasing dose levels, to assess the expected dose situation during the years to come as well as to give advice on actions to reduce occupational doses Ref. (2). The purpose with the program (DORIS=Dosreduction in Swedish BWRs), was to serve as a basis for the utility ALARA-programs.

The base of the investigation was a comprehensive analysis of exposure and radiation data from the ABB Atom BWRs. Extensive computer simulations were performed to find the factors responsible for this radiation build-up.

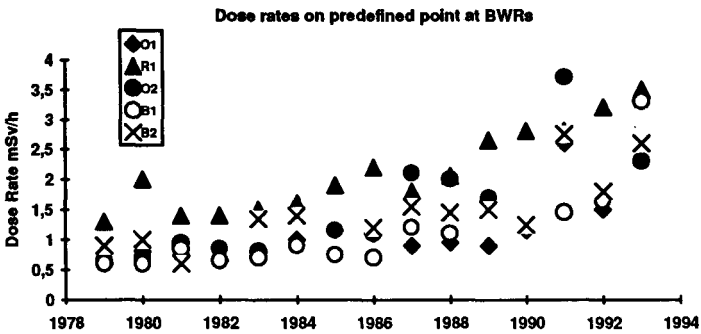
Dose rates

To get a measure of the evolution of the dose rates in the reactor systems, the nuclear industry is measuring continuously the dose rates at a number of places at the reactors. One such series of measurements is shown in Figure 4, from which it is evident that the radiation levels at that particular place on the recirculation loops are increasing with time.

The dose rates are in general higher the closer to the reactor and its primary systems you are. The five oldest BWR-reactors are here of particular interest in that their recirculation loops require significant inspection and

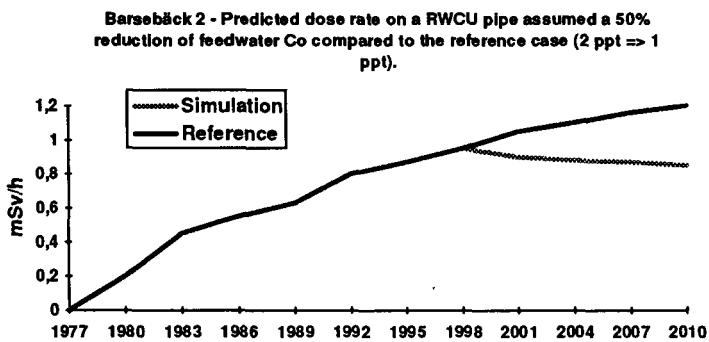
test activities causing important doses to the personnel. In PWR similar problems exist as far as their steam generators are concerned.

Figure 5



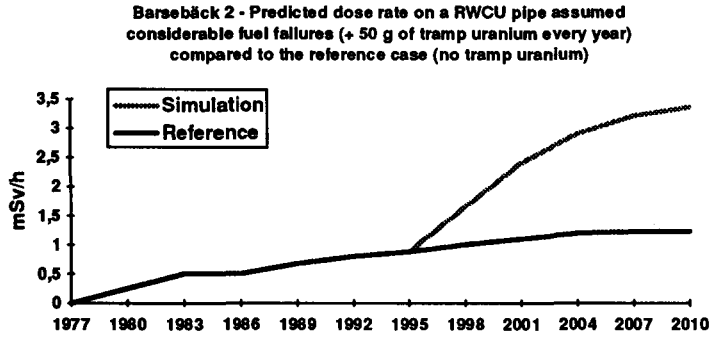
Erosion and corrosion of base material in the reactor systems mean that large amounts of corrosion products are fed into the reactor. An important part of them are deposited onto the fuel, activated and thereafter spread in the reactor systems. Activated corrosion products and in particular Cobalt-60 are the main source of the radiation fields in the nuclear power plants and thus to the resulting radiation doses. Cobalt is one element in stainless steel and amounts up to 60 per cent in the hard facing alloy Stellite, common in valves. The following figure shows the predicted dose rates assuming various levels of inflow of Cobalt to the reactor.

Figure 6



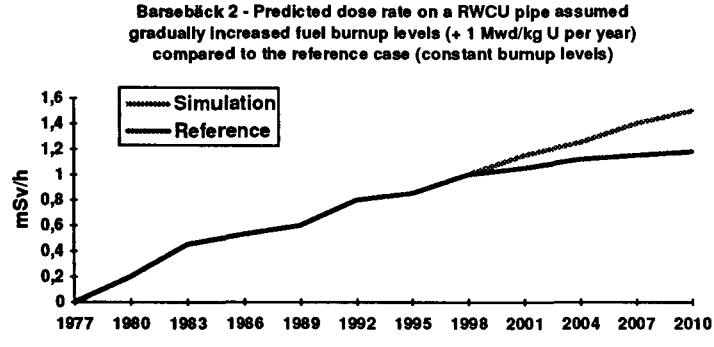
Also, fuel failures are causing an increased spread of cobalt-60 from the fuel to the reactor systems. This phenomenon is presently studied in more detail, but it is already now evident that increased attention to fuel failures are needed also from the occupational exposure point of view as in shown in the figure below.

Figure 7



As shown in the following figure, increased burnup level of more recent BWR fuel is also a factor responsible for the increasing radiation levels in Swedish BWRs. The effect is delayed, which means that the increasing radiation levels turn up after 5 years of operation or more with the new fuel with higher burnup level. The present burnup level is around 40 MWd/kg U.

Figure 8



With the results from project DORIS in fresh memory, we asked ABB, on our behalf, to do a feasibility study on ultrasonic decontamination of nuclear fuel.

The objectives of this study was:

- To determine the possibilities of decontaminating nuclear fuel using ultrasonics
- To outline how an ultrasonic decontamination could be performed and examine technical limitations due to fuel
  and fuel handling
- To determine the long-term aspects of radiation protection and compare the benefits in exposure reductions with the costs

The reasons for performing a fuel decontamination:

- Removal of Co and Co-60 from the cladding surface reduces radiation exposure
- Removal of loosely adherent crud may give a significant decrease of particle transients during reactor shut-down
- Removal of tramp uranium deposited on the core following fuel failures or minor core accidents mitigates the negative effects of these incidents

The study shows us as one of the results that, if two year old fuel elements are decontaminated each year there is a potential for dose reduction with up to 40-50 %.
For a typical BWR it corresponds to a reduction of the collective dose from approximately 2 to 1-1,2 manSv per year.

NEW REGULATIONS

In our new regulations (SSI FS 1994:2) on occupational exposure, new requirements were included. First of all we decided to introduce a new individual dose limit, 100 mSv in 5 consecutive year in addition to the annual individual dose limit which is 50 mSv.

We have also required an extended education and training program in radiation protection, addressed especially to foremen and team-leaders, working for the utilities as well as for contractors. We believe that this program will increase the understanding and motivation of the personnel to more heavily engagement in dose reduction.

Additionally, we believe in an ALARA, or work management approach, i e where the utilities systematically review their strategy towards radiation protection and develop goals in the area of occupational exposure.

We also require that each utility have to prepare an ALARA program. These programs shall contain objectives and dose targets for the short and longer terms, discussions on the basic considerations behind the choice of such objectives and targets, dose reduction plans (source and exposure time reductions to be considered) and ways to monitor, follow up and analysing experience. Finally, the plans shall contain programs for education and training of the workforce as well as the organisational aspects related to all the above.

WORK MANAGEMENT AND ALARA-PROGRAM

The SSI supervises through inspections and reporting the radiation protection situation at the Swedish nuclear power plants and monitored thereby early on the negative trend described above. One action taken by the SSI was to alert the plant managements on the situation and to explain the concerns of the SSI as regards this development. The SSI pointed out the importance of taking powerful measures to strengthen the radiation protection at the plants. To get doses to the ALARA level, it is, according to the SSI, necessary to go through and review *all* the components that make up the doses, one by one, and judge their dose reduction potential in relation to their respective costs Ref (3).

Management approach

The opinion of the SSI is that the management approach adopted towards radiation work can have a major influence on the degree of radiation exposure in the workplace. Experience has also shown that effective dose reduction needs firm management involvement and support as well as appropriate dosimetric systems and other tools.
In other words, the organisation, control and follow up of radiation works to ensure that doses are ALARA is a management issue and must not be left to the radiation protection department alone.

Also, the involvement of top management seems to be a very important measure to improve the attitude and awareness for effective radiation protection of all personnel. This is further enhanced if specific radiation protection goals are set up and all the personnel is informed about the importance management attaches to the achievement of those goals.

Policy defined by management is not enough, however, continuous support is needed; a support that has to penetrate and be made known at all levels in the organisation. A key to successfully pursuing ALARA seems to be **commitment**; a commitment that has to exist at all levels of management, not just at the top level. Many countries have realised this and several of them have defined ALARA programs and some more are in the progress of doing it.

In Sweden, the above mentioned regulatory requirement to prepare an ALARA program by each utility is part of such a management approach. These programs shall contain objectives and dose targets for the short and longer terms, discussions on the basic considerations behind the choice of such objectives and targets, dose

reduction plans (source and exposure time reductions to be considered) and ways to monitor, follow up and analysing experience. Finally, the plans shall contain programs for education and training of the workforce as well as the organisational aspects related to all the above.

Industry response

The Swedish nuclear industry has responded positively to the initiatives of the SSI. All the nuclear power plant managements have taken actions in a very constructive way, administratively as well as technically. They have clarified the responsibilities for radiation protection by delegated it to the line management. The industry has initiated a number of development projects aiming at dose reduction and is in the process of developing the ALARA programs referred to above, including explicit goals and targets for radiation protection for all the reactors. Finally, one has to emphasis that a number of technical actions have been taken or are in the process of being taken at each individual power plant, e.g. finding replacement material for Stellite, optimisation of water chemistry, decontamination of components and systems and development of improved strategies for fuel burnup and handling of fuel failures.

THE FUTURE

SSI thinks that is it necessary to go through and review *all* the components that make up the doses, one by one, and judge their dose reduction potential in relation to their respective costs. Such component comprise actions that will contribute to reducing the dose rates in the plants, and in particular to radically decrease the inflow of cobalt into the reactor core. Here the Stellite reduction efforts will be crucial. Other actions that most likely will be important are chemical decontamination, permanent shields, prevention against fuel failures and the limitation of fuel burnup by a skilled operation strategy.

When it comes to the other components that make up the collective doses, namely time and number of persons involved, planning, education and training as well as automations and robotisation will be important. However, a systematic approach will be needed including a review of

- working conditions (protections, working environment, etc.)
- worker characteristics (qualification, experience, information about the work, etc.)
- work organisation (scheduling, preparation, co-ordination, etc.).

The modification of one or several of the above factors will have a direct impact on the productivity of workers and then influence directly the exposed time and usually the costs of carrying out the work.

In addition to the above actions the SSI has emphasised to the nuclear industry the importance of having the management of the plants engaging themselves in radiation protection issues. Also, the SSI sees the importance of maintaining an open dialogue with all the work force including the outside workers that participate in the maintenance of the plants, particularly during the outage periods. Finally, the importance of education and training as well as setting up systems allowing analysis and feed back of experience has been pointed out by the SSI.

CONCLUSIONS

The nuclear industry has come to a point where greater emphasis on systematic dose reduction is needed. This is not only for the health and safety of the personnel, but also for maintaining the safety and economic viability of the plants and for public acceptance purposes. In Sweden the doses have increased significantly during a couple of years and great efforts are needed to turn the trend. To succeed in this, the plant management has to adopt a structured approach to radiation risks and tackle all the factors influencing exposure. The ALARA principle applied through, and by, all levels of management and in all important works seems to be a useful instrument in this respect. Management should deal with doses as they deal with money, i.e. establish systems containing targets, mechanisms to follow the results and to take corrective actions, when deviations so require. In this respect it should be pointed out that the dose targets should be challenging but possible to achieve, expressed in measurable terms and accepted by those who are responsible for the results at the company.

INDIVIDUAL MONITORING FOR EXTERNAL RADIATION, SOME CONCEPTUAL AND PRACTICAL ASPECTS

H.W. Julius

TNO Centre for Radiological Protection and Dosimetry
P.O. Box 9034, NL-6800 ES, Arnhem, The Netherlands

INTRODUCTION

Statistics show that, at least in the Western world, each member of the public is, on average, subjected to one X-ray examination per year. It is recognized that radiation doses due to the medical application of ionizing radiation are far from negligible but also that the benefits gained are significant, often life saving. Although reference values are presently being considered, dose limits do not exist for patients and doses are assessed only on an ad hoc basis.

For those, however, who professionally deal with sources of ionizing radiation the situation is quite different. For this category of workers a system of dose limitations has long ago been developed and includes the measurement of the actual exposure of the individual worker. In 1982 the International Commission on Radiological Protection (ICRP) state, in Publication 35 (1), that: "The primary purpose of individual monitoring is to obtain an estimate of the mean dose equivalent and of the effective dose equivalent in significantly exposed tissues. This information is useful in limiting radiation doses to individual workers and in demonstrating compliance with the full system of dose limitation recommended by the Commission and with authorized limits." Indeed, monitoring of workers constitutes an integral part of radiological protection. The main objectives of individual monitoring and some of the benefits that may accrue from it are:

- demonstration of compliance with legal requirements and regulations
- provision of information for the evaluation of the dose received by an individual in the event of an accidental exposure
- demonstration of good working practices and the adequacy of supervision and training which will motivate workers to reduce their exposures to the lowest possible level
- information on collective doses as a useful tool for risk-benefit analyses.

In 1991 ICRP (2) recommended a concise system of radiological protection, including dose limits for workers. This system formed the basis for the safety standards of international organizations such as the IAEA and the European Union from which national regulations are derived.

PRIMARY AND OPERATIONAL QUANTITIES IN INDIVIDUAL MONITORING

The ICRP system of dose limits (2) is based on the concept of effective dose, E. E is the sum of the weighted doses in all tissues and organs of the body as given by the expression

$$E = \sum_T w_T \cdot H_T \qquad (1)$$

where H_T is the equivalent dose in tissue or organ T and w_T is the weighting factor for tissue T. The equivalent dose in tissue T is given by

$$H_T = \sum_R w_R \cdot D_{T,R} \qquad (2)$$

where w_R is the radiation weighting factor and $D_{T,R}$ is the absorbed dose averaged over the tissue or organ T due to radiation R. Values for w_T and w_R are given in ICRP Report 60 (2).

The purpose of this *primary quantity*, E, (also called the *protection or limiting quantity*) is to provide a measure of detriment from stochastic effects for non-uniform irradiation of the body which could be equated to the detriment for uniform irradiation (3). Although it was recognized that the risk associated with a given exposure would vary – by up to a factor of about 10 – with the age and sex of the individual exposed, only one set of values for w_T (derived from averages for a population of workers) has been recommended by ICRP as being appropriate for the protection of any worker regardless of these sources of variability (2, 3). It is clear that effective dose, although in concept applicable to individuals, corresponds to an expectation of average detriment and therefore is, in practice, assumed to be applicable to an average population of workers.

In most national and international regulations annual dose limits are also given in terms of the primary quantity and are taken to apply to the individual concerned. Therefore, in principle, E (formerly H_E the effective dose equivalent (3)) is the quantity that should be determined in radiation protection dosimetry. However, this requires detailed knowledge of the equivalent dose in various organs and tissues in the body, and thus the quantity is difficult to assess and impossible to measure directly. For this reason ICRU, in 1985, introduced in Report 39 (4) the concept of *operational quantities* which was further elaborated in ICRU Reports 43 and 47 (5, 6). Presently, for individual monitoring the operational quantity is the *personal dose equivalent, $H_p(d)$*. This quantity is defined as the dose equivalent in soft tissue (ICRU 4-element composition) at an appropriate depth, d, below a specified point on the body (6) (usually taken to be the point at which the dosemeter is worn). For weakly penetrating and strongly penetrating radiations the recommended depths are 0.07 mm and 10 mm respectively (notations: $H_p(0.07)$ and $H_p(10)$).

The concept of personal dose equivalent has been created to provide a quantity considered to be metrologically sound and able to give a reasonable estimate of the protection quantity. In ICRU Report 43 (5) it was shown that, for uniform irradiation of the body, $H_p(10)$ could be considered a satisfactory representative of the effective dose equivalent, H_E (3), overestimating this (former) protection quantity by only some 20% for photon radiations of 50 keV and greater. In essence, this is also true for the effective dose, E, as introduced by ICRP in 1991 (2). For lower photon energies the overestimate, however, is significant and may be as high as a factor of 5 at 15 keV. (It is useful to note that practical dosemeters tend to underestimate $H_p(10)$ in this energy region and therefore may give a better estimate of E, see below).
The definition of $H_p(10)$ implies that, for a given orientation of an individual in a given radiation field, this quantity is multi-valued, it being dependent on the individual concerned, i.e. on the individual's size and shape (influencing, by scattering and attenuation, the dose equivalent at the depth d) and on the "specified point on the body" where the dosemeter is worn. These variations may, however, not be judged important in the context of the much larger variations in detriment resulting from sex and age.

It is worth noting that, as far as practical measurements are concerned, many current dosemeters do not strictly measure the dose equivalent in the adjacent tissues because they often use non tissue equivalent detectors covered with filters of various materials in combination with algorithms applied to match the calibration quantities under calibration conditions. Also, significant variations in dosemeter readings may occur due to variations in the separation of dosemeter and body and resulting from differences in the energy and angle characteristics of the radiation backscattered from the body (7). These variations, however, critically depend on the dosemeter design.

DOSIMETRIC REQUIREMENTS FOR PERSONAL DOSEMETERS

Personal dosemeters should be capable of providing reliable measurements of the appropriate quantities $H_p(0.07)$ and $H_p(10)$. ICRP (1) requires that in individual monitoring the maximum error in the measurement of a dose at the level of the annual dose limit should not exceed a factor of 1.5 at the 95% confidence level. This means that the measured dose should be within the interval of –33% and +50% of the conventional true value of the quantity of interest (8, 9, 10). Hence, if S is the standard deviation of the measurement,

$$1.96\ |S| \leq 0.5\ (\ 0.33 + 0.50\ ) \rightarrow S \leq 0.212 \qquad (3)$$

Here S is supposed to include all errors – both random and systematic – in the dosimetry system. If δ_r and δ_s are the resultant random and systematic standard deviations respectively then S can be obtained from:

$$S = (\delta_r^2 + \delta_s^2)^{1/2} \qquad (4)$$

Following the convention, δ_s can be calculated by assuming that systematic uncertainties follow a rectangular probability distribution (8, 9).
Among the systematic errors, the variation in the response of the dosemeter as a function of photon-energy and angle of incidence is the most important, the remaining systematic errors usually being relatively small.

The corresponding error and its relative standard deviation, ($\delta_{E,\phi}$), obviously depends on the design of the dosemeter, which includes the choice of the detector material(s), the filters used and the housing.
Hence (4) can be rewritten as:

$$S = \sqrt{\delta_r^2 + \delta_s^2 + \delta_{E,\phi}^2} \leq 0.212 \qquad (5)$$

where δ_r and δ_S are the relative standard deviations of the resultant random and remaining systematic errors

respectively.

By Equation (5) the performance criteria for personnel dosimetry systems are expressed in general terms, without specifically limiting the uncertainties of any of the parameters involved. This approach leaves some freedom with respect to the physical and technical characteristics of the dosimetry system used. If, for example, the radiation energy and angular dependence is small, relatively large random errors can be tolerated, and vice versa. This implies that if, for a particular dosimetry system, the relative standard deviations due to the overall random error (δ_r) and the remaining systematic error (δ_s) are known, the maximum allowable value, Δ, for the dosemeter design error ($\delta_{E,\phi}$) can be determined. For example, if $\delta_r = 0.06$ and $\delta_s = 0.04$, then $(\delta_{E,\phi})_{max} = \Delta = 0.20$ (10).

TYPE TESTING OF PERSONAL DOSEMETERS: THE PHANTOM PROBLEM

Type testing is the determination of the dosemeter response characteristics under laboratory conditions that come reasonably close to real life situations. E.g., when testing for $H_p(10)$ for photon radiation, a personal dosemeter is irradiated on a phantom under standardized laboratory irradiation conditions (8, 11) and its response as a function of radiation energy and angle of incidence, $R_{E,\phi}$, is compared to the dose at a depth of 10 mm in the phantom. $H_p(10)_{phantom}$ can be calculated from air kerma measurements (phantom absent) by multiplying K_a by $C(E,\phi)$, the conversion coefficient for energy E and angle of incidence ϕ (8, 12, 13). Ideally

$$R_{E,\phi} = H_p(10)_{phantom} = C(E,\phi)\, K_a \qquad (6)$$

Although the concept of operational quantities would suggest a straight forward recipe for type testing of personal dosemeters, this is not true. ICRU gave some hints in Report 39 (4): "The calibration of the dosemeters is done under simplified conventional conditions at the depth d in an appropriate phantom. For dosemeters to be worn on the trunk, a suitable phantom is the ICRU sphere" (30 cm in diameter and consisting of ICRU tissue). However, not only is it impossible to fabricate ICRU tissue, also there are several practical problems in the manufacture and use of spherical phantoms. Therefore, taking into account extensive discussion on this topic, ICRU gave further guidance in Report 47 (6): After indicating that "the calibration of dosemeters is generally performed under simplified conditions on an appropriate phantom", various phantoms in use are listed and, for the reason that "it is .... desirable to achieve uniformity in calibration procedures", the 30 x 30 x 15 cm PMMA phantom is recommended. The report also extends the definition of the operational quantities for individual monitoring to include the dose equivalent at a depth d in a phantom made of ICRU tissue, and states: "The quantity to be used for calibration is therefore $H_p(10)$ in a phantom having the composition of ICRU tissue, and the same size and shape as the calibration phantom". This "is the dose equivalent at the depth d below the point where the dosemeter is to be calibrated".
As was done earlier for the ICRU sphere, coefficients were calculated to convert air kerma to $H_p(10)$ at various depths (including 10 mm) in the ICRU slab and phantoms of different shapes and materials for various angles of incidence of the radiation (12, 13, 14). Detailed type testing procedures have also been published (8, 15).

As mentioned above, PMMA has been suggested and even recommended (6) as a satisfactory surrogate for ICRU tissue material. Although PMMA is cheap and easily available, it has the disadvantage that it produces dosimetric complications resulting from differences in absorption and backscatter as compared to tissue. It is important to be aware of these complications, especially because the interpretation of type test results in terms of performance criteria (8, 15) is a crucial part of the official approval of a dosimetry system for individual monitoring. In view of this the concept of using PMMA phantoms in conjunction with PMMA related dosimetric reference data for the purpose of type testing (and/or for the design) of personal dosemeter is a very dangerous one, for various reasons: Dosemeters designed to correctly measure the dose in the ICRU tissue slab phantom may, when type tested on a PMMA phantom, show a relative response as a function of photon energy and angle of radiation incidence different from $H_p(10)$ in PMMA and, as a result, may not comply with the officially required performance criteria and hence not be approved. Alternatively, dosemeters with relatively poor response characteristics in terms of $H_p(10)$ in tissue, might show fortuitous agreement with the results of tests made on a PMMA phantom.

One might indeed wonder whether a dosemeter which is designed to correctly measure the dose in a PMMA phantom (in order to make it pass the test) can be expected to, as intended, correctly measure the dose in soft

tissue. The fact that, between 25 and 70 keV, $H_p(10)$ in PMMA is about 20% higher than $H_p(10)$ in tissue (7) may find some compensation by the increased fluence (some 10 to 15%) at the PMMA phantom surface. This compensation, however, only applies to dosemeters that are sensitive to and able to correctly measure the dose from backscattered radiation. Clearly a dosemeter, which is entirely insensitive to backscatter (hence does not respond to the presence of a phantom or an individual at all), designed to correctly measure $H_p(10)$ in PMMA and successfully tested on a PMMA phantom will, when worn by a person, be in error by some 20% in the photon energy range between 25 and 70 keV (important in diagnostic radiology). Factors meant to correct for the larger contribution of backscatter radiation, produced by PMMA (15, 16), are not generally applicable because such corrections strongly depend on the design of the dosemeter.

From the above it may be concluded that, from both a conceptual and a practical point of view, the PMMA slab phantom can be considered unsuitable (7). This seems to be gradually becoming recognized. ISO is in the process of adopting a better substitute for the ICRU tissue slab, i.e. a water filled PMMA phantom of the same dimensions (30 cm x 30 cm x 15 cm) the front wall of which is thin, 2.5 mm, while the remaining walls are 10 mm thick (17). Backscatter properties of this phantom are very close to (i.e. less then 3% different from) those of the ICRU tissue slab. $H_p(10)$ in the latter will still be the reference quantity. This will certainly help to dissolve the confusion which still remains in the minds of many who run an individual dosimetry service. It will, however, not solve the still remaining problem of type testing dosemeters for angular responses at angles larger than 60 degrees (7).

TYPE TESTING FOR PHOTON ENERGY AND ANGULAR RESPONSE

In the case of type testing of personal dosemeters for photon-energy and angular dependence it is recommended (8) to determine the energy response for both $H_p(0.07)$ and $H_p(10)$ at four angles of incidence: 0° (normal incidence), 20°, 40° and 60°. Irradiations should be made on a suitable phantom (preferably the 30 x 30 x 15 cm water filled PMMA ISO slab (17)) using the narrow spectrum reference radiations as specified by ISO (8, 11). A combined energy and angular response can be calculated and plotted by, for each energy E, averaging the response over all angles of radiation incidence. The resulting average response, $\overline{R}_E$, then becomes:

$$\overline{R}_E = 0.25 \left(R_{E,0} + R_{E,20} + R_{E,40} + R_{E,60} \right) \tag{7}$$

$R_{E,\phi}$, the relative response at energy E and angle ϕ, is obtained from:

$$R_{E,\phi} = \frac{\left(H_{E,\phi}\right)_m}{\left(H_{E,\phi}\right)_t} \tag{8}$$

where $\left(H_{E,\phi}\right)_m$ = the measured dose and $\left(H_{E,\phi}\right)_t$ = the conventional true value. $\left(H_{E,\phi}\right)_t$ should, when type testing for $H_p(0.07)$ and $H_p(10)$, be taken to be the dose equivalents at depths of 7 mg.cm^{-2} and 1000 mg.cm^{-2} respectively in the ICRU tissue equivalent slab phantom (*not* in the ISO phantom, which only serves the purpose of creating realistic back scatter conditions!). In Equation (7) the responses at each angle are weighted equally, which is assumed to be acceptable in practical situations where irradiation conditions are likely to be two dimensional rotationally isotropic (18).

The average uncertainty related to the angular response at energy E is represented by $| \overline{R}_E - 1 |$.

If, as indicated above, the maximum allowable value of $(\delta_{E,\phi})$, i.e. $(\delta_{E,\phi})_{max} = \Delta$, due to variations in the combined energy and angular response is calculated according to Equation (5) then the performance requirement for $\overline{R}_E$ becomes:

$$| \overline{R}_E - 1 | \leq 1.96 \Delta \tag{9}$$

for all energies between 15 keV and 1.25 MeV.

A typical example of the response for $H_p(10)$ for various photon energies and angles of incidence of a TLD (LiF) based personal dosemeter (10) is given in Figure 1.

SHOULD AN INDIVIDUAL DOSEMETER BE SENSITIVE TO BACKSCATTER?

At first sight effective dose, as defined by ICRP in Publication 60 (2), would seem – and is usually considered – to be an individual oriented quantity. Not true: Even if it were possible to obtain the equivalent doses in the organs of the individual concerned, the next step would be to weight these values using tissue weighting factors as given by ICRP. These factors, however, are – as mentioned earlier – population values averaged over sex and age. E therefore cannot be assessed for a given individual. Conceptually, E is more related to a mathematical model (such as the anthropomorphic models ADAM and EVA as used in Monte Carlo (MCNP) calculations), with population averaged weighting factors. Both from a fundamental and a practical point of view it is clearly illogical to have a multi-valued individual related quantity, $H_p(10)$, as an estimator of a single-valued, sex and age dependent quantity (7).

If one were to attempt to estimate an individual specific value of effective dose from a measurement of personal dose equivalent, it would at least be required that variations in E, caused by differences in H_T resulting from differences in shape and/or size of the individual, are reflected in similar changes in $H_p(10)$ and (for the purpose of measurement) in the reading of the dosemeter worn on the surface of the body. However, it is generally to be expected that $H_p(10)$, as well as the radiation field at the surface of the body and therefore – possibly – the reading of the dosemeter, will increase with increased size of the individual, owing to increased backscatter, whereas the equivalent dose to organs is expected to decrease owing to greater attenuation of the radiation within the body. Furthermore, E includes in its formulation the term $0.05\ H_T$ for the female breast, which can neither be reflected in $H_p(10)$ for the male nor in the reading of a dosemeter (assuming that the latter is not different for female and male workers). Consequently, the answer to the question: "Should a personal dosemeter be sensitive to backscatter? " is: No. This is not meant to imply that personal dosemeters should *not at all* be sensitive to backscatter, which would be difficult to realize in practice. It just indicates that there is no point in expending a great deal of effort to design personal dosemeters capable of responding to or measuring radiation backscattered from the wearers body.

It would, in fact, seem more straight forward to design dosemeters to assess $H_p(10)$ in the ISO water filled slab phantom, irrespective whether they will or will not be responding to backscatter. It can be assumed that such dosemeters, when worn at an appropriate position on a person, would measure $H_p(10)$ with sufficient accuracy to provide an estimate of E as good as $H_p(10)$ does (or better). If they were also performance tested on this type of phantom, difficulties in interpreting the results would also disappear. Moreover, when justified by the magnitude of the exposure and provided information on the energy and angular distribution of the radiation concerned is available, corrections can be made to the reading of the dosemeter to improve the assessment of $H_p(10)$. Further corrections, based on the relationship between $H_p(10)$ and E for the actual radiation condition, could then be applied to obtain a better assessment of E. Final effort could then still, in principle, be made to correct the assessed value of detriment knowing details of the individual exposed.

It has been suggested (7) that a more direct estimate of E from a dosemeter reading should be considered at some future stage. Arguments against this approach, e.g. that this is only valid if the field is uniform, are also applicable to the utility of $H_p(10)$. Where the field is non-uniform. e.g. resulting from the wearing of lead aprons, ICRP states (2) that more extensive measurements may need to be made. Here more than one dosemeter is frequently worn and the estimate is made of E, not of $H_p(10)$ which can have no meaning for a multi-badged person.

Following this suggestion, dosemeters might be designed to have an air kerma response matching that of E, rather than of $H_p(10)$. This means that the relative response of a dosemeter as a function of energy and angle of incidence, $R_{E,\phi}$, should follow as closely as possible the relation

$$R_{E,\phi} = C(E,\phi)\, K_a \tag{10}$$

where

$$C(E,\phi) = E\,(E,\phi)_{Adam(or\ Eva)} / K_a. \tag{11}$$

The fact that many (if not most) TLD based dosemeters, used today, show a severe underresponse relative to $H_p(10)$ at low (photon) energies and therefore compensate for the fact that $H_p(10)$ gives a significant overestimate of E in this energy region, seems to support this idea.
Type testing of dosemeters could be performed on a standard phantom (e.g. a water-filled thin walled PMMA elliptical cylinder may be preferred) the backscatter characteristics of which are adequately similar to the mathematical models (ADAM, EVA.). The field quantity used to determine the response characteristics

would be unchanged, i.e. air kerma for photons. Difficulties arising because of inappropriate wearing positions are no different from those currently for $H_p(10)$.

DOSE RECORD KEEPING

Often the concepts and physical aspects of personal dosimetry gain more attention than the recording, reporting and analysis of the data obtained. It should be borne in mind, however, that proper recording of radiation doses is an equally essential part of the process of individual monitoring and shares in the same objectives.

Specific objectives of dose record keeping are (19):

- to inform the workers and the management on occupationally received doses to, e.g. optimize operations and to demonstrate the effectiveness of ALARA.
- to prevent overexposure of individuals, particularly important for outside workers.
- to provide data for analysis of dose distributions and for evaluation of trends, on the basis of which radiation protection procedures and monitoring programs can be developed and, if necessary, improved.
- to provide data for legal and medical purposes
- to provide data for epidemiological studies.

From the above it will be clear that a dose record keeping system serves a broader goal than just satisfying the local, regional or national legal authorities. It should rather be a Dose Registration and Information System (DRIS) (8,19), to be used as a multi-purpose tool in radiation protection. For the larger Individual Monitoring Services dose record keeping systems are often integrated in an overall automated management system.

It should be emphasized that a DRIS– if properly set up – contains information that can be used as a tool for assessing the performance of a personnel dosimetry service by statistical analysis of measuring results, especially those at low doses (see below).

Within the European Communities, co-operation and exchange of personnel between countries is increasing as a result of an on-going integration of the member states. This will enforce the need for international data communication by means of computer networks. The latter is even explicitly mentioned in the CEC Directive 90/641, which deals with the "operational protection of outside workers exposed to the risk of ionizing radiation during their activities in controlled areas" (20). These developments emphasize the necessity for international harmonization of dose record keeping systems and categorization of the data they contain. Such harmonization is of vital importance to solve the problems related to significant differences in the way international bodies – CEC, UNSCEAR, NEA, WHO – approach statistical analyses of occupational exposures.

Because of the availability of relative user friendly data base management systems, setting up a dose record keeping system may seem relatively easy. It should, however, be emphasized that numerous difficulties can be encountered in both programming and in developing adequate procedures. Special attention should be given to size, structure, accessibility, dissemination of information, organization and quality assurance procedures. This is especially important if a DRIS covers a wide range of customers (e.g. hospitals, nuclear power plants, military installations etc.) and even more so if the system operates as a National Dose Registration and Information System (NDRIS). For the latter it is crucial to keep the dose information up-to-date which, however, may be difficult if workers move from one employer to another or if they switch from one monitoring service to another.

Because it is of paramount importance that the effectiveness of the system, the quality of the recorded data and the confidentiality are guaranteed, the persons responsible for the system need to be well trained and competent.

STATISTICAL ANALYSIS OF ROUTINE MONITORING DATA

As stated above, statistical analysis of the dose data stored in a DRIS is a useful tool for quality control, especially for the performance at low dose levels. Regular analysis of the dose distributions can show the stability of both the dosemeters and the measuring equipment (21). Depending on the population monitored, often the majority of the workers will not receive any occupational dose at all. This means that the frequency distribution of the occupational dose (i.e. the measured dose minus the contribution due to natural background) will show its maximum at 0.00 mSv, i.e. the modal dose is 0.00 mSv. Due to variations in the natural background from place to place and due to intrinsic variations in the dosimetry system, the dose distribution will have a gauss like shape, which will be slightly skewed to a somewhat higher level, due to real occupational doses. An example is given in Figure 2, in which data taken from the TNO individual monitoring service are plotted. The width of the dose distribution should be in agreement with independently obtained information on variations in the natural background and noise of the dosimetry system. Consequently variations in the position of the modal dose or in the width of the dose distribution are indicators for possible

problems with the dosimetry systems at very low dose levels. Using more advanced techniques the various contributions to the width of the distribution can be traced, giving an indication where to look for the source of problems, which allows for fine tuning of the system.

QUALITY ASSESSMENT IN INDIVIDUAL MONITORING: THE ULTIMATE PROOF

Quality Assurance (QA) and Quality Control (QC) are more and more becoming integral parts of our societies. Originally QA and QC mainly applied to the manufacturing of industrial products, to-day also public services are required to provide high quality products for a reasonable price. This can be guaranteed only by developing and implementing a QA/QC program that is tailor made and touches the entire organizational and technical structure of the service in question. Some of the basic elements of such a program, applied to Individual Monitoring Services (IMS), have been published (8). These should be considered complementary to more general requirements as published by ISO (22).

A QA/QC program involves every single step in the process of providing dosemeters to the customer, reading and evaluating the dosemeters returned and reporting the results. It is, however, very useful to in addition test the overall performance (dosimetric, organizational, administrative and financial) of the IMS as well as the postal service. This is done at TNO since 1987, by creating a "QA-subscription" for three "dummy" customers to whom dosemeters are assigned: 10 on a bi-weekly, 6 on a four-weekly and 6 on a quarterly basis respectively (21, 23). These dosemeters are randomly chosen, indistinguishable from those for the regular customers, and mailed to the private address of a member of the staff. Subsequently all dosemeters are taken back to the laboratory. Of each set 2 dosemeters are stored in a lead pig, 2 are placed in the IMS processing area and 2 are irradiated to 2.00 mSv ^{60}Co gamma radiation. The 4 remaining dosemeters from the bi-weekly set are, in duplicate, irradiated to 0.20 and 12.00 mSv respectively. At the end of each issuing period the related dosemeters are taken back home and returned to the laboratory by regular mail. Evaluation of the dosemeters and reporting of the results follow the standard (highly automated) procedures. Copies of the reports are sent to the responsible staff members.

Statistical analysis of the results of the QA-subscriptions gives both the accuracy and the precision of the dosimetry system under routine conditions. Figure 3 shows, as an example, the results of the dosemeters of the biweekly QA-subscription which were irradiated to 2.00 mSv. In the figure the statistical parameters for each year are given. Here avg denotes the average, std the standard deviation in the individual values, Hm/Ht the quotient of the measured dose and the conventional true dose and std/Ht the relative standard deviation in the measured values. The annual average of Hm/Ht ranges from 0.99 to 1.03. The relative standard deviation in the individual dose assessments ranges from 7% in early years to 4% in the more recent years.

Applying regression analysis on the standard deviation for all five dose levels used, results in a value for the relative standard deviation over a broad dose range. In 1994 this relative standard deviation was 4.1% (correlation coefficient 0.999) (23).

ENVIRONMENTAL RADIATION MONITORING IN THE CONTEXT OF REGULATIONS ON DOSE LIMITS TO THE PUBLIC

Gladys Klemic
U.S. Department of Energy Environmental Measurements Laboratory
New York, NY 10014-3621

INTRODUCTION

Environmental radiation monitoring is performed for the purpose of assessing the dose to the general public from a nuclear or radiological facility, usually to demonstrate compliance with regulations that limit the allowable dose to the public from manmade sources. Measurements are often made at the property line of the facility or further off-site. Monitoring may be performed by the operator of the facility, and in some cases by government regulatory authorities. Assessment of the total effective dose to the public requires modeling of all source pathways. Wherever possible, input to such models should include measurements of appropriate parameters. For example, measurements at plant vent monitors and meteorological data may be required to make projections of the dose to populations at various locations. In addition, monitoring of air, soil, water, and biota may be required to determine the internal dose, and direct measurements may be required to determine the external dose. This paper focuses only on measurements of the external component of the total dose. Considered is the application of current and proposed public dose limits in the context of the natural radiation background, current measurement technology, appropriate quantities, and the development of standards for the determination of external dose.

ICRP PHILOSOPHY ON DOSE LIMITS FOR THE PUBLIC

In most countries, regulations on radiation dose to the public reflect the basic philosophy of the International Commission on Radiological Protection (ICRP). Wherein, it is assumed that stochastic effects occur with a probability (rather than a severity) that is a function of dose, with no threshold. In determining an acceptable dose limit for the public, ICRP report 26 (1) describes an approach that allows for a risk for fatal cancers to be comparable to risks that are accepted for other aspects of everyday life, such as public transportation. The Commission found that this risk would correspond to a whole body annual dose of 1 mSv (100 mrem). However, they recommended that it would be sufficient to set a whole body dose equivalent limit of 5 mSv y^{-1}, applied to the mean dose received by a "critical group", that is a set of individuals most highly exposed.

ICRP report 60 describes an alternative approach, which is to consider variations in the dose from natural background radiation. Consistent with both approaches, the Commission currently recommends a limit to the general public of 1 mSv y^{-1} (effective dose) (2). The ICRP further specifies that, under special circumstances, a higher effective dose may be allowed in 1 year as long as the average over 5 years does not exceed 1 mSv per year. These limits refer to the whole body dose (mean effective dose to a critical group) from all sources and all pathways, except that from natural background radiation, medical applications, and radon.

NATIONAL REQUIREMENTS AND IMPLICATIONS FOR EXTERNAL DOSE LIMITS

Current and proposed regulations from a few countries are summarized in Table 1. While most national regulations are designed to be consistent with ICRP-26 or ICRP-60, the specific requirements may vary from country to country. For example, the limits may be defined in terms of a maximally exposed individual, rather than the mean dose to a critical group, or there may be additional separate limits for gaseous or liquid effluents. Perhaps the aspect most open to local interpretation is how to allow for the potential exposure from more than one source. ICRP 26 states that consideration must be given to the possibility that some individuals may belong to more than one critical group. ICRP 60 also notes the potential need for source-specific constraints, but does not make quantitative recommendations on this subject. In contrast, the U. S. National Council on Radiation Protection and Measurements (NCRP) recommends a single source limit of 0.25 mSv to the maximally exposed individual, unless an assessment is performed to ensure that the dose from all manmade sources does not exceed 1 mSv (3).

The approach used in the Netherlands is to assume that any individual has the potential to be exposed to 10 sources (4), so that the dose limit from a single source is one tenth of the recommended annual dose. In their current regulations, the Netherlands goes further than the ICRP in setting the annual limit at 400 μSv, with a 40 μSv limit at the fence line of any single facility where the public has access. However, the regulations do allow for higher doses if the site is not in an occupied area, and there is a proposal to increase the annual limit to 1 mSv, with the corresponding limit per source of 100 μSv.

In the U. S. there are three government agencies that have oversight over nuclear and radiological facilities. The Environmental Protection Agency (EPA) is responsible for establishing generally applicable standards for the protection of the public from radioactive material. The Nuclear Regulatory Commission (NRC) is responsible for

[d]Dose to maximally exposed individual

licensing commercial nuclear power reactors; fuel cycle facilities; medical, academic, and industrial uses of nuclear materials; and the disposal of nuclear materials and waste. The Department of Energy's (DOE) responsibility currently includes its uranium separation facilities, nuclear production and research reactors, nuclear weapons assembly and disassembly facilities, tritium recovery facilities, nuclear materials storage vaults, and high energy particle accelerators. Both the NRC and the DOE set specific restrictions on facilities under their jurisdiction to ensure that they meet the EPA's general requirements for protection of the public. The DOE is moving towards codifying its requirements, previously specified as internal DOE orders, which means that they will be enforceable through civil penalties and allow for greater public review, as is the case for NRC and EPA requirements.

The current EPA regulations (5) set the annual whole body dose limit at 5 mSv, but proposed new guidance (6) would change this to 1 mSv y^{-1} and would recommend that additional source-specific limits be established to "take into account the present and future potential for doses from other sources". For example, an earlier EPA regulation (7) set such a source-specific limit for the "uranium fuel cycle" at 0.25 Sv annual whole body dose, and another (8) limits the dose from airborne emissions from DOE facilities to 0.10 mSv y^{-1} to the general public.

The proposed DOE regulations (9) would set the annual whole body dose limit at 1 mSv, and specify that the potential of exposure from other sources need be taken into consideration if the dose to the public from the DOE site exceeds 0.30 mSv. The current NRC regulations (10) limit the dose to the public to 1 mSv y^{-1}. They also state that compliance may be demonstrated by showing that the external dose for an individual continuously present in an unrestricted area would be <0.5 mSv in a year if other requirements for liquid and gaseous effluents are met.

In the U. S., a related topic of increasing importance is the assessment of dose to the public from facilities that have been decommissioned in order to verify that the site can be released for unrestricted use. Currently, about 20 commercial nuclear power reactors and 130 DOE sites are in the process of being decommissioned. As some of the larger facilities reach the end of their useful lives in coming years, the clean up issues are expected to become more complex with an estimated 2000 sites eventually requiring decommissioning. The NRC is in the process of revising its regulations to include explicit criteria for decommissioning. Their proposed criteria specify that radioactivity from decommissioned sites be as low as reasonably achievable below the level that would result in a 0.15 mSv y^{-1} dose from all pathways to the average individual in a critical group (11). The intention of the NRC is to provide a margin of safety below the annual 1 mSv limit to allow for potential exposure from other sources and the fact that there are no controls once a site is released for unrestricted use.

Most of these examples of current and proposed regulations on public dose do not explicitly state a separate limit on the external component, so what is acceptable in a particular situation will depend on the magnitude of the internal component. (An exception being the NRC limit of 0.5 mSv y^{-1}). In any case, the measurement of an

external dose on the order of 1 mSv y^{-1} (about 114 nSv h^{-1}) or less from manmade sources must include consideration of the natural background radiation field which is on the same order.

REVIEW OF EXTERNAL DOSE FROM NATURAL BACKGROUND RADIATION

Spatial Variations

The background radiation field is due to terrestrial and cosmic sources. Photons and beta rays from primordial radionuclides in the soil, mainly ^{40}K and the ^{238}U and ^{232}Th decay chains, make up the significant terrestrial component. Due to the low penetrating power of beta rays, they are not as significant as gamma rays for dose from natural background. Because of weapons tests in the 1950s and 60s, a small contribution from ^{137}Cs may now be considered part of the radiation background. The terrestrial component varies with geography, depending on the relative concentrations of these radionuclides. The external dose equivalent from terrestrial sources can typically range from 0.1 mSv y^{-1} to 1.4 mSv or more per year depending on the local geography. Some localized areas have been identified with higher levels. The worldwide average annual effective dose is estimated to be 0.46 mSv from terrestrial sources (12).

At ground level, the cosmic component mainly consists of high energy muons, photons, and electrons. The cosmic dose at any given location depends on the altitude, about 0.3 mSv y^{-1} at sea level and about twice that at elevations of 1.6 km. There are also smaller variations on the order of a few percent with latitude because of effects of the earth's magnetic field; the dose is about 10% lower near the equator than near the poles.

Temporal Variations

Measurement of a potential manmade dose component is complicated because the natural background radiation dose levels are not constant in time. Figure 1 illustrates some of the well-known natural variations in background radiation that are associated with diurnal and precipitation effects. (The original measurements were of exposure. For this report the exposure data was converted to absorbed dose in air (1 R/8.7 mGy) and the UNSCEAR recommended factor for environmental radiation was used to convert to effective dose (0.7 Sv Gy^{-1}).) The diurnal effects are related to temperature changes and the accompanying atmospheric turbulence. Radon gas exhaled from soil during the night stays near the surface of the earth while the air there is relatively cold, with the gamma emitting progeny causing an increase in the radiation background level during this time. As the air grows warmer during the day, vertical diffusion reduces the radon concentration and the ground level radiation decreases. Diurnal effects can be on the order of a few percent to as much as 10% where the radon exhalation rate is very high.

Precipitation also plays a major role in natural variations in background radiation. For example, rain or snow can scavenge airborne radon progeny causing an increase in radiation levels by up to a factor of two (or in rare cases three) for several hours. Subsequently wet ground or snow deposited on the soil surface attenuates the terrestrial component causing radiation levels to drop below the previous baseline after the precipitation stops. Other possible natural variations are related to seasonal influences on the exhalation rate of radon from the ground, such as frozen soil allowing less of the gas to escape.

The cosmic-ray component does not vary as much as the terrestrial component on a day to day basis, but the 11-year solar cycle can result in variations on the order of 10% from the average value. On occasion, solar flares have been observed to produce measurable increases up to a factor of 3 in the ionizing component at sea level.

QUANTITIES TO BE MEASURED

For environmental monitoring, the use of the operational quantities "ambient dose equivalent" and "directional dose equivalent" is recommended in ICRP 60 as reasonable approximations to the effective dose and the equivalent dose in the skin (see ICRU 51 for precise definitions). For field measurements it would seem logical to use measurable physical quantities rather than dose equivalents, thereby avoiding complications that arise with ongoing developments in radiation biology. However, since the purpose of such measurements is to verify compliance with dose limits, they ultimately have to be related to the quantities specified in regulations. To convert between physical and dose equivalent quantities requires knowledge of the nature and energy of incident radiation. Since the radiation field may not be known, the ideal detector would have a flat response with energy for the quantity of interest.

A typical photon energy distribution from terrestrial sources based on calculations for reasonable soil and source distribution parameters (13) is shown in Figure 2. For comparison, the photon fluence, air kerma rate, and ambient dose equivalent quantities are shown. It is important to note that though most of the fluence (~70%) is due to gammas of energy <500 keV, these low energy photon components do not contribute as much to the air kerma or ambient dose equivalent as the higher energy photons. Most of the total ambient dose equivalent (~70%) is from

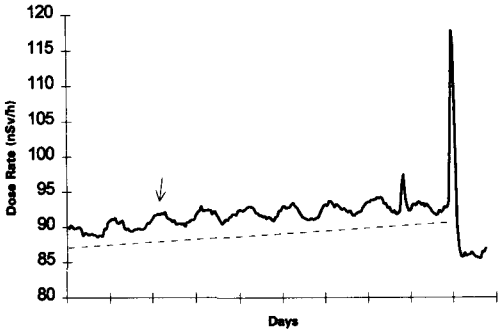

Figure 1. Short-term variations in natural background external dose rate due to temperature and precipitation effects, as measured with a PIC. Arrow indicates changes related to daily temperature effects on radon. Dashed line indicates gradual increase in dose rate due to soil drying out after rainfall. Large peak corresponds to rain scavenging of atmospheric radon progeny.

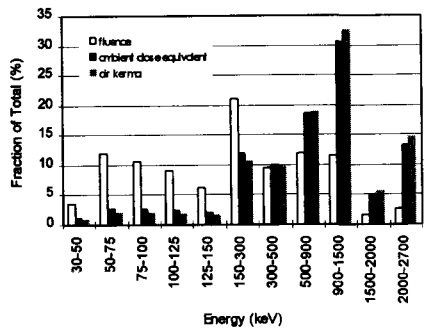

Figure 2. Approximate energy distribution of typical background terrestrial gamma rays at height of 1 m. Derived from data in Beck (13) using ICRU 47 (1992) factors to convert from fluence to ambient dose equivalent. Average factor for each energy range was used.

photons with energies >500 keV. Comparison of the overall energy distribution in terms of the physical quantity air kerma and the operational quantity ambient dose equivalent shows there is very little difference. This is because above about 30 keV the energy response of air and the ICRU sphere is essentially the same. Photons below about 30 keV are weakly penetrating and do not make a significant contribution in environmental radiation monitoring.

INSTRUMENTS FOR DIRECT MEASUREMENTS OF EXTERNAL DOSE

Pressurized Ionization Chambers, Geiger Mueller Tubes

Figure 1 shows data obtained with a pressurized ionization chamber (PIC). Similar data can be obtained with Geiger Mueller (GM) tubes. Both types of instruments are good for providing a detailed time record of the dose rate. Current models are sensitive to changes on the order of 0.6 nSv h^{-1} and typically allow measurements every minute or less and can store over 1 month of data unattended. It is important that they be appropriately calibrated for the environmental spectrum encountered, with consideration given to the relative sensitivity to cosmic and terrestrial components.

Spectrometers

Sodium iodide and germanium detectors (which have superior energy resolution) record the energy of incident gamma radiation and can therefore be used to identify sources. With appropriate calibration, they can also be used to quantify the concentrations of radionuclides to provide *in situ* soil analysis and to distinguish the terrestrial component of the dose (14). This technique has been used for the study of global fallout, and for assessment after the Chernobyl accident. Because of a spectrometer's high cost and more extensive operating requirements (higher voltage biased supply, amplifier, liquid nitrogen in the case of Ge detectors), they are usually not left at a site unattended for long periods for routine environmental monitoring. But for site characterization and final status surveys for decommissioning or where dose limits are very low, the technique of *in situ* gamma spectrometry can be particularly useful, as explained below.

To assist in the interpretation of environmental radiation measurements, it is often useful to combine results from more than one instrument. For example, the increase in radiation levels due to precipitation, as illustrated in Figure 2, could look like an accidental release. Denmark's "early warning system" (15) established after the accident at Chernobyl uses a sodium iodide detector to assess fluctuations of 10% or more in PIC measurements of the ambient background level in order to separate natural events from possible manmade releases. Likewise, precipitation data from a weather station can be applied for the same purpose. As another example, the terrestrial component of the dose rate determined with a spectrometer can be compared to the reading of a PIC or GM detector as a quality assurance check on both instruments, or to correct for the PIC or GM detectors' differing sensitivities to the cosmic and terrestrial components.

Passive Environmental Dosimeters

Passive detectors provide an integrated measure of the total dose. While this information is limited in comparison to that provided by PICs, GM detectors and spectrometers, it is often adequate for environmental monitoring

purposes, as will be illustrated below. While film and electrets are occasionally applied, the most widely used integrating dosimeters for environmental monitoring are thermoluminescent dosimeters (TLDs). Though the laboratory instruments used to process a TLD can be costly, the TLDs themselves are inexpensive, reusable, and rugged, and can therefore be deployed in locations that are remote or subject to potential loss from such factors as vandalism or environmental insults.

To monitor the external dose to the public, nuclear installations may use a few PICs or GM detectors at the fence line, and many more TLDs at the fence line and beyond to provide coverage off site. There are presently over 17,000 sites on earth being monitored with TLDs (16). In the hours immediately following the accident in the U. S. at the Three Mile Island nuclear power plant in 1979, TLDs were the only environmental monitors in the field and they provided significant data about dose since plant vent monitors had reached their upper range limits (17). In the U. S. (partly as a result of this) the NRC established its own network of TLD sites around all power plants, in addition to those used by the private utilities. The NRC's network consists of 13 to 48 monitoring stations around 75 facilities, and typically covers standard windrose sectors circling the site boundary, as well as 3 km from the site, with additional stations 8 km or more from the site, including major population areas (18).

Recently developed TL materials provide increased sensitivity, and have been shown to be capable of measuring daily background doses, i.e., on the order of 2 μSv (19). Some TLD materials such as LiF, $Li_2B_4O_7$, and BeO are nearly tissue equivalent. The differing spectral sensitivity of other materials and the use of additional filters has been exploited to perform crude spectrometry (20). This can be especially useful to monitor for such things as a 6 MeV gamma ray from ^{16}N produced in nuclear power plant, or low energy photons from ^{133}Xe releases.

DISTINGUISHING DOSE ABOVE BACKGROUND LEVELS

While all of the detectors described above are sensitive enough to measure absolute dose levels on the order of the current and proposed limits for public exposure, distinguishing a potential manmade component from the naturally varying background is a more complex problem. The relevant question to address is: Can the available instruments provide data on external dose that would be useful to measure compliance with public dose limits?

To address this question it is useful to look at data from the long-term monitoring of natural background radiation. The Environmental Measurements Laboratory (EML) has been monitoring radiation exposure (and other conditions) at a rural location with no local sources of pollution and undisturbed soil (21). Figure 3 shows PIC and TLD data from 14 years of simultaneous monitoring. The PIC data were obtained with EML designed ionization chambers. The TLD data are from dosimeters consisting of 15 ^{7}LiF:Mg,Ti phosphors ("chips") deployed within about 1 m of the PIC during each calender month (22). While the TLDs measure the total dose, a mean dose rate is obtained by dividing by the field deployment time. This can then be compared with the average dose rate measured by the PICs during the same time period. For the PIC data, each point represents the average of thousands of readings, and the associated statistical uncertainty is small (<<1%). For TLD measurements, the uncertainty tends to be much higher (~5-10%) due variations between chips and possible changes in reader conditions, as well as the expected poorer statistics resulting from averaging over a small number of chips per dosimeter. This is the probable reason for the somewhat larger variations observed in the TLD results.

Figure 3 shows good agreement between the TLD and PIC data, and it illustrates that while the monthly average background dose rate can vary by as much as almost 40%, the yearly average tends to be more stable, varying only a few percent from year to year. The largest monthly variations are low dose rates corresponding to winter months with greater snow cover. The overall PIC average is 87 nSv h^{-1}, and is marked with a solid line in the figure. The dashed lines show the hourly dose rate levels that would correspond to an additional dose, above the PIC average, equal to that of some of the annual public dose limits shown in Table 1.

The dashed lines show that an additional external dose corresponding to an annual dose of 1 mSv (i.e., 114 nSv h^{-1}) above the average background dose would be clearly beyond the range of natural measurement variations, and, therefore, easily detectable. The same is true of the current NRC annual external dose limit of 0.50 mSv. The single source limits being used by EPA (0.25 mSv) and proposed by DOE (0.30 mSv, not shown in Figure 3), are both well above the maximum data variation also. However, the 0.10 mSv limit being considered in the Netherlands and applied to airborne emissions in the U. S. is approaching the measurement variation, as is the 0.15 mSv limit currently proposed by the NRC for decommissioned facilities. As these limits should include internal dose components, the type of TLD and PIC measurements shown here may not be sufficient and additional information would likely be required.

In the case of facilities undergoing decommissioning, it is usually known what contaminant radionuclides could be present. The NRC is in the process of determining specific soil concentrations for various nuclides that would result in a total effective dose below the proposed 0.15 mSv limit ("release criteria") (23). These concentrations are calculated using a dose modeling code (24) that considers various source transport and exposure pathways and

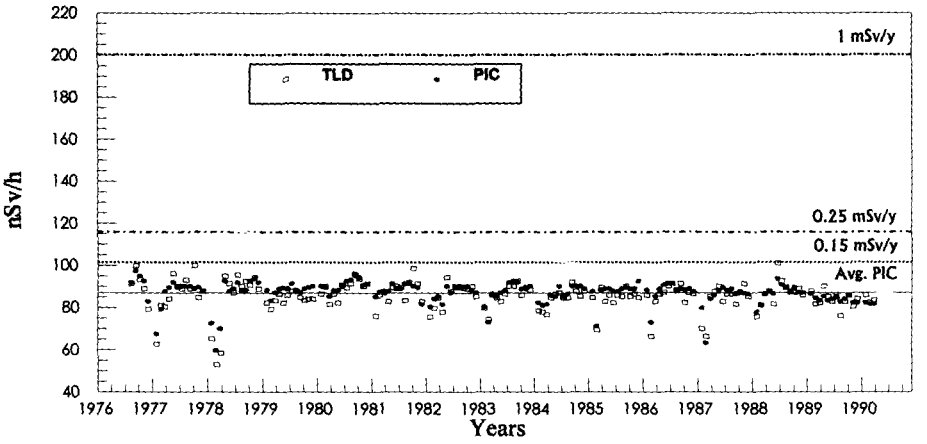

Figure 3. Fourteen years of monthly TLD and PIC environmental monitoring data at a rural site in the U. S. with no local sources of pollution.

land-use scenarios. To demonstrate compliance, it may be sufficient to show that residual soil contamination does not exceed the release criteria. It is interesting to note that while an additional external dose on the order of 0.15 mSv y^{-1} (17 nSv h^{-1}) may be difficult to detect in monthly averages, the corresponding allowable concentration of a specific nuclide can be measurable by the *in situ* gamma spectrometry technique. For example, the release criteria estimated in the current working draft for ^{238}U in soil is about 0.3 Bq g^{-1} (7.8 pCi g^{-1}), or more than 10 times the natural background concentration of uranium (23). For another example, the release criterion for ^{60}Co is about 0.1 Bq g^{-1} (3 pCi g^{-1}).

However, it must be emphasized that the modeling code is being refined and the release criteria have not been finally determined. The calculated value depends on the input parameters used for such things as soil permeability, and the water situation for the modeled site. Such factors are more important for nuclides with a significant internal dose pathway, and the final values for the release criteria could be much different. For these reasons, it would be useful to make measurements of the external dose to verify the assumptions made in the modeling code. It is also worth noting that because the proposed limit applies to the mean dose to a critical group rather than the maximally exposed individual, depending on how the occupancy and shielding factors are determined, an external dose at a field site greater than 0.15 mSv may be allowed. Also, any external dose from a decommissioned site should be static, and a determination would be made based on comparison with a reference site that is not contaminated, in which cases TLD or averaged PIC measurements may yet be adequate for some cases.

Many environmental monitoring programs presently use a quarterly monitoring cycle, which should result in a lower range of variations than those seen in Figure 3. Furthermore, if regulations are stated in terms of an annual dose limit, dose rate measurements near the limiting value would have to be present for more than one quarter to result in a dose in excess of the limit. A dose large enough to exceed annual limits in one quarter would be well beyond the range of data variations for most of the limits now being considered. However, the Netherlands limit of 0.04 mSv would likely be within the natural variations and not detectable in the monthly averages. Real time PIC monitoring may be required in this case. Depending on how other regulations specify what fraction is allowed for internal and external components, the measurability could be difficult as well. It is clear that any monitoring program would have to establish natural levels for a specific site. Where possible, this would ideally be achieved through a few years of monitoring before the facility becomes operational. Where this is not possible, it may be necessary to establish background levels at some distance from a site. Alternatively, gamma spectrometry could be applied to determine if there is any facility contribution.

INTERNATIONAL INTERCOMPARISONS OF ENVIRONMENTAL MONITORING INSTRUMENTS

The European community has sponsored several international intercomparisons of environmental monitoring instruments beginning in 1984. The most recent intercomparison involved eight countries and was held at the PTB in Germany and Riso National Laboratory in Denmark in 1994 (25). In an earlier study, PIC, GM, proportional counter and TLDs were used to measure the routine discharges of a nuclear power plant over a 2-month period (26).

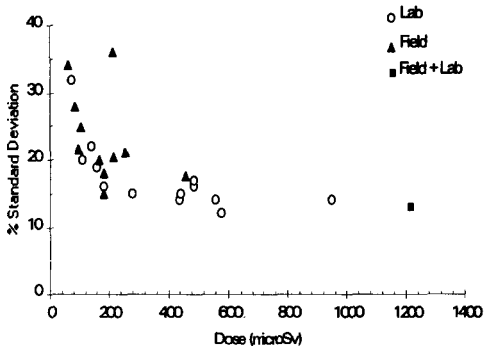

Figure 4. Relationship of dispersion of participants' results and the delivered dose from the International Intercomparisons of Environmental Dosimeters. Most of the participants used TLDs.

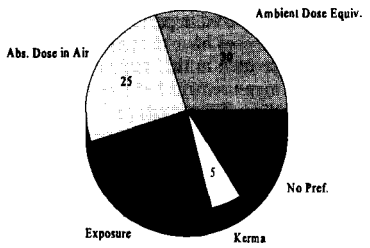

Figure 5. Results of survey of preferred quantity to use for environmental monitoring from 10th International Intercomparison of Environmental Dosimeters (28). Number of participants preferring each quantity is shown, out of 100.

While the active instruments provided an indication of the time of the releases and tracked the power level of the reactor, only the TLDs provided a good measure of the total dose without corrections that required independent knowledge of the energy spectrum of the radiation field (27). This is a result of the LiF TLDs' appropriate energy response for such monitoring. Because of the variations in their energy response, the PIC, GM and proportional counter overestimated the dose by 10%, 40%, and 50%, respectively.

This illustrates that passive integrating dosimeters can be particularly useful for assessing the external dose to the public to check compliance with annual dose limits. While they do not have the time resolution to identify transient dose increases, this information is not required for assessing compliance with annual dose limits. Also, because they are completely passive there is no associated "down" time that is inherent in any type of active instrument which may occasionally not be serviced on schedule because of such things as weather conditions. Active detectors like PICs and GM detectors are most useful to monitor in real time or for short-term studies or for model validation. TLDs are useful for widespread coverage off-site.

The U. S. Department of Energy (EML) has sponsored the "International Intercomparison of Environmental Dosimeters" since 1972. This program is open to any type of integrating dosimeter, and typically includes over 100 participants from 25-30 countries. It provides a measure of the state of the art in passive environmental dosimetry. For example, in the 10th International Intercomparison of Environmental Dosimeters (28) in 1993 it was found that 90% of the participants were within 30% of the delivered dose. Figure 4 shows the dispersion of participants' results plotted against delivered dose from all the intercomparisons. For lower doses, there is greater dispersion, but still most participants were within the performance criteria recommended by the American National Standards Institute (ANSI)(29). The 10th intercomparison included a survey where participants were asked to select their preference from a list of quantities. The results are shown in Figure 5. Thirty percent of the participants selected ambient dose equivalent, 54% selected one of the physical quantities of exposure, absorbed dose in air, or air kerma, and 16% indicated no preference.

NATIONAL AND INTERNATIONAL ENVIRONMENTAL DOSIMETRY STANDARDS

Despite their widespread application in measuring dose to the public, there are presently no testing or accreditation programs for environmental dosimetry providers. In contrast, several national programs exist for the testing of personnel dosimetry services. There may not be a need for such testing unless there are cases where public dose assessments are challenged. In such cases it may be difficult to defend doses derived completely from calculations. In anticipation of such a need the ANSI has developed a draft standard on performance testing of environmental dosimeters (30) that is analogous to the one currently used for the occupational dosimetry National Voluntary Laboratory Accreditation Program (NVLAP) in the U. S. (31). In addition to this, the current standard for environmental thermoluminescence dosimetry, ANSI-N545 is being revised as ANSI-N13.37. The Netherlands is in the process of establishing requirements for environmental dosimeters in its standard NVM5648 (32). There

; a more general international standard already in place that covers this subject as well, IEC 1066. Particularly for nvironmental monitoring where the dose limits are much lower than for occupational settings, one of the most elevant issues to be covered in performance standards is requirements for the lower limit of detection for dosimetry ystems. Many researches have analyzed the methods for defining this quantity, which is not straight forward (33).

Regulations are written in the interest of public health and they do not necessarily take into consideration the abilities of current measurement technologies. National and international standards, on the other hand, may focus on physical properties of detectors and are not necessarily linked to regulations. It would be most useful if both regulations and performance standards could converge on practical methods to meet the needs in dose assessment.

CONCLUSIONS

Many countries have regulations that limit the radiation dose to members of the general public. Most are consistent with the ICRP and are moving towards a 1 mSv annual dose limit, with some specifying additional lower limits to allow for exposure from multiple sources. Such limits currently being considered are in the range of 0.10 mSv to 0.30 mSv. Limits apply to all pathways, and, therefore, will require dose modeling. Measurements of the external dose could help to verify the assumptions made in dose modeling codes. Based on long-term measurements of the natural background radiation, assessing an additional external dose on the order of 0.15 mSv or more would be possible using currently available technology. However, interpretations of any environmental monitoring data require knowledge of the natural background radiation field and its variations. Results from international intercomparisons demonstrate that passive dosimeters, such as TLDs, are appropriate devices for measuring the external dose off-site. National standards being developed for such devices should address the needs of regulations on dose limits. Active instruments such as PICs and GM detectors are useful for real-time monitoring or spot measurements, and provide more information than may be needed to demonstrate compliance with public dose limits. Limits of 0.15 mSv or less may require more extensive measurements with spectrometers and calculations of derived limits for soil concentrations, similar to those being presently developed in the U. S. for decommissioned sites.

AREA MONITORING

I. M. G. Thompson
International Atomic Energy Agency,
Wagramerstrasse 5,
A-1400 Vienna, Austria

INTRODUCTION

The exposure of individuals to ionizing radiation is normally subject to legal controls which specify limits, and restriction, of doses that both occupational workers and members of the public are exposed to.

The dose limits recommended by the International Commission on Radiological Protection (ICRP) (1), and adopted by many countries are specified in terms of body dose equivalents, sometimes referred to as limiting quantities. However these quantities are not measurable since they are defined as average doses in organs and tissues of the human body. Thus for the same physical radiation field the dose delivered to an individual will not have a fixed value but will depend upon each individual's sex, age and physical construction as well as upon their orientation in the field.

Ionizing radiation, also, cannot be detected by a person's physical senses of sight, smell, hearing and touch. Thus to control the levels of radiation to which individuals are exposed, special operational quantities are used and quantitative measurements have to be made using personal dosemeters or area monitoring equipment. This report describes the operational quantities that are being increasingly used worldwide for area monitoring. It provides information on the international standards that are available on the performance requirements for monitoring equipment designed to measure these operational quantities. It also reviews the recent international standards that have been published on the calibration and type testing of area monitors and gives an example of legislative requirements on area monitoring equipment.

OPERATIONAL QUANTITIES

The International Atomic Energy Agency (IAEA) has incorporated into its Basic Safety Standards (2) the ICRP recommendations on a revised system of dose limitation (1). The dose limitation system is based on the equivalent doses in various organs or tissues, H_t, of an individual and the weighted sum of the equivalent doses in some tissues and organs, the effective dose, E. These limiting quantities are essentially unmeasurable so they are estimated through the use of operational quantities that can be measured in the radiation exposure environment.

The operational quantities are defined by the International Commission on Radiation Units and Measurements (ICRU) under receptor-present conditions. For area monitoring the quantities ambient dose equivalent, H*(10), and the directional dose equivalent, H'(0.07) are defined for the ICRU tissue equivalent sphere (3). For personal monitoring the personal dose equivalent, Hp(d) is defined for the human body (4).

For the purpose of demonstrating compliance with the dose limit, ICRP and the IAEA recommend that the following criteria be met:

$$\frac{H_p(d)}{DL} + \sum_j \frac{I_{j,ing}}{I_{j,ing,L}} + \sum_j \frac{I_{j,inh}}{I_{j,inh,L}} \leq 1$$

where DL is the relevant limit for the year of the effective dose, $H_p(d)$ is the personal dose equivalent from external penetrating radiation during the year; $I_{j,ing}$ and $I_{j,inh}$ respectively are the intake via ingestion or inhalation of radionuclide j during the same period, and $I_{j,ing,L}$ and $I_{j,inh,L}$ respectively are the annual limits on intake (ALI) via ingestion or via inhalation of radionuclide j.

Radiations are also characterized as either "weakly" or "strongly" penetrating depending on which dose equivalent is closer to its limiting value. For strongly penetrating radiation, namely from photons with energies above about 15keV, neutrons and for electrons of energy above about 5Mev, the effective dose is

appropriate and for weakly penetrating radiation, namely from photons with energies below about 15keV and electrons with energies below about 5Mev, either the dose equivalent in the lens of the eye or that in the skin is relevant.

A summary of the operational quantities distinguished according to the radiation penetration is given in Table 1; the lower part of the table gives the measurements used from which estimations are made of inhalation and ingestion doses.

Table 1. Summary of the operational quantities

External Radiation	Limiting Quantity	Operational Quantity for	
		Area Monitoring	Individual Monitoring
Strongly Penetrating Radiation	Effective Dose	$H^*(10)$	$H_p(10)$
Weakly Penetrating Radiation	Skin Dose	$H'(0.07,\Omega)$	$H_p(0.07)$
	Dose to the Lens of the Eye	$H'(3,\Omega)$	$H_p(3)$
Contamination		Area Monitoring Measurement	
Airborne	$I_{j,inh,1}$(ALI)	Airborne Contamination Units (Bq m^{-3})	
Surface	$I_{j,ing,1}$(ALI)	Surface Contamination Units (Bq m^{-2})	

EXTERNAL DOSE AREA MONITORING

For external strongly penetrating radiation the effective dose is estimated by measuring the personal dose equivalent $H_p(10)$. However this is measured using a personal dosemeter worn on the trunk of an individual and for most dosemeters the dose can only be evaluated retrospectively after the period of wearing, typically one month. Members of the public are not issued or wear personal dosemeters so their doses have to be assessed from measurements made with area monitors.

For photon radiation from 10 keV to 1.5 MeV at normal incidence to the body the ambient dose equivalent is within 10% of the personal dose equivalent and for other geometries the ambient dose equivalent is always the greater.

For all irradiation geometries for neutrons, except AP and PA, and for all energies up to 10 MeV, area monitoring of the quantity ambient dose equivalent, $H^*(10)$, provides a conservative estimate of the effective dose equivalent (5), for photon radiation see Figure 1. Such measurements can therefore safely be used to assess and optimize the doses of individuals working within controlled and supervised areas.

To control the doses from weakly penetrating radiation, area monitors with thin entrance windows should be used to measure the quantity directional dose equivalent, $H'(0.07)$. In practice, the exposure of the skin is highest for normal radiation incidence. The area dosemeter should therefore be rotated and the maximum reading taken for estimating the skin dose.

AREA MONITORING OF CONTAMINATION

Measurement of the internal doses arising from the inhalation and ingestion of radioactive materials can only be estimated following their retention inside the body. Area monitoring of the surface contamination and airborne contamination do, however, provide information which can be used for preventative radiation protection purposes, such as the delineation of controlled areas, restriction of access to such areas and the

issuing of protective clothing, respirators and breathing air apparatus. Measurements made at the exit to controlled areas also ensure that radiation workers do not spread contamination from themselves or their equipment to non controlled areas.

Monitors used to measure surface contamination are calibrated in terms of the calibration source's certificated emission rate per unit area, S_A. The monitors calibration factor $CF_E$is given by:

$$CF_E = \frac{S_A}{M-M_b}$$

where M is the monitor's count rate (units s^{-1}) when exposed to the calibration source at a specified distance and M_b is the monitor background count rate. The calibration distance, from the surface of the source to the detector window is small and is usually chosen to be equal to, or very close to, the distance that will be used for subsequent measurements of contaminated surfaces. When the instrument is used to assess the amount of radioactive material on a surface it measures the surface emission rate from the surface and so the measurements have to be interpreted in terms of activity per unit area, Bq cm^{-2}. The surface activity per unit area, As, is estimated by multiplying the observed background subtracted reading, $M_{(e-bg)}$ by the calibration factor, CF_E and by a conversion factor, P, which is the ratio of the surface activity per unit area to the surface emission rate i.e. $As = M_{(e-bg)}. CF_E. P$
and P= (a), (b), (c), (d), (e) where:

(a) The number of particles of a given type produced per decay of radionuclide.

(b) Where a parent/daughter radionuclide is being measured the activity refers to the combined number of particles produced by both the parent and daughter(s) when in equilibrium with each other.

(c) Not all the particles are emitted from the surface into the upper 2π solid angle where the detector is making the measurement. Up to a maximum of half will be emitted downwards into the material on which, or in which, the activity being measured is located. Some particles emitted downwards will be backscattered and emerge into the upper 2π solid angle.

(d) Self-absorption will also reduce the number of particles emitted into the upper 2π solid angle. The magnitude of this factor will depend upon the type of radiation, its energy and the thickness and distribution of the radioactive material on or within the surface being measured.

(e) The uniformity and distribution of the radioactive material on the surface. Whilst the calibration source is constructed to provide a uniform distribution (activity per unit area) over the area of the detector, surfaces being measured are very rarely contaminated uniformly.

Factors (a) and (b) are uniquely characterized by the decay scheme for the particular radionuclide and may therefor be quantified. Factors (c), (d) and (e) are dependent upon the characteristics of the contaminated surface and have to be estimated values. When direct measurements are made of a surface contaminated with a different radionuclide than that used for the calibration monitor, the factor (a) is replaced by another factor (a*).

(a*) A correction factor has to be applied to allow for

1) The difference between the number of particles of a given type produced per decay from the calibration radionuclide and from the radionuclide being measured on the surface; and

2) Difference of the monitor's energy response when the particle energies are different for the calibration source and the surface radionuclide. By careful selection of the calibration radionuclide to have a particle energy close to the particle energy of the radionuclide being measured on the surface this factor can be assumed to be unity.

For example where an ^{129}I source is used to calibrate a monitor that will be used to measure surfaces contaminated with ^{125}I the weighted mean energies are respectively 28.8 keV and 26.04 keV so no correction

r factor 2) is required. However, the total probability per decay for ^{129}I is 0.858 and is 1.598 for ^{125}I, so (a*) ould equal 0.858/1.598 = 0.54.

Where a direct measurement is made of a surface contaminated with a mixture of radio isotopes requently the composition will not be known and the relative amounts will probably be less well known. In he interest of safety a conservative estimate may be made by the use of the highest value of the factor (a*) within the considered mixture.

The product (c), (d), (e) may be assumed to have the following values:

For beta emitting radionuclides with a maximum energy >0.4MeV an approximate value of 2 may be used as a general rule. For beta emitting radionuclides with a maximum energy >0.15 MeV and <0.4 MeV, as well as for alpha emitting radionuclides, a value of 4 may be used. For photon emitting radionuclides an approximate value of 2 may be used. However, it should be noted for the measurement of contamination present in very thin layers, the activity would be overestimated if significant backscatter was present. Conversely, for thicker layers of surface contamination, the activity would be underestimated if there was significant attenuation within the contaminated surface. For the lower maximum energy radionuclides considered in this procedure the effect of air path attenuation could be significant if the surface contamination instrument is used to measure surface contamination at distances different from that used for calibration.

AIRBORNE CONTAMINATION MONITORING

For alpha emitting radionuclides and low energy photon radionuclides the limitations on minimum detectable activities by bioassay measurements, namely in vivo and in vitro analysis, means that such measurements may not be practical and that area monitoring may have to be utilized. Such monitoring will provide warnings that preventative action may be required or that intakes may occur and bioassay measurements may be necessary. In some countries it is permitted to use air monitoring results to assess internal doses.

The committed effective dose per unit intake for workers and members of the public via inhalation and ingestion (Sv Bq^{-1}), for different nuclides, are given in the IAEA Basic Safety Standards (2).

The intake can be estimated from the measured air concentration, multiplying this by the time that the worker breathed at this concentration and dividing by the number of working hours in a year and by a factor which allows for protection if a respirator is worn.

Alternatively to estimating the effective dose the derived intakes may be compared with the respective annual limit on intake (ALI).

PERFORMANCE CHARACTERISTICS OF AREA MONITORS

The International Electrotechnical Commission (IEC) have published standards on the performance and testing of monitoring equipment. Examples of some of these IEC standards are given in Table 2.

Table 2. Examples of IEC standards on radiation monitoring equipment

Publication	Equipment
	Photon and Beta Monitoring Equipment
1018	High range beta and photon dose and dose rate portable instruments for emergency radiation protection purposes.
532	Installed dose rate meters, warning assemblies and monitors for X or gamma radiations of energy between 50 keV and 7 MeV
846	Beta, X and gamma radiation dose equivalent and dose equivalent ratemeters for use in radiation protection
1017-1 1017-2	Portable, transportable or installed X or gamma radiation ratemeters for environmental monitoring - Part 1: Ratemeters; Part 2: Integrating assemblies
	Personal Dosimetry
1283	Direct reading personal dose equivalent and/or dose equivalent rate monitors for the measurement of personal dose equivalents $H_p(10)$ and $H_p(0.07)$ for X, gamma and beta radiations
1066	Thermoluminescence dosimetry systems for personal and environmental monitoring
	Neutron Monitoring Equipment
1005	Portable neutron ambient dose equivalent ratemeters for use in radiation protection
1323	Direct reading personal dose equivalent and/or dose equivalent rate monitors for neutron radiation
	Monitoring of Individual Radioactive Contamination
325	Alpha, beta and alpha-beta contamination metes and monitors
504	Hand and/or foot contamination monitors and warning assemblies
1098	Installed personal surface contamination monitoring assemblies for alpha and beta emitters
	Monitoring of Airborne Radioactive Contamination
579	Radioactive aerosol contamination meters and monitors
710	Radiation protection equipment for the measuring and monitoring of airborne tritium
1171	Monitoring equipment - Atmospheric radioactive iodines in the environment

The IEC standards specify the requirements and tests that shall be undertaken to determine the radiation, electrical, mechanical and environmental performance of radiation protection instrumentation. As an example of the requirements of the IEC standards Table 3 gives details of the radiation specifications for

the equipment to measure ambient dose equivalent, Standard 846.

Table 3. Radiation characteristics of ambient dose equivalent (rate) meters

Characteristic under test of influence quantity	Range of value(s) of influence quantity	Limits of variation
Relative intrinsic error - X and gamma radiation	Effective range of measurement	± 15% [1]
X and gamma radiation energy	10 keV to 30 keV 30 keV to 0.2 MeV 0.2 MeV to 1.5 MeV 1.5 MeV to 10 MeV	To be stated by the manufacturer ± 35% [2] ±15% [2] ±35% [2]
Beta radiation energy	Beta radiation up to E_{max} of 4 MeV	±50%
Angle of incidence - X and gamma radiation	0° to 90° from reference direction 90° to 180° from reference direction	±25% To be stated by the manufacturer
Overload	100 times the range maximum for range maxima up to and including 0.1 Svh^{-1} 10 times the range maximum, or 10 Svh^{-1}, whichever is the greater, for range maxima more than 0.1 Svh^{-1}	Indication to be off-scale on the high side or assembly to indicate overload (for 5 min)
Effects of neutron radiation		Response to be stated by the manufacturer

[1] This error is additional to the uncertainty in the determination of the conventionally true dose equivalent (rate).

[2] Limit of variation from indication under reference conditions.

Many countries have legislative requirements on the calibration and use of radiation monitoring equipment. For example, in the UK the Ionising Radiations Regulations 1985 requires that every employer who undertakes work with ionizing radiation shall ensure that levels of ionizing radiation are adequately monitored for each controlled area or supervised area that he has designated. He is required to provide equipment which is suitable for carrying out such monitoring and this equipment has to have had its performance established by tests before it is taken into use for the first time, be properly maintained and be thoroughly examined and tested at least once every 14 months. The employer also has to make suitable records of the results of the monitoring and of his testing, calibration and maintenance of the monitoring equipment. The legislation, as well as good metrological practice, require that the measurements of the radiation characteristics of an instrument made as part of the type, acceptance and routine tests, as well as the calibration, should all be traceable to an appropriate national standard.

The IEC standards give a very good basis upon which to judge its performance and whether it is suitable for carrying out the monitoring task. The IEC testing is based upon the International Standards Organization Standards on reference radiations for calibrating and type testing of radiation monitoring

equipment, one example of which is the photon reference standard (7). These ISO standards give the conversion co-efficients that shall be used to convert the physical quantitives used to characterize the dosimetric properties of the reference calibration fields, e.g. Air Kerma or Fluence, to the quantities used by the area monitoring equipment, e.g. ambient and directional dose equivalent.

UV AND SKIN: THE BIOLOGICAL EFFECTS OF UVA AND UVB

Jean Pierre CESARINI, M.D.,
Institut National de la Santé et de la Recherche Médicale, Laboratoire de Recherche sur les Tumeurs de la Peau Humaine, Fondation Ophtalmologique Adolphe de Rothschild,
25, rue Manin, F-75940 PARIS cedex 19, FRANCE

INTRODUCTION

Almost all of the photobiological reactions that occur in the skin are induced by radiations between 290 and 380 nm. These radiations correspond to the wavelengths from the solar emission which are received at the earth surface after absorption by the terrestrial atmosphere. However, from artificial sources, used at work or in domestic environment, the complete spectrum of UV may present a potential hazard.[1]

After considering the optical properties of the human skin, acute effects of UV on the skin will be considered, followed by the potential phototoxic and photoallergic consequences of UV exposures and finally, the adverse cutaneous reaction to sunlight.[2] Protective measures will be considered.

THE OPTICAL PROPERTIES OF THE SKIN

To establish a photobiological reaction, three components are necessary: the biological system, the radiation and a radiation absorber in the biological system. All the components of the tegument are potentially able to react with the incident UV and, as a consequence, a protective filter for the constituents located below.

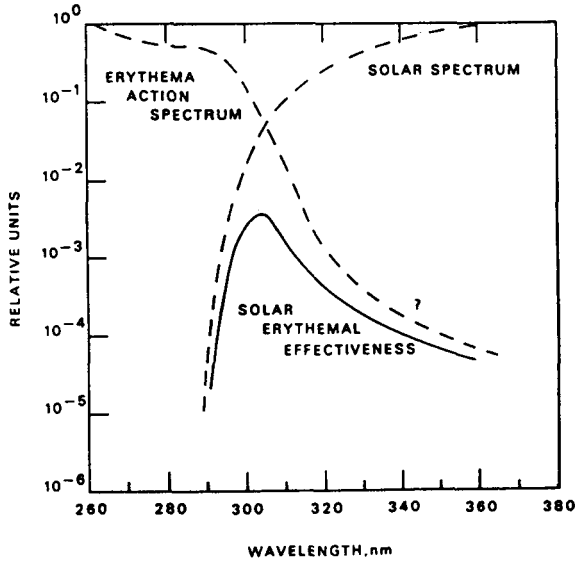

Figure 1. The human solar erythemal effectiveness is obtained by the convolution of the human skin erythema action spectrum and the solar spectrum. It clearly presents a maximum at 307 nm which is the most efficient wavelength to induce sunburn. For artificial sources the erythemal effectiveness shape of the curve may be completely different. The same holds for chemicals with different absorption spectrum.

Skin reflects a large amount of incident visible and near infrared radiation and to a lesser degree, some UVA. Scattering and absorption play a greater role in the attenuation of radiation than reflection. Melanins and melanosomes, nucleic acids, proteins, lipids, urocanic acid, cholesterol, and histidine do limit the penetration of UV.

UVC are absorbed by the stratum corneum and the upper layers of the stratum Malpighi. UVC has only indirect impact on the living layer of the epidermis (melanocytes and keratinocytes), but are able to generate the cytokin production responsible for erythema and to alter the immune function of Langerhans cells.

UVB has indirect impact on the full thickness of the epidermis, 10 to 15% of the longer UVB are reaching the papilla (the upper part of the dermis).

UVA are absorbed at 50% by the epidermis, the rest is able to penetrate the dermis up to 2 mm depth. Because of the importance of the shorter wavelength UV, in the production of the photobiological reaction, the acute effects will be mostly produced at sea level by radiation around 307 nm.

After repeated insults from UVR, and particularly UVB, the thickness of the epidermis is increasing with direct consequences on the UVB absorption, making the basal layer of the epidermis (where keratinocytes, able to divide, are located) out of direct reaction with UVB radiations. Soluble mediators produced by maturing keratinocytes are still efficient.

BIOMOLECULAR EFFECTS OF UVA AND B

The complexity of these reactions are out of the scope of this document. However, it is enough to say that DNA is one of the most important chromophores for both direct and indirect (activated oxygen species mediated) effects of UV. Once a DNA molecule has been altered by either of these processes, the damages have to be repaired by more or less complex pathway. The repair processes may be error-free or error-prone, depending on the severity of the DNA damages. Schematically, UVB are essentially inducing DNA dimers which are, most of the time, error-free repaired. UVA induce DNA strand breaks much less frequently than UVB, but the strand breaks are error-prone lesions. As a consequence, after long term exposures, the genetic code is altered equally by UVA and UVB. UVA-1 (340-400 nm) , considered for long time as inefficient in producing damages, are responsible for only strand breaks, while UVA-2 and UVB are inducing mixture of dimers and strand breaks (the 50/50 ratio being obtained around 320 nm).[3-4]

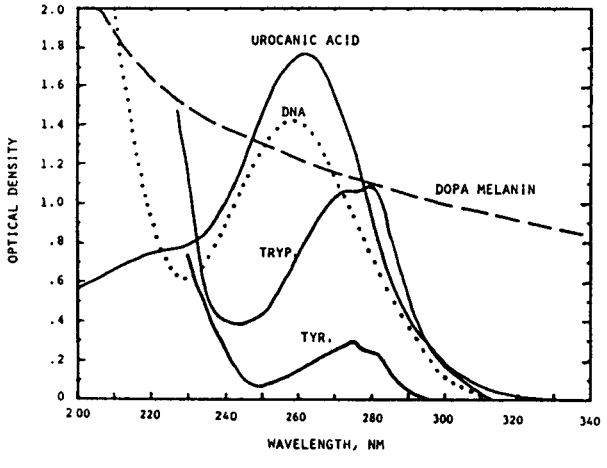

Figure 2. Absorption spectrum for different chromophores of the epidermis. The peaks of absorption for urocanic acid and DNA lie in the UVC and the small tails in the UVB are responsible for most of the deleterious biological effects, when human skin is exposed to sunlight.

The second most action of UV is on lipids which undergo peroxidation through indirect mechanisms. Other chromophores are able to absorb and react with UVB and UVA leading to activated molecules responsible for the production of several cytokins, biological inducers of mitosis, vascular changes, and systemic distant effects. The urocanic acid (maximum absorption at 265 nm) is still absorbing up to 315 nm

and is thought to play some role as an "endogenous sunscreen" of the epidermis. The energy of the photons are transferred to the chemical *cis-trans* isomerization of the urocanic acid.[5]

ACUTE EFFECT OF SUNLIGHT ON THE SKIN

- **Sunburn reaction and minimal erythemal dose.**

The sunburn reaction is the most common adverse effect produced by sunlight. The cutaneous changes induced by the erythemogenic radiation depend on the amount of radiation, the degree and the quality of melanins and the thickness of the stratum corneum. The erythema (reddening of the skin) is a visual aspect of the sunburn response. It is delayed 2-4 hours after the irradiation and peak at 14-20 hours, persisting normally for 72 hours. A severe sunburn is usually followed by an increase of the epidermal thickness and desquamation of dead epidermal cells. A minimal sunburn is light red and not painful. An extremely severe sunburn is followed, 48 hours after, by blisters. The UVA sunburn is more violaceous with prominent vasodilatation.

Based upon their personal[6] and previous works[7], McKinlay and Diffey proposed an action spectrum for a minimal sunburn. The action spectrum was adopted by CIE and, later, by several international agencies. This action spectrum is very closed in the UVB range to the absorption of UV by DNA and several other biological events like bacteria mutagenesis, cell toxicity, delayed pigmentation. It has also a good correlation in the UVB range with the ACGIH action spectrum[8], adopted by IRPA and ICNIRP for UV-induced biological hazards including eye hazards. It should be noted that in the UVA, the erythema action spectrum is not representative of pigmentation or mutagenesis.

The minimal erythemal dose (MED) is a useful tool to define the biological effects of a UV dose. It is generally expressed in mJ.cm^{-2} or J.m^{-2}. Unfortunately, international agreement has not been reached on the value of the MED. However, it is commonly set à 21 mJ.cm^{-2} when normalized at 297 nm which corresponds to the dose necessary to induce a minimal redness on the back of a very sensitive skin. This value has been adopted by most of the agencies to calculate for example, the UV risk for indoor/outdoor workers or the potential consequences of changes in the ozone layer thickness.

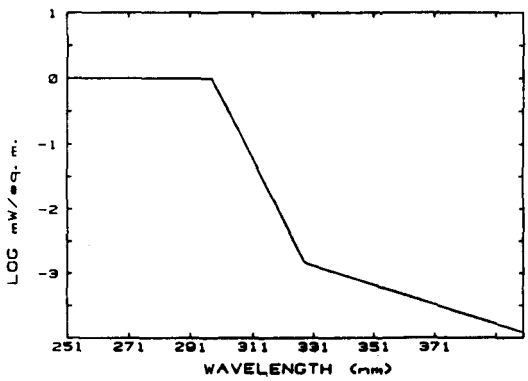

Figure 3. CIE human skin erythema action spectrum adopted after McKinlay and Diffey proposals.

For epidemiological inquiries related to skin cancers, melanocompromized subjects have an average MED of 25 ± 5 mJ.cm^{-2}, and melanocompetent subjects, an average MED of 45 ± 15 mJ.cm^{-2}. These values are characteristic of Caucasian subjects, mongoloid and metis have values closed to 90 mJ.cm^{-2}, and Negro skin, closed to 180 mJ.cm^{-2}.

- **Skin pigmentation**

Skin pigmentation is considered as an adaptation process, a direct consequence of UV radiations for a sufficient dose. It takes at least 24 hours to notice an increased pigmentation and it culminates at 8 days for a single irradiation. This **delayed pigmentation** is a consequence of an increased production of melanin pigment and its transfer to surrounding keratinocytes. In the UVB range, the induced division of the keratinocytes increases the thickness of the epidermis and so, the total content in melanin. This photoadaptative complex mechanism may be enhanced by further consecutive irradiations to an equilibrium state reached by almost doubling the total epidermal thickness, including the stratum corneum and a large load of melanin which increases the basic MED by a factor 4 to 10. In the UVA range, the multiplication of keratinocytes is

minimum while the increased pigmentation is provided directly by stimulation of melanogenesis. In this case, the basic MED is only increased by a factor 2. Phaeo and eumelanins coexist in melanocytes and keratinocytes in different ratios rendering the protection by melanins very much dependent on the quantity of phaemelanins which have been found more phototoxic than photoprotective when irradiated by either UVA or UVB. Melanocompromized subjects[9] have a large load of phaeomelanins which increases after irradiation and it is believed nowadays that the phenomenon is responsible for greater actinic damages and their consequences.

If the erythema action spectrum and the delayed pigment action spectrum for melanocompromized and melanocompetent subjects are nearly same in the UVB range, and in the shorter part of UVA, the action spectrum for pigmentation of melanocompetent subjects is diverging from the action spectrum for pigmentation of melanocompromized subjects. The same pigmentation is achieved for 5 times less dose of UVA in melanocompetent than in melanocompromized which remain closed to the UVA erythema dose[7].

The **immediate pigment darkening** reaction, a skin color observed immediately after UVA irradiation, is a totally different phenomenon which is believed to be the consequence of rapid oxidative reaction of colorless precursors of eumelanins. This transient phenomenon is nearly fully reversible with few hours and does not have any protective effect[10]. Only melanocompetent subjects are able to exhibit clearly this phenomenon which is readily perceptible after a 10 J.cm^{-2} UVA irradiation. The action spectrum has been obtained in the UVA range and is nearly flat from 330 to 380 nm, extending into the visible blue band.

- **Immunological effects**

The epidermis being an interface between environment and the body, it is naturally presenting a physical defense against external chemical or xenobiotics, but also an immunological organ able to control through immunological processes, the penetration of xenobiotic agents or the emergence of abnormal cells within the epidermis. The Langerhans cells located underneath the stratum corneum is the major afferent pathway toward a central lymphnode system, immunologically competent cells circulating by and through the capillary vessels, constituting the afferent pathway (response). For UV doses as low as half MED, the Langerhans cell functions are deeply altered within 24 hours and it takes almost 3 weeks to restore these functions[11]. Cytokins produced by other epidermal constituents, including the UV absorbing urocanic acid in its *trans* form, are able to modify either the afferent or efferent pathways, inducing a state of tolerance vis à vis any foreign substance. Several action spectra for this UV-induced tolerance have been proposed but are not yet acknowledged by the international scientific community.

In the modern vision of skin cancer initiation, promotion, and diffusion, the immunological consequences of UVR play an important role in favorishing the emergence of abnormal clones of cells[12].

- **Vitamin D_3 synthesis**

This important beneficial effect of solar radiations on the skin has been extensively studied: the UVB irradiation of 7-dehydrocholesterol by UVB produces previtamin D_3 which later will be converted into vitamin D_3 by thermal energy. The hyperproduction of previtamin D_3, by excess of UVB, is prevented by the conversion of previtamin D_3 by the production of lumisterol and tachysterol when previtamin D_3 is further irradiated. Upon continued irradiation, a photoequilibrium state is reached. As a consequence of the prevention of rickets, the production of vitamin D has probably been responsible for the establishment of skin variegated color population at the surface of the earth. Without supplementation of the diet in vitamin D_3, dark skin population children will be affected by rickets in countries with low level of UVB radiations (Nordic countries)

ADVERSE CUTANEOUS REACTIONS TO SUNLIGHT

Most of the cutaneous effects of sunlight are injurious. Beside the constitutional effects that we have already exposed, true pathogenic effects have been observed[13]. Two types of photomediated reactions may occur: phototoxic or photoallergic. Some molecules, either naturally produced, or absorbed through the skin or by the diet, present in the skin (epidermis/dermis) may absorb UVR and most of the time in the presence of oxygen, become toxic for the tissues. Clinically, **phototoxic reactions** are characterized by erythema and edema occurring within a few minutes to several hours after exposure. These chromophores may absorb at the maximum in any wavelength of the UV spectrum. For example, furocoumarins, following UVA radiation, are in their triplet state which is able to react with DNA to form adducts. Chlorpromazine reacts to form similar adducts with RNA. After the excitation, the photosensitizing molecule will return to the ground state and will be structurally unchanged, ready for more phototoxic reactions. Most of the photosensitizing molecules present this type of reaction in the UVA range.

Photoallergy can be defined as an acquired capacity of the skin to react in the presence of the photosensitizer by the development of circulating antibody or cell mediated immune response. These reactions are generally uncommon, not depending on the concentration of the photosensitizer and extend beyond the

exposed areas. Usually, less radiation exposure is required to induce a photoallergic response than a phototoxic response, the later being dose-dependent.

Among the adverse cutaneous reactions, **photo-induced diseases or photo-aggravated diseases have been** described. The spectrum of the diseases is very large from viral activation like herpes, to unknown agents responsible for polymorphic light eruptions which are afflicting 10% of the women population of clear skin complexion. The course of systemic diseases, metabolic disorders (porphyry) and complex immunological disorders (lupus), may be severely altered.

PROTECTIVE MEASURES

It is desirable to provide skin protection against acute and hypothesized chronic exposure hazards. In order to reduce the ambient solar aggression or the leisure/vacation overexposures, several measures should be taken[1]. Education should play a great role. The education programs should start very early at school and be regularly repeated for adults, through publicity campaigns, using all media. Staying in the shade during the most solar aggressive hours, wearing adapted clothing, hat with minimal 7 cm brim, applying adapted protective sunscreens, are elementary measures. The concept of a protection factor is useful to characterize items such as sunscreens, clothing. Generally, the protection factor is defined as the ratio of effective dose (unprotected) to effective dose (protected). It should take in account the spectral irradiance and the relative spectral effectiveness, the spectral transmission of the protective item. To communicate for the protective measures, the global UV-Index established in 1996, is a very effective tool.

CONCLUSIONS

International guide lines on exposure to ultraviolet radiations have been based on the same basic criteria of ACGIH (1993) and IRPA / ICNIRP (1991). The basic exposure limit (EL) for general public and occupational exposure to UV incident on the skin is 30 $J.m^{-2}$ effective when the spectral irradiance on skin surface is mathematically weighted by the hazard relative spectral effectiveness factor from 180 nm to 400 nm. Several tables express the relative spectral effectiveness of each wavelength and the maximum values of radiant UV exposure incident upon the unprotected skin with an 8-hour period.

ULTRAVIOLET RADIATION: THE EYE

Jean-Pierre Cesarini, M.D.[1] and David H. Sliney, Ph.D.[2]

[1]Laboratoire de Recherche sur les Tumeurs de la Peau Humaine, INSERM, Fondation Ophtalmologique Adolpe de Rothschild, 25, rue Manin, F-75940 Paris CEDEX 19, France
[2]Laser/Optical Radiation Program, US Army Center for Health Promotion and Preventive Medicine, Aberdeen Proving Ground, MD 21010-5422 USA

INTRODUCTION

Under most conditions, the eye is well adapted to protect itself against ultraviolet radiation encountered in the outdoor environment as a result of the exposure geometry of the sun. Only when snow is on the ground does one experience acute effects of UV sunlight exposure (i.e., "snow blindness," or photokeratitis).[1-6]

With regard to artificial sources, there are many occasions where one views bright light sources such as tungsten-halogen lamps, arc lamps and welding arcs. Such viewing is normally only momentary because of the aversion response to bright light and due to discomfort glare. However, such an aversion does not take place for germicidal lamps and other UV lamps which do not contain a strong visible component in their spectrum. The adverse effects from viewing such sources has been studied for decades and during the last two decades guidelines for limiting exposure to protect the eye have been developed. The guidelines were fostered to a large extent by the growing use of lasers and the quickly recognized hazard posed by viewing laser sources.[3,7-12]

BIOLOGICAL EFFECTS

For each adverse effect upon the eye in the UV spectral region, the dominant injury mechanism is initially a photochemical reaction in the exposed tissue. The relative spectral risk for each type of injury is determined by a photobiological *action spectrum*. As with any photochemical reaction, the action spectrum describes the relative effectiveness of different wavelengths in causing a photobiological effect. The action spectra for UV photokeratitis (or "welder's flash") for humans as well as animals,[13-14] for photoretinitis[15-17] and acute cataractogenesis[18-19] have been published. Epidemiological studies of UV effects upon the eye support laboratory findings that acute effects are largely the result of UV-B radiation exposure.[3] The product of the dose-rate and the exposure duration always must result in the same exposure dose (in J/cm^2) to produce a threshold injury. This characteristic of photochemical injury mechanisms is termed the *Bunsen-Roscoe Law*, or the rule of reciprocity (of exposure duration and irradiance), and helps to distinguish these effects from thermal burns.

There are at least four separate types of hazards to the eye from UVR exposure, and protective measures must be chosen with an understanding of each:

1. *Photokeratoconjunctivitis* (acute inflammation of the cornea and conjunctiva as in "welders' flash") has been defined for wavelengths from 200 nm to 400 nm and cataractogenesis (lens cataract) has been demonstrated principally in the wavelength range from 290 to 320 nm, and perhaps occurs at greater wavelengths. The clear relationship between UV-B exposure and the onset of symptoms a few hours later conclusively prove that UVR causes this acute ocular effect. The signs and symptoms seldom last for more than a day or two.[13-14]

NOTE: The opinions or assertions herein are those of the author and should not be construed as reflecting official positions of the Department of the Army or Department of Defense.

2. *Pterygium and droplet keratopathies*, as age related pathologies of the cornea, which are common in island environments rich in UVR exposure have frequently been linked to chronic, life-long UVR exposure.[20] There are clearly other potential factors.

3. *Cataractogenesis*. There has long been a suggestion that UVR causes cataracts. The earlier age of onset of cataract in equatorial zones has led to a number of theories to explain this latitudinal dependence. Although some studies conclude (and it has long been argued) that exposure of the human eye to UVR plays an etiologic role in the development of some corneal pathologies,[17-20] this role in cataractogenesis has been questioned by others.[20-27] Even more under debate are theories that suggest that UVR and light may affect retinal disease.[22,26-27] However, epidemiologic studies which carefully consider individual exposure and ocular dosimetry show a clear relationship between life-long UV-B exposure and cataract.[23]

4. *Photoretinitis*. The principal retinal hazard resulting from viewing bright visible light sources is photoretinitis, e.g., *solar retinitis* with an accompanying scotoma ("blind spot"), which can result when one stares at the sun for several minutes. Solar retinitis was once referred to as "eclipse blindness" with an associated "retinal burn." Only in recent years has it become clear that photoretinitis results from a *photochemical* injury mechanism following exposure of the retina to shorter wavelengths in the visible spectrum, i.e., from violet and blue light. Prior to conclusive animal experiments at that time (1976),[3] photoretinitis was thought to result from a thermal injury mechanism. However, it has been shown conclusively that an intense exposure to short-wavelength light (hereafter referred to as "blue light") can cause retinal injury. The action spectrum has been defined principally from 400 nm to 550 nm in the visible; but, wavelengths from 310 nm to 400 nm in the UV can also produce effects in aphakic eyes (i.e., eyes with lens surgically removed), and possibly even somewhat in normal eyes. Normally, UV-A radiant energy is <u>not</u> implicated in this type of retinal injury unless the normal (UV-absorbing) crystallin lens of the eye has been surgically removed, as during cataract surgery. Accelerated ageing of the macula (age-related macular [central retinal] degeneration) may also be related to chronic retinal exposure to UV-A and short-wavelength visible light.[15]

Blue-light retinal injury (photoretinitis) can result from viewing either an extremely bright light source (e.g., the sun) for a short time, or a bright light of lesser brightness (e.g, a tungsten-halogen filament) for longer exposure periods.[3] Figure 1 summarizes the aforementioned biological effects.

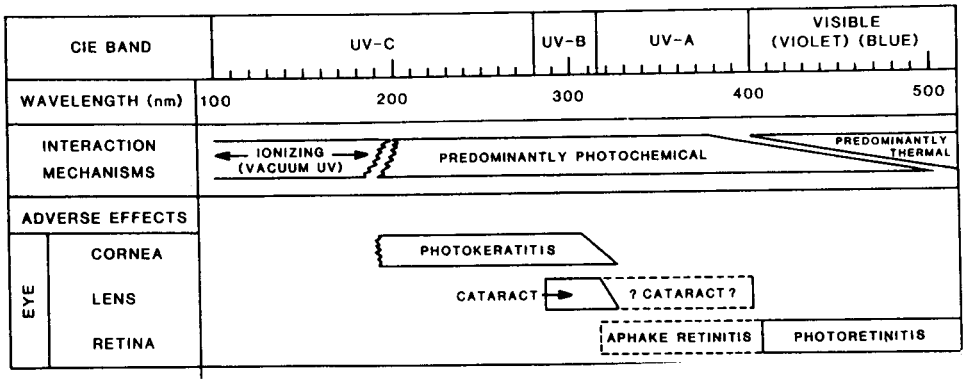

Figure 1. Adverse Biological Effects Attributed to Ultraviolet Radiation and Short-Wavelength Light.

GEOMETRY OF EXPOSURE

Exposures of the anterior structures of the human eye to UVR depend upon the relative position of the light source and the degree of lid closure. In bright sunlight, the orbital ridge above the eye and the upper lid considerably shade the cornea from excessive UVR exposure, thus limiting the chance for UVR photokeratitis in bright sunlight, except when viewing highly reflective snow.[3-6] Geometrical factors dominate the determination of ultraviolet radiation (UVR) exposure of the eye. The degree of lid opening limits ocular exposure to rays entering at angles near the horizon. Clouds redistribute overhead UVR to the horizon sky. Mountains, trees and building shield the eye from direct sky exposure. Most ground surfaces reflect little UVR. The result is that highest UVR exposure occurs during light overcast where the horizon is visible and ground surface reflection is high. By contrast, exposure in a high mountain valley with green foliage results in a much lower ocular dose. Other findings of these studies show that retinal exposure to light and UVR in daylight occurs largely in the superior retina.[6]

Despite a substantial literature on the adverse effects of ultraviolet radiation (UVR) and intense visible light upon ocular structures--particularly upon the retina--controversy still surrounds the question of whether natural and man-made light sources are really hazardous under normal viewing conditions. Acute studies of UVR and light injury of the cornea, lens and retina of experimental animals have generally employed excessive light levels. Although scientific evidence accumulates to indicate that chronic exposure conditions may accelerate ageing processes in the retina, the quantitative question of: What is safe?" remains to be conclusively answered. In recent years the potentially adverse effect of UVR exposure of the eye have been the subject of numerous scientific reviews and meetings. Present scientific knowledge in this area impacts upon the determination of optical product safety, ophthalmic instrument safety, and the design of sunglasses, and ophthalmic lenses. The one apparent controversy with respect to thresholds of UV photokeratitis and the ACGIH EL for UV-B can be seen at 310 nm in Figure 2. The reported threshold may be higher, since the bandwidth of the xenon-arc monochromator exposure system was at least 5 nm, and the effective wavelength would be less than 310 nm along such a steep slope.

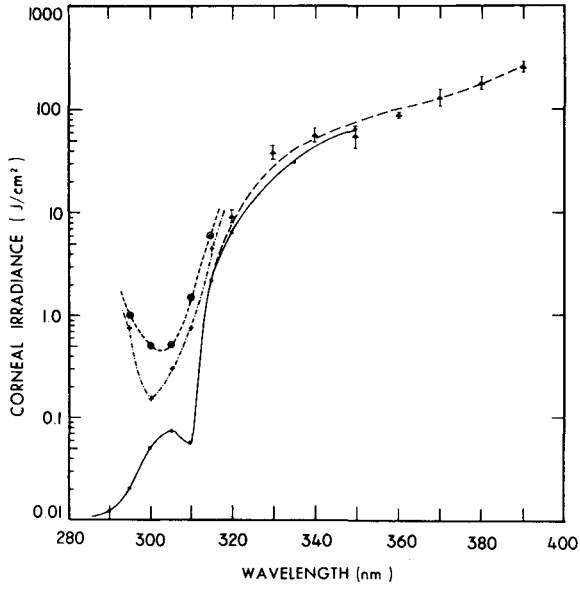

Figure 2. The thresholds (inverted action spectra) for photokeratitis[13-14] and cataractogenesis[18] are shown as a function of wavelength. Note the logarithmic ordinate.

Ultraviolet radiant energy at wavelengths shorter than 280 nm (referred to as UV-C) is totally absorbed in the cornea and is totally imperceptible. Wavelengths in the UV-B (280 - 315 nm) are absorbed largely in the cornea, but also reach the crystallin lens, and at wavelengths greater than 300 nm, there is a very small fraction of energy (of the order of 1 % or less) that may reach the retina.[3,15-17] Higher UV-A transmittance of the lens is most notable during youth.[3,20] Wavelengths in the UV-A (315 - 400 nm) spectral band are strongly absorbed in the lens; much of this energy is re-emitted as fluorescence in the visible spectrum.[28] In the absence of visible light, UV-A radiant energy may be perceived by fluorescence of the lens and some visual sensitivity to wavelengths below 400 nm which reach the retina. This general perception of a UV-A source can be described as a fuzzy, somewhat discomforting-to-view, blue-grayish light.[28] UV-A emitting lamps (frequently termed "black lights") are used extensively in industry for non-destructive testing by fluorescence techniques, and in entertainment and novelty applications to illuminate fluorescent signs, posters, in discos for special effects, in mineralogy to classify certain minerals, etc. In these applications, the eye is normally exposed to UV-A irradiances less than 1 mW/cm^2.[3] Although the UV-A at ground level from sunlight is 1 - 5 mW/cm^2, the actual UV ocular exposure to ground reflections and skylight is normally about 1 mW/cm^2 or less.[21]

THE EYE'S EXPOSURE OUTDOORS

Our exposure to UVR and light outdoors constantly changes during the day. We are largely unaware of the degree of these changes--especially the change in exposure rate of UV-B (the shortest wavelengths in terrestrial sunlight). This spectral change is not apparent in the visible part of the sun's spectrum until nearly sunset; and an attempt to take a color photograph either very early or very late in the day will result in a picture that is yellowish or orange in hue. We are fortunate that the Rayleigh scattering of sunlight by air molecules favors UVR and blue light (hence the blue sky). For longer pathlengths through the atmosphere when the sun is low in the sky, much more UVR and sunlight is scattered and the sun which is white at noonday becomes yellow and then orange as less UVR and blue light are present in the direct rays. When the sun is overhead and "white," it would take only 90 seconds to stare at the sun and receive a blue-light retinal burn. A few hours later, it would take several minutes, and it is virtually impossible at sunset. Thus, the geometry of exposure as well as the spectrum (hue) plays a major role in determining the hazards of viewing the sun. Fortunately, we seldom look directly overhead when the sun is very hazardous to view, and the sun is not very hazardous to view when the sun is sufficiently low in the sky to fall within our normal field-of-view. Furthermore, when the sun is greater than about 10° above the horizon, we squint, thus shielding the retina from direct exposure. Figure 3 illustrates the limited angular exposure.

Although the cornea is more sensitive to UVR injury than the skin, we seldom experience a corneal burn when out in sunlight. Again, the geometry of exposure helps. When the sun is overhead and UVR exposure is most severe, the brow ridge and upper lid shield the cornea, and if the eye is turned away from the sun, the more intense scattered UVR from overhead strikes the cornea at a grazing incidence where most is reflected and little is absorbed. Only when the incident UV rays are parallel to the pupillary axis are most rays absorbed (in fact, 98 % are absorbed). When one looks down at the snow the UVR is reflected directly into the eye, hence the eskimos' traditional eye protector, the slit in whalebone, provided geometrical rather than spectral protection against the UVR exposure. The strong dependence of reflections with angle of incidence is termed Fresnel's Law of Reflection. This Law not only explains the survivability of the cornea in an overhead bath of UVR, but also the glare experienced over water. When the sun is overhead, a body of water reflects the UVR upward, but only approximately 2% is reflected. When the sun is low in the sky, much of the incident light is reflected, but now the UVR and blue light have been filtered out of the direct rays by the atmosphere and are therefore harmless. Nevertheless, discomfort glare originates from the strong water reflections which because of polarization by reflection and scattering can be selectively filtered by polarizing lenses. Such lenses may not necessarily filter out the UVR.

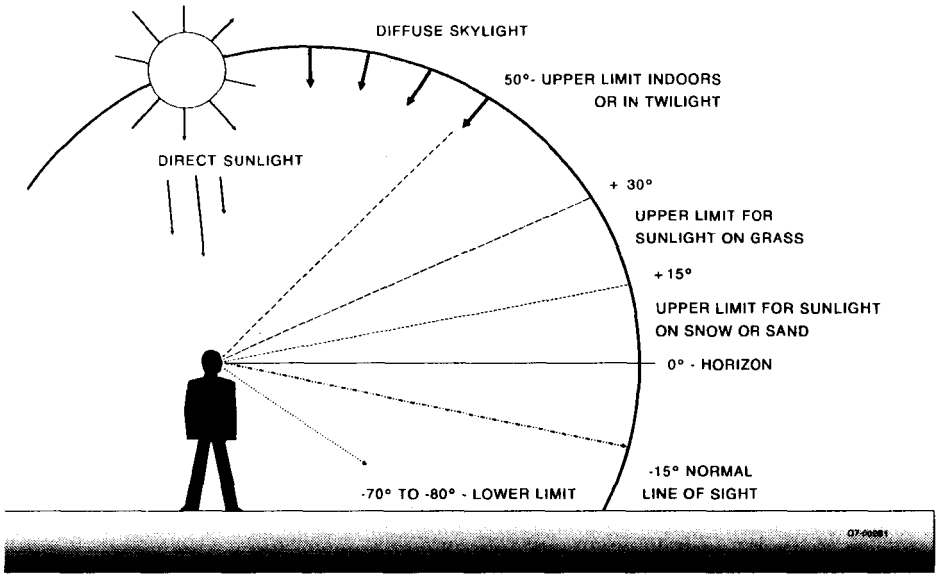

Figure 3. The limited solid angular exposure to UVR in the outdoor environment is limited by the geometry of the brow-ridge, but also strongly affected by lid position (squinting), which depends on the brightness of the visible light environment.[4-6]

UVR EXPOSURE FROM ARTIFICIAL SOURCES

The envelopes of most commercial lamps used for illumination filter out UV-B or are installed in a filtering lighting fixture. However, in some industrial processes, workers may actually be exposed to levels greater than one would experience in the outdoor environment. In this figure, the relative risk of fixating upon different types of bare lamps after the spectral distribution has been weighted by biological action spectra for uv photokeratitis and the retinal "blue-light" hazard. Since the ambient optical radiation levels in our natural environment are barely tolerated, it is hard to imagine that an exposure to an artificial light source would be tolerated at an exposure level exceeding the outdoor levels. Aside from pulsed lasers, where the individual may have no natural protective mechanisms such as the blink reflex of the eye, I have not encountered an instance where an individual repeatedly exposed himself or herself to levels where acute injury took place.

PROTECTIVE MEASURES

Where feasible, it would appear to be desirable to provide eye protection against an hypothesized chronic-exposure hazard simply to be on the safe side. If eye protection is worn, peripheral protection is paramount because of the *Coroneo Effect*.[6] However, when protective measures are extremely costly, or they possibly introduce another hazard, one has a serious dilemma. Such a dilemma has apparently arisen with regard to ultraviolet absorbing intraocular lenses.[17]

CONCLUSIONS

The present ICNIRP EL's and ACGIH threshold limit values (TLV's) for UVR are based upon an understanding of both acute and chronic effects upon the eye. Although exposures to optical radiation in the physiological range have generally been accepted as safe, greater knowledge today suggests that the absence of acute effects does not mean that some damage has not occurred at the

molecular level. Delayed effects appear to be possible from UVR exposure to the eye as well as the skin. Furthermore, growing evidence suggests that retinal degradation may also occur from chronic exposure to short wavelength light, and possibly from the trace amount of UV-A that reaches the retina as well. The present exposure limits probably reduce the risk from all of these delayed effects quite significantly, but one cannot argue that the risk is zero. As with almost all physical and chemical agents, one cannot speak of "zero risk" -- it is scientifically specious.

CLIMATOLOGY OF UVB AND OZONE VARIATIONS & THE GLOBAL SOLAR UV-INDEX

C.R. Roy , H.P. Gies and S.J. Toomey
Australian Radiation Laboratory, Lower Plenty Road, Yallambie, Victoria, Australia 3085

INTRODUCTION

Human overexposure to solar ultraviolet radiation (UVR) can result in acute and chronic adverse health effects on both the skin and the eye. Skin cancer (both non-melanoma and malignant melanoma) and cataract impose a huge social and cost burden on many societies throughout the world. Such human health problems can be avoided if the individual reduces their UVR exposure. Unfortunately enlightenment may not help persons who have experienced high episodic exposures during childhood as this appears to be an important causal factor in melanoma. In some countries public educational campaigns have been underway for decades in other countries they are just beginning; the global solar uv-index provides a globally consistent means of reporting or predicting UVR as part of public education on UVR exposure. There are now indications that some of these programs have been effective in halting the climb in melanoma incidence.

The UVR, and in particular UVB, reaching the earth's surface varies with both latitude and time (both of the day and year). The transmission of the extraterrestrial radiation through the atmosphere is determined by ozone, clouds, aerosols and to a lesser extent, trace gases. In recent decades there has been considerable concern that long-term changes in ozone and perhaps clouds and aerosols may result in changes in the UVB at the earth's surface.

Atmospheric attenuation of solar UVR

The extraterrestrial solar spectrum is rich in UVC (200-280 nm), UVB (280-315 nm) and UVA (315-400 nm). However passage through the atmosphere removes the UVC and most of the UVB component. This reduction is due mainly to absorption by ozone and molecular scattering. The amount of transmitted UVB is sensitive to even small changes in the ozone column (see Figure 1).

The spectral irradiance can be calculated for different total ozone amounts using an ARL-modified version of the Björn model (1). The decrease in the ozone column from 300 to 270 DU results in the UVB increasing by 95%, 20% and <5% for the wavelengths of 295, 305 and 315 nm, respectively. Overall this 10% decrease in ozone results in about a 10% increase in total UVB (280-315 nm).

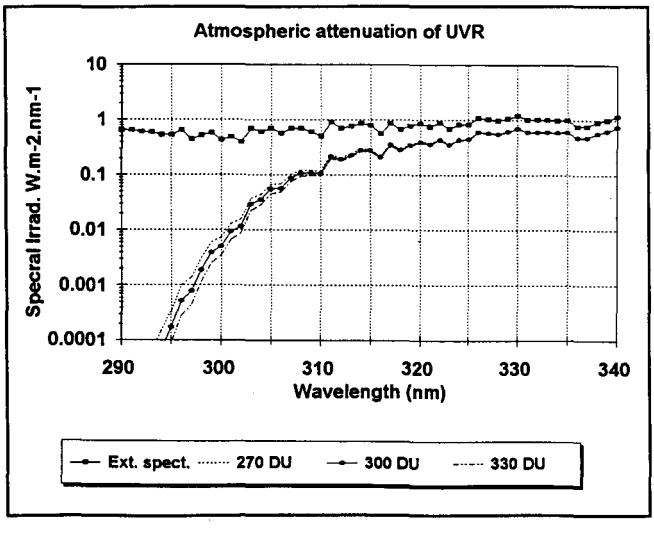

Figure 1
Spectral irradiance at the earth's surface for clear skies, a SZA of 5° and for three different ozone columns. Also shown is the extraterrestrial spectral irradiance.

Solar zenith angle (SZA)

The SZA describes the angle between the local vertical direction and the direction of the solar disk. The smaller the SZA, the less atmosphere the solar radiation must pass through and hence the greater the solar UVR (see Figure 2). The SZA varies with time of day and year and with latitude. Only within the tropics is a SZA of 0° attainable (as the sun passes overhead).

For a given ozone column (here 270 DU) the total UVB for SZA=35° is 64% of its value at SZA=5°. At 70° the corresponding value has dropped to 6.4%. For total UVR the effect is less with values of 77% (35°) and 23% (70°) obtained for the two examples.

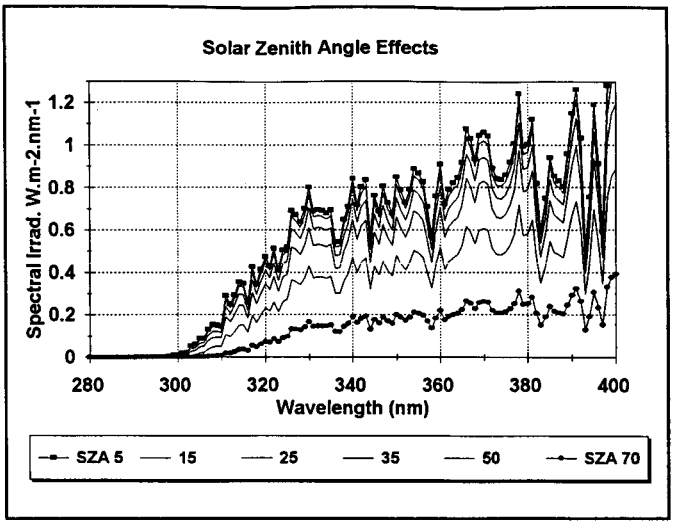

Figure 2.
The effect of changing SZA on the spectral irradiance at the earth's surface.

Total ozone

Stratospheric ozone is produced by the photolysis of oxygen molecules by short-wavelength solar UVR (wavelengths <242 nm). Ozone is formed largely in the equatorial regions and it is transported polewards. The amount of ozone is determined by the dynamic balance between the production and several catalytic destruction cycles and by transportation processes. Ozone depletion concerns in recent decades result from a man-made chlorine destruction cycle.

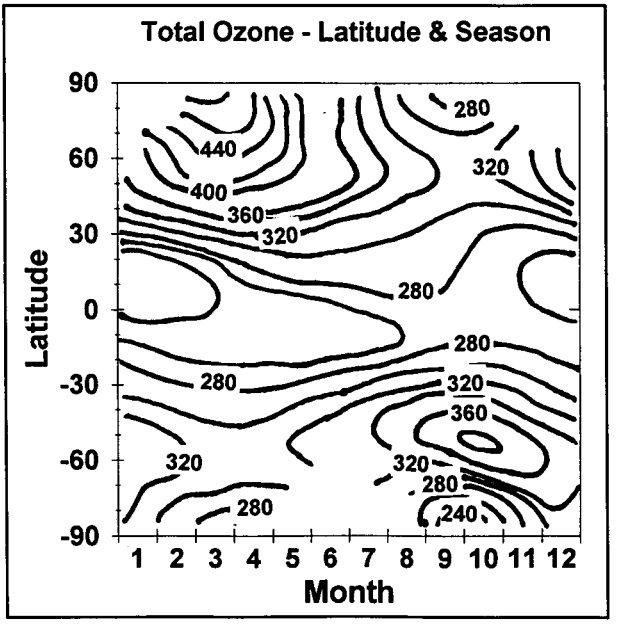

Figure 3.
Indicative latitudinal and monthly variation of total ozone (DU). Values are averages for the years 1979-89 from the TOMS satellite data (2).

Ozone depletion

Both satellite and Dobson ground-based measurements show decreases of total ozone in winter in the Northern Hemisphere. There is evidence of significant decreases in spring and summer in both the Northern and Southern Hemispheres at middle and high latitudes. There is no evidence for any significant trends in the tropics. Throughout the 1980s and 1990s there have been deep and extensive ozone holes in the southern spring.

Table 1.
Total ozone trends in units of percentage change per decade (3).

Season	TOMS Data: 1979-91 45°S	Equator	45°N
Dec-Mar	-5.2	+0.3	-5.6
May-Aug	-6.2	+0.1	-2.9
Sep-Nov	-4.4	+0.3	-1.7

The analysis shown in Table 1 indicates that little or no depletion has occurred in the equatorial region and at 45°N the greatest depletion occurs during winter when solar UVB is at its lowest. At 45°S significant depletion occurs all year with summer only slightly less than winter.

Effective UVR: computed and measured

The biological effectiveness of ultraviolet radiation is very wavelength dependent with UVB being considerably more biologically effective than UVA radiation. Within the UVB, between 300 and 315 nm, the relative spectral effectiveness decreases by three orders of magnitude which means that spectral measurements within this region must be very precise or large errors in the calculated effective radiation will result. The erythemal response curve of the International Commission on Illumination (4 and Table 2) is used to weight the spectral irradiance distribution.

Table 2
CIE erythemal effectiveness function.

Effectiveness function (S_λ)	Wavelength region (nm)
1.0	$250 \leq \lambda \leq 298$
$10^{0.094(298-\lambda)}$	$298 \leq \lambda \leq 328$
$10^{0.015(139-\lambda)}$	$328 \leq \lambda \leq 400$

The amount of UVR required to induce sunburn or erythema in normal human skin is usually designated as the minimum erythemal dose (MED). Using the CIE erythemal effectiveness function, the MED for skin type I, the most sensitive type (skin that always burns and never tans), is approximately 200 J m^{-2} (5).

The monthly average daily erythemal UVR for Melbourne (37.8°S) is shown in Figure 4 for six of the years between 1986 and 1993. The general shape is typical of a mid-latitude site and is determined by the SZA variation over the year. The annual total MEDs are also given. The average annual total is 4160±270 (SD). Year-to-year differences are due largely to variations in cloud cover and total ozone.

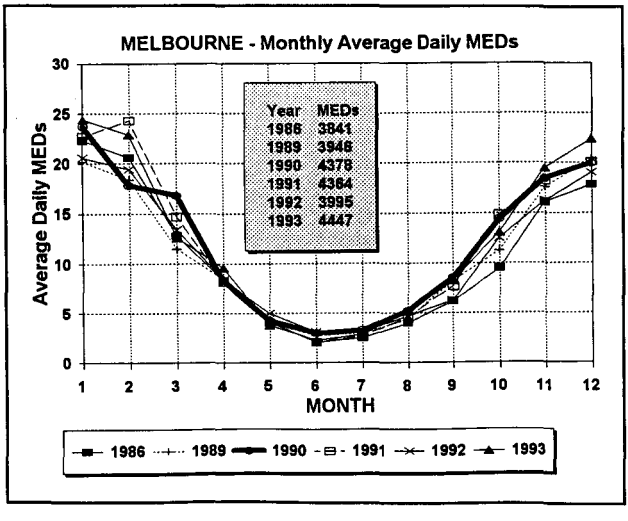

Figure 4. Variation of the total mean erythemal UVR (in MED units) for Melbourne in the years indicated.

The global distribution of erythemal irradiance can be calculated (3) and this is shown in Figure 5. The patterns are as expected with very high and relatively constant values throughout the equatorial and tropical regions. In the mid-latitudes the values are high in summer but are very low in winter. The high levels in Antarctica as a result of the ozone hole are not represented in this plot.

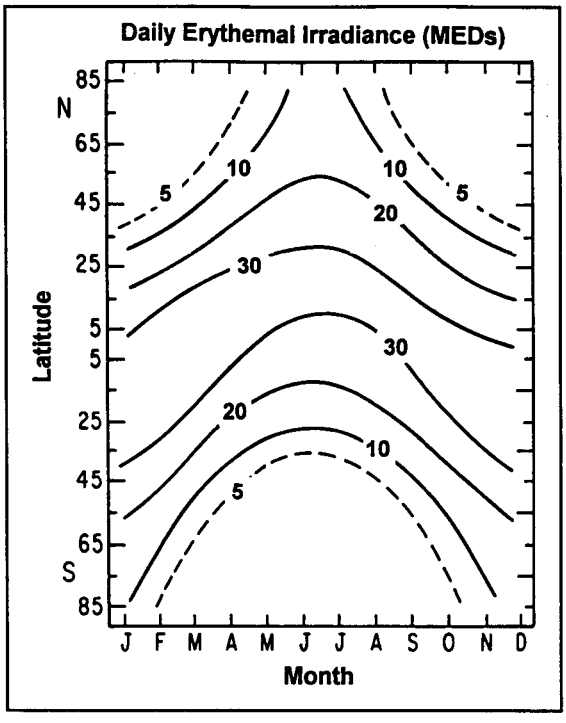

Figure 5. Latitudinal and monthly distribution of integrated daily erythemal irradiance in units of MEDs. Computed for clear skies and based on TOMS zonally averaged total ozone for 1980 (3).

Measurements and calculations have been made of erythemal or effective UVR for a number of locations in both the Northern and Southern Hemisphere and some of these are shown in Figure 6. The results are consistent with the data presented in Figure 5. The results for the southern hemisphere (6) are measurements and hence include the effect of cloud cover which can be quite significant; for example, during the tropical 'wet-season'. The high latitude results (9) are measurements from Finland. The more recent results of Seckmeyer et al.(10) agree largely with Figure 5 but also illustrate the impact of the Antarctic ozone hole on the southern hemisphere results.

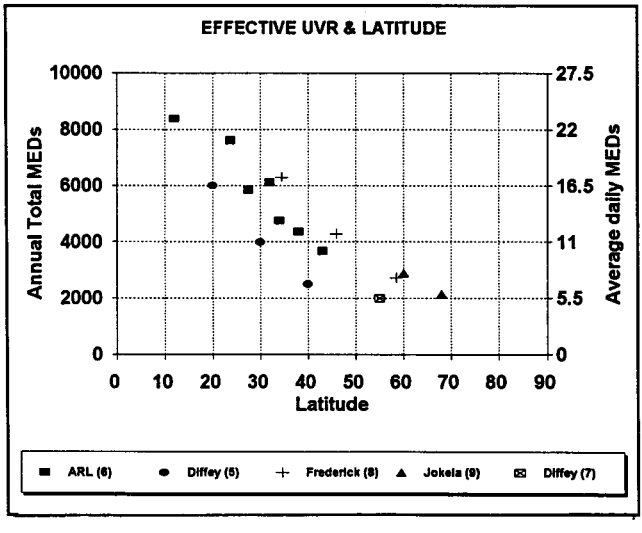

Figure 6. Measured effective UVR during the years 1989-1991. The results for the NH and SH are not differentiated on the plot.

Erythemal UVR and clouds

The transmission of UVR through clouds is a function of the optical depth. Solar UVR transmissions can range from a few percent up to 80 or 90% for cirrus clouds. In the presence of clouds measured UVR at the earth's

surface can range from practically 0% to 120% of the clear sky value. The enhanced solar UVR (11) is the result of scattering from the sides of cumulus clouds - obviously these levels will only be obtained when the solar disk is not blocked by cloud.

There is still much research to be done in this area. Difficulty arises when there is the need to include cloud cover in computer-generated UVR irradiances. A number of different parameterisations have been used (2). Data for Australia is reasonably well-represented by: $Irrad_{cloud}/Irrad_{clear} = 1 - 0.06C$; where C is the cloud cover in octas.

Cloud droplets which are considerably larger than aerosols are assumed to have scattering cross-sections that will be largely independent of wavelength throughout the UV region and therefore clouds are not expected to have any wavelength dependence transmission factors in the UV.

Four years of daily total erythemal data (in MEDs) is shown in Figure 7 along with the computed clear sky data. The large variation is due mainly to cloud although the enhanced summer values are the result of short-term total ozone reductions.

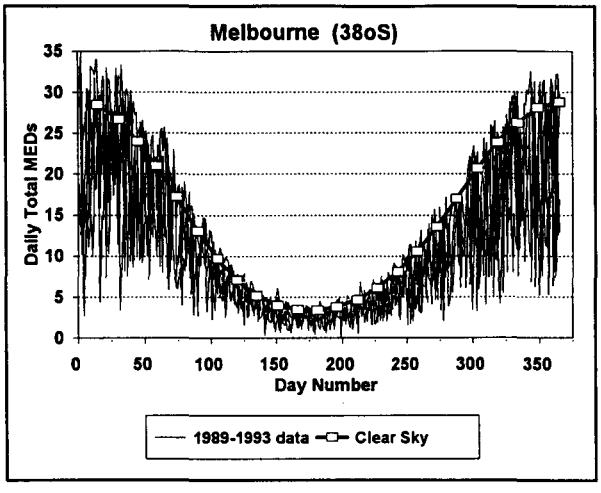

Figure 7. Fours years of erythemal data for Melbourne (37.8°S). Also shown is the computed clear sky data.

Erythemal UVR and SZA

The erythemal UVR is obviously quite dependent on the SZA. With increasing SZA there is a disproportionately greater drop in the UVB than the UVA and because of the greater biological responsivity in the UVB the weighted irradiance will drop at an even greater rate (Figure 8).

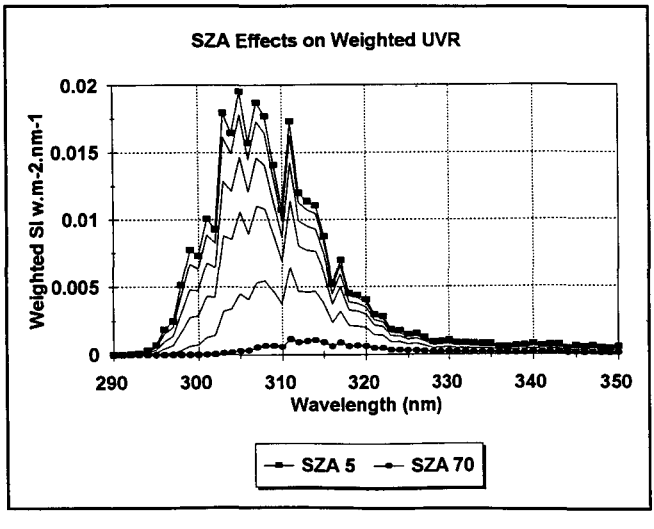

Figure 8. The effect of SZA (5°, 15°, 25°, 35°, 50° and 70°) on the effective spectral irradiance. Computations have been performed for an ozone column of 270 DU. The unweighted spectral irradiances are given in Figure 2.

It can be seen that the peak in the weighted spectral irradiance shifts to longer wavelengths with increasing SZAs.

Table 3 provides the integrated effective irradiances (280-400 nm) for different SZAs. Similar results are also provided for total ozone columns of 300 and 330 DU. The numbers in parentheses give the time (minutes) to reach 1 MED at that constant irradiance. Values range from 10.9 to 190 minutes or 5.50 to 0.3 MEDs/hour.

Table 3

Effect of SZA on the integrated effective irradiance ($W.m^{-2}.nm^{-1}$) for different ozone column amounts. The number in parentheses is the time in minutes to achieve 1 MED.

SZA	270 DU	300 DU	330 DU
5	.307 (10.9)	.269 (12.4)	.239 (13.9)
15	.283 (11.8)	.249 (13.4)	.221 (15.1)
25	.240 (13.7)	.211 (15.8)	.188 (17.7)
35	.185 (18.0)	.163 (20.5)	.145 (23.0)
50	.100 (33.4)	.088 (37.8)	.079 (42.2)
70	.022 (154)	.019 (171)	.018 (187)

Trends in ozone and calculated trend in erythemal UVR

The averaged trend in ozone and the corresponding trend in erythemal UVR is shown in Figure 9 for the period 1979-89 (2).

The asymmetrical nature of the plot is due to the large springtime losses in Antarctica. Unfortunately the erythemal data which has been computed for clear skies has not been verified at this point in time because of the absence of accurate measurement over a sufficient period of time.

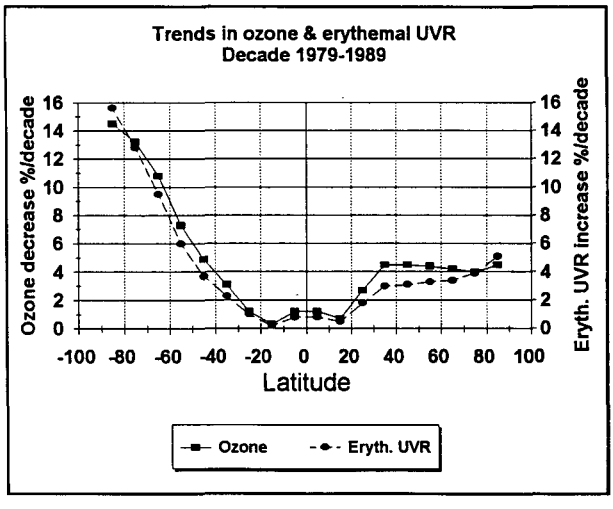

Figure 9. Trend in ozone (zonally averaged) for the decade 1979-89. The computed change in erythemal UVR is also given (2).

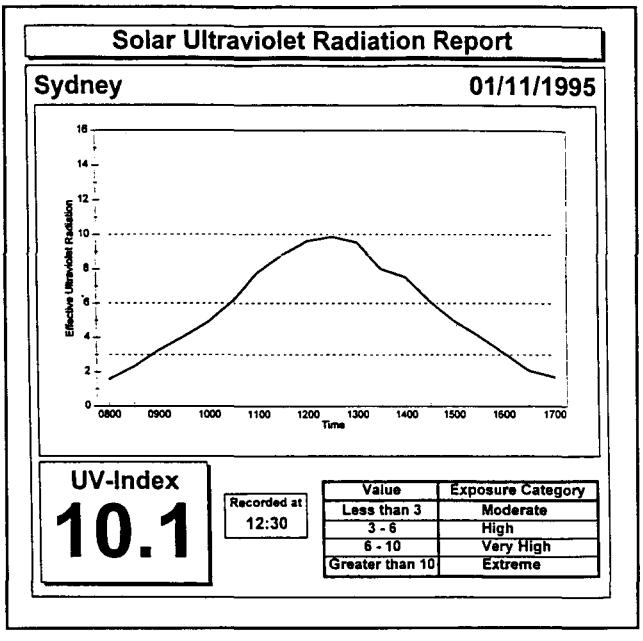
Educational campaigns

Public and professional education about skin cancer commenced in Australia in about 1960 with programmes in both Queensland and Victoria (12). Since 1981 the Anti-Cancer Council of Victoria has run a "Slip!, Slop!, Slap!" and later "Sunsmart" national campaigns (13). The two aspects to skin cancer control - prevention and early detection - are both embraced by what is now a national program coordinated by the Australian Cancer Society.

The Australian Radiation Laboratory, using data from its national measurement network (14), provides to the media a daily chart of UVB for the capital cities in each state. These are broadcast in the weather section on the nightly television news report. This 12-15 second time slot provides a unique opportunity to reach a large audience and to help educate the public about UVR and the link or otherwise to ozone, cloud cover and daily temperature. This has generated considerable public interest. Figure 10 shows a typical report that is provided to the media at 1700 hours, local time. The template the media uses is colour graded with red and orange representing the highest UV categories.

Figure 10. Typical daily UVR chart provided to the media.



Global Solar UV-Index

The index, a joint recommendation of WHO, WMO, UNEP, ICNIRP and IARC (15) is a measure of the solar UV levels relevant to health effects and is useful for warning people about the degree of hazard that existed or could exist on a particular day. The index is calculated by multiplying the daily maximum CIE-weighted UVR, averaged over 30 minutes, by 40. For the first time there will be a global system in place which will make comparisons straightforward and will also assist tourists. Figure 10 also provides the index for the day and this allows the public to compare with the previous day's prediction.

Many schools and community groups are taking a greater interest in minimising UVR exposure and a variety of initiatives have emerged from the enforced wearing of hats in school grounds, modification of the hours that schoolchildren spend outdoors to the planting of more shade trees in open areas. The provision of shade structures in homes, school grounds and in public areas including parks is strongly advocated as a sensible radiation protection strategy. Appropriate materials are available (16,17) although care should be taken in design as users can often still be exposed to scattered solar UVR.

Evaluation of programs

Evaluation of a prevention program measures initially a change in knowledge and attitudes, then a change in behaviour and eventually a change in the incidence and mortality rates of skin cancer (13).

A survey of sunscreen use conducted on Brisbane beaches (18) found about 70% of females and males applied sunscreen. Half of the sunscreens provided the maximum protection (SPF 15+) and almost 90% used a waterproof formulation. However the sunscreen was not applied over the entire body with over half neglecting ears and lower limbs.

Following the introduction of the Sunsmart programme, Hill (19,20) conducted surveys in three summers in the period 1988-1990 to determine trends in exposure to sunlight by monitoring the prevalence of sunburn and sun-related attitudes and behaviours in 4,400 adults. In 1988 up to 18% of some groups reported sunburn in a given weekend. Over the three years the average proportion sunburnt dropped from 11% to 7%. They also found that substantial attitudinal changes also occurred with hat wearing and sunscreen use increased to 29% and 21% respectively. There was no clear trend in the proportion of the body covered by clothing - the mean proportion of body surface area covered being 70%. However, there was significant evidence that beliefs were more realistic and conducive to sun-protective measures.

With regard to skin cancers it is still too early to fully evaluate the effectiveness of the educational campaigns but there are promising indications. It has been reported that excised cutaneous malignant melanomas are becoming thinner which indicates that they are being found earlier (in more than 90 per cent of cases there is no clinical evidence of secondary spread of the cancer) which in turn results in a higher 10 year survival rate (21). In Australia it has been found that melanoma mortality has peaked with figures showing a small but significant fall in rates for women and a plateau in the male death rate. For 1990-91 the age-standardised

mortality rates in Australia were 4.9 and 2.5 per 100,000 for males and females respectively (22). It is expected that a consistent fall will be found over the next two years (23).

Conclusions

Much of the world's population reside in locations where it is easy to obtain large doses of solar UVB for at least part of the year. The individual's genetic susceptibility and personal behaviour will determine whether or not exposure will ultimately result in adverse health effects. Continuing atmospheric ozone depletion places even more pressure on the individual to adopt sensible outdoor behaviour.

Educational programs aimed at both the workforce and the public have succeeded in creating an awareness of the dangers of overexposure to ultraviolet radiation. The global solar UV-index is a useful addition to this campaign. The fact that changes in knowledge and attitudes have been accompanied by behaviour changes indicate that educational programmes are having an effect in some countries. Consumers have the products available which will provide good personal protection and the information to enable a proper choice. The adoption of sensible behaviour and personal protection can help to achieve :

- avoidance of sunburn which is accepted to be a major risk factor for melanoma and
- a reduction of an individual's accumulated UVR dose during work and leisure hours which has a role in non-melanoma skin cancer.

CHRONIC EFFECTS OF UV ON HUMAN SKIN

Jean Pierre CESARINI, M.D.,
Institut National de la Santé et de la Recherche Médicale, Laboratoire de Recherche sur les Tumeurs de la Peau Humaine, Fondation Ophtalmologique Adolphe de Rothschild,

INTRODUCTION

UV radiation causes a number of chronic degenerative changes in the skin, mainly in Caucasian populations as a result of its action on keratinocytes, melanocytes and components of the dermal stroma including fibrous tissues (collagen, elastin) fibroblasts and blood vessels. Among the degenerative changes, skin cancers are the most dreadful perspectives, but photoaging is of the most important general concern for the population.

MECHANISMS OF UV CARCINOGENESIS

There is abundant evidence that UV causes damages by direct photochemical effects and oxidative effects[1]. There is also evidence that activated oncogenes and mutated tumor-suppressor genes are present in some skin cancers[2-3]. From a review of the animal studies, it has been found that the effectiveness is to peak in the UVB range, that UVA is also carcinogenic at a much lower level of effectiveness[4]. It is believed that UVC is not effective for human carcinogenesis and that visible light will not play a significant role. Also from animal studies, the immune system may be deeply altered[5]. The suppression of systemic responses may favor the malignant cell proliferation and the metastatic processes. In man, beside anecdotal reports, no firm assessment can be made. Figure 1 represents the most comprehensive scheme to illustrate the complexity of carcinogenesis

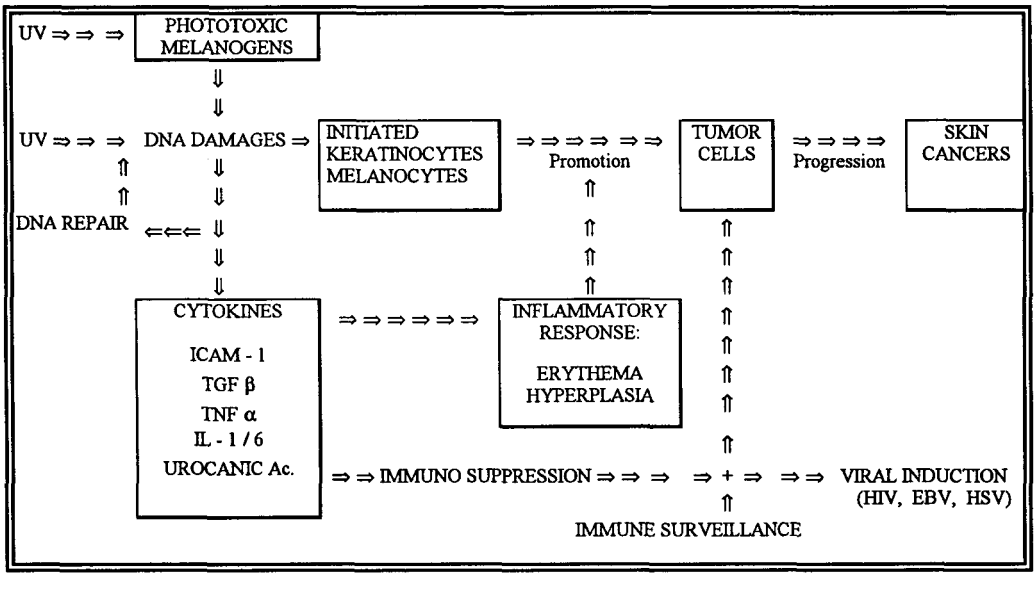

Figure 1. Scheme adapted from Ref. 5, modified to include melanin and melanocytic system.

Following irradiation, one can observe the production of p53 protein[2], the expression of a tumor suppressor gene which blocks the cell division in G1, allowing the DNA damages to be repaired[6]. The p53 protein is rapidly induced and has normally a very short half-life. If the damage is unreparable, the p53 pushes the cell into programmed cell death, called apoptosis (sunburn cells)[3]. Loss of normal function of the product of the p53 gene is usually caused by missense point mutations. The mutations in the p53 gene are very common alterations[8] and 5 specific loci of the gene have been found target for UV-induced lesions. The mutated p53 accumulates in the nucleus and is correlated with more aggressive tumors, metastasis and lower 5-year survival rate[6]. The discovery of the role of the p53 gene and other genes involved in the control of cell division is of a major importance to the understanding of the photocarcinogenesis process[7] as illustrated on the following figures 2 and 3.

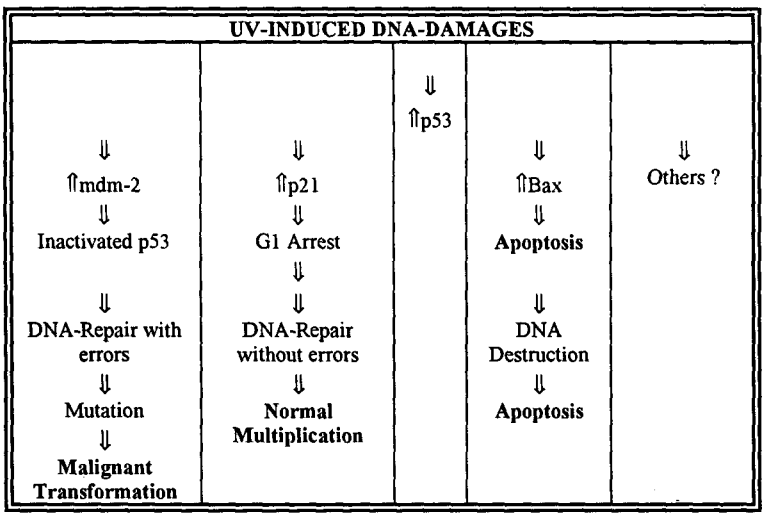

Figure 2. Molecular events following UV irradiation.

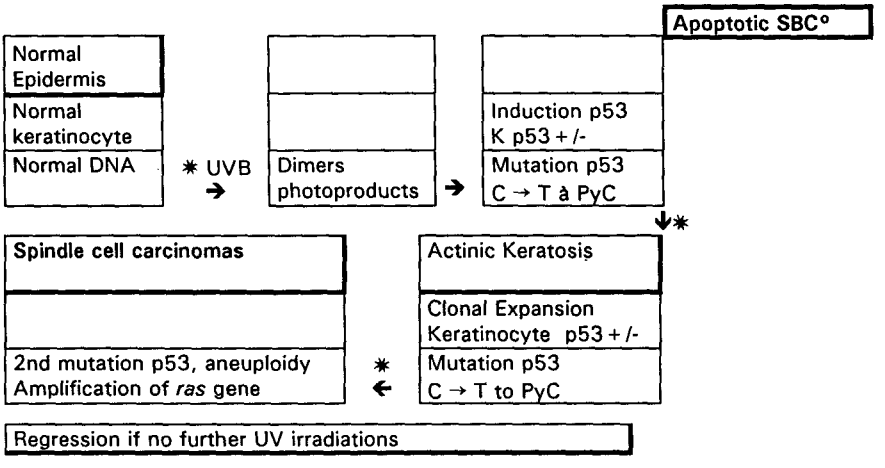

Figure 3: Synthetic aspects of steps initiating photocarcinogenesis

Benign lesions induced by solar exposures

Freckles and **solar lentigo** are pigmented macules occurring on the sun-exposed skin of Caucasians. Their prevalence is increased in highly sun-sensitive skin. Freckles occur commonly in children and are considered as marker for high sensitivity in most of the melanocompromized subjects. Solar lentigo increase with age, and are characterized by an increased number of melanocytes and increased concentration of melanin in the basal layer. An increased risk of melanoma has been observed in relation to freckling in childhood and an increased risk for non melanocytic skin cancer has been found in relation with freckling and prevalence of solar lentigo[9].
Melanocytic nevi are benign proliferations of melanocytes associated, in white populations, with phenotypic indicators of constitutional high sensitivity to the sun. They occurs mainly on body sites, maximally or intermittently exposed to the sun. There number and size are inconsistently associated with multiple sunburns in early life. They are associated with an increased risk for cutaneous melanoma. Precursors of melanins may induce DNA damages by photosensitization reaction[10] and might be responsible for melanocytic proliferation and melanoma.
Solar keratosis are benign proliferations of epidermal keratinocytes. They are very common on permanently exposed body sites in elderly people, in Caucasian populations living in areas of high ambient solar irradiance. They have been considered as phenotypic indicators of cutaneous sun-sensitivity and estimates of total sun-exposure. They are strongly associated with a risk of non-melanocytic skin cancers and are considered as precancerous lesions. They are also regularly associated with signs of dermal sun-induced degeneration (heliodermatosis).

Non-melanocytic skin cancers
There are 2 major types of non-melanocytic skin cancers: basal cell carcinoma (BCC) and squamous cell carcinoma (SCC). They represent one half of all cancers in the white population. Ethnic background is an important determinant for the risk on non-melanocytic skin cancer in Caucasians. In people of southern European origin, born in Australia, relatively to other people born in Australia, the risk of BCC was found 0.56 for those with one southern European grand-parents, 0.17 for two, and 0.1 for three or four[11]. Among recent case control and cohort studies, the relative risk for red or light hair-color population is around 2 for BCC and 2.4 for SCC. The incidence rate of non-melanocytic skin cancers does appear to increase with proximity of the equator with similar gradients for men, women at all ages. The same pattern was observed in Australia and in USA. Epidemiological studies on migrants reveal that the incidence and the mortality is lower in migrants coming from areas of lower sun-exposure when they arrive in the high solar irradiance countries, after 10 years of age. This has shown for BCC and malignant melanoma (studies performed in Australia, Israel, and California).
Beside the skin sensitivity, the total solar exposure has been found of out-most importance. Attempts have been made to estimate the dose-response relationship between UV and SCC and BCC in retrospective cohort study in general[12]. An alternative approach is estimating a dose-response relationship in a whole population. This work has been made in the context of estimating the increase in skin cancer expected from some increment in ground level UV caused by depletion of atmospheric ozone. The results have commonly been expressed in term of biological amplification factor (BAF)[13].

Table I. Recent estimates of BAF for non-melanocytic skin cancers and cutaneous melanoma based on geographical correlation between average annual ambient UV and skin cancer incidence of mortality.

ACTION SPECTRUM FOR PHOTOCARCINOGENESIS

Recently, two large collections of data on carcinogenicity of UV in albino hairless mice, following exposure to multiple sources emitting in the UVA, B, and C ranges, have been combined to produce the best estimate for action spectrum for skin carcinogenesis in animal strains[4]. The figure 4 reproduces the action spectrum and its adaptation to the human skin situation taking in account the absorption by the multiple layers[14]. The definition of the action spectrum is excellent in the UVB range following closely the erythema action spectrum. A large uncertainty is still observed in the UVA range which can be considered as a plateau from 340 to 380 nm. This plateau is closer from the melanogenesis action spectrum in sensitive skin than from pigmentation in darker skin[15].

In a fish model in which UV radiations are able to induce melanomas, the action spectrum is confounded with the erythema action spectrum from 290 to 315 nm, but in the UVA, the tumor develops for 10 times less dose than for the mouse non-melanocytic tumors[16]. This observation raises the possibility of a specific deleterious role of melanin in the genesis of melanocytic tumors, a point which should be linked with some specific melanin-DNA induced damages in vitro[10, 17, 18].

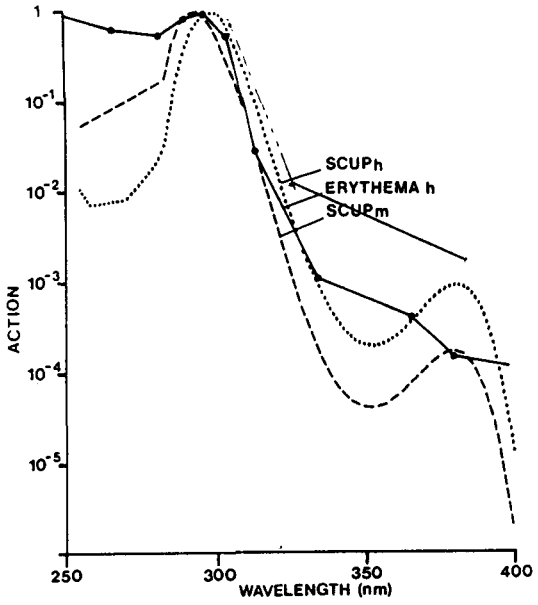

Figure 4. Estimated action spectrum ($SCUP_m$) for induction by UV of SCC in the skin of albino hairless mice (Skh-Hr1). The $SCUP_h$ is for human. On the top, the fish melanoma action spectrum is reproduced.

SKIN AGING AND ELASTOSIS

Chronic excessive UVR leads to the clinical picture recognized as photoaging. The clinical aspect is typically present on permanently exposed body sites, associating dryness, wrinkling and telangiectasia. Irregular pigmentation and solar lentigo are also observed. Histologically, this is caused by thinning of the skin, reduction in the papillary dermis thickness and replacement of the normal collagen-elastic material by elastotic bundles which lacks the elastic properties of the normal dermis. These changes are always associated with BCC and SCC and with a special form of malignant melanoma lentiginous type. The solar aging is dose-related and also related with the skin complexion. The disorders have been reproduced in hairless mice and attempts have been made to produce an action spectrum, using a specific clinical aspect of the mouse skin named sagging. Sayre and Kligman[19] have produced an action spectrum very close to the human erythema

action spectrum. However, Bissett[20] and Wulf[21] proposed a completely different action spectrum where UVA is 100 times more important. A final consensual action spectrum has not been yet obtained.

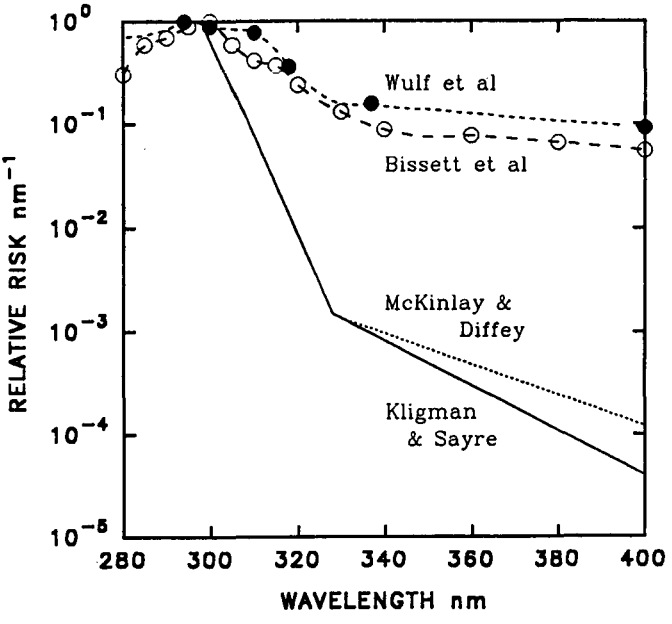

Figure 5. Mouse aging action spectra from reference 19

CONCLUSIONS

Chronic exposures and acute accidents of the skin to UV has been recognized as an important risk for skin cancers in human. Attempts have been made with mathematical models to correlate the ambient UV dose and occupational irradiations with the risk of skin cancers. Development of accurate global measurements of solar irradiance and personal dosimetry is expected in the future in order to reduce the exposure of the general population, to precise the measures to be taken for indoor and outdoor workers.

RECENT DEVELOPMENT ON RADIOLOGICAL PROTECTION AND RADIOACTIVE WASTE DISPOSAL

Annie Sugier
Nuclear Protection and Safety Institute, France

Throughout the world there are numerous specialised conferences organised on radioactive waste. Why debate this subject at IRPA9 among radiation protection specialists ?

In the nineteen sixties and seventies, the aim was claimed to be the finding of a satisfactory technical option. It was the time when the advantages and drawbacks of each option were weighed carefully : shallow land and underground disposal, sea bed, and sea dumping, sending it into space, transmutation... The range of options progressively decreased as public awareness increased particularly regarding any form of disposal in the sea. Therefore, those in charge of waste management attempted to gain international consensus from experts to demonstrate that disposal was technically feasible and that long term safety could be assessed.

The most recent developments on the social and ethical dimensions are opening new perspectives on how properly take into account the interest of future generations.

Within this context, attention is particularly focused on the difficulty of applying to long-term waste management the principles of radiation protection as defined by the International Commission on Radiological Protection (1).

From whence does this difficulty arise ?

Schematically, the radiation protection system which is applied to « practices » in general requires that the source of radiation be under active control. Protection options (physical, institutional and operational) put into place just as much at the design stage as during operation of the corresponding installations are such that exposure levels can be kept below individual dose limits (limitation principle), and, for each source, below dose constraints corresponding to well managed operations (optimisation principle). Practices can even be prevented from being adopted if the disadvantages that could result from it outweigh the advantages (justification principle).

The protection system for practices must take into account both normal as well as potential exposure which are not certain to occur and could be the result of accidental departures from the planned operating conditions following internal or external events.

By analogy with the normal exposures, ICRP recommends for potential exposure compliance with risks limits and risk constraints. The two terms of the risk which must be considered in this case are the probability of an event which could lead to exposure, and the consequences of this exposure.

It is important to stress that, should the potential exposure really occur i.e. the source be no longer under control, it could be necessary to intervene (intervention situation).

For what concerns long term solid waste disposal, there are some specific aspects to be taken into account in applying the radioprotection system. These aspects makes it more complex to demonstrate that the source is under control :

- it is difficult to guarantee institutional monitoring beyond a certain number of years, thus active control of the source ceases. Yet monitoring is a key part of the system because it means application of the principles can be verified and makes it possible to intervene should control be lost.

- it is difficult to assess the exposure situations which correspond to normal or potential development of disposal situations because of the large degree of uncertainty involved, the complexity of the degradation process, the variety of possible events and the difficulties involved in assessing the environmental characteristics.

In 1985, the ICRP dedicated a specialised publication to the disposal of solid waste, ICRP46 (2). This states that during the long time periods of disposal two kind of scenarios of radionuclides release from the site has to be envisaged :

a) normal scenarios involving the gradual degradation of the barriers leading to the slow migration of radioactive elements : these are scenarios which are very likely to come about ;

b) probabilistic scenarios which correspond to processes or events which have constant or time varying probabilistic occurrence.

ICRP46 represented significant conceptual progress because it was the first publication by the Commission which extended the protection system to cover probabilistic situations and thus introduced the idea of potential exposure.

The introduction of this concept was both the result of ideas developed among ICRP experts as well as NEA and the IAEA experts from a broad range of situations, and at the same time was the beginning of the revision of the radiation protection system in light of this concept. As noted above, this concept is dealt with in the 1990 general recommendations of the ICRP (ICRP60) and is the subject of a specialised publication, the ICRP64 : Potential Exposure. A Framework. (3)

However, to the taste of some, the ICRP46, like many pioneering works, presents a too schemative view of the problem of waste. According to these critics, the emphasis is too heavily placed on the quantitative criteria which have to be respected, furthermore the aggregation of the terms of risk does not help the analytical approach to safety assessment.

One of the essential aspects not sufficiently pointed out in ICRP46 in applying the radiation protection system to solid long lived waste lies in the importance of the design phase, and the way in which all the various bits of information convince us that the long-term safety of disposal will be assured *The licensing issue of most concern is not what formal criteria should be, but rather how one can demonstrate compliance with a given set of criteria. (4)*

It is indeed essential to allow the authorities to make decisions based on precise regulatory requirements. These requirements should not be expressed in terms of probability or exposure levels which are likely to occur in the very long term. Everyone knows that complex models with numerous parameters can be implemented so as to reach a desired conclusion. Rather, the regulatory requirement need to be a technical one which should be chosen in such a way that they are easily checked.

As regards the development of the concept of potential exposure, particularly taking into account the debates which have brought together specialists in radiation protection, waste and safety in the context of the NEA and the IAEA, (5) (6) the emphasis is placed on :

- the distinction between individual and collective risk, the latter being more than merely the sum of individual risks,

- the drawbacks inherent to an over-aggregation of the various components of the risk, and to the consequent need to respect a criterion for design of the waste repository based on limitation of individual risks.

Recent work within INSAG has tended to show that if the exposure were actually to occur and give rise to levels of exposure higher than the 10 mSv - 100 mSv range, considerations in addition to that of simple individual risk would need to be taken into account. Indeed, the authorities would be expected to intervene, changing the scale of the problem. (7)

This reasoning, directly coming from the reflexion on the safety of installations, needs to be adapted to waste disposal as far as the potential over exposure of some individual does not result from the loss of active control

but from a voluntary or unvoluntary intrusion. Moreover, the accidental dispersion of activity in time and space, even at low level, could be considered.

In conclusion, we feel it is important to underline that, essentially, protection of the radioactive waste disposal systems is clearly defined by the principles of the ICRP. However, the numerous current debates must lead to the establishment of concrete ways to apply these principles, particularly for the benefit of the decision makers. This matter has taken on even greater importance since development has begun within the framework of the IAEA, of a convention on radioactive waste which must correspond to an international consensus, yet national regulations are still not in line with each other and correspond to more or less narrow interpretation of the ICRP's intentions.

At the light of this general considerations, and along the line of the conceptual framework established by the ICRP46, the ideas now being developed by waste specialists tend to explore or go deeper into the specific aspects of the problem and integrate with ideas on the following themes :

- to refine the considerations which relate to the ethical aspects of disposal of long-lived waste. This dimension must indeed be taken into consideration because we are transferring a risk to future generations who have not directly benefited from the activities which generated it, and who have not been able to have a say in the decisions which are being made today, or will be made later, on the disposal options. (8)

- to clarify the safety approach by identifying the different stages of this approach in such a way that the decision makers and the public may have « reasonable confidence » in the long term safety of the disposal system. One of the ways to clarify this matter is to divide the future into periods of time. Expressing an increasing degree of uncertainty the further away they are. To propose that the safety criteria be replaced with different « indicators » enabling the impact of disposal to be assessed. (4) (9) (10)

- to ensure that the management methods for the different categories of waste to be assessed are in line with each other high active and long-lived waste, low and medium active short-lived waste and waste from mining and milling of uranium and thorium bearing ores. The latter present particular difficulties due to their vast quantity, the specific radionuclides involved and to their extremely long life span. (11)

I thought it would be interesting to examine these different topics during the IRPA-9 seminar on waste management.

Ethical Aspects of Long-Lived Waste Disposal

C. McCombie, Nagra, 5430 Wettingen, Switzerland

Introduction

Independent of the long debate on the use of nuclear power, waste management specialists have a clear, unassailable set of environmental goals aimed at protecting the public and workers from any unjustifiable exposure to radiation. It is recognised that releases to the environment must be minimised, operational doses from waste handling kept low, and storage facilities constructed and operated with very high levels of safety. A philosophy of how to make best use of the available resources is embedded into the established principles of the ICRP, requiring justification of practices, limitation of doses and optimisation.

Absolving these responsibilities within the scope of most current waste management practices requires a philosophical or ethical basis, primarily addressing the issue of **intragenerational equity**. Are we being fair and equitable to our present society? Are the levels of protection required in the radiation field compatible with those for other hazards? Could one promote public health and safety better by allocating resources differently? These questions are difficult to answer in practice. However, they can, in principle, be resolved by making the costs and benefits of enhanced radiation protection transparent to today's society which can then, explicitly or implicitly, make the appropriate choices. This approach is possible as long as the same individuals who benefit from any enhanced protection measures also are those who pay for these additional benefits.

The situation is different when we consider the particular case of disposal of long-lived radioactive waste. Properly designed and sited repositories will present only low levels of risk - but these risks are predicted to peak only after many thousands of years. It is obvious, therefore, that this disposal involves the present and immediately following generations investing resources into the protection of far-future individuals. Attention has focused upon this **intergeneration** issue in recent years, leading to intensified debate on all ethical aspects of waste disposal. In this paper, I will try to provide a short overview of recent relevant work, to indicate the ethical principles agreed upon and to highlight the currently most controversial issues.

Does waste disposal really present unique ethical issues?

As mentioned, the specific point leading to emphasis on ethical aspects of waste disposal is that any negative impacts are likely to affect far-future generations who will not directly benefit from the activities producing waste and who will not have shared in the relevant decision making. There are, in fact, other activities today for which the same dilemma arises. Global warming due to CO_2 is the most topical subject, but there are numerous older examples for which the issue of fairness to future generations has

not been recognised explicitly enough. A clear case is the exploitation of natural resources in the earth's crust. The fact that our current voracious consumption of fossil fuels will exhaust in centuries valuable resources which have been built up over millions of years, leaving future generations a fundamentally altered planet, deserves more emphasis in ethical debates. Why is the debate on the long-term aspects of radioactive waste disposal so much more intensive than for other cases where much more dramatic permanent changes in the environment may occur?

One reason, paradoxically, is that the radiotoxicity of nuclear wastes is not permanent but decays with time. This draws attention to the sometimes very long timescales and increases public anxiety; the timescales tend to be compared to human lifetimes and not, for example, to the infinitely long-lasting toxicity of some other wastes. A further reason for so much time and effort being devoted to debate on radioactive waste issues is that, relative to other comparable areas, high funding levels and advanced technological solutions are available for solving nuclear waste disposal problems. The nuclear power industry produces concentrated volumes of long-lived wastes which are small when measured against the energy produced; waste management is a minor (although growing) part of nuclear power costs. Thus, resources have been made available for developing advanced solutions which are hardly practicable for more voluminous wastes (e.g. heavy metal mine tailings) or for more diffuse wastes (e.g. CO_2).

A further reason for particular controversy surrounding the ethics of waste disposal is, of course, that some nuclear power opponents are constantly seeking chinks in the armour of this technology and are therefore interested in hindering any "solution to the waste problem" and in generally raising public anxiety. This is no difficult task since the well documented "nuclear dread" to be found in our westernised societies can be exploited here.

There are also more objective explanations for the topicality of the discussion on ethics and on inter- and intragenerational equity in waste disposal. Repository projects are becoming more mature and both the technical community and the public are conscious of the importance of responsibly taking care of hazardous wastes. This implies that specific guidelines for judging the safety and the acceptability of such projects must be formulated. Accordingly, there has been debate at national and international levels on the principles and criteria which must be applied and this debate has included intensive discussions on the ethical questions involved.

Ethical issues are debated in many national programmes

At a national level there have been numerous meetings and position papers on ethical issues. In Sweden, for example, the advisory council, KASAM, organised a Symposium on the subject in 1987; emphasis was placed in the discussions on the overriding importance of keeping future options open - a topic to which we will return later. In Canada, a workshop was held to give ethical input to the national strategy for disposal

of spent fuel. In Switzerland, as a preliminary to revision of the government regulations governing long-term disposal of radioactive wastes, a seminar was held at which ethical issues were presented by experts from outside the nuclear community. The USA has an extensive literature on the general question of achieving equity between successive generations and this discussion has been taken up by those concerned with radioactive waste management.

The ideas developed in these national programmes and many others have fed into international efforts aimed at achieving consensus on the ethical aspects of waste disposal. As a result, the IAEA produced in 1995, following a long period of iterative comments, an important document entitled "The Principles of Radioactive Waste Management". This paper with its strong emphasis on ethical issues is described in more detail below. A further, equally important document is the "Collective Opinion on the Environmental and Ethical Basis of Geological Disposal" produced by the NEA/IAEA/ EEC in 1995. This consensus view, drafted following a 2-day, wide-ranging workshop on Environmental Aspects of Long-Lived Radioactive Waste Disposal, is also commented upon in more detail below.

Ethical issues highlighted by the IAEA

In the above mentioned IAEA paper on waste management, the following 3 principles are most directly related to issues of ethics:

Principle 3: ***Protection beyond national borders***
Radioactive waste shall be managed in such a way as to assure that possible effects on human health and the environment beyond national borders will also be taken into account.

Principle 4: ***Protection of future generations***
Radioactive waste shall be managed in a way that predicted impacts on the health of future generations will not be greater than relevant levels of impact that are acceptable today.

Principle 5: ***Burdens on future generations***
Radioactive waste shall be managed in a way that will not impose burdens on future generations.

Each of those principles is obviously based on sound ethical beliefs and may appear at first sight to be immune to criticism. Each, however was the subject of intensive debate and a source of substantial disagreements. Principle 3, for example, was originally framed so as to prohibit explicitly any state from causing potential radiation exposures in neighbouring countries **higher** than those in the country of origin. Some countries, however, - especially those with no, or limited nuclear programmes - did not believe it ethical to expose their populations even to impacts **equal to or less** than those in the source country.

These states advocated that, ethically, a source country should have to accept any potential exposure limits set by the receiving country. With a no-threshold assumption for dose to risk conversion, however, this proposal could allow any state, by imposing a zero limit, to render disposal activities in neighbouring countries impossible - even if only trivial releases at far future times could be predicted. The final formulation leaves scope for bilateral discussions; it could set a good ethical example for other technologies where localised emissions can have regional or global impacts.

Principle 4 provoked a long debate on acceptable levels of exposures for future generations. Should these exposures be, as stated, "not greater" than those allowed today? Should they be decidedly **lower** than today's levels since future generations will not have the benefits of today's nuclear energy? Should they be allowed to be **higher** because far-future detriments may be (and are in practice) discounted.

The comforting logic of Principle 5 is shaken by the conviction of a large body of persons who believe that imposing burdens on future generations is, in fact, **more ethical** than unnecessarily restricting their freedom of choice. This body of opinion includes the vocal lobby calling for (indefinite) surface storage of radioactive wastes as an alternative to implementing deep repositories. Included amongst the supporters of this view are, however, not only declared opponents of nuclear power (such as those propagating the "guardianship concept") but also more neutral bodies such as the KASAM organisation mentioned above or the Dutch Government, which has recently ruled that all toxic wastes must be retrievably stored.

The Collective Opinion of the NEA/IAEA/EEC

The OCED/NEA has issued over the years selected "collective opinions" intended to record the views of its senior committee of experts on key waste management issues. Somewhat paradoxical - and directly indicative of the defensive battle being fought by the nuclear community - is the sequence of these opinions. A first paper gave the consensus view that radioactive waste disposal **could be carried out safely**. A second recorded and justified the consensus view that **adequate methods were available for assessing repository safety**. The most recent should in fact have preceded the others in that the documented consensus is that the concept of geological waste disposal **rests on a firm ethical basis.**

The collective opinion on ethical aspects was carefully prepared following the previously mentioned workshop on the topic. For the workshop, a background document was prepared listing in an open manner the numerous issues to be tackled and posing the direct question as to whether disposal concepts fit into the framework of sustainable development and ethical responsibility which is accepted today.

In the background text to the Collective Opinion, attention is focused upon "the achievement of intergenerational equity by choosing technologies and strategies which minimise the resource and risk burdens passed to future generations" and it is recognised "that each generation leaves a heritage to posterity involving a mix of burdens and benefits and that today's decisions may foreclose options or open new horizons for the future".

A set of guiding ethical principles is developed in the NEA document; these are broadly similar to the above mentioned principles of the IAEA. Two issues, however, are more strongly emphasised. One is that "a waste management strategy should not be based on a presumption of a stable societal structure for the indefinite future, nor of technological advance". This principle leads to rejection of indefinite storage strategies in favour of geologic disposal concepts offering permanent protection. The second issue discussed more extensively in the Collective Opinion is the wish to ensure that one does "not unduly restrict the freedom of choice of future generations". It is judged that an incremental process, involving development of deep repositories in a stepwise fashion over decades, meets this requirement - even when disposal facilities have no deliberate provisions for waste retrieval following repository closure.

In its summary opinion on the ethical aspects of waste disposal, the Radioactive Waste Management Committee considers that responsibilities to future generations are best discharged by the strategy of geologic disposal and believes that both inter- and intra-generational issues are thereby taken into account. Ethical responsibilities to current generations require also that we should keep in perspective resource deployment in all areas where there is potential for reduction of risks to humans and that the implementation of geological disposal should proceed stepwise with ample opportunity for proper public participation in the decision process.

Consensus in the waste management community - necessary but not sufficient

It is apparent from the above overview that the waste management community has in recent years devoted much time and effort to examination of relevant ethical issues. A broad consensus, reflected in the international documents described, has been arrived at **within the community**. This consensus is that waste disposal concepts and plans do indeed satisfy the requirements of ethical behaviour. In fact, amongst waste management specialists, there is a widespread belief that, because of the specific measures taken to ensure intra- and intergenerational equity, radioactive waste disposal can actually play a pioneering rôle, pointing the way ahead for other environmental activities.

It is, of course, reassuring for those experts in the waste business to learn that numerous outside, neutral specialists in the topic of ethics agree with this positive judgement. It must not, however, be overlooked that agreement on all issues is by no means unanimous. Even within the waste community there are important divergent views. A strong body of opinion would argue that intragenerational equity is certainly not given

in our society which devotes too much of its resources to reducing already trivial levels of radiation to the public rather than focusing on the many obvious major health concerns. There is also a strong argument that potential doses in the far-future should be weighted less than real doses today. Put extremely, would we sacrifice 10 lives today to potentially save 20, or even 100, lives some generations ahead?

Perhaps more important than these continuing internal debates is, however, the fact that the highly ethical picture which the waste management community has of its activities has not been communicated to, or accepted by, the general public. Anti-nuclear groups, sometimes using real examples of poor waste management and thoughtless environmental contamination, are allowed to push the idea that waste disposal is a cheap and nasty, "out-of-sight, out-of-mind" solution. For those involved in waste management, it is comforting to realise that they can go about their business with a clear conscience. But this is not enough. If the waste community sincerely believes in the high ethical standing of its activities, then they should be out there taking the moral "high ground" in this debate. We have a responsibility to future generations which begins right now. We must make today's public aware of our ethical concerns for these future generations and we must continue to work towards implementing the disposal concepts intended to meet those responsibilities.

AN INTEGRATED SAFETY APPROACH AND CONSIDERATION OF SOME BASIC CRITERIA FOR THE DISPOSAL OF RADIOACTIVE WASTE

Sören Norrby[1], Jack Valentin[2]

[1]Swedish Nuclear Power Inspectorate, S-106 58 Stockholm
[2]Swedish Radiation Protection Institute, S-171 16 Stockholm

Abstract

According to Swedish regulations the nuclear power plant owner is responsible for the safe management and disposal of radioactive waste. Criteria for protection of health and environment are set by the Swedish Radiation Protection Institute (SSI). The Swedish Nuclear Power Inspectorate (SKI) sets corresponding safety criteria and is responsible for review and supervision of the safety of facilities for management of nuclear waste, the nuclear industries R&D programme and the funding system for future costs for nuclear waste disposal. All of these tasks of SKI include assessments of safety.

An assessment of the safety of final disposal of radioactive waste should cover the total disposal system (all barriers of the repository system; operational phase as well as post-closure phase of the repository).

Each step in a handling sequence must consider earlier as well as subsequent steps, so that a waste product resulting from one step is suitable for all subsequent steps.

The safety of a repository for high level waste and spent nuclear fuel should rely on a robust system of multiple barriers. The application of this principle means that the function of one of the barriers might be lost without seriously jeopardizing the safety. Deep geological disposal seems to be the only option available today which complies with this requirement. Even if the assessment relies on an assessment of the total system and not on technical subsystems, technical requirements on the individual barriers must be defined.

The safety case is defined by a set of scenarios. Also possible human actions that could affect the integrity of the repository system should be included. A safety assessment includes an uncertainty analysis of models, scenarios and data. The need for verification/validation of models and the reliance on expert judgement is pointed out as well as the need to accept "reasonable assurance" as the realistic attitude in the demonstration of safety.

Roles of the operators and authorities in Sweden

Operators have a cradle-to-grave responsibility for the environmental effects of their activities. Authorities regulate and monitor those activities, but should not take over the operators' responsibilities.

In Sweden the regulatory system very clearly assigns the responsibility for all measures for the safe management and disposal of nuclear waste to the nuclear plant owner, the waste producer. Occupational and public health and environmental preservation during all phases of nuclear

power operation, including waste management and disposal, must conform with criteria which the Radiation Protection Institute (SSI) sets in accordance with its task to protect man and the environment against harmful effects of radiation. The Swedish Nuclear Power Inspectorate (SKI) sets corresponding safety criteria for the technical performance of every aspect of nuclear power, including waste management, in accordance with its task to supervise that nuclear facilities and activities offer the needed level of safety and also the system for safeguarding nuclear material. These two authorities review and supervise facilities for management of nuclear waste according to their responsibilities. Furthermore, SKI reviews the periodic R&D programme of the nuclear industry that is required by law and supervises the funding system for future costs for nuclear waste disposal.

Basic criteria for the disposal of high level waste

International and national bodies setting criteria agree that in principle, waste management and disposal must correspond with the same safety and protection criteria as of other aspects of nuclear power operation. However, in the context of disposal of long-lived waste, the possibility of potential future exposures complicates assessment. For long time scales, conventional radiation dose criteria must be supplemented, e.g. with criteria addressing release of activity.

The International Commission on Radiological Protection (ICRP) has set fundamental criteria for practices involving radiation, viz. that the practice must be justified, and that concomitant doses must be optimized to be as low as reasonably achievable and in any case below specified dose limits (1). These criteria apply also to management and disposal of waste, although such activities would normally automatically be justified once the practice generating the waste is permitted. However, after closure, a repository for deep geological disposal will not generate any doses at all, if a complete isolation of the waste is achieved. Thus, optimisation and dose limitation must address potential exposures due to unscheduled events, possibly in the far future, as envisaged by ICRP (2). ICRP has developed the concept of potential exposures further (3), albeit not primarily with a view to long-lived waste. It is understood that the possibility of providing further guidance on waste management questions is under discussion within ICRP.

The International Atomic Energy Agency (IAEA) has issued Safety Standards covering basic requirements on radioactive waste management addressing e.g. protection of human health and the environment, the need for establishment of national regulatory systems for radioactive waste management including the need for laws, a clear definition of roles between regulator and implementor, QA-systems etc (4, 5). The OECD/Nuclear Energy Agency (NEA) has published several documents on waste management issues, e.g. collective opinions by experts on final disposal addressing the possibilities for evaluation of the long term safety of disposal of radioactive waste (6) and on the environmental and ethical basis of geological disposal (7). The collective opinion is that the long term safety can be evaluated and that there is an environmental and ethical basis for acceptance of geological disposal.

These publications reflect different aspects of radioactive waste management. Basically they are not in conflict with each other, but should rather be seen as complementary. Various national organisations have also published recommendations and statements. For instance, in 1993 the Nordic Safety and Radiation Protection Authorities published a document on "Disposal of High Level Radioactive Waste. Considerations of Some Basic Criteria" (8). This document is also in

agreement with the views of international organisations as referenced above. The recommendations in the Nordic document are presented here as a rather extensive and fairly operational set of criteria.

Summary of main guidelines and recommendations considered by the Nordic Safety and Radiation Protection Authorities

General objective
The disposal of high level waste shall aim at protecting human health and the environment and at limiting the burdens on future generations.

Long term safety
The risk to human health and the effects on the environment from waste disposal, at any time in the future, shall be low and not greater than would be currently accepted. The judgement of the acceptability of a disposal option shall be based on radiological impact irrespective of any national boundaries.

Burden on future generations
The burden on future generations shall be limited by implementing, at any appropriate time, a safe disposal option that does not rely on long term institutional control or remedial actions as a necessary safety factor.

Justification of practice
No practice involving exposure to radiation should be adopted unless it provides sufficient benefit to the exposed individuals or to society to offset the radiation detriment it causes.

Optimisation
Radiation protection related to waste disposal shall be optimised. In doing so, radiation and risks must be compared and balanced against many other factors that should influence the optimised solution.

Individual protection
Up to reasonably predictable time periods, the radiation doses to individuals from the expected evolution of the disposal system shall be less than 0.1 mSv/year. In addition, the probabilities and consequences of unlikely disruptive events shall be studied, discussed and presented in qualitative terms and whenever practicable, assessed in quantitative terms in relation to the risk of death corresponding to a dose of 0.1 mSv/year.

Long term environmental protection
The radionuclides released from the repository shall not lead to any significant changes in the radiation environment. This implies that the inflow of the disposed radionuclides in the biosphere, averaged over long time periods, shall be low in comparison with the respective inflow of natural alpha emitters.

Safety assessment
Compliance of the overall disposal system with the radiation protection criteria shall be convincingly demonstrated through safety assessments which are based on qualitative judgement and quantitative results from models that are validated as far as possible.

Quality assurance
A quality assurance program for components of the disposal system and for all activities from site confirmation through construction and operation to closure of the disposal facility shall be established to achieve compliance with the design bases and pertinent regulations.

Multibarrier principle
The long term safety of the waste disposal shall be based on passive multiple barriers so that deficiencies in one of the barriers do not substantially impair the overall performance of the disposal system and so that realistic geological changes are likely to only partly affect the system of barriers.

The Swedish regulatory authorities, SKI and SSI, are now developing national regulations

based on the Nordic document and on other relevant documents, *inter alia* publications by ICRP, IAEA and OECD/NEA.

No technical subsystem criteria are defined by the authorities. This would restrict the possibilities of the nuclear power plant owners to shoulder the responsibility given to them by Swedish law to take all necessary actions to ensure safety.

Demonstration of compliance with criteria

Criteria and regulations should be formulated in such a way that compliance can be demonstrated.

Criteria and regulations should aim at defining a required level of safety but in order to be useful they must be set up in such a way that compliance can be demonstrated by accepted methods of assessment. The very long time perspectives in final disposal of HLW and spent fuel will lead to large uncertainties in the assessments. This is a difficulty but does not change the principal requirements on evaluation and demonstration of compliance with given criteria.

Criteria and safety assessments will normally be of both qualitative and quantitative nature. Even such safety assessments that are presented in a quantitative form will to a great extent be based on understandings of qualitative nature (expert judgement). Given the qualitative elements of safety assessments the demonstration of compliance will never be very precise. Reasonable assurance is however required.

Performance assessment as a regulatory tool

Performance assessment methods offer a possibility to assess a technical system in a comprehensive manner. They may be used for assessing safety, identifying R&D needs and may also be valuable as a background for calculating costs for future radioactive waste management.

In order to fulfill their obligations as producers of waste, the nuclear power plant owners have formed a joint company, the Swedish Nuclear Fuel and Radioactive Waste Management Co (SKB), to construct and operate radioactive waste management facilities and to perform the necessary R&D work. The responsibilities given to the nuclear power plant owners and to SKB put a demand on competence and resources. The regulations require the safe operation of facilities, but also the presentation of a comprehensive R&D programme to cover e.g. storage and disposal of spent fuel every third year, and also a funding system to cover the future costs for spent fuel management and disposal. It is very evident that the nuclear power plant owners and the SKB need to have competence in evaluating the safety of nuclear waste facilities and practices. SKB has spent a lot of efforts in developing competence in performance assessment methodology and continues to do so.

Also a regulatory authority in the field of radioactive waste management needs to have competence and tools for evaluating safety and radiation protection. The Swedish Nuclear Power Inspectorate has since many years engaged itself in competence building in performance assessment methodology. SKI as a matter of fact regards performance assessment methods as a regulatory tool to be valuable in the review and assessment of disposal concepts presented by SKB. This will be even more valuable in the expected license application for the encapsulation

facility for spent fuel and the deep geological repository. An application will, according to SKB's plans, within a couple of years be submitted to SKI and referred for comments to SSI and other authorities.

Performance assessment methods may also be valuable in identifying needs for improved understanding. This may be achieved through uncertainty and sensitivity analysis. SKI has recently concluded a performance assessment project addressing the safety of a deep geological repository for spent fuel (SITE-94) (9) and earlier an effort of the same character (Project-90) (10). Project-90 was based on data for a hypothetical site for a deep geological repository for spent fuel. The geological data were chosen to be representative for Swedish geology. In the SITE-94 project real geological data from an actual site (not intended for a repository) was used. The intention with these projects have been to increase the competence of the SKI and to prepare for coming licence applications. The two projects have clearly demonstrated the usefulness of performance assessment methods as a regulatory tool.

The Swedish Radiation Protection Institute is engaged in problems of optimisation under uncertainty. Disposal of high level radioactive waste constitutes an extreme case where hypothetical, potential future exposures of "the public" (which may no longer be formed of humans!) must be balanced against current occupational exposures of the public due to accidents before closure of a repository. Obviously, no single calculation could lead to a definitive answer to this problem. However, SSI is currently concluding an environmental impact assessment project called MKB-95 (11). This has resulted in a computerised tool aimed at sensitivity analyses, so as to illustrate the effects of changing assumptions and parameters in the optimisation process.

Performance assessment methodology is valuable in many respects. It's essential in verification and validation of models of the system. It's valuable in understanding how scenarios and time frames for assessing a repository system should be formulated. It can give quantitative results on the long term performance of a repository as a radiation dose or as an indicator of safety in the very long time perspective. It is needed in the definition of technical requirements on the canister for HLW or spent fuel. Above all it is useful in assessing the long term impact on the environment from a repository system. It must always be born in mind, however, that the quantitative results are to a very great extent based on qualitative evidence, expert judgement etc.

Total systems assessment

The ultimate goal in assessing safety is to cover all aspects of risk. All phases in the development of a waste management system should be evaluated. All facilities and practices being part of the system should be evaluated. In a repository system the total system including all barriers must be evaluated. Also the consequences of human intrusion into a repository should be evaluated.

A complete system for the management of radioactive waste and spent fuel from a nuclear power programme consists of many different activities; e.g. handling, treatment, storage, transport and disposal. Most of these activities require specially designed facilities. It is quite obvious that radiation protection and safety aspects have to be identified and analysed in all these activities and related facilities. The character of risk may differ considerably between e.g. storage and transport but the need for evaluation will always be there.

Some of the effects of waste management will occur during the operation of waste management facilities (doses to workers handling the waste) and some effects may occur in the very far future (during the post closure phase of a deep geological repository). Doses during the operational phase can be monitored and controlled. The potential doses from the post closure phase of a deep geological repository will occur in the very far future and we can not rely on monitoring and control. The system must be so designed that we have confidence in its long term behaviour. However careful we are we must accept that uncertainties exist. The proper balance between risks today (possible to monitor and control) and risks in the very far future (for which we can have no reliance on monitoring and control) is a difficult matter involving not only the uncertainties in the technical system but also philosophical and ethical aspects.

Interdependencies

A waste management system can be subdivided in separate parts and steps. It may be valuable to assess individual parts separately. In evaluating a separate step it must however be recognized that the following steps may be effected by preceding steps. This fact should also be observed in the decision process. A decision may partly or strongly be binding for the following steps.

The management system for nuclear waste, especially HLW and spent fuel, will be a complex system of activities and facilities of sometimes very different character. It is necessary to see the system as being built up by individual parts. Otherwise it will not be possible to plan and construct individual facilities being parts of the total system. In doing so it must however be remembered that these activities and facilities are parts of a total system. This means that interdependencies between all these parts have to be assessed. During the planning and construction phase performance assessment and planning activities will form an iterative process. One example of these interdependencies is the Swedish programme for spent fuel disposal which includes an encapsulation facility for spent fuel and a deep geological repository. In planning for the encapsulation plant it must be remembered that the canisters for spent fuel produced in this facility will eventually be disposed of in the repository. It is quite evident that the canisters must fulfill the requirements given by the repository system. Decisions on the encapsulation plant can not be taken without consideration of the deep geological repository. In some degree of detail the total system (encapsulation facility, canister, geological repository etc) must be assessed (12).

Another example may be the Swedish repository for nuclear waste (intermediate and low level waste) from the operation of the nuclear power plants; the SFR facility, near the Forsmark nuclear power plant. Waste types already produced existed when the repository was planned. The repository thus had to be designed to be able to accept these waste types. New waste types have to conform with the given design of the repository (13).

The effects on the decision process must be observed. A decision to design and construct a facility, e.g. an encapsulation plant, will influence the subsequent steps, e.g. a repository. The level of freedom to take further decisions on the disposal system will decrease. Decisions on individual parts of the disposal system will also influence future costs for the remaining parts and for the total system.

Deep geological disposal

Deep geological disposal of HLW and spent fuel is judged to be justified both from an environmental and ethical point of view.

It is not possible to rely on institutional control of storage for high level waste or spent fuel for very long time. A more reliable solution is needed. Deep geological disposal is the preferred option for high level radioactive waste and for spent fuel. Even if no repository for HLW or spent fuel is yet in operation, this option is under development in many countries. The Radioactive Waste Management Committee (RWMC) of the OECD/Nuclear Energy Agency (NEA) has in a recent statement declared that it is justified, both environmentally and ethically, to continue the development of geological repositories for long-lived radioactive waste (7).

Deep geological disposal typically means a repository excavated in a geological formation (e.g. crystalline rock, salt or clay) at the depth of several hundred meters. The HLW or the spent fuel is encapsulated in long-lived canisters which are deposited in repository. No long-term surveillance is required. Institutional control may however be performed for some period of time.

The reason for choosing deep geological disposal is the reliance we can put on the long term stability of the geology at a carefully chosen site. Arguments for this has recently been given by the NEA, mentioned above, and by the US National Academy of Sciences (14) in its report on the Yucca Mountain project. The SKI and SSI also share this view.

There are however other views. Some experts may find it too early to take decisions on final disposal as alternatives may be available in the future. One example of this is partitioning and transmutation of long-lived radioactive waste, a technique that may transform longlived radionuclides into less harmful nuclides. This will require a lot of work and time and there is no guarantee for success, that is an overall reduction of risk at a reasonable cost. In the NEA statement it was made clear that from an ethical standpoint, geological disposal is preferred over long term storage (waiting for new solutions) which requires long term surveillance.

Multibarrier system

Taking into account the very long-term perspectives and the uncertainties associated with the safety of a repository for long-lived waste, e.g. spent fuel, a robust system is needed. A repository built up by multiple barriers offers a more robust system than a repository relying essentially on a single barrier.

Final disposal of radioactive waste puts demands on the repository system. The intention with a repository system is to isolate the radionuclides and to restrict the release if and when releases occur. For HLW and spent fuel the relevant time perspectives for the functioning of the repository will be in the order of hundreds of thousands of years and more. Even if the geological environment will be stable for very long time periods it is evident that uncertainties in the evolution of the repository system in the long term may be great e.g. because of climate changes and human actions.

A quotation from the Nordic document (8) reads:

"The long term safety of the waste disposal shall be based on passive multiple barriers so that deficiencies in one of the barriers do not substantially impair the overall performance of the disposal system and so that realistic geological changes are likely to only partly affect the system of barriers."

The system should not rely on one single barrier but rather on a set of barriers that together offer a system robust to degrading mechanisms of different kinds, release and transport of radionuclides and to disruptive events. All this is best achieved with a multibarrier system comprising for example the spent fuel matrix, a long-lived canister, back-fill around the canisters in the repository and the geological medium itself. The process for transportation of radionuclides from the repository is dominated by groundwater transport. The depth of the repository must be sufficient to withstand erosion, glaciations etc. A sufficient depth also helps in protecting the repository against possible human actions.

The safety case

To define the safety case for disposal of long lived waste the disposal system and the features, events and processes affecting the system have to be defined. Normally this is done in terms of defining a set of scenarios.

In order to assess a disposal system and to see if regulatory criteria can be met, it is necessary to define the system. In the case of a repository the multibarrier system must be defined. The different barriers (waste matrix/spent fuel, canister, back-fill, geological medium etc) and their properties must be described. Also the system boundaries must be defined. The behaviour of the system is affected by features, events and processes (FEPs) within the system but also external FEPs may influence the system. The exact definition of the boundaries is a matter of judgement. Normally climatic changes, major disruptive event (e.g. faulting) etc are regarded as external FEPs.

The development of the repository system can not be observed and verified in the very long time perspective. A basic understanding of the system and the FEPs that may affect the system is needed.

FEPs affecting the system are normally combined and described as a scenario. Different combinations constitute different scenarios. Because of the uncertainties, mainly due to the very long term perspectives, a set of scenarios is needed to cover the development of the repository system.

Safety assessment and uncertainty

Safety assessments for very long term periods will always be uncertain. If we know and understand the reasons for uncertainty and if we can quantify the uncertainty much is achieved in assessing safety.

Safety assessment methods for the normal operation of a nuclear facility can be based on actual experience and statistics. In addition to deterministic evaluation, probabilistic methods utilising existing data can be used. Corrective measures can be initiated if needed. This also includes a repository in its operational phase (before closure).

For the post-closure phase of a repository, monitoring and control are not possible in the very long time perspectives. Assessments must be based on a genuine understanding of the repository system and its environment, including also the development of the system in the very long term perspective. The underlying knowledge base is both of qualitative and quantitative nature.

The definition of the safety case can be seen as a part of the safety assessment. Other parts are then related to the modelling and consequence analysis.

Modelling includes the formulation of conceptual models of the disposal system (e.g. the repository and the geologic medium) and the translation of the conceptual models to computer codes. The input to the codes and the output are quantitative. If the models and the codes are good representations of what they are supposed to represent then the results will be good representations of the consequences. Are the models and codes good representations? This is a key question. Much effort has been spent on development of performance assessment methodology. Despite the difficulties there is confidence in the possibility to evaluate long term safety. Expert committees of the NEA, IAEA and the European Communities in 1991 (6) stated as a collective opinion that long-term safety in radioactive waste disposal can be evaluated.

As mentioned earlier the uncertainties in the safety assessments increase with time. This issue has been discussed in an IAEA document that also addresses the concept of safety indicators (15). It should be remembered that already in time perspectives of a hundred to a thousand years considerable changes in climate, living habits etc may occur. The quantitative results should for the long time perspectives not be regarded as exact representations of the effects on human health and the environment but rather as indicators of safety. Even if this is true, calculations covering long time periods are meaningful for certain purposes, such as ranking of alternative disposal options. The quantitative assessments will help in understanding the uncertainties and sensitivities in different parameters and couplings of processes within the system, and will thus help in understanding the long term behaviour of the system. A good understanding of the long term behaviour of the system is expected to be of value also for understanding of shorter time periods. For the performance assessment of the repository system, it appears that the inevitable cut-off in time should come considerably later than the time frame (say, 10 000 years) over which calculations of doses to humans retain any relevance. This view is supported by the fact that releases from a deep geological repository may increase and peak well beyond 10 000 years. It is however important to keep two things in mind: the results from calculations for such long time periods should not be regarded as a true representation of risk but rather as indicators of safety; and the risk associated with releases of long-lived radionuclides well after the short-lived gamma emitters have decayed should be compared to risks associated with stable chemotoxic nuclides.

Conclusions

In the development and review of a system for waste management and disposal it is necessary to assess the total system. All phases should be analysed: treatment, storage, transport, deposition of waste and the long term safety of the repository after closure. The complete repository system should be assessed including man made structures and the geological environment and the biosphere.

A well organised and well structured comprehensive assessment of the waste management and

disposal system is very useful in relation to defining scenarios and time frames for evaluation of the repository performance as well as in defining technical criteria for selection of a repository site. It will also be valuable in defining the technical criteria for a canister for spent fuel or high level waste. Performance assessment methods will make it possible to evaluate the long term performance of a system for final disposal of radioactive waste.

It should always be born in mind, however, that the quantitative results from performance assessment calculations to a great part are based on evidence of qualitative nature. For the long term the results from performance assessment calculations should be regarded as indicators of safety rather than exact representations of risk.

From a regulatory perspective performance assessment methods are very useful and needed in understanding if a proposed system complies with given criteria. The answer to this may not always be simple but reasonable assurance is needed.

MANAGEMENT OF WASTE FROM THE MINING AND MILLING OF URANIUM AND THORIUM BEARING ORES

P E Metcalf

Council for Nuclear Safety
South Africa

ABSTRACT

Mining and processing of uranium and thorium bearing ores for the extraction of uranium and other minerals gives rise to the production of various radioactively contaminated wastes and other re-cyclable materials. The wastes are characterised generally by their bulk nature , their low specific activity and the long radioactive half-lives of several of the radionuclides involved. The contaminated re-cyclable materials are mostly steels, timber and plastic and the contaminants can be of higher specific activity due to various chemical and physical concentration processes. The mining and minerals processing residues , essentially waste rock and tailings, present particular waste management problems. Their bulk nature precludes underground disposal and the long radioactive half-lives present problems of assuring their long term containment. In addition, the residues contain radium at elevated levels, corresponding generally to that in the original mined ore, and presenting a source of radon progeny. The nature of mining waste is such that they are often an inexpensive source of raw materials for use in building materials. Their diversion to such use must be considered in respect of both external and radon progeny exposure.

The paper describes the nature and characteristics of the wastes and re-cyclable materials arising from mining and minerals processing activities. It discusses the various management options adopted for these wastes in various countries and addresses the process of hazard assessment for these wastes and the associated safety criteria. The paper also discusses the consideration of these wastes in terms of the RADWASS programme and the principles of radioactive waste management embodied in the safety fundamentals which form the basis for the RADWASS programme.

1. The Nature and Characteristics of Radioactive Wastes From the Mining Industry

Uranium and thorium are present in the earth's crust at average mass concentrations of around ten parts per million. They can, however, be concentrated in mineral deposits and concentrations can range up to tens of percent. Such concentrations are exceptional, but extensive deposits are found with concentrations hundreds of times the average concentration. Both uranium and thorium are naturally occurring radioactive materials and in nature are comprised of several isotopes. The parent radionuclides, U-238, U-235 and Th-232 are primordial radionuclides with half-lives of 4 500 million, 700 million and 14 000 million years. They decay by alpha particle emission and give rise to subsequent radioactive decay series comprised of various radioactive progeny as illustrated in Table 1. The members of the decay series posses significantly differing physical and radiological characteristics which greatly influence the potential radiological hazards associated with wastes arising from mining and minerals processing activities.

Since the advent of nuclear weapons development and the evolution of nuclear power generation, uranium as a mineral has been widely extracted. Thorium has been exploited to a much lesser degree, however, numerous other minerals are extracted from ore bodies containing elevated levels of uranium and thorium and giving rise to radioactive wastes. The latter include, inter alia, monazite, ilmanite, rutile, zircon baddelyite, phosphates, copper, lead, zinc, silver, flourospar, gold and coal. Radium rich mineral deposits have been exploited since the first quarter of the century and uranium mining activities commenced in the 1940's and accelerated considerably in the early 1950's. To date over thirty countries have produced in excess of 30 tonnes with six countries producing greater than 100 000 tonnes in the period up to the early 1990's as illustrated in Table 2. Greater than 1 800 000 tonnes of uranium have been extracted world-wide and projections are that by the turn of the century this will be in excess of 2 000 000 tonnes.

The mining and minerals extraction process entails mining of the ore body, either underground or by way of an open pit, crushing and milling the ore, possibly concentration of the minerals by various physical processes and extraction of the mineral being exploited by chemical processes. In addition, a limited number of in-situ leaching activities have been undertaken. More often than not these steps are followed by various purification processes. The outcome of the overall process is the mineral product together with various waste residues which will be combinations of:

- waste rock

  rock removed from the mine in winning the ore but which contains mineral concentrations too low to economically extract.

- tailings

  the crushed and milled rock from which the mineral has been extracted together with any chemicals and fluids remaining after the extraction process.

- chemical residues

  spent ion exchange resins, solvent extraction sludges, active charcoal etc.

- other waste

  In addition, various mine and plant consumables such as filters, catalytic saddles, timber etc. and scrap arisings such as metal and plastic become contaminated giving rise to radioactive wastes.

As a primary product, uranium bearing ores are generally exploitable at concentrations in excess of several hundred parts per million. As a by-product, however, uranium can be economically extracted at concentrations of around one to two hundred parts per million as in South African gold mines. At the extreme, uranium is extracted from copper and phosphate ore deposits at concentrations of around fifty parts per million. A representative average grade in the region of 0,1% or one thousand parts per million indicates that associated with

the world wide production to the end of the current century will result somewhere in the region of 2 000 million tonnes of mill tailings from primary uranium producers.

The total arising of other wastes are less well documented, however, the estimated waste arisings for South African gold/uranium mining operations together with the characteristics of such wastes are indicated in Tables 3, 4 and 5.

Table 3. Illustrative Concentration Levels in a Selection of Waste Streams From South African Mining Operations

WASTE TYPE	TOTAL ACTIVITY Bq g^{-1}
Gold tailings	2 - 200 +
Calcine	30 - 2 000
Calcine Scale	200 - 300 000
Pyrites	< 1 - 400
Pyrite scales	1 - 25 000
ADU Section Scales	up to 30 000
Rubber lined components e.g. pipes	up to 200
Contaminated Soils	< 0,2 - 50 000
PMC scales	up to 350 000
Gypsum	up to 10
Waste rock	< 0,1 - 200

Table 4. Annual Waste Production Estimates From South African Mining Operations

MINES	TAILINGS M tonnes	WASTE ROCK M tonnes	SCRAP METAL SCO-I[2] tonnes	SCRAP METAL > SCO-I[3] tonnes
Gold (29)	121	37	15 000	2 000
Tailings re-cycling[1]	48	0,1	1 000	350
Other	60	Unknown	6 000	400

1. Reprocesses already existing tailings dams it does not add to the growing inventory of tailings.
2. Estimates of SCO-1 contaminated scrap are based on the indications that about 10% of all ferrous scrap is contaminated. More accurate statistics are not available at present. Use is made of the Surface Contaminated Object (SCO) classification criteria embodied in the IAEA Regulations for the Safe Transport of Radioactive Material.
3. Estimates of scrap contaminated above SCO-1 levels are based on actual data statistics in waste reports.

Table 5. Demolition wastes

Decommissioning and Demolition

There are a number of contaminated plants on mines awaiting demolition and site rehabilitation which will give rise to significant amounts of waste arisings in the future. The majority of these plants are associated with the gold mines and include acid, pyrite, calcine, uranium and gold plants. About 40 contaminated acid, pyrite, calcine, and uranium plants and their sites require to be demolished and rehabilitated. In many cases the plants have been completely or partially stripped but the sites have not been decontaminated and rehabilitated.

Figures from recent demolition activities indicate the following approximate quantities per site:

• metal SCO-1:	up to 10 000 tonnes
• metal > SCO-1:	100 - 200 tonnes
• Rubber, resins, plastics :	a few hundred tonnes
• Contaminated soil and rubble (< 1 000 Bq g^{-1} LLA):	up to 100 000 tonnes
• Contaminated soil, rubble and scales (> 1 000 Bq g^{-1} LLA):	a few hundred tonnes

In the undisturbed ore body, the uranium and thorium isotopes will exist in their natural ratios and the radioactive progeny will be present within the ore body in secular equilibrium with the parent radionuclides. If some separation has taken place for instance by the intrusion of water into the ore body, this state of equilibrium may have been disturbed. The mining and minerals processing activities significantly alter this state of equilibrium, primarily separating the uranium or thorium from their decay series progeny. Depending upon the extraction efficiency, the bulk waste arisings, i.e. the tailings, will contain only a few percent of the original uranium or thorium concentration. It will, however, still contain most of the radioactive progeny. In the case of uranium mining, this means that the radioactive content of the tailings will be dominated by Th - 230 with a radioactive half life of 80 000 years. Should the ore being processed contain elevated levels of uranium, which are, however, not economically viable for extraction at that time, clearly the majority of this uranium would be present in the tailings and the longer half life of U - 238 would in such cases predominate.

The various other wastes arise due to contamination of materials during the mining and extraction processes. This may be contamination by ore or can arise due to the selective concentration of particular species from the decay series by chemical and physical processes. In particular, radium is found to be concentrated and taken up in several waste arisings.

In terms of overall waste management, due consideration must also be given to the mine following closure. Both underground and surface mining operations result in the original ore body being in an altered state which may have given rise to exposure pathways that did not exist prior to mining activities. Such pathways require consideration in closing-out of the facility.

2. Radiation Hazards Associated With Mining Waste and Management Options

Possible Hazards

In view of the bulk nature of mining and processing wastes and the limited considerations that were originally given to their long term management, disposal options are generally limited to some form of in-situ stabilisation. Whilst there are some significant differences between uranium mining methods and extraction technologies and the resulting wastes, the radiation hazards associated with their management are generally dominated by Th - 230, Ra - 226, Rn - 222 and its short lived progeny and the longer lived radon progeny. In addition, the wastes associated with mining and processing of thorium bearing ores and other radioactive ores all have their own particular characteristics. However, consideration of uranium mining wastes covers all the potential issues associated with the latter.

There are numerous mechanisms by which radionuclides associated with mining and minerals processing waste can enter or give rise to exposure pathways to humans. These may arise during both the operational and post close-out phases and are elaborated below:

- Airborne dispersion from tailings piles and waste rock dumps of particulate material or radon emanating from the piles. This may arise during the operational phase and following close-out if cover material is eroded due to precipitation, wind or frost damage.

- Seepage from tailings and waste rock piles can transport dissolved radionuclides into ground water. The dissolution of nuclides is often enhanced by the presence of pyrite causing the wastes to be acid generating. Subsequent migration can cause the nuclides to enter exposure pathways involving the use of the groundwater or discharge of the groundwater to surface.

- Seepage at ground level may give rise to contamination of surface waters and is also a potential source for airborne dispersion.

- Intrusion on sites were mining and minerals processing residues are present by way of construction, agricultural and recreational activities. The associated exposure pathways include inhalation - both radon progeny and long lived alpha emitting species, direct exposure and ingestion due to uptake or contamination of feed stuffs.

- Diversion of mining residues from operating or closed-out sites. Tailings material often provides an inexpensive source of land fill or construction sand and waste rock an equally inexpensive source for the manufacture of aggregate for various construction purposes. Scrap materials including steel, timber and plastic are often desirable sources of raw material for re-cycling operations and give rise to a variety of exposure pathways depending on the re-cycling operation and the subsequent use of the re-cycled material.

- Closed-out mines may become flooded following operations and give rise to sources of enhance nuclide migration into surface and ground waters. They may also be a source of radon emanation into the atmosphere.

- The mechanisms of migration and transportation included above can also be affected by the impacts of natural phenomena such as earthquakes, floods etc. which may cause damage to engineered and natural containment barriers.

Waste Management Options

Waste management associated with operating mining and minerals processing facilities generally entails the siting, design and operation of tailings dams, siting and placing of waste rock piles, control of surface drainage, control and discharge of mine water, suppression of airborne dispersion from the site and management of consumable waste arisings such as chemical processing residues, scrap steel and timber.

At the time of mine closure, rehabilitation activities generally involve the dismantling of plant, demolition of buildings, stabilisation of tailings and waste rock piles, sealing of the mine and general site rehabilitation. Practice in tailings management has involved relocation, in-situ stabilisation and cover. The latter is aimed at preventing radon emanation, moisture infiltration, gamma radiation, oxidation, intrusion and erosion. Various methods of tailings cover have been used and depend on the local geological, climatological, and geographic characteristics. Often clay, sand and various grades of rock are used, vegetation is also appropriate in some locations and water cover has been used. Mines have been backfilled with mining residues and open pits have been backfilled, re-contoured or flooded.

In view of the limited attention paid to waste management on many sites during the early years of uranium mining, some countries have experienced the contamination of other properties in the vicinity of mining and minerals processing sites. This has been caused by the diversion of materials or from the uncontrolled dispersion of material from the sites. It has resulted in extensive rehabilitation efforts having to have been expended in the cleaning of these properties.

Where mining and minerals processing activities have given rise to the contamination of groundwater various engineered approaches have been adopted. These include isolation of the contaminated groundwater compartments and treatment of the contaminated water and increased natural flushing. In both instances, some institutional control on the site and its environs is necessary, such measures may be required over relatively long time scales - up to hundreds of years.

3. Hazard Assessment and Safety Criteria

Operating Phase

During the operating phase, consideration must be given to; which mining activities will be subject to regulatory control and which can be exempted, the control of effluent discharges from regulated facilities, the management of waste arisings stored or intended for disposal on the site and clearance of materials from the site. All these aspects can reasonably be addressed by deterministic hazard assessments and compared against laid down dose limits and subjected to optimisation assessments. The exception in this regard may be contamination of groundwater, where, due to the uncertainties in groundwater movement and

transport of contaminants into and by the groundwater, elements of the assessment may have to be subject to probabilistic considerations.

Exemption gives rise to particular problems due to the existence of natural background levels of uranium and thorium, together with their progeny, and the variable nature of these background levels. This is compounded by the presence of radium, which, at relatively modestly elevated levels above average levels can, in building related scenarios, give rise to dose levels well in excess of recommended exemption levels of dose and in fact in excess of public dose limits. Exemption levels quoted in the Basic Safety Standards Ref [1] for natural uranium, natural thorium and radium-226 respectively are; 1 $Bq.g^{-1}$, 1 $Bq.g^{-1}$ and 10 $Bq.g^{-1}$. It is explicitly stated, however, that these values are not applicable to bulk materials. Control over building on land with radium levels greater than around 0,1 Bq $.g^{-1}$ of radium-226 are recommended in some countries Ref [2] although modelling of the resulting exposures is dependent on numerous factors including soil porosity, building construction method and building ventilation rates. Many countries adopt values in the range of 0,2 $Bq.g^{-1}$ as exemption levels. These correspond to the values laid down in the United States for clean-up of uranium mill tailings and contaminated vicinity properties associated with uranium mining and milling operations Ref [3, 4].

The concept of effluent discharge control in respect of mining and minerals processing facilities is complicated by the range of sources, the extended nature of some sources, such as tailings piles, the various transport pathways and mechanisms and the existence of discrete controlled discharges together with those less amenable to control such as surface run-off and wind-borne dispersion. Nevertheless, assessments can be carried out for comparison with laid down criteria and release control mechanisms are possible. Dose limits vary between different countries spanning the range from a fraction of 1mSv for discrete facilities to 5mSv Ref [5].

The management of waste on mining sites is generally dictated by the tailings and waste rock management programmes. The associated hazard assessment is more related to the eventual close-out of the mine and will be addressed later. One factor giving rise to problems in respect of on-site waste management is the handling of other wastes exhibiting concentrated levels of contamination. Mine tailings contain radium-226 concentrations generally up to around 10 $Bq.g^{-1}$ and in exceptional cases higher. Waste with concentrations up to tens of thousands of $Bq.g^{-1}$ can arise and pose particular waste management problems. Such material would generally not be acceptable for disposal in near surface repositories Ref [6], rather deep geological disposal being indicated. Practice in some mining operations has been to dispose of such materials within tailings dams or waste rock piles and, at this stage, there is no consistent management strategy for such materials. The classification of these types of waste also gives rise to problems, particularly when the waste is in the form of non-active, components contaminated with relatively thick contaminated surface deposits such as scales.

Clearance of materials from mining and minerals processing operations gives rise to many of the issues raised in terms of exemption. Materials which could be considered as candidates for clearance from mining operations could include tailings for land fill and construction purposes, waste rock for building aggregate and scrap steel, timber and plastic. On the assumption that the former materials if released will in fact be used for construction purposes, the selection of an appropriate dose criteria poses problems. Selecting a value at a fraction of

the recommended public limit would result in a very restrictive derived levels for radium-226 in the material and basically preclude the clearance of any material with levels marginally above "average" levels of around 0,03 - 0,05 $Bq.g^{-1}$. The current practice being adopted in South Africa is to employ a process of conditional exemption whereby the end use of cleared material must be specified and must not be use in building construction. This process has many associated procedural and legal complications. Similar problems arise also with the "clearance" of former mining land.

The clearance of scrap materials is also complicated by the fact that a large fraction of contaminated materials arise from the deposition of scales on material and the concept of surface contamination as a criteria for clearance is questionable. Also, as a criteria for release, the concept of bulk contamination, taking into consideration the mass of the non-active object raises questions as invariably subsequent handling and processing of the material results in the scales being removed and giving rise to loose radioactive material of much higher unit density. These problems are presently addressed in South Africa by assuming that all surface deposited material is "loose" and by applying surface contamination levels for clearance at the lower end of the spectrum of values used in various countries Ref [7].

End of Mine Life

For many operations which commenced in the 1940's and 1950's, very little consideration was given to closure and to the potential radiological hazards that may be associated with the mining and processing residues. The potential hazards have become apparent within the past twenty years and hence the associated efforts to rehabilitate mines and sites and to implement engineered waste management solutions. The approach generally adopted is to demolish the buildings and to clear the site of contamination with a view to allowing unrestricted future use of the site. The tailings and waste rock piles are then effectively the resulting radioactive waste requiring disposal. The solutions adopted to date have included in-situ stabilisation, removal to engineered on surface containment cells, backfilling into mines and pits and disposal in water bodies. These solutions have necessarily involved the conduct of hazard assessments to demonstrate their adequacy. Such assessment has involved both deterministic and probabilistic modelling techniques both separately and complimentary. The most difficult challenges facing acceptance of the assessments is selection of the time periods required for demonstration of adequacy combined with predicting the performance of the engineered covers, migration barriers and erosion control features over long periods. The impact assessment of the closed mine poses similar problems.

Design criteria for performance demonstration have generally been limited to between two hundred and a thousand years and radiological criteria have often been set in terms of radon emanation rate from the surface of covers, gamma dose rates and ground water contamination levels. Typical levels being in the range of 700 $mBq.m^2$ s, 0,2 $\mu Sv.-h^{-1}$ and 0,2 $Bq.l^{-1}$ Ra-226 Ref [7].

Because of the need to prevent intrusion into the stabilised tailings , the need to prevent removal of the material for construction purposes and because of the extensive nature of the wastes, and the vulnerability of the covers and barriers, the need for ongoing institution control over these facilities appears to be inevitable.

4. Mining Wastes in the Context of the RADWASS Fundamentals

In view of the relatively low specific activity of mining wastes and the very large bulk volumes, mining wastes have often been viewed in a different light to radioactive waste arising from other parts of the nuclear fuel cycle. The approaches currently being adopted to their management, however, go a long way to respecting the fundamental principles of radioactive waste management adopted by the Member States of the International Atomic Energy Agency.

The principle of protecting human health is respected by adoption of safety standards in line with those recommended by ICRP Ref [8] and endorsed in the Basic Safety Standards Ref [1]. The second principle of protecting the environment is particularly pertinent when considering uranium mill tailings which are often acid generating and contain other non-radioactive potential pollutants such as arsenic, barium, cadmium, chromium, lead and several others. Again the rehabilitation and containment processes often take these other pollutants into account and provide for their isolation from the biosphere. Protection beyond national borders will generally be achieved by the engineered solutions being implemented, although, if mining facilities are close to national borders, the need for demonstration remains. The fourth and fifth principles dealing with protection of future generations and the burden on future generations do raise some questions with mining waste because of the need for perpetual institutional control and the inevitability of the eventual failure of containment structures over the time scale associated with the radioactive half-lives of the radionuclides involved. Nevertheless, the concerns are ameliorated to an extent by the relatively passive nature of the required institutional controls and the relative ease to repair any degradation of the covers.

Compliance with the sixth principle of managing the wastes within an appropriate national legal framework varies considerably between countries. Countries within which a nuclear industry operates often control mining wastes in terms of their nuclear regulatory programme. Such control, however, is often limited to uranium mining wastes and does not cover mining of radioactive ores from which uranium is not extracted. Principles seven and eight requiring radioactive waste generation to be minimised and interdependencies to be considered are features of more recent mining operations and those subject to good regulatory control regimes. The ninth and final principle addressing safety of waste management practise is less of an issue with mining operations due to the low specific activity and the generally chronic nature of the associated hazards.

In conclusion, mining wastes, whilst being characterised by relatively low specific activity and giving rise to chronic modes of exposure, can cause exposures well in excess of public dose limits and can give rise to substantial collective doses. Because of the attractive nature of mining residues for construction purposes and the utility of many of the waste arisings for re-cycling, and the disposal of such wastes often on the surface, particular attention needs to be given to control over their diversion. In addition, due to the relatively significant radiation doses that can arise from radon progeny clearance levels for bulk material must be carefully selected and administered. Because of the long radioactive half lives associated with mining waste, the concept of waste management options involving eventual removal of restrictions

on the disposal sites cannot be realised. The need for consideration of all mining wastes involving elevated levels of natural radioactivity to be managed effectively and not only those associated with uranium mining require due consideration.

Symposium S-14:

„Safety of Large Radiaton Sources“

Chair and Organizer: D. Beninson
Co-authors: Lubenau, P. Ortiz, J. Croft

Safety of Large Radiation Sources

In this Seminar the main protection problems related to the use of large radiactive sources will be examined, in an interactive discussion with the participants.

The subjects to be covered are:

1. **Types and uses of large radiation sources.**
2. **Protection in the case of normal exposures, for fixed and mobile sources.**
3. **Protection against potential exposures for fixed and mobile sources.**
4. **Special protection problems; ozone and other gases production, corrosion, etc.**
5. **Good operation practice.**
6. **Regulatory aspects of the use of large radiation sources.**

The discussion will be carried out in the framework of the ICRP recommendations and with reference to examples of regulatory practice.

Retrospective Dose Assessment

Marvin Goldman
University of California-Davis

Introduction

Radiation dose reconstruction has become a significant environmental sciences specialty over the past decade. Models to integrate limited radiological measurements have been developed and are being validated and improved. For external exposures, our main tools are computer simulations of radiation output from a "source term", be it the A-bombs dropped on Japan, or a hospital fluoroscope. Validation without actually duplicating the exposure conditions leaves a level of uncertainty that is difficult to reduce. The second major class of radiation dose reconstructions relates to those doses absorbed as a consequence of radionuclide intake. Here too, uncertainties exist as to the exact "dosage" quantity and quality and pharmacokinetic behavior in an individual or population are usually not available. I wish to restrict my remarks to this latter case, but also realize that some of what I have to say may be germane to external exposure problems.

Simply stated, my thesis is that the reconstruction of doses from the outside inward, can be assisted by personal biological radiation dosimetry from the inside out. I believe that the case can be made for the fact that the deficiencies and limitations of both sets of tools, environmental and biological dosimetry, are in different dimensions and that the strengths of one approach can assist in reducing the weaknesses in the other. Ideally, an integration of biological and environmental dosimetry for the same case will be synergistic and the resultant "collective" uncertainty will be minimized. This is particularly true of very low doses, where the sensitivity and detection limits of available techniques are stretched to their utmost. For radionuclide-related dose reconstruction, environmental measurements of concentrations and pathways infrequently sufficient to determine a biological source term, the quantity potentially taken in by the individual of population. Adding the appropriate biological, demographic, and environmental factors generates the consequent dose estimate. In the best of all worlds, the findings might be confirmed by actually measuring excreta, body-burdens, and/or biological indicators of radiation damage. We rarely have been able to realize this ideal, because those exposed may have had doses that were below the sensitivity threshold for the available techniques.

I would like to review some of these techniques and present an argument for increased research and development of biological indicators which may provide more sensitive output. To keep this in perspective, I feel that there is room for improvement and advances in the environmental tools as well as for biological dosimeters. A host of sophisticated computer programs now provide a platform for rapid integration of data and integrated output of results. Atmospheric and environmental transport models have continued their evolution to powerful tools.

Remote sensing of biological indicators, such as infrared reflection and emission signatures of radiation damaged plants are now available. Aerial surveys, yielding planar spatial isoconcentrationn gradients of surface contamination are being improved by integrating global-positioning-systems with focal emission rate data. Faster processing and more sensitive, stable detectors are also providing improvements. On the ground, improved sampling techniques, provide concentration gradients and temporal and spatial profiles important for reconstructing prior situations. Thermoluminescent dosimetry of stable signals form radiation exposed geologic and biologic samples add to our armament. All these techniques present opportunities for dynamic improvement. Added to these tools are the retrospective, historic description and documentation of events and measurements of past exposure related information. At times, I am not too certain if there is adequate support and commitment for the future development activities. I add my personal plea for a more integrated international program to improve sensitivity of techniques, to calibrate and "certify" the techniques and to explore and develop new methods.

Biological Dosimeters

The object of this overview is to indicate some important roles for biological indicators of radiation exposure in our overall planning for modern radiation retrospective dosimetry. These are either bioassays, direct physical measurements of radiation and radioactivity, or they are biological signals which are derived from living systems which record radiation effects.

Biological assays of radioactivity are simply collections of excreta from body burdens, the data from which when input to pharmacokinetic models provide and indirect estimate of the body burden and hence the associated radiation dose. This is particularly important for alpha emitting radionuclides whose emanations are too difficult or impossible to detect in-vivo. Whole body and partial body counting techniques are especially sensitive for body burdens of gamma-emitting radionuclides. Energetic beta-emitters can be assayed using bremmstrahlung counting and appropriate standards. (An important contribution from Chelyabinsk, Russia will illustrate this tool). Post mortem tissue sampling, and in some cases, tissue biopsy, (e.g. tooth), can also provide direct input into body burden estimation.

A renewed interest has developed for the use of electron spin resonance of biological crystals which had received radiation doses. Because of the long stability of the signal in exposed crystals the technique has even been applied to dating of mastodon tusks, using the integrated natural background radiation signal over many thousand years. More practically, it has been used to measure the absorbed dose signal from the jaw of a survivor of the a-bombing of Hiroshima 39 years ago. The crude device had poor sensitivity, (i.e. 1 Gy), but did demonstrate the feasibility of the method. For small chips of tooth enamel, a sensitivity of about 0.1 Gy is reported and a ten-fold improvement is quite possible. (We shall hear more of this in today's Symposium).

I would like to make a plea here for a concentrated effort to truly exploit this technique to its limit, to effectively engineer and develop both an in-vivo and an in-vitro methodology that is internationally calibrated and accepted. My journeys through this technique over the past eight years have proven to me that many well-meaning scientists working in competition have not yet assembled the critical mass needed to achieve this goal in a reasonable time. For the dose reconstructions planned, as well as for accident management needs, there is no reason to continue in present manner. I view this techniques as a biological dosimeter as useful as the thermoluminescent dosimetry as proven to be for personal and environmental dose documentation. This is one of my challenges to you.

Cellular markers or indirect indicators of radiation dose are either cytologic indicators or variations on measurement of somatic gene mutations. The advances in cell and molecular biology have not in my opinion carried adequately over to the arena of biological dosimetry. Years ago we were promised an automated **chromosome aberration scoring** device. We are still waiting for a dependable karyotype scoring device. For the most part, the scoring of chromosomal aberrations is still done manually and tediously as it was some three decades ago. Where is the application of modern pattern recognition, so well developed for space applications, but absent in microscopic assays? There have been a few heroic attempts to solve the problem, but it appears that there is no truly integrated biological-engineering heavy attack on the problem. Since the greatest interest is in stable chromosome translocation scoring, the least plentiful aberration, it is all the more imperative to push this technology as far forward as is possible. In this case, sensitivity and accuracy is a function of the sheer number of cells that are scanned, and is limited to the visual fatigue index of the scoring technician. This is another serious challenge for us to address.

The **micronuclei test** is very useful, accurate and simple. It has a major drawback in that it does not distinguish between dividing and non-dividing cells; thus as an unstable aberration assay it is limited to very short times after exposure and is not very helpful in long term retrospective dosimetry.

A newer cytogenetic tool to identify chromosomal translocations has now been developed. The use of **fluorescent in-situ hybridization** now appears as one of the more powerful techniques for identifying stable damage to chromosomes from radiation. The technique is complex and at present limited to a few laboratories. It is costly and it remains to be seen if some automated modification will be available which can increase its applicability and sensitivity to detect small radiation doses. It has sufficient promise though, that I would encourage a quantum increase of multi-disciplinary expertise focussed on this assay, especially in determining its ultimate sensitivity. This is my third challenge.

For several years we have been presented with an array of somatic gene mutation techniques. One that has received much attention recently is the **glycophorin-A assay**, using a fluorescent labeled monoclonal antibody to the protein

and measuring the loss of a red cell allele in irradiated people. It is purported to be a very stable indicator, with lifelong persistence. I am not enough of a biochemist to go into great detail, but I am concerned that the technique has severe limitations as a radiation biodosimeter. It does not appear very reproducible in the same individual, even though millions of red cells are measured in the assay. There seems to be very great variability among individuals exposed to the same dose, and there has not yet been a careful calibration using persons with known exposures. It is simple, relatively cheap and potentially useful if it can be calibrated and validated.

As with the micronuclei test mentioned above, the **HPRT - mutation assay,** (hypoxanthine phosphoribosyl transferase mutations in T-lymphocytes), is limited to very short times after exposure; it's "signal" faded rapidly. Another assay, the **HLA-A,** (human leukocyte antigen A assay), is tedious, insensitive and not promising at this time. The **beta globulin test** likewise offers some promise, but it is too early to state if this fluorescent antibody indicator of a single base change in hemoglobin can provide a practical tool. There may be other useful techniques in various stages of development.

Individual Biological Dosimetry: an Integral Part of Radiation Dose Reconstruction

What is advocated here is the full utilization of these biomarkers as integral elements in future radiation dose reconstructions. What I have seen thus far is the occasional use of one or more assays, more as an afterthought than an integral part of the protocol. The reason for this which is usually put forth, is that the techniques are too expensive and technology intensive and with insufficient radiation reliability or sensitivity. However the limitations of environmental radiation dose reconstruction also entail significant uncertainties about the variables used in modeling, no matter how sophisticated the tool.

While we are improving the validation and calibration of these models, why not also put in the effort to render the biological tools more sensitive and reproducible? Incorporating statistically appropriate individual measurements in the reconstruction matrix can add a powerful dimension to our efforts at dose reconstruction. I envision a time in the near future when there may be a convergence of these two approaches with a resultant synergy of action that produces dose reconstructions with minimal uncertainty and maximal credibility. I can see where the strengths of each technology can assist in reducing the weakness of the other, to help us answer important questions about prior radiation exposures. Major resources are expended on epidemiology studies, with great emphasis on confounding factors, on subtracting natural disease rates from the subject population, etc. However all this emphasis on reducing uncertainties on the "ordinate" of the relationship, must be accompanied by an equal dedication to minimizing uncertainties about dose. Population estimates based solely on broad environmental models, while sensitive, can only be verified by use of individual measurements. Despite 30 years of work, individual doses in survivors of the

atomic bombing of Japan, still pose large levels of uncertainty. New biological dosimetry is helping to reduce the uncertainty; and so it should in the other populations at risk from prior exposure. That is my final challenge to you.

The Measuring and Modelling of Strontium-90: an Integrated Retrospective Dosimetry Issue

M.O. Degteva, V.P. Kozheurov, E.I. Tolstykh (Urals Research center for Radiation Medicine, Chelyabinsk, 454076, Russia)
A.N. Kovtun (Institute of Marine Transport Hygiene, St. Petersbourg, Russia)

Introduction

Dose reconstruction for internal exposure is generally structured on a paradigm of release-transport-intake-uptake-dose. In some cases when it is necessary to reconstruct individual dose for the long time after intake and historical information on the releases is limited, bioassay measurements can be used for retrospective dosimetry of long-lived radionuclides with long biological residence times. Internal dose is related to the time integral of the body burden, therefore, individual measurements of body burden, metabolic model and some general suggestions on intake pattern are three necessary parts for dose reconstruction process in such cases.

^{90}Sr is long-lived bone-seeking radionuclide with a long biological residence time in the body. The world list of data on strontium in man was restricted to a few experimental findings with a single intake, information on global fallout and the measurements of dial painters. A large multitude of measurements of ^{90}Sr in human body for the residents of the Techa river (Southern Urals, Russia) contaminated by fission products in 1949-1956 has been published in open literature only recently (Kozheurov, 1994; Degteva et al., 1994). The necessity of dose reconstruction from long-lived radionuclides for the population living on the territories contaminated as a result of Chernobyl Accident calls the utilisation of the Urals experience to optimise the efforts. An analysis of a unique and abundant Urals data set on strontium in humans presents also a great interest for general purposes of retrospective dosimetry.

Population exposure in the Urals occurred as a result of failures in the technological processes at the Mayak plutonium facility in the 1950's. Construction of the Mayak facility began in 1945 and was completed in 1948. Initially this complex consisted of three main parts: Reactor plant, radiochemical facility, and waste-management facilities. The major sources of radioactive contamination were: (1) the discharges of 2.7×10^6 curies of liquid wastes into the Techa River (1949–1956); (2) an explosion in the radioactive waste storage facility in 1957 (the so-called Kyshtym Accident) that formed the East Urals Radioactive Trace (EURT) due to dispersion of 2 ×

10^6 curies in the atmosphere; (3) the resuspension of 600 curies with dry silt from the shores of Karachay Lake during a heavy thunderstorm (1967); and (4) routine gaseous aerosol releases within the first decades of the facility's operation (Degteva et al., 1996). The significant portion of activity for the Techa River and EURT consists of long-lived radionuclides, mainly ^{90}Sr. These releases resulted in the long-lived contamination of surrounding territories. The activity released from Karachay Lake also consisted of ^{90}Sr and ^{137}Cs, and it superimposed on already existed EURT.

There are two cohorts of accidentally exposed population in the Urals: the residents of the Techa riverside communities and the residents of the area covered by EURT. The object of primary interest is Techa River population. The Techa River cohort is important because some of whose members have received relatively high doses and a significant increased risk of leukemia with increasing dose was observed (Kossenko and Degteva, 1994). The residents of the villages along the Techa were exposed to both external irradiation (from contaminated river water, sediments, flood plane soils) and internal irradiation due to ingestion of radionuclides (mainly ^{90}Sr) with drinking water and diet.

Whole-body counting system for measuring ^{90}Sr via bremsstrahlung

Since 1974 the large scale investigations of the ^{90}Sr content in the skeleton of Techa riverside residents with the whole body counting system SICH-9.1 were started. A detailed description of SICH-9.1, of the measurement procedure and results were given elswere (Kozheurov, 1994). The shielding for the whole-body counter was made of cast iron rings with a wall thickness of 200 mm. The inner surface has linings of lead (5mm), cadmium (1.5 mm), and copper (1 mm). Four Phoswich detectors are used for measuring. The geometry of measurement is as follows: the detectors are fixed in the central vertical plane with a 30° inclination towards the vertical. The distance between the axes of each pair of detectors is 35 cm at the base. On the bed frame, fabric is stretched which caves in under the weight of the body in such a way that the medium plane of the body is at a distance of 25 cm from the detectors. During the measurement the proband's bed is moved through the detector array. The scanning length is 2 m with stops at the ends lasting 10% each of the whole measurement time. The motion is controlled by impulses from the analyzer real-timer. The duration of the measurements is 20 min. The scanning device used in SICH-9.1 is discussed in (Zaitsev and Kozheurov, 1978), and the calibration technique of

the whole-body counter is described in (Kozheurov et al., 1978). Minimum detectable activity (MDA) for SICH-9.1 is equivalent to 1.85 kBq of ^{90}Sr.

For the calibration of WBC two surrogate human structures were made by two different laboratories. Both phantoms were made of natural human skeletons, paraffin imitations of soft tissues and dry paper imitations of lung. Different methods of introducing ^{90}Sr into the bones of the phantoms were used. In one of the phantoms the isotope was introduced by being dripped into uniformly distributed holes drilled the bones. The bones of the other phantoms were impregnated with ^{90}Sr solution in a vacuum chamber. Each laboratory performed independent experiments aimed at determining bremsstrahlung yields relations and the influence of human soft tissues and the phantom paraffin on the absorption of the bremsstrahlung. Independent activity measurements were carried out on each phantom. After scanning the phantoms and making the appropriate corrections the difference in calibration coefficients was determined to be 6%. This value represents the estimate of the systematic error in ^{90}Sr counting by means of the spectrometer. Water-filled phantoms made of plastic tanks laid out in such a way as to imitate a human body were used for calibration of ^{137}Cs and ^{40}K. The length of the phantom could be changed by removing one or two tanks. Such calibration was done in 1974 and did not confirmed during twenty years period of WBC operating. It is highly desirable to ensure that the old measurement system is once again calibrated in depth on the basis of measurements of a special antropomorphic phantom.

Strontium Registry

The measurements of ^{90}Sr in humans for the residents of the Techa river were started in 1951. The first findings were ^{90}Sr concentrations in different bones received from autopsies (Table 1). Since 1960 the surface beta-activity on the teeth has been measured; this was made possible with the detectors suitable to perform such measurements in the mouth of a person (Kozheurov, 1994). From 1962 through 1979 daily urinary excretion was estimated by radiochemical methods. And since 1974 the Techa river residents have also been examined for their body burdens with the whole-body counter (Kozheurov, 1994). In parallel with whole-body counting the measurements of beta-count of forehead bone are carried out. About 30,000 measurements have been performed on more than 14,000 persons from the contaminated. Both men and women of all ages have been measured. This has given a unique experience of the arrangement of individual monitoring of ^{90}Sr human body contamination. A list of available data is given in Table 1.

Table 1. Techa River Strontium Registry.

Measured values	Number of measurements	Number of subjects measured	Period of observation
Sr-90 whole-body content	28,500	14,200	since 1974
Tooth beta-count	30,200	15,300	since 1960
Forehead beta-count	23,100	12,300	since 1976
Sr-90 urinary excretion	2,910	1,564	1962-1979
Sr-90 concentration in bone	350	160	1951-1973

The results of the multitude of measurements showed a clear dependence of the ^{90}Sr body burden on the year of birth, and formed the basis for the elaboration of age-dependent model for strontium retention in human skeleton.

Metabolic Modelling of Strontium

Our age-dependent model of strontium retention in human bone is descridbed in detail elsewere (Degteva and Kozheurov, 1994). This model represents mathematical function similar to ICRP-20 retention function (in a simplified form), in which parameters are dependent on age at intake. The main task for the model development was to estimate the parameters and to validate the model under different conditions of strontium intake. The approach to the validation of metabolic models established in ICRP Publication 20 and accepted now, was the following: to collect all available sets of data on the metabolism of a particular radionuclide in humans which are suggested to reflect Reference Man (ICRP-23) under various schedules of intake; to fit model calculations for available schedules of intake based on the metabolic parameters of Reference Man to the sets of data. Thus, checking of model fitness and parameter verification are carried out.

As a starting point for parameter fit the general view of some age-dependent functions was identified by combining relatively extensive information concerning the development of the human body with the findings of experiments on different species of animals. Then the available sets of human data were determined for the more precise estimates using empirical fitting technique. Besides the Techa river data, the information on strontium in human bone from global fallout (Leggett et al., 1982; Loutit, 1967; Papworth and Vennart, 1984; Warren, 1972) and experimental findings with single injection (Bishop et al., 1960; Kereiakes et al., 1968; Kohn et al., 1962; Likhtarev et al., 1975; Woodard and Dwyer, 1972) were involved in parameter estimation and the validation of our model. Such approach has allowed to derive the model which takes into account changes in metabolic parameters throughout the entire life beginning from bone formation and growth in childhood and including loss of skeleton calcium in old age. The model gives reliable description of ^{90}Sr retention from one month to thirty years from the moment of intake.

Another possibility of the model verification was given by a set of data on direct assessments of individual strontium excretion rates dated 25-35 years after the basic intake for persons aged 30-70. Excretion rate was estimated by two different methods: using radiochemical analysis of bioassay samples and on the basis of repeated whole-body counter measurements (Table 2). The latter approach made it possible to receive the most detailed information concerning age- and sex-dependencies of the late phase of excretion, in comparison with earlier studies (Muller, 1970). The comparison of model prediction with experimental results has shown that our model overestimates excretion rate for the ages 30-45 years and does not take into account distinct sex differences in excretion rates for the elderly persons. This fact give us reasons to continue our studies and to improve our new model for strontium metabolism. Nevertheless, the model presented served to bring together into a relatively simple framework the majority of experimental data on strontium in humans and can be useful as workable age-dependent model in radiation protection.

Table 2. The comparison of strontium excretion rate estimates in late phase of retention for humans.

Study description	**Muller, 1970**	**Present paper**	**Kozheurov, 1994**
Sample information - sex - age, yr - ^{90}Sr body burdens, kBq	9 luminizers 1 M + 8 F 22 - 41 1.85 - 70.3	40 residents of the Techa riverside 21 M + 19 F 37 - 50 7.4 - 145.0	717 residents of the Techa riverside 367 M + 350 F 30 - 76 3.0 - 164.5
Methods of measurements	Radiochemical analysis of bioassay	Radiochemical analysis of bioassay in parallel with whole-body counting	Repeated WBC measurements made within 5-10-year intervals
Time since exposure, yr	2.2 - 8.2	29 - 30	25 - 35
Statistical evaluation techniques	Model extrapolation using additional data on stable Sr	Direct assessment	Direct assessment
Resultant excretion rate estimates	$(7.7\pm1.0)\ 10^{-5}$ per day 0.028 ± 0.004 per year	$(8.3\pm3.6)\ 10^{-5}$ per day 0.030 ± 0.013 per year	Distinct age- and sex-dependence. Mean value for ages 30-40 years: 0.025 ± 0.016 per year

Conclusions

The results of a long-term investigation of the Techa river population have given a unique experience in the arrangement of individual monitoring of ^{90}Sr human body contamination for the purposes of retrospective dosimetry. Techa River Strontium Registry data base can serve for the development of age-dependent metabolic models for long-lived bone-seeking radionuclides. The data of concern are of major interest to the reconstruction of dose to the red bone marrow and bone surfaces of the members of the Techa river cohort which could give a possibility of direct radiation risk assessments for long-term chronic exposure conditions.

SUMMARY

The residents of the villages along the Techa river, Southern Urals, Russia, were exposed mainly external by γ-rays from ^{137}Cs and internal by β-rays from ^{90}Sr and its daughter ^{90}Y, as a result of the heavy release of radioactive waste from the plutonium production facility Mayak into the Techa in 1950-51. The residents living at the lower part of the river were exposed only little externally but mainly internally due to their ^{90}Sr body burden. Teeth from the latter group of residents which were extracted in 1994-95 in the course of dental care were collected and used for retrospective dosimetry more than 40 years after the main ^{90}Sr ingestion.

The absorbed dose in the enamel of the teeth was measured by EPR dosimetry. In addition the ^{90}Sr content in the roots of the teeth was measured by low-level beta counting. Both measurements at the teeth were done in 1995. The whole-body burden of the tooth donors was measured via bremsstrahlung in 1992-1994. The absorbed dose in the enamel of molars was found to correlate with the retained ^{90}Sr whole-body burden (Fig. 1). The equivalent dose in the enamel of the molars per ^{90}Sr body burden retained 42 years after the ingestion was determined to $3*10^{-5}$ Sv/Bq. The accumulated background dose in the enamel of the in average 60 years old residents was found to be about 100 mSv. This results in an average annual dose rate for the background radiation of 1.7 mSv/a. The results suggest that the absorbed dose measured in the enamel of molars can provide information about the ^{90}Sr burden as a mean of the whole skeleton. In contrast to the encouraging results obtained from the dose measurements in the enamel of molars, no correlation with the ^{90}Sr body burden was found for the dose measured in the enamel of incisors. Similar discrepancies with dose measurement in the enamel of incisors were found earlier by other authors also in the case of predominantly external radiation. At present the reasons for these difficulties are not known but might be due to stronger sensitivity to environmental influences and/or problems in preparing the very thin layers of the enamel of incisors for the EPR measurement. Until these problems are resolved we recommend to exclude measurements of the enamel of incisors for retrospective EPR dosimetry.

No correlation could be found for the absorbed dose in the enamel of neither molars nor incisors with the ^{90}Sr content in the dentine of the roots of the teeth (Fig. 2). Due to the short range of the β-rays from ^{90}Sr and its daughter ^{90}Y, the dose in the enamel is expected to result predominantly from the ^{90}Sr content in the adjacent dentine within the tooth crown and less from the content in the root dentine. The results of the present investigation let suppose that the strontium metabolism in the dentine of the crown is comparable with the that of the mean of all parts of the skeleton. In contrast to the dentine of the root which is under extreme mechanical strain and hence remodels strongly. Therefore, measurements at the root dentine are not expected to provide conclusive information about the ^{90}Sr burden of the overall skeleton.

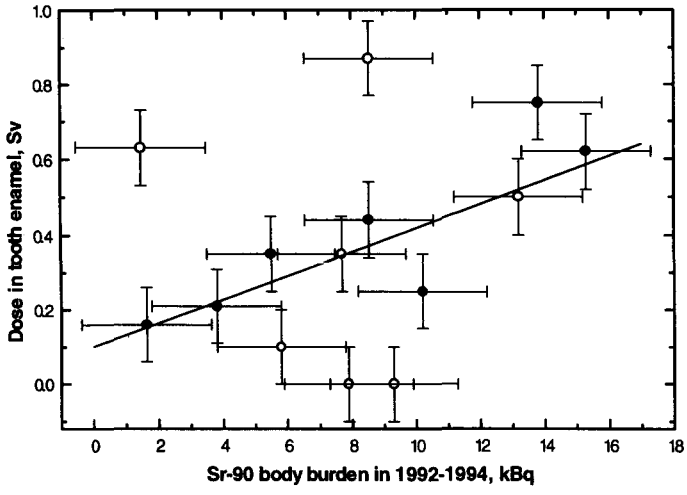

Figure 1. The absorbed dose in tooth enamel as measured by EPR dosimetry versus the ^{90}Sr whole body burden. The dose in the enamel from molars (●) were found to correlate with whole body burden. No correlation is obvious for the dose in the enamel of incisors (○) with the whole body burden.

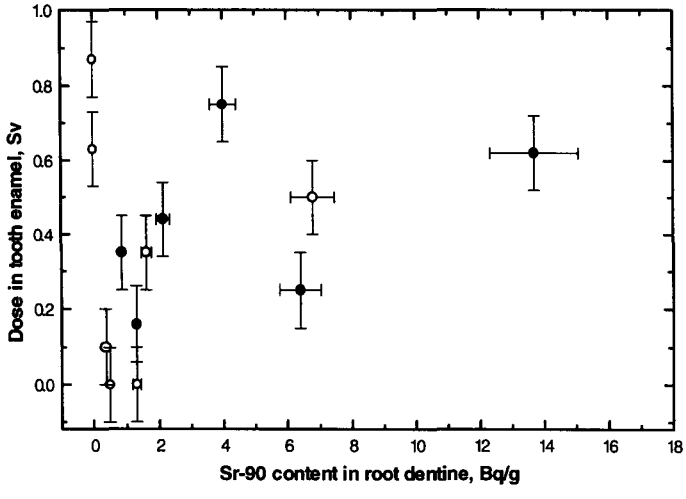

Figure 2. The absorbed dose in tooth enamel as measured by EPR dosimetry versus the ^{90}Sr content in the root of the tooth. The dose in the enamel from molars (●) and incisors (○) were found to correlate not strongly with the ^{90}Sr content in the root.

Retrospective Dosimetry using EPR and TL Techniques: A Status Report

E.H. Haskell

Division of Radiobiology, University of Utah

Methods of retrospective dosimetry, including luminescence and electron paramagnetic resonance spectroscopy (EPR), rely on measurement of accident dose absorbed by naturally occurring materials - ceramics in the case of both thermoluminescence (TL) and optically stimulated luminescence (OSL) and organic materials and bio-minerals in the case of EPR. Each of these methods relies on measurement of radiation defects resulting from accidental exposure. Since defects also result from natural sources of radiation over the lifetime of a sample, analysis is usually restricted to materials for which the natural dose may be determined and subtracted from the measured cumulative dose.

The transient, or accident radiation dose 'D_X' is determined as follows

$$D_X = D_{TL} - (R_\alpha + R_\beta + R_\gamma + R_\chi)A$$

Where

D_{TL}	=	TL measurement of total accrued dose
A	=	Sample Age
R_α	=	alpha dose rate
R_β	=	beta dose rate
R_γ	=	gamma ray dose rate
R_χ	=	cosmic ray dose rate

Luminescence dating techniques rely heavily on an accurate assessment of cumulative dose from natural radiation sources, and dating research has provided us with the bulk of our knowledge in this area [1]. Virtually all of the work on natural dose determination can be directly applied to retrospective techniques. With EPR techniques the cumulative dose from diagnostic x-rays is also of importance.

Electron Paramagnetic Resonance Techniques

EPR analysis of tooth enamel can provide measurements of cumulative dose to teeth. The attraction of enamel as an individual dosimeter lies in the ubiquity of the material and the fact that

wisdom teeth are routinely removed and others are extracted as a result of age related periodontal disease.

Interlaboratory Comparisons of EPR Techniques

EPR dosimetry of tooth enamel is in a rapid stage of development. Two interlaboratory comparisons have produced recent validation of different aspects of the technique. The first, performed as part of ECP-10, was a blind study [2] involving 9 laboratories from the Former Soviet Union (FSU), Europe and an invited laboratory from the U.S. The results of this intercomparison showed marked variation in accuracy produced by individual laboratories, however one laboratory produced results which exceeded expectations (Fig. 1). The study was designed to assess the reliability of different methodologies under ideal conditions. The intercomparison involved the preparation of a homogeneous mixture of grains from unirradiated teeth which were irradiated after crushing. The project did not examine effects which may be associated with the preparation procedure or effects associated with irradiation of whole teeth versus crushed teeth. The results are currently being assessed by the individual members of the project, and the analytical procedures used by the most successful laboratory are being adopted in whole or in part.

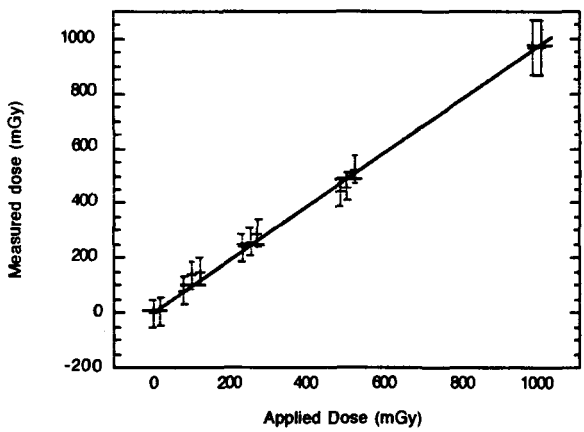

Fig. 1. Most accurate results of the ECP-10 intercomparison

A second, bilateral intercomparison [3], performed by the University of Utah and the Ukrainian Scientific Center for Radiation Medicine (USCRM), was designed as a pilot study for future multilaboratory comparisons. This study involved irradiation of teeth prior to crushing. The design of the blind study allowed assessment of applied dose as well as dose from prior x-rays. Results from both laboratories showed mean deviations of measured versus cumulative dose (including x-rays) of approximately 20% for doses on the order of 0.2 Gy.

Problems associated with EPR analysis of enamel

EPR of enamel is not without its problems, and additional research is needed to clarify and minimize uncertainties. The presence of organic and mechanically induced signals [4,5,6] superimposed on the radiation sensitive signal has been recognized as a potential limiting factor in the ultimate accuracy of the technique. The need for a zero dose background spectrum which is subtracted from the spectrum of an irradiated tooth means that variations in the large organic signal will be translated into significant errors in the overall dose estimate. The approaches to this problem have been threefold. The first involves examination of each spectrum generated from an irradiated tooth and comparison with a well prepared zero dose background tooth [7]. Deviations in the organic signal are, with experience, recognized and eliminated by treatment in NaOH. Once organic signals match, the spectra may then be subtracted. The validity of this approach is evidenced by results (Fig. 1) from the ECP-10 intercomparison. A second approach involves modeling of the EPR signal and computer isolation of the organic and radiation sensitive components. Progress in identifying and isolating the organic component from the mechanical portion has recently been made with the use of organic and synthetically grown apatites [8]. The third approach involves variations on the measurement procedure itself and utilizes differences in signal saturation as a function of microwave power. The differential power method [9,10] allows determination of cumulative dose without the need for a zero dose background signal. Additional work is needed with methods two and three above, however the implementation of the first method offers an immediate reduction in uncertainties due to the background organic signal.

Another recently recognized problem associated with EPR dosimetry of teeth involves the effect of light exposure on the EPR signal of teeth [11]. This problem was identified by observing large variations in dose estimates obtained by analysis of incisors and canine teeth which may be exposed to sunlight. This effect poses a serious limitation in the ability to perform EPR dosimetry on canines and incisors, however it appears to have no effect on analysis of molars or wisdom teeth. It does reduce the total number of collected samples which can be analyzed with confidence, and in some cases it may mean a retrospective deletion of previously measured samples..

Yet another potential source of error of EPR dosimetry of enamel concerns the effect of pre and post crushing sensitivity of the radiation induced signal. Recent research [12,13] indicates that an overestimate of dose may be obtained if grain sizes smaller than 100 μm are used to measure dose delivered prior to crushing. This study, while not yet confirmed by other laboratories also

indicates that use of grain sizes in the range of 250 to 600 μm does not produce this overestimate. This effect also requires further examination and explanation.

Dental x-rays can represent a significant source of uncertainty in dose estimation due to the difference in energy dependence of hydroxyapatite versus that of soft tissue. A seven to one difference in deposited dose in enamel versus that in soft tissue at typical x-ray energies of 60 KeV represents a threat to the utility of EPR as a biological dosimeter. Fortunately, two factors reduce this uncertainty. The first is the purported rarity of dental x-rays in the FSU, an assertion which needs additional documentation, and the second is the differential dose deposition in the outer and inner portions of teeth due to attenuation of the x-ray beam. This effect has been used previously to distinguish dose due to x-irradiation [14,15,16] and was used by USCRM to determine x-ray dose in the teeth used in the bilateral intercomparison mentioned above [28]. Because of the potential overestimation of dose due to dental x-rays, it may be necessary to routinely measure interior and exterior portions of teeth. Molars or wisdom teeth, because of their large size, may again be required for this multiple analysis.

Riding on each of these uncertainties is another potential limitation to the accuracy and ultimate lower limit of detection of EPR techniques. This source of uncertainty is the non-isotropic response associated with measurement of crystalline grains. Theoretically grains sizes sufficiently small will result in an isotropic EPR response which is independent of sample orientation. In practice, use of such small grain sizes may present a problem of sensitivity difference mentioned above. Additionally, the effect of anisotropy is enhanced with increasing microwave power. This places limits on the effectiveness of the two power method discussed previously. A recent addition to the EPR dosimetry process, a constant rotating goniometer [17], reduces the effect of anisotropy making measurements at all microwave powers, and particularly the higher powers, significantly more accurate. Since the organic component of the EPR signal seems to be most effected by anisotropy, this procedure may well result in reduced limits of detection. Fig. 2 shows the result of three spectra obtained following separate shakings with no rotation and three spectra obtained following separate shakings with rotation during spectral measurement. The spectra have been passed through a low bandpass filter to remove high frequency noise and more clearly show the improved reproducibility.

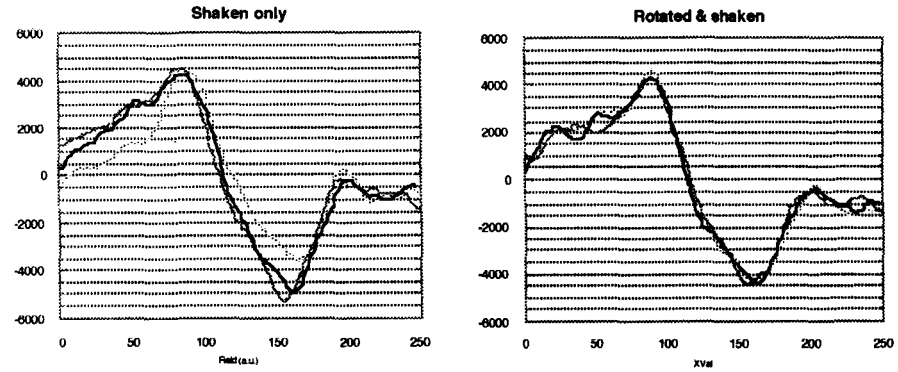

Figure 2. Effect of constant rotation goniometer on EPR reproducibility.

Many of the uncertainties addressed above are serious and can result in significant inaccuracies if not properly recognized and addressed. However, none of them seems insurmountable nor represents a fundamental limit to the utility or accuracy of the technique. Assessment of errors has received recent attention [18] and methods for time optimization of analysis are also being developed [19]. In fact, it seems highly likely that continued research will result in steady improvements in the speed, reliability, and lower limits of detection of teeth as an EPR dosimeter.

A related EPR technique involves measurement of deorganified dentine and comparison with measurements from enamel [20,21]. This technique has the potential of allowing differential measurements of dose due to external gamma rays as well as internal emitters such as Sr-90. An advantage to the use of dentine as a dosimeter is the fact that the organic signal present in enamel is eliminated in the deorganified dentine. Use of dentine also eliminates any possible effects of UV irradiation. At present the lower limit of detection of dentine dose does not reach that of enamel. However, this area of research is still in its infancy.

Luminescence Techniques

Luminescence dosimetry of environmental materials was first associated with accident dose reconstruction during the early 1960's. Thermoluminescence techniques were applied to the reconstruction of doses at Hiroshima and Nagasaki [22,23,24,25,26], the Nevada test site [27,28], and most recently, the regions downwind of the Chernobyl Nuclear power plant [29,30,31]. Several reviews of retrospective techniques used in these studies detail procedures, associated problems and experimental validations which have been conducted [32,33,34]. Perhaps the most extensive effort at technique validation prior to current efforts associated with the Chernobyl

accident was the TL study of Hiroshima and Nagasaki conducted as a part of DS-86 [24]. Validations included tests of dose rate effects, neutron sensitivities, preparation effects and numerous intercomparisons and intercalibrations. A partially blind, multilaboratory study involving NBS-irradiated annealed quartz removed from a Nagasaki brick sample produced measurements of dose which agreed with applied values to within better than ±10% (1s) at each of 3 dose levels ranging form 82 mGy to 417 mGy. Comparison of identical tile samples, when measured by both the high temperature and pre-dose TL techniques, produced agreement of ± 10% [35]. In an intercomparison involving different tiles from the same sampling sites, the laboratories also produced dose estimates agreeing to within ± 10%. The TL results showed close agreement with theoretical calculations in the city of Nagasaki. Interlaboratory agreement was again very close at a site in Hiroshima examined by the laboratories, however the overall measurements in Hiroshima at a distance from the hypocenter of approximately 1.4 km was approximately 20% higher than theoretical calculations. Further measurements using both the pre-dose and high temperature techniques at even greater distances has tended to verify these results [36,37,38]. The reason for the discrepancy between the measured and calculated gamma ray dose values in Hiroshima remains unclear, as does an even greater discrepancy between theoretical and measured neutron fluences in that city[39,40,41].

Concurrent with the Hiroshima/Nagasaki effort was an evaluation of doses delivered to regions downwind of the Nevada Test Site [27,28]. This effort evaluated transient doses of less than 100 mGy and relied exclusively on the use of the predose TL technique. Because the doses of interest were low compared to natural dose accumulation, rigorous diagnostic tests [27,28,42,43] were developed and applied. The study allowed comparison of measured doses in building bricks versus evaluated exposure estimates based on soil sampling measurements, reevaluation of original monitors reports and a comprehensive review project.

The Chernobyl nuclear accident has lead to several recent applications [29,30,31,34] of TL techniques. Again collaborative efforts were employed allowing intercomparisons of separate techniques as well as similar techniques applied by different laboratories.

The multi-national effort sponsored by the European Community (ECP-10) in collaboration with the Former Soviet Union, continues to examine the feasibility of retrospective techniques applied to the Chernobyl accident. The program has contributed to the validation of more recently developed techniques, has incorporated measurement into Monte Carlo models at actual exposed locations has investigated correlation of measured dose depth profiles in ceramics with theoretical calculations and has mounted a series of studies designed to insure interlaboratoy reliability [44].

Perhaps the biggest question currently facing luminescence dosimetry efforts involves optimization of methods for integrating results into modeling efforts. This problem is being addressed by the ECP-10 effort and requires close cooperation of modelers and measurers at the earliest stages of reconstruction.

RISK EVALUATION AND DECISION MAKING

Bo Lindell
Swedish Radiation Protection Institute
S-17116 Stockholm, Sweden

THE THRESHOLD ERA

In the early days of radiation protection, the harm to be avoided (skin damage and deterioration of bloodforming organs) was of *deterministic* nature, with a dose threshold that had to be exceeded for harm to occur. "Tolerance doses" and dose limits were chosen with a margin of safety to make sure that deterministic harm could not arise.

In this case, the doses to control would be the sum of all dose contributions, irrespective of source, since it would be the total dose that would cause the harm. Conceptually, this would have called for inclusion of medical exposures and doses from natural sources in the dose to be controlled, but in practice the latter contribution was believed to be insignificant and not controllable but fairly constant, while the medical exposures fell under the responsibility of the medical doctor. However, in principle, the assessment and control was *individual-related.*

THE STOCHASTIC CASE

On the assumption of dose thresholds for harmful effects, unconditional safety could be guaranteed if the sum of all dose contributions did not approach the threshold. When it was realized that some harm (cancer and hereditary harm) was of *stochastic* nauture and showed dose-response relations in which no thresholds could be assumed, the situation changed strikingly. No dose could be said to be absolutely safe, and the choice of a dose limit implied a decision on acceptable risk rather than the identification of safe doses.

The assumption of a linear, non-threshold relation between radiation doses and the probabilities of the various types of stochastic effect over the dose region of interest in normal operations made it justified to consider the dose contributions from each source or practice without regard to doses from other sources, as long as the total dose was not too high. Each dose increment is expected to cause one and the same detriment increment irrespective of other exposures. This opened the door to *source-related* assessments and decisions.

OPTIMIZATION OF PROTECTION

The awareness of stochastic harm made the situation more complex in some respects but more simple in other ones. To continue with a control system that depended on a fixed dose limit no

longer seemed appropriate; it would have been unnecessarily stringent in some cases and too relaxed in others. The position of the dose limit as the primary means of control was not retained; instead, the main protection principle became the attempt to keep all doses "As Low As Reasonably Achievable, economic and social factors being taken into account" (optimization of protection, sometimes referred to as ALARA). It was obvious that, at some level of protection, the cost and efforts of further dose reduction would not be justified.

Various methods may be applied to reach ALARA. In the first ICRP interpretation [1], the principle was illustrated by means of differential cost-benefit analysis, but (as the Commission says in its 1990 recommendations [2]) the methods range from simple common sense to complex techniques of cost benefit analysis or multiattribute analysis. In all cases the objective is to minimize the sum of the costs of protection and the radiation detriment. Protection costs may include more than money, and the radiation detriment may include more than detriment to health. However, to make comparisons possible, all these components must be expressed in monetary terms, implicitly as in applying common sense or explicitly as in cost-benefit analysis.

THE VALUE OF α

If the collective dose is taken to indicate the radiation detriment, cost-benefit analysis must be based on some *a priori* decision on the amount of money that it would be appropriate to pay to eliminate a unit collective dose. This amount (expressed in, *e.g.* US$ per man·Sv) is often referred to as "α". If all doses are in the region of stochastic harm, the choice of α implies a choice of a corresponding amount of money (we may denote it "A") appropriate to pay for saving, in a statistical sense, a not identified human life. The relationship between A and α is $\alpha = r \cdot A$, if r is the probability coefficient for radiation-induced death or death equivalent harm (in ICRP Publication 60 [2] r is given as 7.3% per Sv for an average member of the population at large and 5.6% per Sv for the average worker).

The appropriate value of A can easily be shown to fall between two extremes. The lowest value may be derived from the annual gross national product *per caput* of the productive population. It would be short-sighted to pay less per man·year saved, and for equity reasons at least the same amount should also be paid in saving non-productive man·years. The highest value may be derived from an estimate of the potential saveable man·years per year in the population and the highest fraction of the annual gross national product that could be used for statistical lifesaving without jeopardizing society's capability to sustain the same capacity for lifesaving over future years. The range for the choice of A in developed countries is then found to be roughly 0.5 - 5 M$ and the available range for the choice of α would be 0.035 - 0.35 M$. The geometric mean of the extremes is about 100.000 $ per manSv.

It is sometimes said that cost-benefit methods would be unethical because we should not "set a price" on a human life. This claim was considered by an expert group appointed by the Pontificial Academy of Sciences in 1983, but it was concluded that it cannot be unethical to use a method designed to save the maximum possible number of lives for the money available for lifesaving.[3] The ethical problem arises with the decision to set aside a certain amount of money for lifesaving rather than for some other purposes, not with the optimized use of that money.

There is, however, another method to derive the value of α, namely what is called "willingness-to-pay". In this case, a review is made of the amount of money that has either actually been spent for protection in various cases or has been said to be appropriate to spend. This sum has then been divided by the number of lives assumed to be saved by the protective action. The disadvantage with this method is that the resulting quotient is not necessarily an indication of the appropriate value of A.

If the total amount of money spent on protection in a particular situation is denoted T and we assume that this is exclusively intended to save N lives, then we have the relation $T = A \cdot N$ and we may conclude that $A = T/N$ is a measure of the willingness-to-pay to save a human life. However, in most cases there is an additional sum of money (W) which is paid to achieve other objectives than lifesaving. In some cases money must be paid for measures taken to prevent prescribed limits from beeing exceeded. In other cases, there may be a willingness to pay for protective actions taken to demonstrate good will without particular attention to lifesaving. We may therefore write

$$T = A \cdot N + W$$

in which case

$$T/N = A + W/N$$

This means that the quotient T/M is often not an implicit measure of A. A striking example is an often quoted value of 72.000.000.000 $ per life in protection against formaldehyde.[4] In that particular case, the protective action must have been needed to protect against non-lethal effects, and because N was very small, we may assume that $T/M \approx W/N$, in which case there is no basis for any estimate of A.

If $W = 0$, we might think that the implied value of A is T/N, but this is only true if T (the amount of money actually paid) was less than or equal to the total amount available. If this amount is small, as is often the case in medical practices, T may not have been derived as $A \cdot N$ (*i.e.* after an *a priori* assessment of a potential N) but paid because it happened to be available, and N is then merely the result. If more money than T was available (as may be the case in the nuclear industry), it is more likely that T was actually derived from knowledge of the potential value of N. If T was exclusively intended for lifesaving and $W = 0$, then, but only then, we might take T/N as an indication of A based on willingness to pay. The range of results reviewed in a recent Swedish study [5] was about 0.1 - 7 M$, amazingly close to the available values mentioned above.

DOSE LIMITS AND SOURCE-RELATED DOSE CONSTRAINTS

For public exposures, the primary dose limits have lost their importance, except as benchmarks for radiation protection authorities in their overview of all sources and practices. Instead, ICRP now recommends source-related dose constraints to be imposed in order to prevent the ALARA result from being achieved at the cost of an unacceptably high risk to some few individuals.[2] This extra safety requirement is needed because harm and benefit are usually not equally distributed and it would not seem reasonable to expect people to accept unusual risks where they see little benefit.

The limits actually enforced by competent authorities would be derived limits of measurable quantities (releases, activity concentrations, etc) as deemed appropriate from ALARA

considerations under the additional requirement that the source-related dose constraint is not exceeded for critical groups.

ETHICAL PROBLEMS

There are a number of ethical problems inherent in risk evaluation for purposes of decision making. Already radiation risk assessment is based on a number of assumptions which imply ethical positions. The existence and magnitude of radiation risks at low doses can never be proven and is only inferred from credible assumptions. It is in line with the precautionary principle to postulate, as ICRP does, that the risk does exist.

Once this is postulated, the quantity "risk" has to be defined. There are two types of risk to consider: (1) the risk to the most exposed individuals, and (2) the overall risk due to a practice or operation. In general, "risk" may be seen as a combination of event probabilites and consequences. In the individual case, the worst consequence is death and "risk" may then mainly be assessed as the probability of radiation-induced death (although it matters how and when death is expected to occur). In the source-related overall risk, there are the two cases of either actual exposures or potential exposures. In the case of actual exposures and collective doses of at least tens of man·Sv, the probability of *some* consequence is near one. The "risk" is then described by the expected number (>1) of deaths, assumed to be proportional to the collective dose. The case of potential exposure is more difficult to handle.

The most exposed individuals

The main objective related to the risk to the most exposed individual is limitation of the probability of death to fall below some chosen level. In the case of actual exposures, there is a corresponding dose constraint or prescribed limit related to the particular radiation source or practice. One ethical question is then whether future individuals shall be protected by the same cautious dose constraints as present individuals. This is a pertinent question in the case of radioactive waste disposal.

The overall risk from the practice

The main objective in controlling the overall risk from a practice is to keep the expected consequence as low as reasonably achievable. If the collective dose is at least some ten man·Sv, there is an expectation of at least some death. If protection is optimized by means of cost-benefit analysis, then a unit collective dose may be costed by $\alpha = r \cdot A$, using for A the valuation of lives that is achievable according to the previous discussion. If the collective dose is less than a few man·Sv, the most likely number of deaths is zero. If we do not want to sub-optimize but look for a method which gives a total optimization, we should use the same value for α also in this case.

The ethical question then arises whether we wish to use the same value for α also for collective dose contributions which are distant in space and time. With regard to distance in space, an IAEA expert group has recommended "As a basic principle, policies and criteria for radiation protection of populations outside national borders from releases of radioactive substances should be at least as stringent as those for the population within the country of release." [6]

The policy with regard to distance in time has been much discussed. From economists there are often proposals for discounting of committed future detriment costs. However, from the

ethical point of view, this is not an economical issue. Discounting future detriment costs merely means that future detriment is not added at full value to present detriment. A common practice is therefore to avoid discounting but disregard radiation doses which would occur in a very distant future, usually 10.000 years is mentioned.[7] There are two reasons not to include these very distant doses without any obvious conflict with ethical principles. One is that the dose assessment becomes so uncertain that it does not provide a useful basis for optimization calculations. The other is that dose reduction by isolation of the radioactive material may not be effective for more than 10.000 years, so that the dose contribution from later years will be the same for all options and would therefore not influence the optimization result

ATTENTION TO ATTITUDES

Decision-making is influenced by attitudes to risk. This is true both for those who evaluate the risk, those who take the decisions and those who are expected to accept the decisions. Distinctions are often made between "objective" risk and "subjective" or "perceived" risk and there are numerous discussions about "acceptable" risks.

In the author's opinion, all these discussions are simplified if we relate acceptability not to risk but to the practice or situation that causes the risk. To ask whether a risk is acceptable is similar to asking "Is this stone too heavy?" Such questions cannot be answered out of context.

Whether a practice or a situation is acceptable or not (to somebody) depends on the balance of advantages and disadvantages. Risk is one of the latter, but so is cost, disturbance, discomfort, etc. This is balanced against various types of benefit. Without knowing the benefit as well as disadvantages other than risk, it is not possible to decide on acceptability.

Everyone has an attitude towards proposed practices and our attitude will influence the balance. Some aspects or foundations of our attitudes may be inherent, depending on our social standing and environment, culture, education, religion, etc. In particular situations, however, there are a number of well known factors that form our attitude. Usually they are said to influence our risk perception, but this view may be too narrow since they influence our attitude to more than just the risk. The most important factors are:

I see a benefit	I don't see a benefit
I control the situation	I have no influence
I understand the risk	I don't understand the risk
The situation is familiar	The situation is new
I accept this voluntarily	It is imposed on me
I trust those responsible	I don't trust them

The items in the first column form a positive attitude, those in the second column contribute to a negative attitude, something which one author calls "outrage".[8] If there are several outrage factors, the practice or situation is not accepted.

The decison-maker is influenced by the same factors, but does not always share them with those exposed to the risk. To what extent should then attention be paid to their attitudes? It is known that risk reduction has rather little influence on acceptance, reducing the outrage is more effective. [8] Some of the outrage factors are subjective but some are indisputable, *e.g.* a

new, unfamiliar type of risk, children being exposed, commitments for the future. The existence of such factors should call for particular caution.

UNDERSTANDING

A major problem for the decision-maker is to device a control system which is understandable and therefore more likely to be accepted. In the old days, the situation was clear-cut. There was a limit. Below the limit it was safe. Simple as that. Today we have a limitation system, very properly based on protection optimization, with constraints and prescribed limits which differ from case to case. Even below the limits no absolute safety can be guaranteed. "You have no reason to worry, but..." We want to have the very best protection, but may ask ourselves if there is a proper way of exchanging some degree of protection and equity for a more understandable system. Since the unswer is likely to be no, how could we nevertheless improve understanding?

SEMINAR ON RISK EVALUATION AND DECISION MAKING

HOW RISK EVALUATION IS BUILT INTO OPTIMIZATION AND DECISION-MAKING: IS IT CLEAR AND ARE THE RESULTS APPROPRIATE?

G A M Webb
Head Radiation Safety Section
Division of Radiation & Waste Safety
International Atomic Energy Agency
Wagramer Strasse 5, A-1400 Vienna, Austria

INTRODUCTION

The concept of optimization of protection is practical in nature. In all aspects of dealing with protection of man against ionizing radiation, it is necessary to make frequent decisions as to the level of protection to be provided, given that all levels of protection achieve doses below the relevant dose limits. Optimization provides a basic framework of thinking - that it is proper to carry out some kind of balancing of the resources put into protection, and the level of protection obtained, against a background of other factors and constraints, so as to obtain the best that can be achieved in the circumstances.

The procedures used in the more formal studies of optimization of protection are all one form or another of "decision-aiding" procedure. They are intended to clarify, for the people who have to decide on the level of protection, the various factors involved, to quantify them where this is reasonable and necessary and to systematize the trade-offs between the various factors.

OPTIMIZATION AND DECISION MAKING

In its first major report on optimization (1) ICRP stated the general concept in broad terms but the report focussed on the use of cost-benefit analysis as a technique to be used in analysing protection problems to determine the optimum solution. It was probably useful in introducing the ideas of balance and trade-off to concentrate on that reasonably simple and quantified technique. In a later report (2) however, it was shown how the general concept could be implemented at different levels of decision and in different contexts using various appropriate techniques, one of which is cost-benefit analysis. The main message of this second report was that the optimization process was a way of structuring the inputs into decisions and the result - the decision - was independent of technique but was determined by the inputs to the decision and the relative evaluation of those inputs against predetermined criteria. In this context the value of unit collective dose or "α" is one such predetermined relative evaluation criterion. This structured approach is shown in Figure 1, which also makes it clear that while optimization of radiological protection can encompass some of the relevant factors there will often exist others that affect the final decision. It is the inclusion, or more often exclusion, of these other factors that has led to difficulties in obtaining acceptance for decisions.

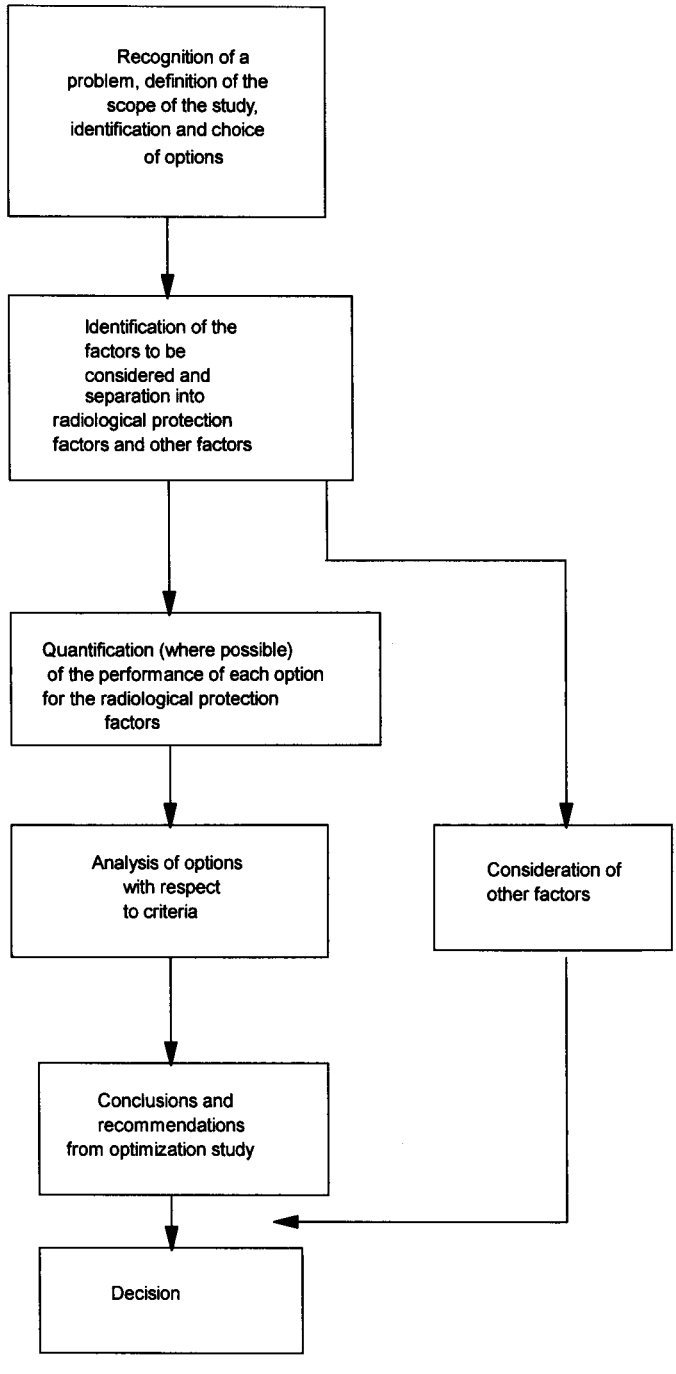

Figure 1. Structured approach to optimization of protection in the context of decision making

RISK EVALUATION IN THE OPTIMIZATION PROCESS

Some aspects of risk evaluation are clearly fundamental to and fully incorporated in the optimization of protection. Even taking the basic measure of detriment - dose - the quantity effective dose equivalent incorporates social judgements. The major such judgements built into the quantity relate to the relative importance given to mortality, morbidity and hereditary disease through the tissue weighting factors, notably those for gonads, thyroids and skin.

Other aspects are incorporated in the trade-off between dose reduction and the cost of achieving it. These components are incorporated in the value of unit collective dose and the broad judgements made are described in a companion paper for this Seminar (3).

In this system collective dose is generally not given additional weighting as a result of any risk "evaluation" and is usually costed largely on the basis of lost statistical production through unidentified premature death. Individual doses approaching the dose limits are sometimes weighted higher to account for some "aversion" to higher doses.

The general characteristic of the evaluations incorporated in procedures for optimization of protection, whether based on cost-benefit analysis (1) or multi-attribute utility analysis (2) are that they relate to the amount of radiation dose and the associated detriment irrespective of the source of the dose and normally irrespective of the recipient of the dose. This is not so much a criticism of the procedures themselves, which are in principle capable of incorporating further judgements as inputs, as it is of the users of the procedures and their willingness to recognize and take account of attitudes.

The other aspect of optimization of protection when applied according to the ICRP guidance, is that each problem has a unique solution (or optimized level of protection). The procedure relates and balances all the inputs, and because these will differ for each problem studied, the outcome of each optimization study will differ in the level of protection that is deemed to be reasonably achievable.

DIFFICULTIES WITH OPTIMIZATION

Application of this system of optimization therefore raises two major questions:

1. Does the application of these techniques adequately reflect the attributes attached to the risk by public and politicians?

These attributes include:

The source of the doses, whether this is for example, a hospital x-ray set, the discharges from a power reactor or the residues from weapons testing affects peoples attitudes (evaluation of risks and benefits) even though the doses may be identical.

The voluntariness or perceived control over the doses whether for example from a discharge to the atmosphere or from choosing to take a transatlantic flight.

Whether the doses result from deliberate acts(practices), from accidents or are "natural".

The time of delivery of the doses, now or in the far future and the associated uncertainty.

Considering only these attributes the answer to this question at the present is that they are not adequately included in optimization, and this may be one of the reasons why proposed decisions that are quite acceptable to the radiation protection community may not be so acceptable to the other communities. To modify the optimization procedures so that more "protection" is explicitly allocated to sources that people do not like is seen by some purists as a misallocation of resources but it could be that it is a better reflection

of society's wishes in the allocation. The problem is not with the procedures but in deciding what inputs to the decisions we want to take into account and how we evaluate the relative importance of these inputs.

2. Is the specificity of the optimization process, which may be reasonable when dealing with the control of doses to individual workers, appropriate when dealing with dose control for members of the public?

It is theoretically clear that the circumstances will affect the result of any particular optimization study. For example the optimized levels of discharge to the environment will depend on the pathways to man and the rates of transfer of radionuclides along these pathways, the costs of discharge reduction and the availability and costs of other options such as storage on site. These will generally vary from site to site so the outputs of optimization studies will be site and installation specific. As another example the levels to which contaminated environments should be cleaned up will differ depending on the cost and complexity of decontamination procedures, the habits including food consumption of the local population and even the extent of the contaminated area.

However, it is becoming increasingly clear that the public, politicians and decision-makers see such differences as confusing and undermining confidence rather than as evidence of scientific rigor.

It is very difficult to explain why it is safe to live in a contaminated environment in a dose rate of - say - 5mSv/a (deemed appropriate as result of an optimization study) while in another environment decontamination has been carried out to reduce doses to less that 1 mSv/a (even if this is also based on an optimization and not a misguided application of the dose limit for the public). How should both levels be compared with the pressure for intervention for Radon in homes at levels which are generally around 10 mSv/a or the lack of interest in moving entire populations from regions of high natural background such as Kerala?

We may have it theoretically correct but is that comforting when "it" is so difficult to explain and defend? Possibly there is a greater role than so far adopted for generic values. One example that was essentially imposed on the radiological protection community after Chernobyl by the politicians is the Codex Alimentarius values for contamination of foodstuffs - we may feel it is too simple and crude but we cannot fail to admit that it works.

The answer to the second question is again probably no but there may in this case be a more reasonably achievable solution, namely to adopt robust generic values rather than maintaining the fine distinctions that result from optimization studies - especially if the studies have failed to encompass all the attributes of the risk.

Does radiation risk exist?

(Synopsis of a paper)

Wim Passchier
Health Council of the Netherlands, PO Box 90517, 2509 LM The Hague, The Netherlands

RISK

Risk is related to human actions (and natural occurrences). It expresses the possibility of harm associated with a given human action, the probability of the harm and its nature and magnitude. By definition risk is a multidimensional concept. Risk is influenced by the social, economical and ecological environment in which the human actions take place.

RISK ASSESSMENT AND RISK MANAGEMENT

Risk assessment and risk management are parts of a dynamic process with the objective to decide on the tolerability of risk and on measures to keep risk within accepted limits. It enables all relevant parties to express their concerns and preferences regarding the different options for the human action involved and regarding the relative importance of criteria to decide on the tolerability of risk.

Risk assessment has three phases: problem definition, risk analysis and risk characterization. Risk analysis is primarily a technical and scientific endeavour. With regard to problem definition and risk characterization consultation between risk assessors and risk managers (and other parties concerned) is a must.

RISK ANALYSIS AND RISK CHARACTERIZATION

In the risk analysis phase the effects of the relevant physical and social stressors generated by the human action are estimated. In case ionizing radiation is one of the relevant (physical) stressors, radiation effects are studied and their probability, nature, distribution over the affected population, etc are estimated.

The results of the risk analysis are expressed in terms of relevant risk characteristics. Which characteristic is relevant is not a purely scientific question. In the case of medical treatment years of healthy life lost may be a suitable characteristic, but in the case of the siting of an airport daytime noise level, nighttime noise level, loss of nature, concentration of air pollutants, threat of crashes, etc. may be more appropriate. Which characteristics are relevant and which characteristics may be neglected is matter of judgment.

CONSEQUENCES FOR ACTIONS INVOLVING RADIATION EXPOSURE

Cancer treatment, biological research, oil exploration and generation of electrical energy are examples of human action in which exposure to ionizing radiation may be involved. The risk characterization involves usually more characteristics than only radiation dose (as a metric for the possible effects from radiation exposure). Furthermore, in deciding on the tolerability of risk the benefits of the action, including those directly related to the application of radiation, are of importance. For different types of action different criteria and norms are applied; this may hold for a judgement of the contribution of radiation exposure to the risk as well.

This viewpoint implies that the contribution of radiation exposure to the risk will, in principle, judged differently if its is associated with medical diagnosis or treatment, with air transport or with

electricity generation by nuclear energy. The risk characteristics for these types of action are different, as well as the benefits derived from the different forms of action.

How to deal with cumulative radiation exposure in this respect? Conceptually this questions pertains to the influence of the social, economical and ecological environment on the risk of a given form of action. The present data on possible effects of radiation exposure indicate that the contribution of radiation exposure to the occurrence of effects in non-accident situations ('low level exposures') is in good approximation independent from other radiation exposures. This means that different radiation exposures need not be combined; a - what Lindell calls - source related exposure would suffice. This does not mean to say that risk need not be justified; radiological examinations need not be repeated if the information is already available, even if the examination in itself was justified.

Risk has many dimensions and many metrics to quantify the dimensions (in so far they can be quantified). Too many risk characteristics may obscure decision making. A way out is to aggregate some dimensions, as has been done in defining the effective dose. In the past such aggregation has had the effect to emphasize the role radon inhalation (the change from whole body dose and separate lung dose to effective dose). However, it may be questioned if the change from the 1977 weighting factors to the 1990 weighting factors in the effective dose aggregation had any relevance. The relative dose values for given exposures changed only in a limited way. It might have been more fruitful to direct efforts to finding methods, criteria and norms to judge the tolerabilty of risk and its radiation component for different types human actions.

WHAT SHOULD WE KEEP:

- exposure quantities as risk characteristic
  - dose equivalent
  - collective dose equivalent
  - dose equivalent committment
  - effective radionuclide concentration
- criteria dependent on the type of action
  - dose constraints (for all exposure characteristics)
  - radionuclide concentration constraints
  - distributional criteria (space and time)
- risk management measures
  - knowledge and experience and quality control
  - striving for risk reduction where this is reasonably achievable

WHAT CAN WE DO WITHOUT?

- effective dose
- general dose limits for members of the public
- licensing only taking radiation exposure into account

ASSESSMENT OF OCCUPATIONAL RADIATION EXPOSURE IN CHINA

Pan Ziqiang

(Bureau of Safety, Protection and Health
China Atomic Energy Agency)

Abstract **Since the eighties, the doses received by the workers of the nuclear industry system in China have been below 5 mSv, excluding uranium miners. Workers involved in the radioisotope and radiation applications received doses in the range of 1~2 mSv. Stringent and effective measures are required to be taken for the radioisotope and radiation applications due to high accident possibility. Average annual effective doses to underground workers in variety of occupations such as uranium, coal and non-ferrous metal mines are 19.3, 8.3 and 33.2 mSv respectively on the rough estimate basis. The nuclear industry contributes only 0.17% to collective dose. Contributions by coal and non-ferrous metal mining to collective dose account for 85.15% and 14.3% of the total respectively. The data available from coal and non-ferrous mines are less, associated with high uncertainty.**

Keywords: **Occupational exposure, nuclear industry, coal mine, non-ferrous metal mine**

Introduction

Occupational radiation exposures may cover three categories: 1) exposure of the workers of the nuclear industry system, including nuclear fuel cycle and the related researches, 2) exposure of workers engaged in the radioisotope and radiation applications, 3) exposure of workers involved in mining and milling operations. The third category involves the largest fraction of workers of such three kinds, which would lead to both the highest collective dose among others and higher annual individual dose. In the light of the fact that the data on the third category of exposure is too far from enough to accurately estimate the resulting collective doses and that the regulatory authority has not defined whether or not this category of exposure belongs to occupational exposure, this paper here is only to estimate the collective doses arising from such operations from the viewpoint of pure science.

1. Levels of radiation exposures from the nuclear industry[1]

1.1 Occupational exposure in normal condition

Table 1 lists annual collective dose equivalents and average annual individual dose equivalents to workers of the nuclear industry. The data listed in this table were in part gained from individual dose monitoring results, which were collected from reactor operation and reprocessing and the related scientific research institutions; the remainders were obtained by calculation according to the concentrations and duration of aerosol in radioactive working places related to uranium mining and milling, fuel fabrication and isotopes separation system. The doses arising from inhalation of radon progeny were estimated on the basis of a conversion factor of 10 mSv WLM^{-1}.

Table 1 Annual collective dose equivalents and average annual individual dose equivalents

Nuclear industry system	Annual collective dose equivalent				Average annual individual dose equivalents, mSv	
	Prior to 1987		1980~1987			
	man·Sv	distribution	man·Sv	distribution	Prior to 1987	1980~1987
Uranium mining	62.5	59.5	59.7	61.42	26.1	19.3
Uranium milling	3.04	2.89	5.31	5.46	1.82	1.8
Fuel fabrication	2.6	2.48	2.9	2.98	4	3
Isotope separation	0.31	0.3	0.12	0.12	0.13	0.08
Reactor operation	13.9	13.2	16.6	17.1	14.2	12.3
Reprocessing	21.6	20.56	10.6	10.9	18.9	5.9
Research institute and Isotope production	1.1	1.05	1.97	2.02	2.3	1.86
Total	105.05		97.2			

The Table 2 shows the monitoring results of individual dose arising from occupational external radiation exposures from the operation of nuclear industry, which indicates that during the period 1967~1976 the workers received the highest doses, with about 10% of workers having received doses in excess of dose limit (50 mSv). The reasons for higher doses to be received by the workers during that period are mainly as follows: 1) reactors and reprocessing plants were put into production in succession in that period, and there was a lack of operation experiences in the initial phase; 2) the implementation of various regulations and rules was seriously interrupted, which resulted in high probability of accident occurrence. Following the end of Culture Revolution that took place during 1966~76, updated various regulations and rules related to safety led to a progressive reduction of doses to the workers. Average annual individual dose dropped by a factor of 50% in the period 1977~1981 and once again decreased by a factor of 50% in the period 1982~1987 in comparison with those several years ago.

Table 2 Individual dose monitoring data of occupational external exposure due to nuclear industry

Items	Years							
	1959~66		1967~76		1977~1981		1982~1987	
	Range	Mean	Range	Mean	Range	Mean	Range	Mean
Number of individuals	289~1064	563	1265~3267	2067	3464~5356	4452	5253-6322	5751

1.2 Accidental exposure

Table 3 shows the annual collective dose equivalents to the workers of the nuclear industry resulting from accidental exposures, excluding those from uranium mines, and not allowing for those from fuel element fabrication and isotope separation plants because of very small magnitude. Internal doses received by the workers arose mainly from the contamination by Pu, accounting for about 92.6% of the total; the remainders were from fission products and tritium, about 3.2% and 3.1%. The exposure pathway was principally from inhalation, which led to about 73% of the total. It is worth while to be noted that internal dose due to plutonium incorporated into body through wounds accounted for 26% of the total. The annual collective dose equivalents shown in Table 4 do not cover overexposure of local skin. During the period 1958~1987, 29 skin injury accidents occurred, involving 51 sufferers. Absorbed doses to skin were estimated to be in the range of 5~196 Gy, with 86% of irradiated area being found on the part of hand. These accidents, except for 1 ^{60}Co accident and 2 accelerator electron beam accidents, were caused by β-ray radiation.

Table 3 Annual collective dose equivalents received by workers of nuclear industry due to accidental exposures

Nuclear systems	Annual collective dose equivalents, man Sv			Percentage to total
	External exposure	Internal exposure	Total	
Reactor	2.65	2.2×10^{-2}	2.67	19.2
Reprocessing	0.31	1.25	1.56	7.2
Research institutes and Isotope production	0.22		0.22	20
Nuclear metallurgy and machining		0.46	0.46	
Total	3.18	1.73	4.91	

2. Levels of radiation exposure resulting from radioisotope and nuclear technology application

2.1 Occupational exposures in normal conditions[2]

The monitoring of individual doses to workers in the radioisotope and nuclear technology applications were carried out at a later time, which began in middle 1980's and has developed gradually. Table 4 shows the occupational radiation exposures of the workers in the field of the radioisotope and nuclear technology applications. The average annual individual dose and collective dose received by workers in industrial radiography, as shown in this table, are relatively high, which includes X ray and γ ray radiography. The internal exposures of workers of nuclear medicine in Beijing were monitored in 1994 and the results showed that the average annual individual effective dose was about 1.1×10^{-1} mSv[3] which is about a few percent of external dose.

Table 4 Occupational external exposure to workers of radioisotope and nuclear research application (1985-1989)

	Workers		Annual individual dose	Annual collective dose (man Sv)	
	monitored (10^3)	Radio monitored	equivalent (mSv)	Workers monitored	All group
Nuclear medicine	0.77	12.8	1.39	1.25	7.78
Radiotherapy	0.36	5.23	1.25	0.52	8.36
Industry Radiography	3.08	35.94	2.01	5.23	16.22
X diagnosis	13.67	14.55	2.06	27	185.5

2.2 Accident exposure

Table 5 shows the radiation accidents leading to radiation damage, which occurred in several irradiation facilities with sealed sources.

3. 1 Occupational radiation exposure of workers in underground mines

For coal mine, equilibrium equivalent concentration (EEC) of radon in underground mines is estimated to be 250 Bq m^{-3}, that would result in average individual dose of 8.3 Sv a^{-1}, and collective effective dose of 5×10^4 man Sv a^{-1} to 6×10^6 underground workers nationwide. For non-ferrous metal mines, if taking typical value of EEC of radon to be 1×10^3 Bq m^{-3}, annual individual effective dose is estimated to be 33.2 mSv and annual collective effective dose to be 8.4×10^3 man Sv to 0.25×10^6 underground miners. For other kinds of mines, the estimating of dose resulting from radon and its daughters is difficult due to less data available from these mines, but high concentrations of radon and its daughters in these mines were found extensively, which may be up to 3.2×10^4 Bq m^{-3}.

Table 5 Accidents leading to irradiation damage at irradiation facilities with sealed sources[3]

Date	Place	Summary	Consequence
29-February, 72	Sichuan	Accidentally entered the irradiation room with a 2.64×10^{14} Bq ^{60}Co source.	resulted in 55~147 rad radiation exposure
December, 72	Wuhan	A 5×10^{12} Bq ^{60}Co source for radiotherapy purpose fell off on copper filter plate, lasting 16 days.	20 patients and 8 workers received doses in range of 5~147 rad dose
September, 80	Shanghai	Entered the irradiation room with a 2.2 $\times10^{15}$ Bq ^{60}Co source due to power failure and interlockout of order.	A worker incurred a 5.22 Gy acute radiation exposure
June, 85	Shanghai	Entered a 1.5 MeV Van de Graff accelerator hall while main motor running.	A worker incurred a 25~210 Gy radiation exposure
March, 86	Beijing	Entered a 0.2 pBq ^{60}Co source room when it is on irradiation position while driven system in failure and door open.	2 workers received doses of 0.7 and 0.8 Sv respectively
May, 86	Hena	Entered a 0.3 Bq ^{60}Co source room while it is on irradiation position.	2 workers incurred 3.5 and 2.6 Gy acute exposure respectively
March, 88	Liaoning	Took source by bare hands when removing a radiographic source of 1.1×10^{12} Bq in failure.	6 workers received doses in range of 0.1~126 Gy on hands.
June, 90	shanghai	Entered a 0.85 pBq ^{60}Co source room when a protection door broken and taken away while the another in failure due to power loss.	7 workers were exposed to 2~12 Gy radiation, resuling in 2 deaths
November 92	Wuhan	Interlock out of order.	4 workers were exposed to radiation, 1 of them incurred acute radiological sickness

4. Conclusions and discussions

Table 6 shows the average annual individual dose and annual collective dose to workers of various occupations arising from occupational radiation exposures in China, which were typical values in 1980's on the whole. As shown in the table, the underground miners in non-ferrous metal mines received the highest annual individual dose among others, even higher than uranium miners by 65%, with the coal miners' dose ranking the second; coal miners received the highest annual collective dose, followed by non-ferrous metal miners; sum of both accounts for 99.45% of the occupational radiation dose. Though the relevant Chinese regulatory body has not yet defined the exposures of these kinds as part of occupational exposure it is necessary, from

the viewpoint of people's health, to take effective measures to reduce the concentrations of radon in working places, especially for non-ferrous metal miners.

Table 6 Average annual individual doses and annual collective doses to occupational workers in China

Categories of occupations	Average annual individual dose (mSv a^{-1})	Annual collective dose	
		Dose (man Sv)	Ratio of dose to dose sum (%)
Uranium mine	~20	$\sim 1\times10^{2}$	0.17
Nuclear stages other rather uranium mine	4.5	$\sim 2.2\times10^{2}$	0.37
Nuclear and radiation applications	2	5×10^{4}	85.15
Coal mine	8.3		
Non-ferrous metal mine	~33	8.4×10^{3}	14.3
		5.872×104	

It should be noted that (1) the stringent and effective measures should be taken in nuclear technology and radiation applications because of highly potential exposure and high frequency of accident occurrence though less annual individal doses in normal conditions; (2) although the nuclear industry has good safety record, there would be possibility of severe accident with very low probability of occurrence but not equal to zero so that to prevent the accident from occurring by reducing the dose to workers and by reinforcing management will be necessary; and (3) the data given in Table 6 is associated with uncertainty to a great extent, mainly from non-ferrous metal mines and coal mines and for the purpose of accurate dose estimate much more typical data are required. Rough estimates indicate that more attention should be paid to this problem.

INTRODUCTION

In a Commission of the European Communities (CEC) research programme spanning the past 10 years all aspects of external environmental radiation dose measurements have been thoroughly investigated (1,2). The aim of this work was to harmonize environmental radiation dose measurements within different countries. The initial studies involved research into practical calibration techniques and this led to the establishment of two unique calibration facilities. One facility developed by the Physikalisch Technische Bundesanstalt (PTB), Braunschweig, Germany in the Asse salt mine at a depth of 970 m where there is an extremely low level of environmental radiation (3). The other calibration facility is the Risø National Terrestrial Radiation Measurement Station (4) where reference measurements of a well determined natural environmental photon spectrum can be made. At Risø a cosmic measurement station has also been established at a wooden pier extending into the Roskilde Fjord, this station is used for the determination of a detector's response to cosmic radiation.

This paper describes the calibration techniques that have been investigated and the intercomparisons that have been performed. The relevance of this research programme was demonstrated by an intercomparison of external photon dose rate measurements by several detectors in the vicinity of a nuclear power station.

CALIBRATION AND TYPE TESTING

Many commercial dose rate instruments, electronic dosemeters and most thermoluminescence dosemeters (TLDs) were calibrated and radiation type tested. These tests included the determination of the inherent responses of the detectors using the Asse facility, namely the contribution to the readings from the active and passive detectors from internal radioactive contamination or from electronic noise.

The energy responses of all the detectors were measured over the photon energy range from 60 keV to 6 MeV.

The cosmic responses of the detectors were evaluated from measurements made on board boats in the North Sea and in the Roskilde Fjord and these results were then compared with measurements made at the Risø cosmic field station.

Free-field and shadow-shield calibration techniques were intensively studied at Risø and several intercalibration experiments using these techniques were carried out among the participating States. Monte Carlo (MC) calculations using the MCNP (Monte Carlo Neutron Photon) code were used to determine the air kerma rates produced by scattered photons from ^{137}Cs, ^{60}Co and ^{226}Ra sources as a result of surrounding media in different free-field and shadow-shield calibration geometries (6).

INTERCOMPARISONS

a) The assessment of external photon dose rates in the vicinity of nuclear power stations.

In 1991 experiments were carried out to investigate the responses of instruments to additional exposures above normal environmental levels. Four environmental dose rate instruments having different detectors, a high pressure ionization chamber, a Geiger-Müller counter, a proportional counter, and a scintillation counter, were used to make continuous measurements over a four month period of the air kerma rate at a location close to the Hinkley Point Nuclear Power Plant in the UK. Three types of TL dosemeters normally used for monitoring environmental radiation were also used to compare the responses of solid state passive dosemeters with those of the active dose rate meters.

The results clearly demonstrated that accurate estimations os doses in the environment arising from a nuclear facility can only be obtained if continuous measurements are made and if the responses of the detectors used to the different radiation components at that location are accurately evaluated. By correcting the measured air kerma values by the accurately determined detector responses the standard deviation, expressed as a percentage of the

mean value of the total air kerma for the instruments and TLDs was reduced from 20% to 5% (5).

b) An international comparison of active and passive detectors used for environmental radiation measurements.

During 1994 an international intercalibration experiment was performed at Risø National Laboratory with participants from the USA, Eastern and Central Europe and the EU member countries. One aim of the experiment was to intercompare the "home" calibration of detectors and dosemeter responses of environmental radiation monitors used in the above countries and to try to make a link between the different reference standards used. A special feature of this recent intercomparison was the testing of a variety of recent designs of electronic dosemeters to see how they respond to environmental radiation. Another important feature was the use of highly sensitive TLD materials over ultra short integration periods (e.g. 3 hours) to determine the natural background air kerma rate. A total of 12 active dose rate meters, 2 spectrometers, 21 electronic dosemeters and 8 different TL materials were used in the experiments which included (i) free-field and shadow-shield calibrations, (ii) measurement of the natural radiation at the terrestrial field site at Risø and (iii) measurement of the cosmic ray component both on a platform at sea and on a boat at sea.

Table 1. Summary of mean results of air kerma rates from field, cosmic and terrestrial radiations, respectively, for each detector type.

Detector Type (Dosemeter type)	Field, cosmic + terrestrial ($nGy.h^{-1}$)	Cosmic (sea) ($nGy.h^{-1}$)	Terrestrial - field - cosmic ($nGy.h^{-1}$)
HPICs (Dose rate meter)	74.4±1.9	36.4±1.6	38.0±0.8
Pl. Scintillators (Dose rate meter)	71.4±7.8	31.5±6.5	39.8±3.4
GM (Dose rate meter)	68.7	37.8	30.9
Spectrometer (NaI)	45.9±1.9	5.7±1.1	39.9±2.2
TLDs, MCPN	70.0±0.3	28.7±0.1*	41.4±0.4
TLDs, GR-200	67.9±3.6	29.8±1.6*	37.7±1.4
TLDs, Al_2O_3:C	102.5±34.6	37.2±9.6*	65.3±25.0
TLDs, $CaSO_4$:Dy	72.0	30.4*	41.6
Electronic dosemeters (GM)	130±22.4	96.7±19.1*	34.0±4.8
Electronic Dosemeters (Solid state)	96.3±62.5	61.0±53.7*	35.3±12.7

* Estimated from measurements made at the Cosmic Pier Station
N.B. The ± values represent 1 SD.

Table 1 shows the mean results for terrestrial and cosmic measurements for each detector type. Substraction of the cosmic (sea) responses from the field measurement responses yielded mean values of the air kerma rates due to the terrestrial radiation component.

Apart from the Al_2O_3:C material, which will be investigated in future intercomparisons, the TLD results for the terrestrial radiation show good agreement with the active dosemeter results.

CONCLUDING REMARKS

The considerable experience and expertise gained by the participants during the CEC research programme is to be disseminated in a European Radiation Dosimetry Group (EURADOS) Technical Recommendation. This publication will give practical advice on all aspects of environmental photon dose monitoring.

TEMPTS TO DETERMINE RADON ENTRY RATE AND AIR EXCHANGE RATE VARIABLE IN TIME FROM THE TIME COURSE OF INDOOR RADON CONCENTRATION

J.Thomas
State Office for Nuclear Safety, 120 29 Praha 10,Czech Republic

INTRODUCTION

For the study and explanation of the diurnal variability of the indoor radon concentration a(t) [Bq/m^3], which is proportional to the ratio of the radon entry rate A [Bq/h] and the air exchange rate k [1/h], it would be of advantage to know separatetely the diurnal variability of both determining quantities A(t) and k(t). To measure directly and continuously the radon entry rate A(t) is possible only in special studies (mostly in experimental rooms) and also continuous measuring of the air exchange rate k(t) is possible also only in special studies for a short time. But continuously measuring radon meters are now common, do not trouble people in normal living regime during day and night. The goal of this endeavour would be the evaluation of the time courses of both determining quantities from the time courses of the indoor radon concentration directly without additional experimental work and so a better utilisation of such measurements.

APPROACHES TO THE TIME ANALYSIS OF THE RADON CONCENTRATION

The variation in time of the radon concentration a(t) in a room with volume V (m^3), radon entry rate A(t) and air exchange rate k(t) is studied here using the linear (compartmental) model

$$a(t)' = - k(t)\, a(t) + A(t)/V \,, \qquad (1)$$

expressing the balance of removal and entry of radon by the differentiate a' [Bq/(h m^3)] and assuming that the air exchange rate is much more quicker than the decay constant of radon. This differential equation has for the initial condition $a(t_0)$ a general analytical solution which could be used in principal for the determination of the unknown functions A(t) and k(t) by numerical methods. This approach seems to be very complicated and unrealistic. The other way is to use the differential equation itself.

Mostly the entry and air exchange rates are evaluated with the assumption of their constancy in time during the measuring period. The solution is in this case simple

$$a(t) = A(1-e^{-kt})/kV + a_0 e^{-kt} \quad \text{for } t>0=t_0 \qquad (2)$$

and the three unknown values a_0, k, and A can be obtained by numerical methods from three concentrations a_1,a_2,a_3 measured in times t_1,t_2,t_3 (at least two of them not in steady-state). The insufficiency of this approach is in the unability to assure the constancy of k and A for a longer time than several hours.

DETERMINISTIC SOLUTION OF AN EQUIVALENT DIFFERENCE EQUATION

Measurements result in average concentrations a_i during the i-th time interval $\{t_i,t_i+d\}$ of duration d [h], therefore also average values A_i and k_i can be only obtained from difference equations equivalent to the differential equation:

$$a_i' = - k_i\, a_i + A_i/V \qquad (3)$$

where the average differences a_i' have to be calculated by a numerical calcul from the measured, or better from smoothed values a_i. To calculate the two unknown values k_i and A_i one needs to evaluate at least two adjacent intervals,i.e. two difference equations. Assuming

the same values k and A for both intervals of a concavely increasing course or a convexly decreasing course of experimental values gives good results but fails for convexly increasing and concavely decreasing courses of the radon concentration resulting in meaningless negative air exchange rates. The reason can be understood from the concavely increasing or convexly decreasing time courses of the exact solution (2) of the differential equation assuming constant k and A.

One possibility to extend the applicability of this approach is to assume linear changes for both quantities $k_i = k + \kappa t_i$ and $A_i = A + \alpha t_i$ - decreasing or increasing in accordance to the sign of κ and α. Then four equations for four adjacent intervals have to be used for a general deterministic evaluation. Three equations can be used if the change in time of one of the quantity can be neglected and two equations are enough, if A and k are nearly the same for two adjacent intervals and the courses are properly concavely increasing or convexly decreasing.

STATISTICAL SOLUTION OF THE EQUIVALENT DIFFERENCE EQUATION

The deterministic approach has two important disadvantages. First the "uncompromising" fit of the deterministic solution to the uncertain input data a_i and a_i, gives manytimes completly meaningless results, second it does not give uncertainties for the calculated results. This can be overwhelmed by a linear regression analysis using the difference equation as the statistical model with index i as the independant variable. This approach gives beside of the four mutually interdependant results A, k , α and κ also their covariance matrix, of course the price for this is a larger number of intervals used for the evaluation with the same tendency of linear change assumed for the entry rate and air exchange rate. The optimal number of intervals suitable for evaluation can be determined by computer using the covariance matrix. Setting the difference equations symetrically over the used intervals and shifting automatically the evaluation to the next interval the evaluation should give reasonable results, but only for properly monotonically increasing or decreasing radon concentrations.

Unfortunately the statistical approach results sometimes in multifolds of the real values k and A, of course with the right ratio for the steady state radon concentration. The reason for this is that the minimalisation process finds the lowest minimum but off the real region. Overwhelming of this disadvantage needs to use constraints, but the evaluation gets more and more complicated. Another disadvantage of the approaches is that it cannot be applied around maximal and minimal radon concentrations because a monotonic tendency of the radon entry rate or the air exchange rate is not justified.

STOCHASTIC APPROACH

A promising approach to evaluate the time courses of the radon entry rate and of the air exchange rate from the whole time course of the measured radon concentration is hoped to be the stochastic approach used for simulation of sequences of data , the theory of which is described e.g. in (1). The equation (3) is the generic model for the evaluation and unrealistic solutions are avoided by limits for the air exchange rate and by realistic estimated starting values.

COMMENT TO THE APPLICABILITY OF THE COMPARTMENTAL MODEL

The compartmental or linear kinetic model used for the description of the indoor radon concentration assumes a perfect and immediate mixing of the entered radon in the whole

volume of the room. This is of course not true and it has to be considered if this is not the reason for failures in the above described evaluation. It seems so that normal circulation of the indoor air in occupied rooms produced by heating systems during heating seasons but even by the entry of daylight through windows or by the inhomogeneity of insulation and temparatures of walls, floors and ceilings leads to quick and homogeneous enough mixing of radon entering mostly at the floor level. At least their may be a delay between the real entry time of radon and the calculated "effective" entry time of radon which could be corrected for.

CONCLUSION

Two approaches are given for the determination of variable in time radon entry rates and air exchange rates from continuously measured indoor radon concentrations by numerical solution of the equivalent difference equations in deterministic or statistic form. Unfortunately these approaches are not always successful. But the analysis of the reasons for the failures leeds to a better understanding of the problem. It is hoped that the more sophisticated simulation approach shall solve the problem.

ABSTRACT (See instructions overleaf)

The infiltration of radon from the ground is usually the predominant source of indoor radon pollution. The uniform method for radon risk classification of foundation soils in the Czech Republic was proposed in 1990. At the same time, the regional radon risk maps were produced to improve the knowledge of radon risk on the large scale. Since the acceptance of the Decree of the Ministry of Health of the CR concerning the requirements for limiting radiation exposure due to radon and other natural radionuclides in 1991, the detailed soil-gas radon measurements have become obligatory for all areas of urban planning. A four years experience resulted in several modifications of the origin radon risk classification method. The new recommendation was given in 1994.

A large number of detailed measurements is available for testing the reliability of regional radon risk maps. The comparison illustrates general reliability of large scale radon risk maps on the significant probability level. On the other hand, the local variability caused by a number of geological and nongeological factors confirms the necessity of detailed measurements for proposing the optimal remedial technology.

TEMPTS TO DETERMINE RADON ENTRY RATE AND AIR EXCHANGE RATE VARIABLE IN TIME FROM THE TIME COURSE OF INDOOR RADON CONCENTRATION

J.Thomas
State Office for Nuclear Safety, 120 29 Praha 10,Czech Republic

INTRODUCTION

For the study and explanation of the diurnal variability of the indoor radon concentration a(t) [Bq/m^3], which is proportional to the ratio of the radon entry rate A [Bq/h] and the air exchange rate k [1/h], it would be of advantage to know separatetely the diurnal variability of both determining quantities A(t) and k(t). To measure directly and continuously the radon entry rate A(t) is possible only in special studies (mostly in experimental rooms) and also continuous measuring of the air exchange rate k(t) is possible also only in special studies for a short time. But continuously measuring radon meters are now common, do not trouble people in normal living regime during day and night. The goal of this endeavour would be the evaluation of the time courses of both determining quantities from the time courses of the indoor radon concentration directly without additional experimental work and so a better utilisation of such measurements.

APPROACHES TO THE TIME ANALYSIS OF THE RADON CONCENTRATION

The variation in time of the radon concentration a(t) in a room with volume V (m^3), radon entry rate A(t) and air exchange rate k(t) is studied here using the linear (compartmental) model

$$a(t)' = - k(t)\, a(t) + A(t)/V \,, \qquad (1)$$

expressing the balance of removal and entry of radon by the differentiate a' [Bq/(h m^3)] and assuming that the air exchange rate is much more quicker than the decay constant of radon. This differential equation has for the initial condition $a(t_0)$ a general analytical solution which could be used in principal for the determination of the unknown functions A(t) and k(t) by numerical methods. This approach seems to be very complicated and unrealistic. The other way is to use the differential equation itself.

Mostly the entry and air exchange rates are evaluated with the assumption of their constancy in time during the measuring period. The solution is in this case simple

$$a(t) = A(1-e^{-kt})/kV + a_0 e^{-kt} \quad \text{for } t>0=t_0 \qquad (2)$$

and the three unknown values a_0, k, and A can be obtained by numerical methods from three concentrations a_1,a_2,a_3 measured in times t_1,t_2,t_3 (at least two of them not in steady-state). The insufficiency of this approach is in the unability to assure the constancy of k and A for a longer time than several hours.

DETERMINISTIC SOLUTION OF AN EQUIVALENT DIFFERENCE EQUATION

Measurements result in average concentrations a_i during the i-th time interval $\{t_i,t_i+d\}$ of duration d [h], therefore also average values A_i and k_i can be only obtained from difference equations equivalent to the differential equation:

$$a_i' = - k_i\, a_i + A_i/V \qquad (3)$$

where the average differences a_i' have to be calculated by a numerical calcul from the measured, or better from smoothed values a_i. To calculate the two unknown values k_i and A_i one needs to evaluate at least two adjacent intervals,i.e. two difference equations. Assuming

the same values k and A for both intervals of a concavely increasing course or a convexly decreasing course of experimental values gives good results but fails for convexly increasing and concavely decreasing courses of the radon concentration resulting in meaningless negative air exchange rates. The reason can be understood from the concavely increasing or convexly decreasing time courses of the exact solution (2) of the differential equation assuming constant k and A.

One possibility to extend the applicability of this approach is to assume linear changes for both quantities $k_i = k + \kappa t_i$ and $A_i = A + \alpha t_i$ - decreasing or increasing in accordance to the sign of κ and α. Then four equations for four adjacent intervals have to be used for a general deterministic evaluation. Three equations can be used if the change in time of one of the quantity can be neglected and two equations are enough, if A and k are nearly the same for two adjacent intervals and the courses are properly concavely increasing or convexly decreasing.

STATISTICAL SOLUTION OF THE EQUIVALENT DIFFERENCE EQUATION

The deterministic approach has two important disadvantages. First the "uncompromising" fit of the deterministic solution to the uncertain input data a_i and a_i, gives manytimes completly meaningless results, second it does not give uncertainties for the calculated results. This can be overwhelmed by a linear regression analysis using the difference equation as the statistical model with index i as the independant variable. This approach gives beside of the four mutually interdependant results A, k , α and κ also their covariance matrix, of course the price for this is a larger number of intervals used for the evaluation with the same tendency of linear change assumed for the entry rate and air exchange rate. The optimal number of intervals suitable for evaluation can be determined by computer using the covariance matrix. Setting the difference equations symetrically over the used intervals and shifting automatically the evaluation to the next interval the evaluation should give reasonable results, but only for properly monotonically increasing or decreasing radon concentrations.

Unfortunately the statistical approach results sometimes in multifolds of the real values k and A, of course with the right ratio for the steady state radon concentration. The reason for this is that the minimalisation process finds the lowest minimum but off the real region. Overwhelming of this disadvantage needs to use constraints, but the evaluation gets more and more complicated. Another disadvantage of the approaches is that it cannot be applied around maximal and minimal radon concentrations because a monotonic tendency of the radon entry rate or the air exchange rate is not justified.

STOCHASTIC APPROACH

A promising approach to evaluate the time courses of the radon entry rate and of the air exchange rate from the whole time course of the measured radon concentration is hoped to be the stochastic approach used for simulation of sequences of data , the theory of which is described e.g. in (1). The equation (3) is the generic model for the evaluation and unrealistic solutions are avoided by limits for the air exchange rate and by realistic estimated starting values.

COMMENT TO THE APPLICABILITY OF THE COMPARTMENTAL MODEL

The compartmental or linear kinetic model used for the description of the indoor radon concentration assumes a perfect and immediate mixing of the entered radon in the whole

volume of the room. This is of course not true and it has to be considered if this is not the reason for failures in the above described evaluation. It seems so that normal circulation of the indoor air in occupied rooms produced by heating systems during heating seasons but even by the entry of daylight through windows or by the inhomogeneity of insulation and temparatures of walls, floors and ceilings leads to quick and homogeneous enough mixing of radon entering mostly at the floor level. At least their may be a delay between the real entry time of radon and the calculated "effective" entry time of radon which could be corrected for.

CONCLUSION

Two approaches are given for the determination of variable in time radon entry rates and air exchange rates from continuously measured indoor radon concentrations by numerical solution of the equivalent difference equations in deterministic or statistic form. Unfortunately these approaches are not always successful. But the analysis of the reasons for the failures leeds to a better understanding of the problem. It is hoped that the more sophisticated simulation approach shall solve the problem.

ABSTRACT (See instructions overleaf)

The infiltration of radon from the ground is usually the predominant source of indoor radon pollution. The uniform method for radon risk classification of foundation soils in the Czech Republic was proposed in 1990. At the same time, the regional radon risk maps were produced to improve the knowledge of radon risk on the large scale. Since the acceptance of the Decree of the Ministry of Health of the CR concerning the requirements for limiting radiation exposure due to radon and other natural radionuclides in 1991, the detailed soil-gas radon measurements have become obligatory for all areas of urban planning. A four years experience resulted in several modifications of the origin radon risk classification method. The new recommendation was given in 1994.

A large number of detailed measurements is available for testing the reliability of regional radon risk maps. The comparison illustrates general reliability of large scale radon risk maps on the significant probability level. On the other hand, the local variability caused by a number of geological and nongeological factors confirms the necessity of detailed measurements for proposing the optimal remedial technology.

MAJOR SCIENTIFIC TOPIC NUMBER 1.1. (see page 7)

ABSTRACT (See instructions overleaf)

In the Czech Republic striking number of solid state nuclear track detectors (SSNTD) has been used in last five years (more than 150 000). The bare detectors Kodak LR115 have been choiced for year-mean estimation. The investigation level in the Czech Republic is defined for EEC (radon progeny). Therefore the response (track density) depending on factor F must be corrected.

The uncertainty caused by the differing F is greater than for the case of SSNTD in diffusion chamber, but still acceptable for this purpose (searching houses with elevated EEC).

One has prefered to place detectors in radon-prone areas (defined with help of geology etc.). So the mean of results is higher than in other countries: 95 $Bq.m^{-3}$ with GSD 2.5 for 115 000 detectors evaluated to the end of 1994. The increase of mean in the past is surprising - we suppose it is caused by tightening of dwellings etc.

There are regions with elevated EEC level - medieval mining town Jachymov with mean about 500 $Bq.m^{-3}$ and villages round the pluton body in Central Bohemia (so called Devil Burden), characterized by mean about 300 $Bq.m^{-3}$. In these regions remedial actions were started.

ON THE SIMULTANEOUS INDOOR MEASUREMENT OF THE EXHALATION RATES OF RADON GAS FROM OPEN SOIL AND THE CONCENTRATION OF RADON PROGENY IN THE SURROUNDING AIR

K. NISHIMURA, [1] S. MOCHIZUKI, [2] and T. TANJI [2]

[1] Science University of Tokyo, Oshamanbe, Hokkaido, Japan

[2] Muroran Institute of Technology, Muroran, Hokkaido, Japan

INTRODUCTION

It is well known that the outdoor measurements of radon exhalation rates and of radon concentration in atmosphere are affected by the temperature, wind and atmospheric pressure (1). So far, no clear correlations have been found between these measurements. However, with indoor measurements, especially those recorded in a basement, the temperature is constant and the air flow minimal. This means that we can expect radon exhalation rates and the concentration of radon progeny to be affected by atmospheric pressure alone.

Taking these environmental conditions into account, the simultaneous measurement of radon exhalation rates and radon concentrations was performed in the basement of SUT (Science University of Tokyo), Oshamanbe campus in order to clarify the nature of the relationship between radon exhalation rates and concentrations and changes in atmospheric pressure. Atmospheric pressure was also measured simultaneously with the above measurements. The present measurements were carried out during the winter, spring, summer and autumn of 1995. Measurements were made in a series of one week periods.

EXPERIMENT

As far as we know, there are few studies based on indoor measurements of radon exhalation rates from the soil. This is because the exhalation source, that is the soil, is essential to measurement, and earth-floored basement areas are seldom found in modern building construction. Fortunately, this campus has a large earth-floored basement room (24 m X 22.4 m X 2.6 m). This was the ideal environment for the measurement of radon exhalation rates from the soil and radon progeny concentration in the surrounding air. Our basement has an exhaust fan, which is turned off between midnight and 5:00 a.m.

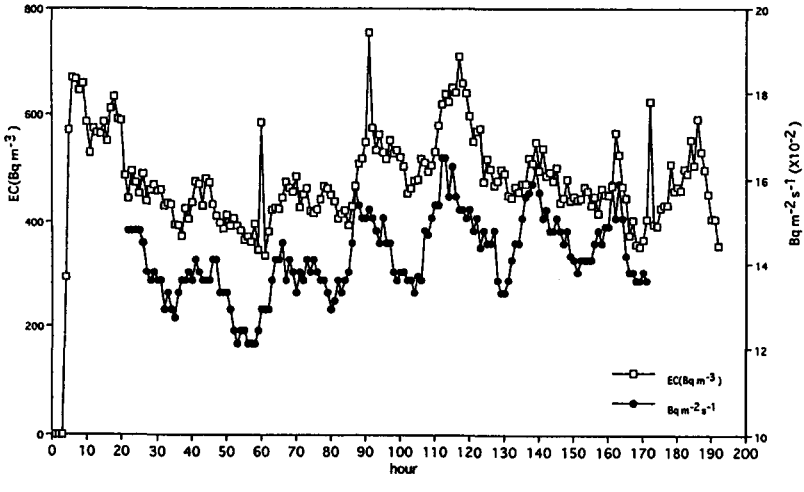

Figure 1. Simultaneous measurement of radon exhalation rates (Bq $m^{-2}s^{-1}$) and radon concentrations [EC(Bq m^{-3})], 17th-23rd May 1995.

The exhalation rates of radon gas from the soil were measured using an ionization chamber (2), whose efficiency was calibrated with a standard radon gas. The ionization currents yielded in the ionization chamber were continuously marked on recording paper. The ionization currents were then converted into exhalation rates in units of Bq $m^{-2}s^{-1}$. The collector of the ionization chamber (covering area 0.85 m X 0.25 m) was placed on the ground surface around the center of the basement room.

The concentrations of radon progeny in the surrounding air were measured using a Radon WL Meter (Thomson & Nielsen Electronics Ltd). The α - ray counts in the Radon WL Meter were measured as they accumulated every hour, and the data processed by an internal computer program. The results were printed out on the recording paper in units of EC(Bq m^{-3}), i.e. Equilibrium-Equivalent Concentration. In order to monitor the concentration of radon gas in the surrounding air near the Radon WL Meter, a dozen "Rad Track" detectors were also fixed at the same time near the inlet of the Radon WL Meter. The Radon WL Meter was set on a table at a height of 0.8 m.

RESULTS and DISCUSSION

As shown in Figure 1, it was found that the upward and downward trends of the radon concentration obtained in the surrounding air were correlative to variations in the radon exhalation rates from the open soil. In other words, the radon concentrations were found to be in phase with the radon exhalation. Sporadic spikes were observed in the tracking curves of the radon progeny concentrations, as shown in Figure 1. The reason for their occurrence is not apparent to the present authors.

Atmospheric pressure affected the yields both of the radon gas from the soil and of the radon progeny concentrations in the air. Whenever atmospheric pressure increased, both the yields of radon gas and of radon concentration decreased, and vice versa. That is, the former tracking curve varied with the latter curves in an inverse relation. An example of this phenomenon is shown in Figure 2.

Periodic daily variations were clearly observed in the tracking curves of both the exhalation rates of radon gas and the radon concentrations, as shown in Figure 2 and Figure 3. The peaks of the radon exhalation rates in Figure 2 and of the radon concentration of (no.1) and (no.2) data in Figure 3 occurred at about 6:00 a.m. every day. The data of (no.1) and (no.2) were obtained simultaneously by two different Radon WL Meters, which were set on tables at the center and corner points of the basement room, respectively.

Seasonal variations in radon exhalation rates from the soil are shown in Figure 4. The autumn level of the radon exhalation rates was the highest, while those in winter and spring were median. The lowest rates were exhibited by the data observed in the summer.

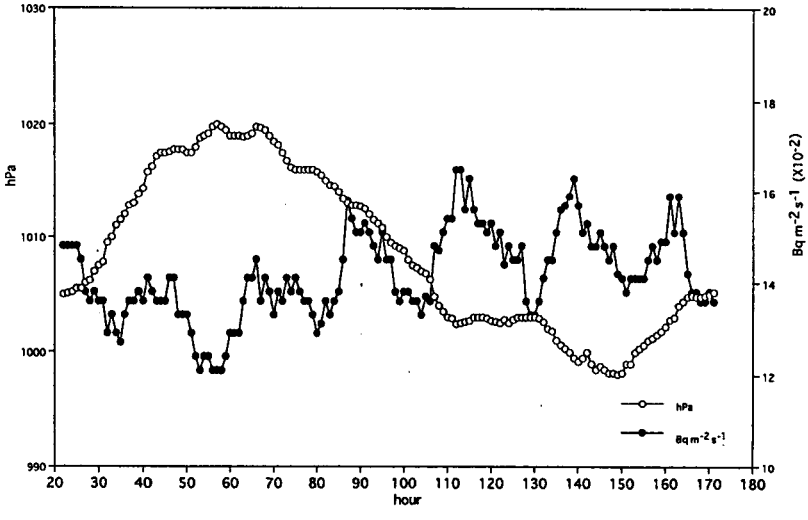

Figure 2. Dependence of radon exhalation rates (Bq $m^{-2}s^{-1}$) from soil on changes in atmospheric pressure (hPa), May 17th-23rd 1995.

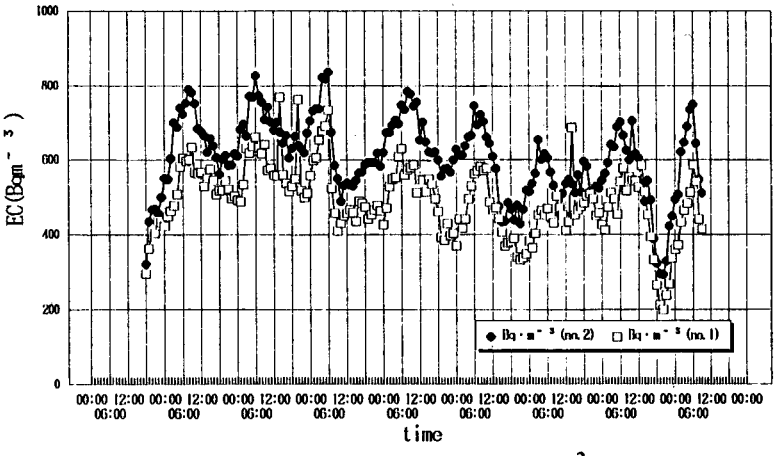

Figure 3. Daily variation of radon concentration [EC(Bq m^{-3}] in air, July 28th-August 5th 1995. The data of (no.1) and (no.2) were obtained at the center and corner points, respectively, in the basement room. Two different Radon WL Meters were used simultaneously. The peaks of radon concentrations occurred at about 6: 00 a.m. daily.

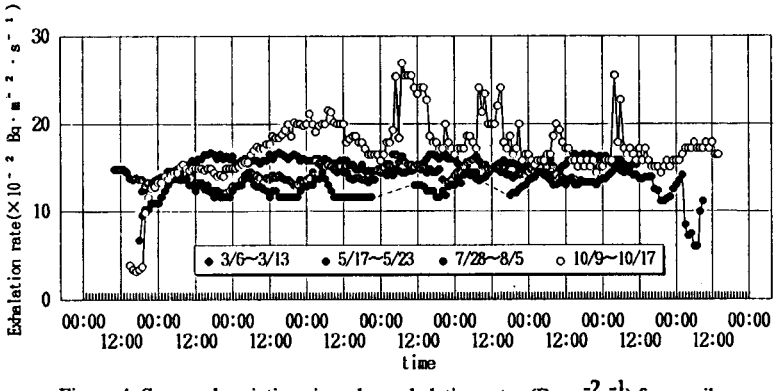

Figure 4. Seasonal variations in radon exhalation rates (Bq $m^{-2}s^{-1}$) from soil during winter, spring, summer and autumn 1995.

The radon concentrations (Bq m^{-3}) obtained by "Rad Track" detectors were compared with the integrated values estimated from the tracking curves of the radon concentrations [EC(Bq m^{-3})]. The results show that the latter values were about 1.7 times greater than the former.

EXHALATION OF RADON AND THORON FROM PHOSPHOGYPSUM USED AS BUILDING MATERIAL

Hans Vanmarcke

SCK•CEN, Nuclear Research Center, Boeretang 200, 2400 Mol, Belgium

ABSTRACT

The radioactive properties of two types of phosphogypsum, were determined. Gypsum plates with different thickness were produced. The ^{226}Ra and ^{232}Th concentrations were measured by means of high resolution gamma spectrometry. The results are for type 1 ^{226}Ra : 75 Bq/kg and ^{232}Th 230 Bq/kg and for type 2 ^{226}Ra : 155 Bq/kg and ^{232}Th : 160 Bq/kg. The radon (^{222}Rn) exhalation rate was evaluated by closing the plates in airtight barrels and measuring the radon concentration. The exhalation rate of type 1 is 1.2 10^{-5} Bq/(kg s) and type 2 4.7 10^{-5} Bq/(kg s). In combination with the ^{226}Ra concentration an emanating fraction of respectively 7.6% and 14% is obtained.

The ^{220}Rn (thoron) exhalation of the plates was determined by measuring the concentration of the decay products in a chamber of 1 m^3 with normal aerosol concentrations. The exhalation rate was found to be independent of the thickness of the plates, as expected from the short half-life of ^{220}Rn. Covering the entire surface of the plates with two layers of a common Latex paint decreased the thoron exhalation by a factor of 10 to 20.

The laboratory results for the radon and thoron exhalation were converted using realistic assumptions for a room. The contribution of phosphogypsum to the average radon concentration in a room is found to be about 1 Bq/m^3 for type 1 and 4 Bq/m^3 for type 2 resulting in an annual effective dose of the order of 0.1 mSv/year. The contribution to the effective dose from the thoron exhalation is much greater, namely, 1.8 mSv/year for type 1 and 0.9 mSv/year for type 2. Painting the gypsum lowers the thoron dose by a factor of 10 to 20 making the thoron dose comparable to that of radon.

INTRODUCTION

Gypsum is widely used in Belgium as a building material. The walls in most dwellings are covered with a layer of 1 to 2 cm of gypsum before they are painted or wallpapered. A considerable fraction of the gypsum applied in Belgian dwellings comes from the phosphate industry. The reaction of phosphate ore with sulfuric acid yields a variety of phosphate products and calcium-sulfate (gypsum). On average 4 kg of gypsum are produced for each kg of phosphoric acid (1). The phosphate ore has generally a high content of ^{238}U and/or ^{232}Th in radioactive equilibium with its daughter products. Most of this radioactivity will be found in the gypsum waste which is called phosphogypsum.

The paper consists of two parts. In the first part the radioactive properties of two types of phosphogypsum are determined. Results are given concerning the ^{226}Ra and ^{232}Th concentration, the radon (^{222}Rn) exhalation rate and the thoron (^{220}Rn) exhalation with and without painting. The radiological impact of using these types of phosphogypsum in home construction are discussed in the second part.

METHODS AND RESULTS

From each of the two types of phosphogypsum 60 plates with a surface of 0.295 x 0.210 m were made. Half of the plates was produced with a thickness of 0.5 cm and the other half with a thickness of 2 cm.

The ^{226}Ra and ^{232}Th concentrations of the two types of phosphogypsum were measured by means of high resolution gamma spectrometry. The detector of the measurement system is a 20% efficient germanium cristal with a resolution of 1.70 keV (fwhm). The detector is calibrated in the same geometry with a ^{134}Cs source traceable to NIST. The results for the two types are:

Type 1 : ^{226}Ra : 75 Bq/kg ^{232}Th : 230 Bq/kg

Type 2 : ^{226}Ra : 155 Bq/kg ^{232}Th : 160 Bq/kg

The radium concentrations are lower and the thorium concentrations are higher than those found in phosphogypsum from Moroccan origin (1).

The radon (^{222}Rn) exhalation rate was measured by closing some of the plates in an airtight barrel flushed previously with radon free air. One week or more later, the radon concentration in the barrel was determined by means of the Lucas technique. From the dimensions of the barrel, the weight of the sample and the radon concentration the exhalation rate was calculated:

Type 1 : 1.2 10^{-5} Bq/(kg s)

Type 2 : 4.7 10^{-5} Bq/(kg s)

In combination with the ^{226}Ra concentration an emanating fraction of 7.6% for type 1 and 14% for type 2 is obtained.

The thoron exhalation (^{220}Rn) of the plates was evaluated by means of its decay products because of the short half-life of thoron (55.6 s). The plates were brought into a 1 m^3 chamber which was ventilated continuously at a rate between 0.3 to 0.4 h^{-1} with outside air containing natural aerosol particles. The outside air was taken at a height of 10 m where the thoron and thoron decay product concentrations are very low. Each sample was measured 3 to 4 times. The reproducibility of the equilibrium equivalent thoron concentration was about 25% due to fluctuations in the aerosol concentration in the chamber. The equilibrium equivalent thoron concentration (EEC_{Th}) is calculated from the ^{212}Pb and ^{212}Bi concentrations in the following way:

$EEC_{Th} = 0.91\ C\ (^{212}Pb) + 0.09\ C\ (^{212}Bi)$

The results given in table 1 are normalised to an exhalation surface of 4 m^2 and corrected for the influence of humidity on the exhalation of the freshly produced gypsum plates.

TABLE 1. Equilibrium equivalent thoron concentration of the phosphogypsum plates with and without painting in the experimental chamber

Type	Thickness cm	Not painted EEC_{Th} Bq/m^3	Painted EEC_{Th} Bq/m^3	Ratio Not painted / Painted
1	0.5	35	2.2	16
1	2.0	25	2.3	11
2	0.5	14	0.7	20
2	2.0	12	1.0	12

The thoron exhalation is, as expected from the short half-life of ^{220}Rn, independed of the thickness of the samples. The exhalation of type 1 is about two times higher than that of type 2. This is more or less in line with the measured ^{232}Th concentrations.

The effect of covering the entire surface of the plates with two layers of a common Latex paint was also investigated. The set-up was identical to the measurements of the un-painted plates. The measured equilibrium equivalent thoron concentrations are shown in table 1. The reduction in thoron exhalation by painting the gypsum plates is a factor of 10 to 20.

DISCUSSION

In order to evaluate the radon and thoron exhalation of the phosphogypsum plates, the laboratory results were converted using realistic assumptions for a room:

- size of the room : 4 x 5 x 3 m (60 m^3);
- ventilation rate : 0.5 h^{-1} ;
- walls and ceiling covered with type 1 or type 2 phosphogypsum (74 m^2);
- residence time : 80%.

Covering the walls and the ceiling of the room with 1 cm of phosphogypsum increases the radon concentration of the room with 1 Bq/m^3 for type 1 and 4 Bq/m^3 for type 2 resulting in a contribution to the effective dose of the order of 0.1 mSv per year.

In the calculation of the effective dose from the thoron exhalation the conversion factor between the equilibrium equivalent thoron concentration and the effective dose from ICRP publication 50 (2) is taken: 3.9 10^{-5} mSv/(Bq h/m^3). The effective dose from the thoron exhalation of the uncovered phosphogypsum is much greater than the one from the radon exhalation, namely, 1.8 mSv/year for type 1 and 0.9 mSv/year for type 2. Painting the gypsum reduces the thoron exhalation by a factor of 10 to 20 making the thoron dose comparable to that of radon

INTRODUCTION

In indoor ^{222}Rn surveys in Japan, high ^{222}Rn concentrations were sometimes observed by passive methods(1) in Japanese traditional dwellings with soil walls. However, the ^{222}Rn progeny concentrations measured by active methods in the dwellings were not so high but thoron (^{220}Rn) progeny concentrations were rather high(2). Moreover, some studies(3,4) have made it clear that high ^{220}Rn concentrations were observed near the soil walls. Since there are the dwellings with soil walls in all over the world, it is important to evaluate the annual effective dose equivalent dose due to ^{220}Rn and its progeny(4).

PASSIVE ^{222}RN AND ^{220}RN CUP MONITORS

A pair of passive ^{222}Rn and ^{220}Rn cup monitors was developed. The cross sections are shown in **Fig. 1**. The ^{222}Rn and ^{220}Rn monitors have a 5 mm exchange opening and four exchange openings of diameter 20 mm, respectively. Calibration factors of the ^{222}Rn and ^{220}Rn monitors were $(2.15\pm0.19)\times10^{-5}$ and $(5.06\pm0.89)\times10^{-4}$ tracks$\cdot$cm^{-2}(Bq$\cdot$m$^{-3}\cdot$h)$^{-1}$ and agree well with the calculated values. The lower detection limit of the ^{222}Rn and ^{220}Rn monitors were 6.4 and 21 Bq$\cdot$m^{-3} for an exposure time of 90 d.

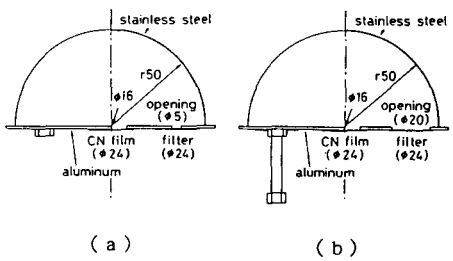

Fig. 1 Passive integrating ^{222}Rn and ^{220}Rn cup monitors (a) for ^{222}Rn measurement and (b) for ^{220}Rn measurement.

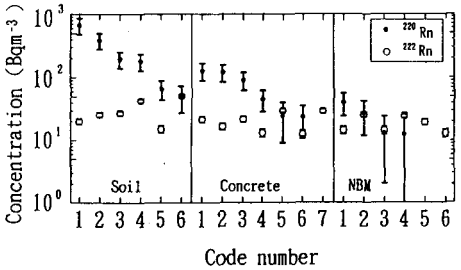

Fig. 2 Result of the survey from 29 Oct. 1991 to 30 Jan. 1992: (●) ^{220}Rn and (○) ^{222}Rn concentrations.

MEASUREMENTS OF INDOOR ^{222}RN AND ^{220}RN CONCENTRATIONS

Small scale surveys of ^{222}Rn and ^{220}Rn concentrations indoors were performed with the cup monitors over three years. An example of the surveys is shown in Fig. 2. Mean ^{220}Rn concentrations of the dwellings with soil walls were the highest compared with dwellings made of concrete and new building material (NBM).

In some dwellings with soil wall, the ^{220}Rn concentrations have been measured by using six pairs of cup monitors. An example of the results is shown in Fig. 3. The ^{220}Rn concentration could be expressed by the following equation(5):

$$Q(X) = \frac{E_{Tn}}{\sqrt{\lambda_{Tn}\cdot D}} \exp(-\sqrt{\lambda_{Tn}/D})X, \qquad (1)$$

where Q(X) is the ^{220}Rn concentration at a distance of X m from wall in Bq•m^{-3}, E_{Tn} is the ^{220}Rn exhalation rate from wall in Bq•m^{-2}•s^{-1}, λ_{Tn} is the ^{220}Rn decay rate in h^{-1}, and D is the effective diffusion coefficient of ^{220}Rn in air in m^2•s^{-1}. The E_{Tn} and D calculated by using the least squares method range from 1.6 to 6.4 Bq•m^{-2}•s^{-1} and 1.2 to 7.4X10^{-5} m^2•s^{-1}, respectively.

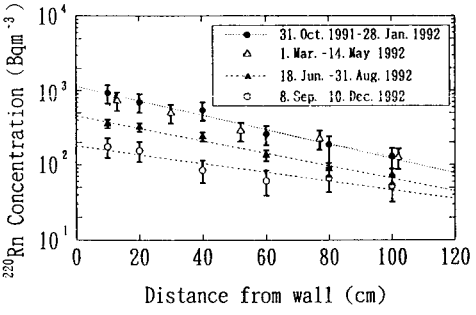

Fig. 3 Distributions of ^{220}Rn concentrations indoors.

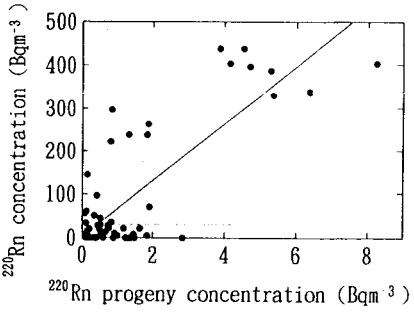

Fig. 4 Relationship between measured ^{220}Rn and ^{220}Rn progeny concentrations.

DOSE ASSESSMENT METHOD

The effective diffusion coefficient ranges from 1.2 to 7.4X10^{-5} m^2•s^{-1} as described above. If we measured ^{220}Rn concentrations at a distance of 20 cm from wall, Q(0.2), exhalation rate of ^{220}Rn from wall can be calculated to be 0.0099Q(0.2) in ranging from 0.0074Q(0.2) to 0.0124Q(0.2) from Eq. (1). Thus, ^{220}Rn exhalation rate could be estimated by uncertainty of only ±25% from the ^{220}Rn concentration at 20 cm from wall.

The ^{212}Pb (ThB) concentration in dwelling is expressed as follows(5):

$$C_B = \frac{\lambda_a \cdot \lambda_B \cdot N_B \cdot S/V + \lambda_v \cdot C_{Bo}}{\lambda_B + \lambda_v + \lambda_d}, \qquad (2)$$

where N_B is defined by

$$N_B = E_{Tn}[\lambda_{Tn}(\lambda_B + \lambda_a + \sqrt{\lambda_{Tn}(\lambda_B + \lambda_a)})], \qquad (3)$$

C_B is indoor ^{212}Pb concentration in Bq•m^{-3}, λ_a is the attached coefficient of free nuclei to aerosol particles in s^{-1}, λ_B is the decay rate of ^{212}Pb in s^{-1}, S is the surface area of wall in m^2 from which ^{220}Rn exhales, V is the volume of the room in m^3, λ_v is the ventilation rate of the room air in s^{-1}, C_{Bo} is outdoor ^{212}Pb concentration in Bq•m^{-3}, and λ_d is the deposition rate of attached ^{212}Pb atoms in s^{-1}. Here, we assume that the ratio of surface area exhaling ^{220}Rn to volume of the room is about 1/3 and does not vary on dwellings. The values of the another parameters are assumed to be; λ_a = 0.0139 s^{-1}(6), λ_v= 1.39X10^{-4} s^{-1}(7) and λ_d = 5.6X10^{-6} s^{-1}(6). Moreover, ^{220}Rn progeny concentration is equal to about 1.1 times ^{212}Pb, if ^{212}Pb and ^{212}Bi are in equilibrium. Consequently, ^{220}Rn progeny concentration could be expressed by ^{220}Rn exhalation rate as follows:

$$C_{TP} = 1.3E_{Tn}, \qquad (4)$$

where C_{TP} is ^{220}Rn progeny concentration in Bq•m^{-3}. As E_{Tn}=0.0099Q(0.2) described above,

$$C_{TP} = 0.013Q(0.2). \qquad (5)$$

Equation (5) indicates that indoor ^{220}Rn progeny concentration could be estimated from the ^{220}Rn concentration measured with passive cup monitors at 20 cm from wall.

In some dwellings, ^{220}Rn progeny concentrations were measured by active methods(2, 8) during the surveys of ^{220}Rn concentrations with cup monitors. Figure 4 shows the relationship between measured ^{220}Rn and ^{220}Rn progeny concentrations. The correlation coefficient between ^{220}Rn and ^{220}Rn progeny concentrations was 0.79. The relationship between ^{220}Rn progeny and ^{220}Rn concentrations is therefore given by

$$C_{TPm} = 0.015Q(0.2)_m. \quad (6)$$

where C_{TPm} and $Q(0.2)_m$ are the measured concentrations of ^{220}Rn progeny and ^{220}Rn. The relation of Eq. (6) gives fairly good agreement with the theoretical relation in Eq. (5).

Annual effective dose equivalents due to ^{222}Rn and ^{220}Rn progeny were estimated by using the measured values of small scale surveys. The results classified by building materials are shown in **Table 1**. The effective dose equivalent factors of ^{222}Rn and ^{220}Rn progeny are estimated to be 70 and 280 $\mu Sv \cdot y^{-1}$ per $Bq \cdot m^{-3}$ using a mean breathing rate of 0.8 $m^3 \cdot h^{-1}$ indoors and an average occupancy factor of 0.8 indoors(9). An equilibrium factor between ^{222}Rn and its progeny was assumed to be 0.4 indoors. On the other hand, ^{220}Rn progeny concentration were calculated by Eq. (5). The annual effective dose equivalents due to ^{220}Rn progeny in the dwellings with soil wall was calculated to be 0.67 $mSv \cdot y^{-1}$ and may be equal to that due to ^{222}Rn and its progeny.

Table 1 Estimation of annual effective dose equivalents due to ^{222}Rn and ^{220}Rn progeny.

	^{222}Rn		^{220}Rn

CONCLUSIONS

A pair of passive cup monitors with a different air exchange openings was developed for measuring simultaneously ^{222}Rn and ^{220}Rn concentrations. Indoor ^{220}Rn concentrations were very high in traditional Japanese dwellings with soil walls. The ^{220}Rn concentration decreases exponentially with the distance from wall. The effective diffusion coefficient of ^{220}Rn in dwelling and the exhalation rate of ^{220}Rn from wall were evaluated from the distribution of the ^{220}Rn concentrations. Then, indoor ^{220}Rn progeny concentration could be estimated from the ^{220}Rn concentration at a 20 cm distance from wall. From the results of the surveys, the average annual effective dose equivalent due to ^{220}Rn progeny was expected to be 0.67 $mSv \cdot y^{-1}$ in the traditional Japanese dwellings.

INTRODUCTION

The inhalation of airborne short-lived radon decay products occured from the two main isotopic forms of radon, ^{222}Rn and ^{220}Rn (thoron), which are ubiquitous in the human environment and contributed to the greatest part of the natural radiation exposure. The laboratory rat has been particularly used to estimate the hazard to human health following exposures to radon and progeny (1). These data on lung cancer risk in rats are consistent with the epidemiological findings for uranium miners in all exposure categories considered and in typical aerosol characteristics, so that the exposure-dose conversion factor estimated by lung modelling are comparable in the two species (2). It has been shown that measurements of deposition of ^{214}Pb in excised lungs and nuclear aberrations in alveolar macrophages allow us to estimate the dose delivered to the deep lung after radon progeny inhalation (3). In contrast, experimental data for thoron and thoron progeny are quite limited. The aim of this study was to develop an experimental device suitable for the exposure of few rats to thoron, - to measure the deposition of thoron progeny within the excised lung of rats by gamma spectrometry of ^{212}Pb and to compare this deposition for a similar cumulative exposure with the incidence of micronuclei and binucleated alveolar macrophages observed after radon progeny inhalation in well characterized atmospheres.

EXPERIMENTAL METHODS

An available and convenient source of thoron gas is ^{228}Th, involatile at room temperature, which decays rapidly via thoron gas in ^{216}Po and ^{212}Pb. It is possible to increase dramatically the rate of emanation by heating. Such a small experimental design was performed for nose-only animal exposures (Algade-Cogéma, France). It consists in a small glass volume (15 liters) in which the heated generator was previously located and where the rats were restrained in specially designed tubes so that only the noses of the animals protruded into the chamber. Due to its very short half-live, ^{216}Po is in equilibrium with thoron so that the activities are comparable. A smoke aerosol was introduced to allow the attachment of ^{212}Pb and limit its plate-out on surfaces. Six rats were exposed in a single session to thoron and progeny for 3 hours under these experimental conditions.

Two animals were euthanazied to determine the gross deposition in the excised lungs by gamma spectrometry of the emission of ^{212}Pb at 239 keV. The retention of ^{212}Pb was measured within an annulus shaped NaI detector (Crismatec, France). All these measurements were performed according to the recommendations decided between the European laboratories involved in animal studies on radon (4).

Two of the remaining rats were euthanazied 6 days after thoron exposure and the two last ones, 12 days after the end of thoron exposure. Micronuclei and binucleated cells were scored in alveolar macrophages extracted by bronchoalveolar lavage, 8 days after exposure. Cytospins of cell suspension were air-dried, fixed in ethanol-ether (1/1 v) and stained with Giemsa before light microscopic observation.

RESULTS AND DISCUSSION

Table 1 shows the inhalation parameters measured in exposure chambers and lead deposition measured in excised lungs of thoron exposed rats compared to those previously measured in rats exposed to radon (^{222}Rn) in the inhalation facility of Razès under different aerosol atmospheres and using a quite similar potential alpha energy concentration (PAEC).

Table 1. Inhalation parameters of radon and thoron exposures and Pb retention in the deep lung of rats under different conditions and for a similar potential alpha energy concentration (PAEC).

RADON INHALATIONS			THORON INHALATION	
Aerosol parameters	High equilibrium	Low equilibrium	Aerosol parameters	High equilibrium
^{222}Rn activity	4632 kBq/m3	9925 kBq/m3	^{220}Rn activity	1268 kBq/m3
^{218}Po activity	2408 kBq/m3	7146 kBq/m3	^{216}Po activity	1100 kBq/m3
^{214}Pb activity	1713 kBq/m3	1488 kBq/m3	^{212}Pb activity	330 kBq/m3
^{214}Bi activity	1667 kBq/m3	397 kBq/m3	^{212}Bi activity	< 1 kBq/m3
Equilibrium factor	0.36	0.16	Equilibrium factor	0.30
PAEC	9.3 mJ/m3 450 WL	8.9 mJ/m3 429 WL	PAEC	15 mJ/m3 720 WL
Cumulative dose (after 3 hours)	27.9 mJ/m3.h 7.9 WLM	26.7 mJ/m3.h 7.5 WLM	Cumulative dose (after 3 hours)	43 mJ/m3.h 12 WLM
^{214}Pb activity in 3 excised lungs	5.0 ± 2.9 kBq/g	5.3 ± 3.2 kBq/g	^{212}Pb activity in 2 excised lungs	0.36± 0.2 kBq/g

Table 2 shows the percentage of micronucleated and binucleated alveolar macrophages recovered from the rats exposed to radon and euthanazied 8 days later. The controls corresponded to 5 unexposed rats killed at the same age.

Table 2. Percentage of micronucleated and binucleated alveolar macrophages (AM) one week after radon and thoron exposures (mean value ± SD).

	% of micronucleated AM	% of multinucleated AM
Controls	0.19 ± 0.10	1.34 ± 0.69
radon at high equilibrium	1.22 ± 0.26	2.91 ± 0.74
radon at low equilibrium	1.47 ± 0.42	2.30 ± 0.78
thoron at high equilibrium	0.59 ± 0.06	2.64 ± 0.98

If the micronuclei index is similar for radon inhalations under different aerosol characteristics, the number of micronuclei after thoron is lower as regards the level of concentration but higher than that found spontaneously in unexposed rats. However it is now possible to expose rats to an aerosol mixture of thoron and progeny inducing an increased incidence of alveolar cell nuclei aberrations. Further studies are still in progress to improve the measurements of the aerosol characteristics, thoron progeny deposition and dose distribution compared with radon progeny exposures.

THORON PROGENY CONCENTRATIONS IN LIVING SPACE

T.Yamasaki[1] and T.Iida[2]

[1]Chubu Electric Power Co. Inc., Nagoya, Japan
[2]Nagoya University, Nagoya, Japan

INTRODUCTION

In the UNSCEAR 1988 report(1), it was estimated that the inhalation of short-lived decay products of radon(^{222}Rn) and thoron(^{220}Rn) accounts on average for about one half of the effective dose equivalent from all natural sources of radiation. In recent years, several studies on radon and its progeny in mines and in dwellings have been performed, but for indoor thoron progeny there are only a few measurements. In Europe, the mean thoron progeny levels represented by equilibrium equivalent thoron concentration in dwellings seem to lie between 0.1 and 1.0 Bqm^{-3}(2), and the thoron progeny makes a contribution of about 10 to 30% of the effective lung dose equivalent from all indoor radon plus thoron and their progeny. However, Doi(3) reported that thoron concentration in Japanese dwellings may be is higher than in other countries because the interior walls of typical Japanese dwellings are covered with a soil based plaster. Therefore, the dose due to indoor thoron progeny may be higher in Japan.

Thoron concentration depends on a distance from wall which is a source of thoron, but less information is available concerning the distribution of indoor thoron progeny concentrations. It is necessary to study the characteristics of thoron progeny for estimation of the absorbed dose. The concentration distributions of indoor thoron progeny have not been studied and calculated in detail. Thereby more research of thoron progeny should be required.

This report shows (i)the theoretical distributions of indoor thoron progeny concentration that could be predicted by a model calculation using the numerical method(4) and (ii)the development of a quiet portable monitor for measuring both thoron and radon progeny(5).

CONCENTRATION DISTRIBUTION

The behavior of thoron and its progeny almost depend on the diffusion in the room because of a very short half-life time of thoron which emanates from the wall. For describing movement of the nuclides in the dwelling, we introduce an effective diffusion coefficient D[m^{2}s^{-1}] which expresses the diffusion in the room macroscopically, then we suppose the effective diffusion coefficients of thoron and its progeny have the same value. Distinguishing between attached (superscript 'a') and unattached or free (superscript 'f') atoms, the formation and the extinction of thoron decay chain is considered as follows:

$$\begin{array}{ccccccccc} & & \lambda_T & & \lambda_A & & \lambda_a & & \lambda_B & & \lambda_C \\ ^{220}\mathrm{Rn} & \rightarrow & ^{216}\mathrm{Po}^f & \rightarrow & ^{212}\mathrm{Pb}^f & \rightarrow & ^{212}\mathrm{Pb}^a & \rightarrow & ^{212}\mathrm{Bi} & \rightarrow \\ & & \downarrow & & \downarrow & & \downarrow & & \downarrow & \\ & & \lambda_d & & \lambda_d & & \lambda_d+\lambda_v & & \lambda_d+\lambda_v & \end{array}$$

Thoron and its progeny concentrations were calculated by two dimension and steady state model. For considering the distribution of thoron and its progeny, the plane was divided into K^2 cells. Considering the diffusion, deposition and ventilation at each cell, 5 K^2 sets of the simultaneous equations are obtained. Since all differential equations are equal to zero under the steady state conditions. These equations could be solved directly by the method of LU-factorization. Substituting the appropriate parameters, distributions of thoron and its progeny concentrations are calculated .

MEASUREMENT

The measurement method for radon and thoron progeny is based on the solid state nuclear track detector. A schematic diagram of the potential alpha-energy monitor head is given in Figure 1. The measurement system is composed of the monitor head, a diaphragm pump, an integrating flow meter and a timer. The pump is selected to be as silent as possible for long term measurements in the living space. The total weight of the system is about 2kg. The system is portable, and can be easily moved from dwelling to dwelling. The monitor head has four windows, two for radon progeny and two for thoron progeny. The thickness of absorbers are different for radon or thoron progeny because of the difference of the emitted alpha particle energies.

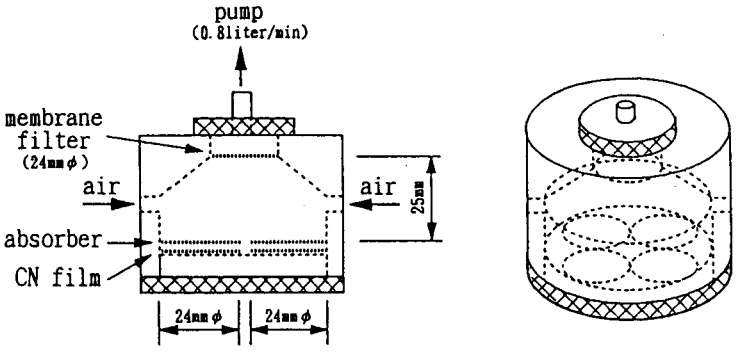

Figure 1. Schematic drawing of a potential alpha-energy monitor for radon and thoron progeny.

In equations(1) and (2), the equilibrium equivalent radon concentration(E.E.R.) and the equilibrium equivalent thoron concentration(E.E.T.) could be obtained by the collecting volume(V) and etch pits on the CN film(N_R,N_T), where N_R and N_T are the count of etched tracks in radon and thoron window, respectively. The unit of V is m^3.

$$E.E.R. = \frac{6.79\ 10^{-2}\ N_R}{V} \qquad (1)$$

$$E.E.T. = \frac{7.59\ 10^{-3}\ N_T}{V} \qquad (2)$$

RESULTS AND DISCUSSION

Figure 2 shows the distributions of thoron, ^{212}Pb(unattached) and ^{212}Bi concentration in dwellings calculated by this method. Thoron emanates only from the whole left side wall and diffuses to the right. The effective diffusion coefficient ,D=0.005 m^2s^{-1}, in Figure 2 is normal value in the ordinary dwellings(6). Thoron concentration is decreasing exponentially with the distance from the wall of thoron emanation. Both the atoms of ^{212}Pb and that of ^{212}Bi, which are closely related to human exposure, are the constant concentrations whether at the center or the corner in the room. Therefore, it is easy to estimate the absorbed dose due to inhalation of thoron progeny which has uniform concentration in the room.

In the model dwelling, the equilibrium equivalent thoron concentration calculated by plausible parameters is compared to the experimental value. The calculated concentration was 3Bqm^{-3}. It is little higher than experimental value of 1.1 Bqm^{-3}. If the ventilation rate equals to 2.0h^{-1} which is four times higher than the above calculation, the calculated concentration becomes to be 1.1 Bqm^{-3}.

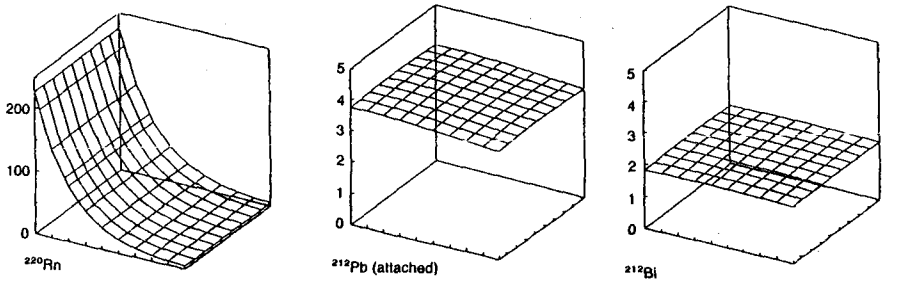

Figure 2. The general views of concentration distributions. The vertical axes show the activity concentrations.

Figure 3 shows measurement results at four locations as a example. The measurement period is one week at each location. Figure 4 shows the RT-ratio, which is defined by the ratio of E.E.T. to E.E.R. The indoor RT-ratio is about 0.1, which is about three times higher than outdoor. The indoor thoron progeny may make a significant contribution to the public dose equivalent of Japanese.

BODY CONTENT OF ^{210}Pb: A MEASURE OF CUMULATIVE EXPOSURE TO RADON ?

Paul Roth, W. Wahl, E. Werner, W. Jacobi

GSF - Forschungszentrum für Umwelt und Gesundheit
Institut für Strahlenschutz
D - 85758 Oberschleißheim / Germany

INTRODUCTION

The content of the long-lived ^{222}Rn daughter ^{210}Pb in the human body has been proposed as a measure of cumulative exposure to radon/radon progeny for occupational and residential environments. However, there are various sources that contribute to the ^{210}Pb accumulation in the body. For a reliable interpretation of any measured ^{210}Pb value, it is imperative that the significance and variability of these different sources are sufficiently well understood. In this study, the accumulation of ^{210}Pbe in the human body was modelled for a variety of exposure conditions, applying the most recent knowledge on lead metabolism in man.

SOURCES OF ^{210}Pb IN THE BODY

Age dependent values for the uptake of ^{210}Pb from the various natural sources are summarized in Table 1. Under normal residential conditions, consumption of food is the most important route by which ^{210}Pb enters the human body. Whereas the short-lived ^{222}Rn daughters account for the majority of the lung dose, they contribute relatively little to the ^{210}Pb accumulation in the body. For normal radon levels, the blood uptake of ^{210}Pb by direct inhalation of air borne ^{210}Pb is a factor of five higher than uptake from the short-lived ^{222}Rn daughters (Table 1). Cigarette smoking may significantly contribute to the deposition of ^{210}Pb. Additional small components of ^{210}Pb uptake result from the presence of ^{222}Rn and ^{226}Ra in the human body. The contributions to ^{210}Pb accumulation in the body can be clearly grouped into two categories: components that are independent of the level of ^{222}Rn and components that are related to environmental ^{222}Rn (Table 1).

CALCULATIONS FOR DIFFERENT EXPOSURE MODELS

The accumulation of ^{210}Pb in various organs and tissues of the body and the excretion pattern were predicted on the basis of the age-dependent uptake values given in Table 1. The distribution and retention after systemic uptake was described applying the age-dependent metabolic model for lead as described in ICRP Publication 67 [1]. The model calculations were performed employing the computer program SAAM-31 [2].

RESULTS

In Fig. 1, the ^{210}Pb activity in whole body, total skeleton, soft tissues and blood during life-time are shown for "normal" exposure conditions. The effect of regular smoking on the accumulation of ^{210}Pb under otherwise "normal" conditions is shown in Fig. 2. The effects of variations in the ^{222}Rn level and hence in the ^{222}Rn dependent components of ^{210}Pb uptake are shown in Fig. 3. For higher radon level environments these components dominate by far the ^{210}Pb accumulation. Results for the simulation of elevated occupational exposures during a certain time period are shown in Fig.4. It shows the time course of ^{210}Pb activity for the two bone compartments (trabecular and cortical) and the whole skeleton. The subsequent decrease after returning to "normal" exposures is very different for the two types of bone. Whereas the half time for trabecular bone is about 4.4 years, it is about 19 years for cortical bone.

Table 1. Average daily uptake to blood of ^{210}Pb from natural sources (mBq · d^{-1})

Age group	Ingestion [a]	Direct inhalation of airborne ^{210}Pb [b,c]	Production of ^{210}Pb from inhaled ^{222}Rn daughters [b,d]	Production of ^{210}Pb from ^{222}Rn dissolved in body fluids [e]	Production of ^{210}Pb from ^{226}Ra in body [f]

[d] Derived for a typical indoor atmosphere of 40 Bq m^{-3} of ^{222}Rn, 33 Bq m^{-3} of ^{218}Po, 22 Bq m^{-3} of ^{214}Pb, and 15 Bq m^{-3} of ^{214}Bi [3]; ^{210}Pb equivalent ($8.46 \cdot 10^{-5}$ Bq ^{210}Pb per m^3)

[e] Derived for indoor atmosphere with 40 Bq m^{-3} of ^{222}Rn. (0.085 mBq·d^{-1} of ^{210}Pb per Bq ^{222}Rn in body)

[f] Assuming 0.85 Bq of ^{226}Ra per kg of calcium [5]. Assuming 30% of the produced ^{222}Rn and its daughters are retained long enough to decay to ^{210}Pb

[g] Estimate for 20 cigarettes per day (20 mBq ^{210}Pb per cigarette; 10% inhalable) [5]. Applying new lung model of ICRP [4].

DISCUSSION

The uptake of ^{210}Pb via the lung through inhalation of ^{210}Pb and the short-lived ^{222}Rn daughters depends not only on their concentrations in air but also on the physical properties of the inhaled particles on which the Rn daughters and ^{210}Pb collect. Whereas extensive measurements of ^{222}Rn concentrations have been made in residential and occupational settings, little information is available on indoor concentrations of ^{210}Pb. Preliminary results indicate that changes in indoor ^{222}Rn concentrations are accompanied by corresponding changes in airborne ^{210}Pb.

The calculated ^{210}Pb contents are in good agreement with available autopsy data [6]. From these data, a total skeleton content of 15 Bq of ^{210}Pb can be derived for normal exposures, which is in very close agreement with the results of the present calculations.

Estimates of body ^{210}Pb are finally aimed to estimate cumulative exposures to the short-lived ^{222}Rn daughters, since it is the lung dose from these radionuclides which determines the health risk from radon. However, the short lived Rn daughters contribute relatively little to the ^{210}Pb accumulation in the body (2% under normal conditions vs. 12% from the direct inhalation of ^{210}Pb and 86% from ingestion). The relative importance of the short lived Rn daughter component for the ^{210}Pb accumulation at increasing Rn levels depends strongly on the relationship between the concentrations of short lived Rn daughters and ^{210}Pb in air at increasing indoor Rn levels, which until now has not yet been established. It must be concluded therefore that all components contributing to body ^{210}Pb must be known with sufficient accuracy and for a large range of Rn levels before a relationship between body ^{210}Pb and lung dose can be postulated. Without a sound knowledge of these components and their variabilities, no reliable estimates for the lung dose can be obtained, even when the body content of ^{210}Pb can be assessed very accurately. The smaller the contribution of Rn daughters to the ^{210}Pb accumulation, the smaller will be the lung dose per unit of exposure and the larger will be the inherent uncertainties.

RADIATION EXPOSURE DUE TO RADON IN DRINKING WATER IN REGIONS WITH HIGH TERRESTRIC ACTIVITY

K.-H. Lehmann [1]; A. Reichelt [1]; P. Guglhör [1]; E. Eder [2])

[1])Technical Inspectorate of Bavaria (TÜV Bayern Sachsen, München)
[2])Bavarian State Ministry of State Development and Environmental Affairs, München

INTRODUCTION

We performed investigations to evaluate the radiation exposure due to the private use of drinking water in the region of the German Fichtelgebirge (300 km North Munich near the Czech border), where the content of Radon in ground water is very high. Besides the drinking water pathway the different practices in the household were investigated such as taking showers, stay in a hairdressing salon, operating a washing machine.

RADON CONTENT IN WATER

In water Radon concentrations from less than 0,1 mBq/l up to more than 5 kBq/l are to be found. In Germany the mean concentration of tap-water is 7,2 Bq Rn 222 per litre [3].

In table 1 there are listed the results of our measurements in the German Fichtelgebirge (300 km North Munich near the Czech border).

Location		C(Rn-222) [Bq/l]

Table 1: Rn-222 concentration in drinking water, emanation free taken

RADIATION EXPOSURE DUE TO CONSUMPTION OF DRINKING WATER

Following [2] we assumed equilibrium between Rn 222 and his short lived daughter nuclides Po 218, Pb 214, Bi 214 and Po 214. For Rn 222 concentrations above 100 Bq/l we assumed Pb 210, Bi 210 and Po 210 concentrations of 5 mBq/l due to Radon. These nuclides are negligible for Rn 222 concentrations below 100 Bq/l. These assumptions arise from the results given in [2].

There are 3 pathways to distinguish:

- Intake of freshly taken drinking water (concentration of Rn 222, short and long lived daughter nuclides as measured, see above)
- Consumption of drinks made of heated up drinking water such as tea, coffee (Rn 222 completely off, short and long lived daughter nuclides as above)
- Use of drinking water for cooking of liquid foodstuff (duration $\geq$ 1 hour; Rn 222 completely off, short lived daughter nuclides 25% of freshly taken water, long lived daughter nuclides as above)

Based on the highest measured Radon concentration of about 1000 Bq/l for freshly taken water, assuming an average consumption rate of 400 l drinking water per year [1] and the distribution of the total consumption as 1 : 3 : 2 (70 l : 200 l : 130 l per year) into the above mentioned three pathways an effective dose of 1,5 mSv per year has been estimated. For the German average Rn 222 concentration in freshly taken water of about 5 Bq/l the effective dose yields to 7 μSv per year. In both cases the main part (about 95%) of the estimated effective dose results from the intake of freshly taken drinking water.

RADIATION EXPOSURE DUE TO TAKING SHOWERS

Figure 1 shows the measured concentration of Rn 222 and his daughter nuclides during taking showers for a measured Rn 222 concentration in water of 685 Bq/l. The maximum values of Rn 222 concentration in air and EER respectively are 21.350 Bq/m³ and 5.860 Bq/m³. A 1 hour shower taking of a family was simulated. After taking the shower a 20 minute stay in the bathroom was assumed for hair drying, e. g. As expected the air concentration is lower leaving the window ajar (approximately by a factor of 3). Assuming a stay of 20 minutes per day at the most unfavourable time the integration of EER given in figure 1 yields to an exposure of 1 WLM and hence an effective dose of 4 mSv per year using the dose conversion convention 4 mSv per WLM according to ICRP 65.

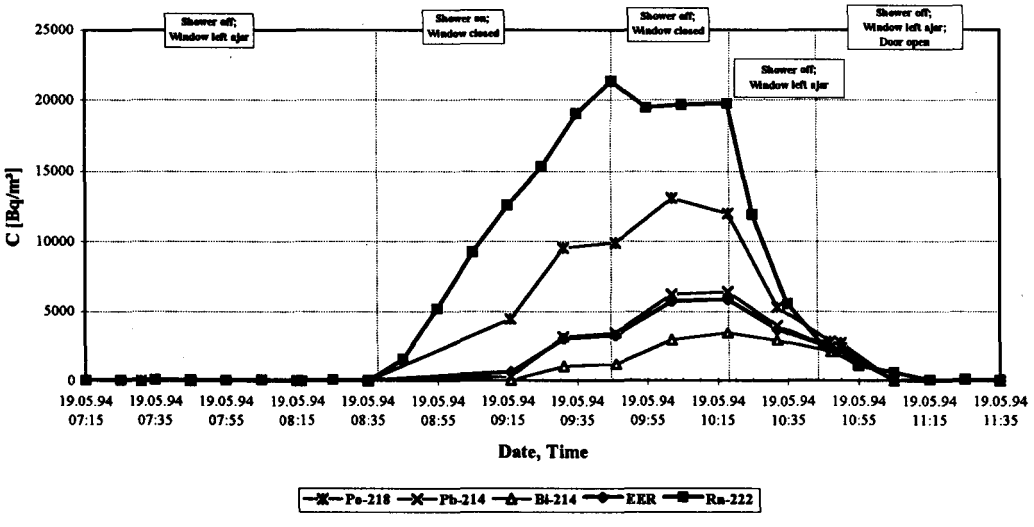

Figure 1 ***Rn-222- and Rn-222 Daughter Nuclides Concentration in Air while Taking Showers (Volume 11,25 m³; Rn 222 concentration in Water 685 Bq/l; 9 °C; 15 - 18 l/min)***

RADIATION EXPOSURE DUE TO OPERATING A WASHING MACHINE AND FOR STAY IN A HAIRDRESSING SALON

Concerning the radiation exposure due to the Radon concentration in water for a stay in a hairdressing salon and for operating a washing machine the same investigations have been conducted.

The washing machine has been running with a Rn 222 concentration in water of 280 Bq/l. The maximum values of Rn 222 concentration in air and EER respectively (volume 31,2 m^3) are 925 Bq/m^3 and 85 Bq/m^3. Assuming a 20 minutes stay in the room per week after finishing the machine operation the integration of EER yields to an exposure of 0,002 WLM and hence an effective dose of 8 µSv per year using the dose conversion convention 4 mSv per WLM according to ICRP 65.

The water used in the hairdressing salon had a Rn 222 concentration of 400 Bq/l. The maximum values of Rn 222 concentration in air and EER respectively were 285 Bq/m^3 and 120 Bq/m^3. Assuming a 2 hours stay in the hairdressing salon per month the integration of EER yields to an exposure of 0,002 WLM and hence an effective dose of 8 µSv per year using the dose conversion convention 4 mSv per WLM according to ICRP 65.

AN ATTEMPT TO EVALUATE DOSE EQUIVALENT DUE TO THE INHALATION OF ^{222}Rn AND ITS PROGENY IN INDOOR AIR

Jae-Shik Jun, Ha-Seok Chai and Chul-Young Yi
Department of Physics, Chungnam National University
Taejeon 305-764, Korea.

INTRODUCTION

An attempt to evaluate alpha dose equivalent given by inhaled ^{222}Rn and its daughter nuclides has been made based on the measured concentrations of ^{222}Rn and its progeny in indoor air and the estimated equilibrium factor between the parent and daughter nuclides. Three different dosimetric lung models were used for the evaluation of the dose equivalent, and a brief comparison was made.

MEASUREMENT

1) ^{222}Rn Concentration

An activated charcoal canister of 10 cm diameter × 2.85 cm height, which contains 70 ± 1 g of 6 × 16 mesh charcoal powder, was used for collecting ^{222}Rn in indoor air by adsorption process for a period of certain time interval. Concentration of ^{222}Rn in the air was determined by gamma-ray spectrometry using a 3″ ϕ ×3″ cylindrical NaI(Tl) detector that detects 242, 295 and 352 keV photons emitted from ^{214}Pb , and 609 keV from ^{214}Bi, both of which are the equilibrated daughter nuclides of ^{222}Rn in the canister. Calibration factors(CF) for the canister were determined with the aid of a reference canister that contains a uniformly distributed known amount of equilibrated ^{226}Ra. The humidity correction factor for the CF were deduced through a series of appraisal test for the water adsorption characteristics of the charcoal canister. CF for ^{222}Rn concentration in the air was obtained by the calibration of the canister exposed in a Rn-Chamber containing ^{222}Rn of known concentration.

The measurements of the ^{222}Rn concentration in indoor air were carried out in a laboratory room of the C. N. University where average relative humidity was maintained to be 32±2 % during the course of the measurement. Five measurements for 24 hrs and 72 hrs periods, respectively, were performed, and in each measurement 3 canisters were exposed to the indoor air. Resultant mean concentration of ^{222}Rn in the room was found to be (40.0 ± 1.9) $Bq \cdot m^{-3}$.

2) ^{222}Rn Daughter Concentration and Equilibrium Factor

In order to determine the equilibrium factor, F, between the concentrations of ^{222}Rn and its progeny in the indoor air, a series of α-spectrometry was performed for the air particulate collected on a membrane filter of 47 mm diameter with 0.22 μm pore by use of an ion implanted Si detector of effective diameter of 24 mm. As the result of the spectrometry the concentrations of α-emitting daughters, ^{218}Po and ^{214}Po, were obtained. And the F is determined by[1)]

$$F = \sum_i a_i F_i \qquad (1)$$

where $a_i = k \cdot (\frac{E_{p,i}}{\lambda_i})$, $F_i = (\frac{C_i}{C_{Rn}})$, and $E_{p,i}$ and λ_i are potential α-energy concentration and decay constant of ith daughter nuclide. C_i and C_{Rn} are the concentrations of ith daughter and that of ^{222}Rn in the air, respectively. k is a constant that depends on the used system of units.

Thus determined overall mean F in the room where the measurements were performed was 0.36 ± 0.12. Using this value of F the equilibrium equivalent concentration(EEC) of ^{222}Rn in the indoor air was determined to be (14.4 ± 1.9) $Bq \cdot m^{-3}$.

ASSESSMENT OF THE DOSE EQUIVALENT

With the value of the F or EEC refered above the potential α-energy concentration, E_p, is estimated by[2)]

$$E_p = \frac{F \cdot C_{Rn}}{1.78 \times 10^8} \quad (J \cdot m^{-3}) \qquad (2)$$

to be $(80.8 \pm 10.4) \times 10^{-9}$ J · m^{-3},

By use of the presumed mean breathing rate of 1.2 m^3 · h^{-1} and 0.75 m^3 · h^{-1} for occupational and public exposures, respectively, the potential α-energy intakes, I_p, can be estimated to be $(97.0 \pm 12.5) \times 10^{-9}$ and $(97.0 \pm 12.5) \times 10^{-9}$ m^3 · h^{-1}, respectively, using the equation[2)]

$$I_p = B \cdot E_p \qquad (3)$$

where B is the mean breathing rate in m^3 · h^{-1}.

It was attempted to evaluate the regional and total lung dose equivalent rate given by the inhalation of ^{222}Rn daughters in the indoor air based on the data mentioned above and by adopting three different dosimetric lung models, namely, Jacobi-Eisfeld(J-E), James-Birchall(J-B), and ICRP models, which appeared in the Table 1 of the reference 2 and the Table 2.9 of the reference 3. The dose equivalent rates were evaluated for two target tissues, the basal cell layer in the tracheo-bronchial(T-B) region and the epithelium in the pulmonary(p) region, in addition to the total lung dose. In this estimation the unattached fraction, f_i , of the ^{222}Rn daughters, which is given by

$$f_i = \frac{E^u_p}{F \cdot C_{Rn}} \quad \text{or} \quad E^u_p = F \cdot C_{Rn} \cdot f_i \qquad (4)$$

where E_p^u is the potential α-energy concentration of unattached ^{222}Rn daughter nuclide in J · m^{-3}, was used. The results obtained by use of f_i values of 0 and 0.05 are summarized in Table 1. With an assumption of an occupancy factor of 0.8, the annual effectived dose equivalent due to the inhalation of ^{222}Rn and its progeny is also assessed and summarized in Table 2.

COMPARISON OF THE MODELS

A brief comparison in regard to the dose equivalent rate assessed by the ICRP model in the case of occupational exposure reveals that the T-D doses by the J-E and J-B models, in general, shown to be larger, except for f_i = 0, while P dose and total lung dose by both models appeared to be much smaller. Those evaluated by the J-E and J-B models were 0.65 ~ 0.70 and 0.25 ~ 0.26 times that obtained by the ICRP model, respectively.

The annual dose equivalents given by the ^{222}Rn daughters and the total lung dose estimated by the J-E model nearly coincide with(for f_i = 0) or slightly larger (for f_i = 0.05) than those given by the ICRP model, while those estimated by the J-B model for f_i = 0 are 0.7 times those by the ICRP model and 1.6 times the ICRP for f_i = 0.05. As a summary, it may be said that the J-E model looks closer to that of the ICRP than the J-B model for the evaluation of radon dose in the occupational exposure.

CONCLUDING REMARK

Through this study it was reconfirmed that the dose due to the inhalation of ^{222}Rn and its progeny in the air comes mainly from the daughter products with negligible contribution of ^{222}Rn itself. The respiratory organ dose given by the daughter products appeared to be region dependent, and T-D dose increases with unattached fraction of the progeny, while P dose decreases with the fraction.

THE RADON SURVEY AND ITS CONTRIBUTION TO THE RADIATION EXPOSURE

Ildikó Mócsy, Nicoleta Muntean

Medical Center for Health Services and Management Cluj-Napoca, Str.Pasteur No.6, 3400 Cluj-Napoca, Romania

INTRODUCTION

Nowadays, the change of life conditions, the intense increase and diversified pollution of the environmental factors have a complex effect over the health status of the population. A compound of pollutants produces a stronger negative effect than the virtual sum of its components taken separately, determining their investigation as a whole. Radioactive pollution and exposure to natural and artificial radiations play a distinct role among the contemporary health hazards. It is well known that the most important contribution to human exposure to the ionizing radiations of natural origin is due to ^{222}Rn and its short-term daughters (1). In the 80's, this nobel gas was discovered to be accumulated mostly in the indoor air of the buildings. The accumulation of these radionucludes in dwellings depends on some factors such as: geochemical and geophysical properties of the sol where is the location of the construction, the building materials, the nature of the building foundation, the type of dwellings, the dimensions of rooms, the rate of ventilation, the radon and radium content of the tap water, type of heating used and the living and working conditions (2).

In this study we present the level of radon concentration in different types of buildings. Based on our results we estimated the yearly effective dose equivalent for these groups of the population.

MATERIAL AND METHOD

Two types of dwellings were taken under study: detached houses (built in 1920) and a ten floor block-of-flats, (built in 1970), in Cluj-Napoca situated in an area with "normal" radiation background. These buildings are characteristic for Transilvania, Romania. Cluj has 350000 inhabitants and according to the statistical data from 1992 the proportion of the population living in detached houses is 36 %.

The walls of the detached houses are made red brick while stone and slog were used for the basement. There is a cellar under the kitchen of the house I. In 1975, a new room (C) was attached to the old building (room A and B), having brick-made walls, while the basement, the floor and the ceiling were made of concrete. The rooms were the same volume 5m x 5m x 3.5m. Natural gas is used for cooking and heating. The block of flats is built out of prefabricated elements and all the flats have central heating. The living rooms volume are 4m x 4m x 2.5m.

The determinations of the ^{222}Rn content were performed under normal living conditions, in the autumn of 1994 using the "PRASSI - Portable Radon Survey Meter" instrument. The air samples were collected in the middle of the premises, at 0.5 m from the floor. In order to assess and compare the values of the indoor ^{222}Rn concentrations, measurements were performed in the outside as well, at 0.5 m from the ground, during the same period of time.

We estimated the Effective Dose Equivalent (EDE) of the people considering the internal dose absorbed in respiratory tract from radon and its daughters. The following assumptions has been made: the mean radon concentrations -determined in autumn- represent a yearly average, the equilibrium factor between ^{222}Rn and its daughters is 0.5, people spend 19 hours/day in dwellings, the mean inhalation rate of people is considered to be 14 l/min (3,4). The annual number of the expected lung cancer cases induced by radon daughters exposure can be calculated based on our results and the absolute lung cancer risk (5).

RESULTS AND DISCUSSION

The mean values of ^{222}Rn concentrations in the inside and outside of the buildings are shown in table 1. The indoor values are significantly higher in the rooms A,B (house I) and A' (house II) as compared to those found in the other rooms in detached house or to the block of flats.

The building materials being identical for the rooms, the bathroom and the kitchen, the high differences between

^{222}Rn concentrations could be explained by the dissimilarities in their respective basements.
Beneath the rooms A,B and A', the high porosity pavement made of stone and slag allows this noble gas to easily spread and reach the interior of the rooms. Moreover, the room B has only one wall in direct contact with the outside air so that the speed of the indoor natural air exchange is lower than in room A, that has two free walls

Table 1 ^{222}Rn CONCENTRATION IN FAMILY HOUSES AND BLOCK OF FLATS

PLACES	NUMBER OF SAMPLING	NUMBER OF MEASUREMENTS	Rn-222 CONCENTRATION (Bq/m^3)		
			MEAN ± SD	MIN.	MAX.
DETACHED HOUSE					
1.Room A	1	351	335 ± 76	22	520
Room B	2	151	436 ± 109	42	585
Room C	5	62	91 ± 20	27	124
Kitchen	4	90	45 ± 11	14	85
Bathroom	3	55	85 ± 25	47	162
2. Room A'	-	78	799 ± 293	310	1316
BLOCK OF FLATS					
Ground floor	-	4	70 ± 25	52	88
First floor	-	72	61 ± 14	19	90
Four floor	-	8	65 ± 25	50	81
Seven floor	-	41	49 ± 11	21	70
Eight floor					
Room	1	125	68 ± 20	23	102
Kitchen	2	66	61 ± 15	33	97
Bathroom	3	5	101 ± 14	81	117
OUTDOOR	6	50	29 ± 12	14	39

and, therefore, a lower air ^{222}Rn concentration. The ^{222}Rn concentration is approximately 7.5 times lower (45 Bq/m^3). This could be explained partially by the presence of the cellar under the kitchen (where the diffused underground ^{222}Rn is temporarily deposited and easily evacuated through the windows of the cellar into the open air) and partially by the fact that the kitchen, by its function, is more frequently ventilated. The daily variations of the radon concentration in the kichen's air are show in Figure 1.

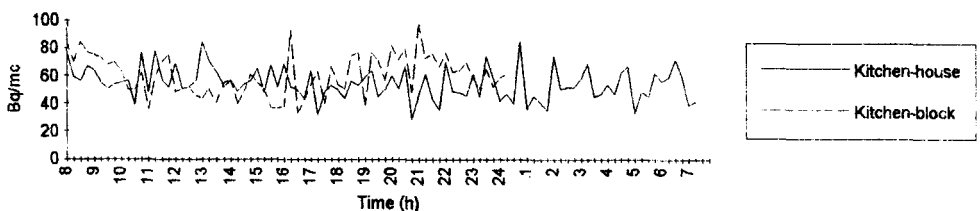

Figure 1. Distribution of radon concentration in kitchens' air.

The bathroom has no outside walls and there is no cellar under it, but the ^{222}Rn concentrations in the air are approximately 4.5 times lower as compared to those found in the rooms A and B, due to a permanently opened ventilation aperture through the chimney. Measurements in the air of the bathroom after running the shower for 15 minutes proved an increase in the radon concentration of 20 Bq/m^3.

Finally, the ^{222}Rn concentration in room C, being 3...4 times lower than those measured in the rooms A and B, can be explained by the presence of a concrete foundation that plays the role of a screen for the ^{222}Rn coming out from the soil.

Regarding the ^{222}Rn concentrations found inside the block flat, a lowering of the values along the first floors and a slight increase of them at the upper levels are to be noticed. The overall values are 2...3 times smaller than those measured in the detached house.

Out of the measurements performed in the initially ventilated rooms, during standard periods of 24 hours, it can be noticed that during the first 3 hours after closing the windows and the doors, the speed of ^{222}Rn accumulation is 50 Bq/m^3/hour in room A and approximately 90 Bq/m^3/hour in room B followed by a slower accumulation, of 22 and, respectively, 28 Bq/m^3/hour, determined during a 9 hour period. Sudden decreases of ^{222}Rn concentrations after the opening of the windows have been observed in all sampling points. During the first 15 minutes of natural ventilation, the concentrations reached values similar to those measured in the open air (Fig.2).

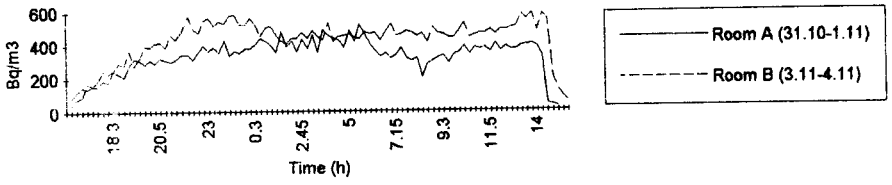

Figure 2. Radon accumulation in living rooms.

The deviations of the daily means from the previous day mean value ranged in the 10...24 % interval.
We have estimated respiratory system doses attributable to the inhalation of the radon and its daughters in dwellings for the investigated population groups from Cluj-Napoca (0.35 to 16..54 mSv/y). The maximum value of was obtained for people who live in detached houses. In Table 2. we give the Equivalent Dose Effective (EDE) and the weighted averages and the lung cancer risk for these groups of people.

Table 1. WEIGHTED AVERAGE ANNUALE EQUIVALENT DOSE EFFECTIVE INDUCED BY INHALATION OF ^{222}Rn DAUGHTERS AND LUNG CANCER RISK

BUILDING	INHABITANTS	EDE (mSv/y)	LUNG CANCER EXPECTED
DETACHED Ground floor (with cellar) (without cellar)	126000	2.99 2.47 6.50	7.41
BLOCK Ground floor First floor Four floor Seven floor Eight floor	224000	1.06 0.79 0.76 0.76 0.76 0.69	2.71

CONCLUSIONS

The measured values of indoor radon concentration have demonstrated that the high concentration levels in similar conditions can be attributed to radon entering the house through the building foundation.

Measurements of the ^{222}Rn concentrations in the indoor air of the same detached building showed values with a great variation. In the rooms with stone and slag basement, the ^{222}Rn concentration exceeded the value recommended by ICRP 65/95 (the recommended action level for the annual average radon concentration in air in dwellings should not exceed 200 Bq/m^3) (7).

In the future the increasing indoor exposure of the population to radon and its daughters might be the consequence of a reduced ventilation by mean of the energy conserving measures and utilizing the new building materials

Determining the radon concentration as well as the origins of the indoor radon contribute to finding out the solutions for reducing at most the risk due to ionizing radiations.

The significance of radon for the human health is well known and thus the measurement of indoor radon is important for the evaluation of its impact in the public health field. A difficulty in evaluating the risk of lung cancer is the evaluation of the cumulative exposure. The relationship between radon, its daughters exposure and other carcinogenic pollutants is still uncertain.

AKNOWLEDGEMENT

We aknowledge and thank to the inhabitants in whose flats these measurements were performed.

RADON AND REPRODUTIVE HEALTH OF POPULATIONS LIVING IN THE REGIONS OF URANIUM MINERS ON NORD CAUCASUS.

P.W. Izhewskij, A.M. Ljaginskaja

State Research Centre of Russia - Institute of Biophysics, Moscow.

1. The estimation of the combined influence of technogenically increased natural background made by human activities and radon on the health in current and future generations of people is of great importance. A particular interest is the investigation of population exposure fraught with medical effects in the areas where the constructed houses were build with materials containing the higher doses of natural radionuclides emanating radon and its daughter products of disintegration.

2. One of the areas with the increased irradiation of the population due to Rn and its daughter products is the town of Lermontov. It is situated in the centre of the region of the Caucasian Mineral Waters. It is the territory of the Mineral Waters foothills plain near the mountain Beshtow (the hight is 1200 m).

3. The inhabitancy of this town are workers of the uranium output and processing enterprises. In the past for the house construction especially for the private living blocks, the local raw materials having the higher quantity of radionucleids were widely used as a material for building up houses.

4. From the date of the foundation of the town in 1957 to 1994 the number of its population increased from 11000 to 24300. The growth of the population in average is 300 persons per a year, with the natural growth being 100 - 200 persons a year. The most part of the population deals with the uranium output and processing inductry (within 1952 - 1991).

5. The range of gamma-background in the town of Lermontow is 10 - 120 μR/h, with the mean Russian index being μR/h. In addition, the higher level of emanating Rn from the soil reaching 4,5 Bq/m^2 per a second was observed. The high concentrations of Rn and its daughter products were found out in the living blocks of houses in the town of Lermontov.

6. The content increasing the level of 200 Bq/m^3 in the living flats on the ground floor of the multiflact houses was shown by the long-term control (the total number of analysis is over 2000) to be recorded in more than 50% flats examined, with the five-fold increase being (1000 Bq/m^3 and more) observed in 10% investigated living accommodations. In the air of the living accomodations analysed in 1994 the equivalent equilibrium volume activity of Rn was between 5 - 913 Bq/m^3 and that of toron is within the range of 0,3 - 17,2 Bq/m^3 . The maximum indices increase as high as 25 times the Russian standards for Rn daughter products as tot the toron product standard the index is 5,7 times higher.

7. Thus, in the town of Lermontov where for a very long term (during the three generations) the stable (in the migration aspect) population is living, there is a unique opportunity for making radiological, hygienic, clinical, epidemiological investigation together with scientists of different countries in the great schedule.

8. The results of epidemiological observations of uranium miners living in the houses with the higher Rn concentrations (that is they were under chronic influence of Rn and its daughter products for less then 20 hours

per a day are given. Besides, their familieswere also under the chronic influence (in less doses) of Rn and its daughter products.

9. The oncological mortality in the town of Lermontov for the last years was estimated to be higher in comparison with that of the town population in the Stavropol Kray. Particular attention is drawn to the fact of raising the death rate from pulmonary cancer.

10. It was an attempt to determine the exposure of Rn daughter products on the reproductive health of the population that was first made in studying the Rn influence.

11. The main indices of reproductive health are as follows: health status of the pregnant women, untoward outcomes of pregnancy (miscarriages and spontaneous abortions, premature born children, stillbirths, early neonatal and perinatal death of the newborns), the status of health of the newborns including the estimation of the frequency and character of congenital pathology. On the strength of all the aforementioned evidence it is possible to forecast the consequences of radiation on the health status of the current and future generations.

12. The results of the first step of the investigation made in 1994 - 1995 are full of discrepancy: namely, the rate of stillbirths is less, but there is a growth of newborn with normal adaptive weight (2500 g - 3499 g) and there is an increase of morbidity among the hypoxia and asphyxia (1,49%) and cephalohaematomes (5,24%). The frequency of congenital anomalies in newborns of the town of Lermontov increased 54% in 1993 compared to 1987.

13. The investigation performed between 1982 - 1994 showed the unfavourable medico-demographic evidence in the town of lermontov: the decrease in the birth-rate, the growth of total and oncological mortality, first of all due to lung cancer.

14. For the determination of the extent of correlation of the mentioned tendencies connected with the radioecological surrounding in the town of Lermontov the further investigations both in finding out the houses with Rn higher concentration and in estimating the health status of the population living in those houses remain to be arranged.

Human Exposure Assessment from Radon in Water - Comparison of Experimental and Theoretical Data

Jiří Hůlka[1], J.Vlček[1], E.Bílková[1] , L.Moučka [1], J.Thomas [2]

[1] National Radiation Protection Institute, Praha, Šrobárova 48, 100 42

[2] State Office for Nuclear Safety, Praha 2, Slezská 9, 120 29

ABSTRACT

In this paper are analysed the results of continuous monitoring of indoor radon in family house with high radon concentration in drinking water (4000 Bq/l). The simultaneous variation of indoor radon in the bathroom and other rooms while taking shower is studied. Human exposure during the stay in the bathroom and other parts of the house is estimated for different types of houses. Finally, assessment of human exposure from radon in drinking water in Eastern Bohemia Region is carried out.

INTRODUCTION

Human exposure caused by water having high radon concentration was studied in last years again[1]. One of the reasons is measured local short-term and extremely high radon concentration in the bathroom during showering or taking bath (water having Rn concentration of 1000 Bq/l , radon emanation during showering around 50 %, can cause in the bathroom volume of 10 m^3 short-term indoor radon concentration of 5000 Bq/m^3 and increase radon concentration in rest of the house). This paper presents estimation of human exposure during stay in the bathroom and during stay in the rest of the house and contribution of this exposure to total exposure from other radon sources.

POTENTIAL ALPHA ENERGY EXPOSURE DURING SHOWERING

Taking shower or bath is a process, that can be described by two steps 1) the water use with rapid radon release into the air, 2) the stay in the bathroom (some minutes to up 1 hour) in approximately constant radon concentration (ventilation rate is usually small) with increasing of radon daughters concentration. It is complex process in which steady state is not reached during normal stay of person in the bathroom (<1 hour) . From this reason human exposure cannot be easily evaluated from radon concentration but directly from potential alpha energy concentration (PAEC). This can be done by evaluation of time integral of potential alpha energy concentration PAEC (theoretically predicted or measured) during stay in the bathroom, or this exposure can be also experimentally measured by continual spectroscopy WL monitors, the response of which is proportional to human exposure in cases described below. This attitude was used in following experiment.

FIELD EXPERIMENT

Set of continuous alpha spectroscopy monitors (with Milipore filters 0.8 m, flow rate of 1 l/min and 3 minutes sample interval) were placed in the bathroom having volume of 11 m^3. During experimental showering 100 l of water was used having radon concentration of 4 100 Bq/l . Indoor radon concentration was measured by set of Lucas cells, maximum value of radon concentration immediately after showering was 20 700 Bq/m3 (ventilation rate was <0.15 h^{-1} · so decrease of Rn concentration during 1.5 hour experiment was <25 %,). After intervals 10,20,30,...90 minutes (simulation of different stay of person in the bathroom) was

the airflow through the monitors stopped in sequence, but monitors continued in alpha counting. Response of monitors is proportional to dose rate in the respiratory tract during and after stay in bathroom. From total registered number of alpha counts (and alpha counts from Po-218) can be calculated potential alpha energy exposure as a function of time spent in the bathroom (and the fraction of this exposure caused by Po-218 itself, this fraction varied from 50 % for 10 minutes stay to 25 % for 1 hour stay in bathroom) . Results of measurements were normalised to initial Rn concentration in bathroom of 5000Bq/m³ (that corresponds to use of 100 l water having of 1000 Bq/l with 50% radon emanation in the room of 10m³) and are summarised in the fig.1.

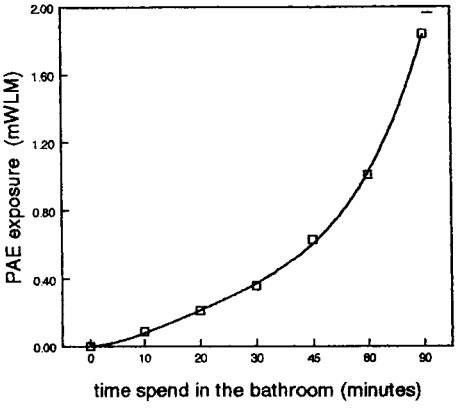

Fig. 1: Potential alpha energy exposure as the function of the time spend in the bathroom (indoor Rn conc.of 5000 Bq/m3)

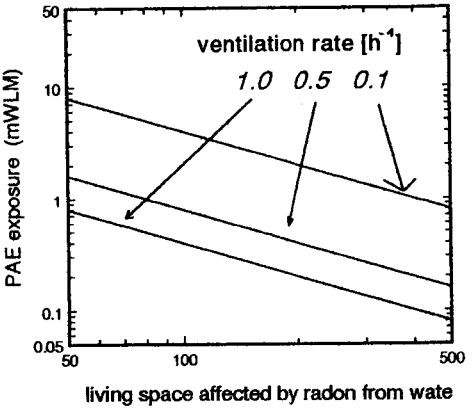

Figure 2: Potential alpha energy exposure in the space adjacent to the bathroom (for radon release of 50000 Bq)

EXPOSURE IN THE REST OF THE HOUSE

During showering usually well closed bathroom is then opened and radon is transferred into the adjacent part of the house and can contribute to elevated average indoor radon concentration. This process is described by transfer coefficient (the ratio of average indoor radon concentration caused by radon release from the water and radon concentration in the water) usually assumed to be 0.0001 (or lower[2]). In fact, there exist a lot of completely different situations depending on the mutual disposition of the bathroom and others rooms and their volumes and also on family habits in ventilation, etc. From these reasons, great variability of human exposures can be expected and therefore lot of scenarios must be considered. There exist two extreme cases: a) after showering the bathroom is immediately opened to the outer atmosphere and there is no radon transfer to the house, b) the bathroom is after showering opened only to the small living part of the house (e.g. one room relatively well closed from other parts of the house) and only this space is affected by radon release from water. Radon is then removed by ventilation Most of real situations are between these two extreme cases. Estimation of radon concentration can be evaluated from elementary consideration: radon release of total radon activity A is transferred from the bathroom to the space of volume V of the house, that is ventilated (average ventilation rate λ). Radon concentration in affected space is

$$a = A/V \cdot e^{-\lambda t} \qquad (1)$$

and PAE exposure can be approximately evaluated (such calculation, of course, overestimates PAE exposure due to non equilibrium state in this space, especially in case of high ventilation rate) from the time integral of radon concentration and equilibrium factor F (assumed to be F=0.5) as

$$PAEE\ [J\ h\ m^{-3}] = 5.6 \cdot 10^{-9} \cdot F. \int a.dt = 2.8 \cdot 10^{-9} \cdot A / (V. \lambda) \qquad (2)$$

$$PAEE\ [mWLM] = 0.00159 \cdot F. \int a.dt = 0.00080 \cdot A / (V. \lambda) \qquad (2)$$

Results of calculated PAE exposure for possible scenarios - different ventilation rate and different affected volume of the house - are on the fig 2. Calculation is done for one release of 50000 Bq of radon in the bathroom, what corresponds to use of 100 l of water having 1000 Bq/l and 50% radon emanation mentioned above. Total exposure is, of course, sum of the individual releases.

OTHER EXPOSURE

In the indoor radon survey carried out in Czech republic in last years by solid track detectors was discovered the average EEC of radon 68 Bq/m3 that correspond PAE exposure of $6.3\ 10^{-6}$ J h m^{-3} (1.8 mWLM) per day (for occupational factor 0.7).

CONCLUSIONS

Comparison of exposures (from one radon release) in the bathroom and in other affected parts of the house is seen from figure 1 and figure 2 (resp.equation 2). From these can be derived, that e.g. 1 hour of stay in the bathroom is equivalent to exposure in affected space of house of volume 100 m^3 and ventilation rate of about 0.5 h^{-1} . What exposure is dominating depends on individual habits and house disposition.

If water having of 1000 Bq/l radon concentration is used for showering (100 l of water in $10m^3$ bathroom) exposure about 1 mWLM can be expected in case of 1 hour stay in bathroom. This is similar to typical exposure from other radon sources in normal house. Beside this water with 1000 Bq/l radon concentration is, in fact, relatively rare case. Distribution of radon in ground-water in Eastern Bohemia (where the problem was studied) is lognormal with geometric mean value 23 Bq/l , that correspond to average PAE exposure during 1 hour showering only about $8.1\ 10^{-10}$ J h m^{-3} (0.023 mWLM.)

As a result, the exposure from showering in case of typical Rn concentration in water was found to be small compared to typical exposures from other radon sources. Even in rare cases of high radon concentration in water (1000 Bq/l) it is less then exposure from other radon sources in typical house.

INDOOR RADON SURVEY IN JAPAN

Kenzo Fujimoto, Sadayoshi Kobayashi, Masafumi Uchiyama,
Masahiro Doi, and Yuji Nakamura

National Institute of Radiological Sciences
4-9-1 Anagawa, Inage, Chiba 263 Japan

INTRODUCTION

Radon and its progeny are the major source of exposure to the general public. Large scale radon surveys have been performed in many countries with various passive radon detectors. Our group in National Institute of Radiological Sciences has also conducted a nation-wide radon survey in Japan using passive radon detectors which were originally developed at Karlsruhe Nuclear Research Center in Germany. The main purpose of our survey is to obtain annual average indoor radon concentration and to estimate dose due to radon progeny as well as to find out high radon areas in Japan.

METHOD

The survey was planed to cover more than 7,000 houses throughout Japan which corresponds to 0.017% of the total houses in Japan. The number of sampling houses in each prefecture was selected in principle in proportion with the total number of houses in prefecture in order to obtain radon concentration profile of the present stock of houses. The results are also expected to reveal the approximate population averaged radon concentration in each prefecture as well as the whole nation. Each house is measured in two places namely a living room and bed room for two successive periods of six months for the estimation of annual average radon concentrations. After six months of exposure in a house, the dosimeters were returned to our institute, NIRS by mail for the further processing. New detector foils (polycarbonate) were placed in the dosimeter housings and were sent again to the same house for the second six months measurements. These two sets of successive six months measurements provide annual average radon concentration in the selected houses. As a total more than 30,000 detector foils were used for the survey. The detector foils which were retrieved from the selected houses, were subjected to a combined chemical and electrochemical etching processes to develop etch pits due to alpha particles from radon and its progeny. The number of etch pits was then counted either automatically by an image counter or manually depending on the number of etch pits developed in the unit area ($1cm^2$) in the center of the foil. The etch pits were read manually when track density was more than 300 tracks/cm^2 since the machine could not distinguish overlapping etch pits. The overlapping correction for the counting by the machine were executed by an equation determined from the correlation between automatic and manual counting (1).

Self-background of 26 etch pits per cm^2 during the six months exposure as well as inherent background for each batch of foils were then subtracted from the measured track density (2) and the net counts were converted to average radon concentrations during the measurements. The conversion factor of 21.8 tracks/cm^2 per kBq/m^3 day was used to obtain radon concentration. The conversion factor was estimated by a series of calibration exercises which were made available by the Australian Radiation Laboratory, Melbourne, Australia and the Environmental Measurement Laboratory, New York, U.S.A.

The results obtained from more than 7,000 houses were carefully checked to identify abnormal conditions during the measurements. All the data measured not in a living room or bed room were eliminated. The results obtained from the house with no answer to the questionnaire were not included in the final results. Only the results with at least one set of successive six months measurements were used for the estimation of the annual average radon concentration. Total number of houses where the annual radon concentration could be obtained was reduced to 6,645 houses.

Additional measurements were conducted in Hokkaido, Hiroshima and Kochi Prefectures to clarify the thoron contribution to the first measurement undertaken throughout Japan. Two sets of passive detectors were installed in two places (living room and bed room) in each house. One passive detector was the same as the original detector used in the first survey. The other passive detector used plastic foil as a filter to prevent thoron entry into the housing of the detector. The air exchange rates of the original and modified passive detector were estimated to be 27.7, 1.79 h^{-1} by the experiment using SF_6 gas. The original passive detector measures radon

plus thoron and the modified passive detector measures mainly radon since the modified detector is expected to show one tenth of the response of the original detector to thoron due to the slower air exchange rate.

RESULTS AND DISCUSSION

The indoor radon concentrations obtained by the survey shows roughly a log-normal distribution as shown in Fig. 1. The estimated arithmetic mean of the radon concentrations in 6,645 houses is 21.3 Bq/m^3 (S.D. 18.8 Bq/m^3), and the geometric mean and its standard deviation are 17.3 Bq/m^3 and 1.83, respectively. The median of the concentration is 16.4 Bq/m^3. The number of houses having a concentration of ten times higher than the geometric mean is only 17 in 6,645 houses, i.e., 0.26% of the measured houses. Ninety percent of the houses are less than 38 Bq/m^3, 97.5% less than 68 Bq/m^3, 99% less than 96 Bq/m^3. Only 27 houses are over the action level set by EPA in the U.S.A. These high radon concentration houses are distributed in the western part of Japan except one house found in Niigata Prefecture. However, no radon prone area is found, although Hiroshima Prefecture has 6 high radon houses out of total 27 houses. All these high radon concentration houses are wooden houses except two concrete houses in Okinawa Prefecture. The average radon concentrations in each municipality (city, town, village) are shown in Fig. 2. Many higher radon concentrations are found in Chubu, Kinki, Chugoku and Shikoku districts, where winter is relatively mild and the air exchange rate of the houses in these regions is not low, the concentrations seems to have a relationship with the geology as found by the measurements of exposure rates due to terrestrial gamma rays (3). These areas are typical granite region in Japan. The areas covered with volcanic ash, in Kanto District around Tokyo and Kagoshima Prefecture in Kyushu district shows lower concentrations.

The results of the additional measurements carried out in Hokkaido, Hiroshima and Kochi Prefectures shows three different profiles of the correlation between radon and thoron concentrations. In Hokkaido Prefecture no significant thoron contribution was found in the indoor radon measurements. The arithmetic, geometric mean and median for radon plus thoron concentration (27.4, 21.6, 21.4 Bq/m^3) measured by original detectors are very close to the corresponding values for radon (26.3, 20.4, 19.9 Bq/m^3) measured by modified detectors. In Kochi Prefecture the difference is somewhat larger, i.e., the arithmetic, geometric mean and median for radon plus thoron concentrations are 20.4, 16.3, 15.4 Bq/m^3, while the corresponding values for radon are 14.3, 12.9, 11.9 Bq/m^3. The difference is much significant in Hiroshima Prefecture. These values are 49.9, 36.3, 32.0 Bq/m^3 for radon plus thoron, and 27.8, 24.5, 24.3 Bq/m^3 for radon. No indication of large contribution of thoron is available from the values, such as mean, standard deviation, percentile. Most high thoron concentrations were found in traditional wooden houses where they have walls made of clay and straw. The straw is used for adhesive material to keep clay in the wall. Thoron might pass through the air space in the straw and reach indoor air without much delay usually confronted during the diffusion in the normal wall. It infers that thoron concentration may have high values in wooden houses. However, other type of houses may sometimes have high thoron contribution as found in Austria with the same way of measurements by the authors in collaboration with Dr. M. Tschurlovits in Atom Institute of Austrian University.

CONCLUSION

The arithmetic mean radon concentration was estimated to be 21.3 Bq/m^3 (S.D. 18.8 Bq/m^3) by a nation-wide survey in Japan. The geometric mean was found to be 17.3 Bq/m^3. Ninety nine percent of the measured houses are less than 96 Bq/m^3. No radon prone area was found, although a little elevation of radon concentration was found in the western part of Japan due to granite formation. Our detectors have a disadvantage of detection of thoron since the air filtration rate of the detector is very high. The estimated radon concentration based on the first survey of indoor radon might have been overestimated due to thoron contribution to the radon measurements. In the additional survey one prefecture showed no thoron contribution while the other two prefectures showed significant thoron contribution in the radon measurements. No clear-cut indication of high thoron houses has not been obtained.

[1]UFZ - Umweltforschungszentrum Leipzig-Halle GmbH
[2]Hochschule für Technik und Wirtschaft Dresden

1. INTRODUCTION

Radon is a radioactive gas known to occur in groundwater. During the last years as well public interest in dosimetrical aspects of radon in Germany [1] as in scientific applications using radon as a natural tracer in hydrology and hydrogeology (e.g. [2]) has increased significantly.
Sampling and measurement of radon in water are complicated and often incorrect caused by the volatility of the gas.The aim of this work was to develop and test a low cost radon measurement method including sampling, transportation, and analysis, which allows a quick measurement of many samples with high reproducibility.
The paper describes a modified [3] experimental procedure based on liquid scintillation spectrometry

2. SAMPLING TECHNIQUE

2.1. Sampling devices

Different water sampling devices (submersible pump, membrane pump, bailer) were compared to check their applicability for the sampling method to measure radon concentrations. A submersible pump and a membrane pump were used together in a observation well for a continuous sampling. The period of representative sampling starts after 40 minutes of flushing. The radon concentration of samples collected with the submersible pump is found to be (2690 ± 60) cpm/L and those collected with the membrane pump obtained to (2670 ± 100) cpm/L. Therefore, both pumps lead to the same results. Comparing the two single measurements of the bailer with the pump series means, that all of the used devices are suitable for sampling.

2.2. Flushing time

Every sampling starts with flushing the water located in the observation well and in the screen zone. The time for representative sampling must be determined. A too short initial flushing time represents a major source of error, because the measured radon concentration could be influenced by mixing of the pore water of the filter gravel, stagnant water of the observation well and water influenced by natural emanation rate of the aquifer. Figure 1 shows the behaviour of the radon concentration during continuous sampling in a deep observation well (well screen 44 m below land surface) in which the pump depth is only 9 m below land surface. In the first period of flushing the stagnant water radon concentrations of groundwater samples increased rapidly by 7000 cpm/L. After a time of about 35 minutes (2.6 standpipe volumes of water plus pore water of filter gravel) a representative sampling is possible. The radon concentration on this observation well was (7920 ± 150) cpm/L (29 measurements). Some tests lead to the proposal for practical use to fix the flushing time as a function of the sum of standpipe volume of stagnant water in an observation well plus the pore water of the filter gravel. For qualified measurements of radon concentrations in aquifers flushing with four to five standpipe volumes are necessary. If the pumping depth equals the screening depth the flushing time can be reduced drastically.

The behaviour of radon concentration during flushing gives a new reliable tool to fix the beginning of representative sampling for any chemical parameter especially for older, unknown observation wells. Normally, the constant electrical conductivity and constant water temperature is being accepted to indicate the end of flushing time. However, these are necessary conditions but not sufficient ones. A continuous sampling and measurement of radon concentrations leads to an increasing concentration curve as a function of flushing time or number of removed standpipe volumes starting at a low level and approaching a constant plateau value. The approaching of the plateau is the moment where representative sampling may start for any parameter. It is often necessary to check unknown observation wells for possible use in future measurement campaigns, in these cases radon concentration is the most reliable parameter to do that.

2.3. Filling arrangement

The sample bottle and the filling arrangement must be designed in relation to the mobility of the radon gas. For this reason a glass mensure calibrated to one litre with a narrow neck sealed by a polyethylene stopper with teflon gasket was chosen as sample device. It realises sampling with minimisation of loss of radon. At first

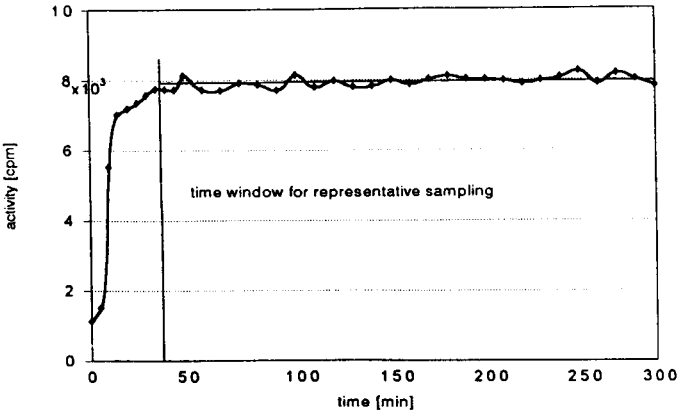

Figure 1: Behaviour of the radon concentration during continuous sampling in a deep observation well

20 mL toluene scintillation cocktail is filled into the mensure. After that the water is filled in through a glass tube specially made for radon measurement by underlayering the scintillation cocktail without air contact. Sampling has to be free of turbulence and air bubbles. After filling the glass tube is removed and the mensure is closed with the polyethylene stopper with teflon gasket for transport. The usefulness of the above described filling arrangement was tested with several measurement series. The results show an improvement of measured radon concentration in groundwater samples between 2 and 8 % depending on the quantity of natural radon concentration in the aquifer. A second reason to use that filling arrangement is the better objectivity of sampling.

3. MEASUREMENT TECHNIQUE

The activity concentration of radon in groundwater is determined as described by HORIUCHI and MURAKAMI [4]. Radon solved in water is extracted by toluene mixed with liquid scintillator cocktail. The toluene phase is filled into a glass vial. The radon activity of this toluene phase is determined by liquid scintillation spectrometry. The calibration of the measurement is carried out by using a liquid solvent of Ra-226, which is in equilibrium with its daughter nuclides especially with Rn-222. The water sample volume amounts to 1 litre. A commercial toluene cocktail with 5 g PPO and 0.1 g POPOP per litre is used as extraction and scintillation cocktail.

The water samples are transported to the laboratory in glass mensures sealed with a polyethylene stopper with teflon gasket. During the transport the water sample is covered by 20 mL toluene cocktail. 10 equivalent water samples were stored after transportation 4.5 hours, 1 day, 2 and 5 days. The measurement results relative to the sampling moment did not change.

The transport mensures with the water samples and the floating scintillation cocktail are shaken in the laboratory to reach a stable distribution of radon between water and toluene. The shaking time amounts to 10 minutes. After shaking a first extraction of 10 mL toluene cocktail is removed and filled into a glass vial, 10 mL fresh cocktail is added to the water sample. Afterwards, the mensure with the water sample and the scintillation cocktail is shaken a second time for 10 minutes. At last, 10 mL of the toluene cocktail is removed again and added finally to the 10 mL in the same glass vial to measure the radon concentration in the next step.

For the measurement of the radon activity high performance glass vials produced from borosilicate glass with cork/aluminium sealed caps and a liquid scintillation spectrometer TRI-CARB 2550 TR/AB (Packard) with a special hard- and software option for α/β discrimination were used. The optimum measuring time is 60 minutes. The measurement error is < 5 % for count rates between 40 and 8000 cpm. To reach a high sensitivity the energy window has a range from 0 to 2000 keV (open channel). Before sampling the background count rates of all used vials are measured with 20 mL scintillation cocktail. After the sampling and extraction procedure the cocktail is filled back into the same vial. The vials are measured about five times in a period of five days. Before the first measurement starts it has to pass a waiting time of at least three hours to reach the equilibrium between radon and its daughter nuclides.

4. EVALUATION AND CALIBRATION

The results of the TRI-CARB measurements are determined in units of counts per minute (cpm). It is essential to control that only the activity of radon is measured. The TRI-CARB 2550 TR/AB has two possibilities to check the correctness of the results:

- Using the software SPECTRAGRAPH it is possible to view the α spectrum (Fig. 2). The peaks of radon-222 (5.49 MeV), polonium-218 (6.00 MeV) and polonium-214 (7.69 MeV) can be distinguished.
- The α/β discrimination allows to calculate the α/β ratio after calibration e.g. by Am-241/C-14. In the case of radon-222 the ratio must be 60/40.

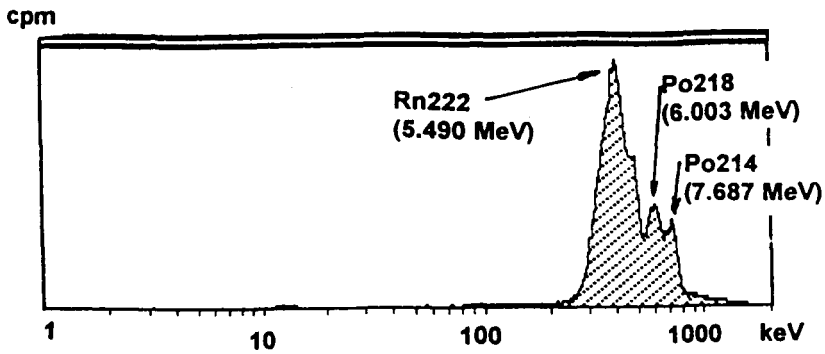

Figure 2: Alpha spectrum of radon-222 and its daughter nuclides represented by TRI-CARB software SPECTRAGRAPH

For the exact measurement of radon activities in water by liquid scintillation spectrometry one of these two possibilities should be integrated in the used equipment.

By means of five measurements in a five days period the radon activity in the moment of sampling can be calculated by regression. Also the possible untightnesses of the vials are visible in this calculation procedure. Then the measured half life times are apparently shorter.

For calibration the radon activity concentration of ground water samples was determined by gamma spectrometry using the daughter nuclides Pb-214 and Bi-214. The calibration factor of $(8.3 \pm 0.7)\ 10^{-3}$ Bq/cpm was calculated related to the mean value of the results of liquid scintillation spectrometry of similar groundwater samples. However it must be taken into account that the chemistry of the water (characterized e.g. by pH and electrical conductivity) can influence the efficiency of the radon extraction.

The presence of radium-226 in the water sample makes the measurement results errorprone because it produces radon-222 continuously. To exclude this possibility the water samples should be stored for about 20 days and then measured again.

5. RESULTS AND CONCLUSION

A modified experimental method for the determination of radon in water including all steps of sampling, sample transportation and analysis has been tested successfully.

The method is characterized by a new onsite technique for sampling water by pumping with minimized aeration and losses of radon during transportation. Submersible pumps as well as other sampling systems like membrane pumps or bailer are equally useful. The waiting time between sampling and measurement can be up to five days. The radon is extracted from the water sample by extraction using toluene scintillator cocktail The radon activity is measured by liquid scintillation spectrometry

The described method is useful for measurement of radon concentration in groundwater samples as well as in other water samples like drinking water, surface water or spring water.

INTRODUCTION

Many epidemiological studies especially made on different cohorts of uranium miners clearly showed the influence of radon and radon progeny in lung cancer diseases (1).

At present, about ten important epidemiological studies regarding indoor radon concentration and lung cancer risk are in the world under observation (2).

The indoor radon concentrations are strongly dependent on the meteorological factors, the ventilation conditions and on the radon soil potentiality. In some earth areas the radon generated in upper part of the lithosphere or in the wall material may produce high radon concentrations in dwellings (3).

In Romania have been performed measurements in uranium and nonuranium mines (4) also in some country centres (5) by Kusnetz's method. The Kusnetz's method being an instantaneous method for indoor radon concentrations may not provides a correct estimation for average indoor radon content. In some cases, if the measurements are made in determined conditions (after a few hours of the windows and doors closing) it is possible to obtain a certain average value for indoor radon concentration more or less deviated from the real value (6).

Therefore, for a good estimation of the average indoor radon content, the measurements may be made for 3-6 months period, that is integrating determinations. Such measurements usually performed by track method or by electret detectors in the last years (7) are used for the radon indoors in dwellings.

Beginning from 1994 under collaboration with Gent University (Belgium) and NRPB (England) financed by CEC in Romania were started the first integrating measurements of radon in dwellings.

This work presents these measurements in three regions of Romania. In the first two, respectively the Bihor and Cluj districts also an epidemiological pilot study in connection with the lung cancer risk due to radon was started. The third region is the Herculane Spa area where also many radon determinations in different environmental factors exist (8).

EXPERIMENTAL METHOD

The Karlsruhe radon diffusion chambers using makrofol electrochemical etched track detectors were used (9). After a previous chemical etching (0.5 hours) at 25 °C using a 6N KOH solution follows the electrochemical etching performed in the same solution applying an effective voltage of 800 V at 2 kHz during 3 hours (Gent conditions) (10).

The makrofol detectors were exposed for 3 months period in different buildings. The indoor radon concentrations were also performed by the Kusnetz's method using the scintillation flasks of 0.5l which were calibrated with romanian $RaCl_2$ standard solution.

RESULTS AND DISCUSSION

Table 1 presents the average values and the standard deviation for three areas from Romania. For the first two areas (Cluj-Napoca and Oradea cities) the measurements have been made in the cold season

and for the Herculane Spa region the measurements were made measurements both in cold season and warm season. For comparison in the last column of this table we present the measurements for indoor radon obtained by the Kusnetz's method. The values of 76 $Bq.m^{-3}$ and 115 $Bq.m^{-3}$ in each town represent the mean value of 30-35 dwellings and in each dwelling these were measured twice a year in cold and in warm season. These values are smaller than integrating measurements made only in cold season when the ventilation is smaller.

A rather high value was find for ^{14}C-laboratory (1d) and for the cave of one author (1e).

The measurements made in Herculane Spa show an average value for the cold season (185 $Bq.m^{-3}$) of two times greater than the average value for the warm season. Figure 1 also shows the indoor radon distribution for the cold and warm season.

Table 1. Integrating measurements of radon in three areas of Romania.

No.	Place	Number of dwellings	Average indoor radon ($Bq.m^{-3}$)	Standard deviation ($Bq.m^{-3}$)	Time period	Kusnetz's method (5,6) ($Bq.m^{-3}$)
1	Cluj-Napoca city					
	a) houses-downstairs	11	182.6	102	10.12.94 to 10.03.95	76
	b) block flats	8	125.7	20	idem	
	c) University-downstairs	4	127.3	21	idem	(annual
	d) ^{14}C laboratory (ITIM)	1	282	-	idem	average)
	e) author cave	1	1060	-	idem	
	f) Dej (town in Cluj district) houses-downstairs	2	100	15	06.12.94 to 06.03.95	
2	Oradea city houses-downstairs	5	124	15	06.12.94 to 06.03.95	115 (annual average)
3	Herculane Spa					
	a) buildings-downstairs in warm season	15	98.2	82	16.04.94 to 16.07.94	
	b) the same dwellings in the cold season	15	185.1	68	20.11.94 to 20.02.95	-
	TOTAL COULD SEASON AVERAGE (without 1e and 3a) 161 $Bq.m^{-3}$					

The mean value in the cold season (161 $Bq.m^{-3}$) obtained for all measurements from Table 1 is high enough but many integrating determinations are necessary for configuration of this value.

MEASUREMENT OF ^{222}Rn AND ^{220}Rn EXHALATION RATES BY MEANS OF ALPHA SPECTROSCOPY

Tieh-Chi Chu
National Tsing Hua University, Hsinchu 300, Taiwan, R. O. C.

Abstract

The measurement of ^{222}Rn and ^{220}Rn exhalation rates by means of alpha spectroscopy are presented. A metallic hemisphere cup with a hole at the bottom of the cup was used. A surface barrier detector is placed on the top of the hole and sealed with silicone in order to provide good insulation. Radon flux emitted from the surface of the material was measured by placing the inverted cup mentioned above on the top of the material. The increase of activity due to ^{222}Rn and ^{220}Rn inside the inverted cup was continuously measured by electrostatic deposition of ^{218}Po and ^{216}Po onto surface barrier detector. This method can also be applied in the measurement of radon exhalation rate from soil and building materials.

Introduction

The production of ^{222}Rn and ^{220}Rn in terrestrial materials depends on the activity concentration of ^{226}Ra and ^{228}Ra present. The UNSCEAR (1993) report indicates that the precursors of ^{222}Rn and ^{220}Rn have about activity in earth and building materials, and the rates at which the two isotopes are produced are also about equal. It is usually assumed that the emanation fraction is the same for both of them. The ratio for the potential alpha energy concentration of ^{220} Rn to ^{222}Rn is about 0.62, and the dose contribution from α decay of ^{220}Rn and its daughters is about 38.27 % of Rn isotopes[1]. An instrumentation was developed to detect ^{222}Rn and ^{220}Rn by α spectroscopy with electrostatic collector and to measure ^{222}Rn and ^{220}Rn in some of the building materials available in Taiwan.

Experimental

A metallic hemisphere cup with a hole at the bottom of the cup was used. The hole has a diameter of 2.6 cm. A surface barrier detector was placed on the top of the hole and sealed with silicone in order to provide good insulation. The opening part of the cup connects to a fine metal net. The circuit between the metal net and the cup must be open. The whole device is shown in Fig. 1. The detector is connected to preamplifier, amplifier, analogy / digital converter, multiple channel analyzer and personal computer to analyze the data. When ^{222}Rn and ^{220}Rn decay to ^{218}Po and ^{216}Po, the daughters are mostly positively charged. This positive electricity creates an electrostatic field. Then they were expelled to the bottom of the cup and collected on the surface barrier detector by electrifying the cup with high voltage. The α spectrum analysis for the decay daughters can infer the radioactive concentration of ^{222}Rn and ^{220}Rn [2].

The Calibration of Detection Efficiency

The radioactive source used is a Pylon Model-1025, standard radon source. The activity of radium is 1147 k Bq. The equilibrium activity of radon is 1147 k Bq. As shown in Fig. 2 its detection efficiency is 23.2 % for ^{222}Rn and 17.4 % for ^{220}Rn. Because the decay daughters of

^{222}Rn and ^{220}Rn, namely ^{218}Po and ^{216}Po, are positively charged, the detection efficiency of them will be increased with the increasing positive electricity electrified to the metal cup. As shown in Fig. 2 when the voltage is higher than 3600 V, the detection efficiency for ^{218}Po will achieve a steady value, 87%. Meanwhile, when the voltage is higher than 4800 V, the detection efficiency for ^{216}Po will achieve a steady value, 52 %. Therefore, the collector has a higher collection efficiency for ^{218}Po. The half-life of ^{220}Rn and ^{216}Po is very short (55.6 and 0.15 respectively). Therefore, even the detection efficiency can be improved by electrifying, they can not reach the surface of the detector.

The measurement of ^{222}Rn and ^{220}Rn Exhalation rates in Building Materials

The voltage was set at 4000 V with relative humidity (R. H.) between 41.0 ± 0.2 % and temperature was placed 25 ± 2 °C. The building materials sample was placed in the cup. By measuring α-particle decayed from ^{222}Rn and ^{220}Rn and analyzing the α spectra, the concentration of ^{222}Rn and ^{220}Rn can be obtained. There are two exhalation rates: the initial exhalation rate and the equilibrium exhalation rate. The former is the instant exhalation rate after the building materials is airtight. It is influenced by the quantity of radium and the density of cracks in building materials. The latter is the exhalation rate while the production rate and the decay rate of ^{220}Rn and ^{222}Rn achieve equilibrium in the cup. In this experiment 8 different kinds of building materials were selected. The results obtained are listed in Table 1.

Results and Discussion

The detection efficiency can be raised gradually when the applied voltage is over 3600 V. The collection efficiency of ^{218}Po and ^{216}Po decreases as the R. H. increases and the latter has a greater influence on ^{216}Po rather than on ^{218}Po. While the R. H. varies from 10 % to 40 %, the collection efficiency declines from 40 ~ 50 % to 15 ~ 40 %. Table 1 shows the exhalation rate of building materials, and the equilibrium exhalation rate of ^{220}Rn is higher than that of ^{222}Rn. Inside the collector cup, air has the least amount, of ^{220}Rn with a concentration of 0.008 $kBqm^{-3}$. However, marble and granite have the highest amount, 2.78 $kBqm^{-3}$. The average concentration of ^{222}Rn in air tested by 8 different building materials is about two times greater than that of ^{220}Rn. The average concentration ratio of ^{220}Rn to ^{222}Rn is from 0.13 to 0.44 which means the quantity of ^{220}Rn is about one-third of that of ^{222}Rn. This result matches with the published documents in which the dose contribution of ^{220}Rn is about 30 % of radon[1,3,4]. The experimental setup mentioned above can thus improve the detection efficiency, measure the amount of ^{222}Rn and ^{220}Rn, and detect them instantaneously or continuously.

ABSTRACT (See instructions overleaf)

This paper reports the monitored results of Radon in air indoor and outdoor in Changchun city area with static accumulation collector for the daughters of Radon from July 1991 to July 1992. The static accumulaton collector is developed, designed and was supplied to us by University of NAGONA, Japan.

Six monitoring points were selected in Changchun city area, the collector is laid horizontally, settled at 1 m above the ground of monitoring point, the sample is collected every two months. Annual average activity of Radon is 9.7~1.8 bq.m^{-3} outdoor, 18.6~6.5 bq.m^{-3} indoor, 35.6~8.6 bq.m^{-3} in underground plaza.

HE/a for lung of residents was estimated according to the parameters published by UNSCEAR, the value of 0.76 msv a^{-1} is obtained

ABSTRACT (See instructions overleaf)

This paper reports the estimation of Rn concentration level, and population HE/a in underground construction in part of cities in China. In this study, the average staying time for working people is 9 hours in underground construction , 5 hours staying outdoor on the ground, 10 hours staying in construction on the ground.

HE/a for people working in underground construction is 0.82 - 1.44 msv a^{-1}. The Rn concentration in underground construction is 1.30 - 7.36 time as large as the value in construction on the ground. That means strenghtening ventilation of underground construction, or other measures to reduc Rn concentration must be taken for people's safety reason.

EVALUATION OF RADON DOSES OF THE POPULATION OF KARELIA AND COLA PENINSULA

F. I. Zuevich, A.V. Lazarev

Research Institute of Industrial and Marine Medicine, St. Petersburg, Russia

INTRODUCTION

In opinion of the experts of UNSCEAR, radon and radon irradiation are major components of a natural radiating background. The effective equivalent doze of the planet population irradiation by radon and its affiliated products makes not less than halves of total doze from all natural sources of radiation (up to 70 %).The inhaling of the air, containing 1 Bq m^{-3} of radon, by different literary sources creates an effective doze on lungs from 50 up to 150 μSv y^{-1} (1, 2).

The natural sources of radiation influence the people, both in municipal and industrial spheres.

The heaviest contribution to irradiation of the population introduce radon and its affiliated products, locating in air of premises. The separate groups of the population can receive at the expense of the inhaling of radon extremely high emergency dozes (thousand BER y^{-1} on lungs). On UNSCEAR data , from 20 up to 40 % of all lung cancers are stipulated by radon and its affiliated products.

Total for autumn- winter stages of the work 950 detectors were installed and 1310 instant measurements of radon and its daughters were conducted. It is surveyed 47 towns, from them in details Petrozavodsk, Murmansk, Vyartsila, Snezhnogorsk.

ANALYSIS OF DATA ON KARELIA

The geometrical means of radon concentration in Karelia for separate towns by results of integrated measurements of a "pure" radon(i.e. radon without its daughters products) are represented for 42 towns in a diagram on fig. 1. The analysis of all set of available materials permits to reveal some general laws, describing the contents of a radon in houses of Karelia: for the majority of towns a rather high similar average level of concentration of a pure radon is characteristic. Geometric mean (GM) on whole Karelia is 72 Bq m^{-3}, and expectation value for lognormal distribution is equal to Bq m^{-3}. The difference between maximum and minimum values does not exceed 2 - 4 times. Lower GM of radon concentration was found in Belomorsk and Kemm (up to 50 Bq m^{-3}). Probability of excess of allowable values of radon concentration, determined from parameters of lognormal distribution, makes for whole Karelia about 1 %. Thus, on a background relatively high stable year concentration of radon in air of premises for towns of surveyed regions as a whole, significant percent of buildings with extremely high its levels emerges. The analysis shows, that the highest levels are registered in small settlements, i.e. the design of buildings plays here the significant role. The analysis of the relationship of geology and radon levels with using geological data and data on Finland and Cola peninsula shows the following: - correlation of high radon levels with intrusion of rapakivy granite is doubtless.

In Finland the average concentration of radon in region with such geology lies within the limits of 200 - 300 Bq m^{-3}. The similar geological structure is present in Karelia on north-east coast of Ladoga lake. The least concentration of a radon (30 - 50 Bq m^{-3}) is marked in gneiss zones and in amphibolites of belomorsk series. The large part of Karelia, as a geological structure, belongs to regions with most ancient gneisses and oligoclases granitoids. For them it is possible to expect wide spreading of radon concentration, from 70 up to 400 Bq m^{-3}.

ANALYSIS OF DATA ON COLA PENINSULA

Results of integrated radon measurements are represented for 6 towns in the diagram on fig. 2. The analysis of set of available materials does not allowed to reveal general laws, describing the contents of a radon in houses of Murmansk area: in surveyed towns average levels of radon concentration (GM on all Cola peninsula is equal 29.6 Bq m^{-3}, and expectation value for lognormal distribution is equal 40.7 Bq m^{-3}) lie in a wide range from 20 up to 93 Bq m^{-3}. Lower GM of radon concentration was found in Murmansk and Kovdor (up to 25 Bq m^{-3}).

The analysis of measurements distributions shows, that, as well as in Karelia, wide spreading of radon levels from several ten up to thousand Bq m-3 is observed. Probabilities of excess of allowable levels of radon concentration, determined from parameters of lognormal distributions, equal for Murmansk - 0.001 %, for Kovdor - 0.01 %, for Kirovsk and Revda - 0.1 %

DETAILED INSPECTION OF PETROZAVODSK AND VYARTSILA

Measurements of radon were executed within the limits of 12 sites, located in regular intervals within the limits of Petrozavodsk. Total in Petrozavodsk more than 600 measurements were conducted. By results of

conducted research is established, that the background values of equivalent equilibrium volumetric activity of radon (EEVA) in buildings of various purpose change from the first units up to first dozens Bq m^{-3}.
On the majority of surveyed sites abnormal objects with volumetric activity of radon and its daughters products from the first hundreds up to thousands Bq m^{-3} (Center, Kukkovka, Perevalovka) are found out. Number of buildings with the abnormal content of radon, more than 100 Bq m^{-3}, is about 9 %.
However, using the complex approach to valuation radon danger of buildings (volumetric activity of radon and its daughters, specific flow of a radon), the total number of potentially radon dangerous buildings reaches 34 %. The accumulation EEVA in a premise and determination of radon flow, used in this work, are described in (3).

Attracts attention the fact, that objects with a high radon EEVA level were poorly found out at the survey. At the same time high levels of a "pure" radon are found out at low EEVA values, that specifies high receipt of radon and potential opportunity under other conditions of reception of very high EEVA values, down to dangerous levels.

The valuation additional deaths at the expense of irradiation by radon only at Petrozavodsk (calculations are made in conformity with ICRP 50 publication) makes of 60 cases per year.

In Vyartsila settlment, located directly on border with Finland, active construction both of industrial premises and residential fund was assumed within the framework of economic commonwealth. Provided emanation survey of the settlement territory differs from all spent early by direct measuring of radon flow from a soil surface, instead of measuring volumetric activity of radon in soil air . The measured flow of radon from a soil surface on different sites was in a range from 10-15 up to 300 Bq m^{-2} h^{-1} with average level equal to 40 Bq m^{-2} h^{-1}. The volumetric activity of a radon in soil air was from 20 up to 100 kBq m^{-3} at average 60 kBq m^{-3}. The maximum registered value was equal to 150 Bq m^{-3}, at average on surveyed premises equal to 30 Bq m^{-3}. Survey in Vyartsila settlement has clearly shown, that it is not enough to have knowledge only about the radon content in soil air. Accounts of the radon contents in the basements and radon flow very well correlate by average values.

THE DOSE LOADS ON THE POPULATION OF KARELIA

The average level of irradiation by the expense of availability of radon in air of premises (on average EER) makes for Karelia 4,5 mSv in a year. In separate settlements range of fluctuations from this average value is about 4 times decrease or increase (from 0.8 up to 14.3 mSv in a year). Annual ED of irradiation, were designed for the adult . With the children in age till 10 years they can be at 1.52 time above (1,2).These dozes make up in average about 0.3 from the accepted normative level. However with separate inhabitants, living in houses with high radon levels in air, the last value can be exceeded 23 times (as it is, for example, in Pudozhgorsky settlement). According to the available demographic data, there were 700000 persons in the Karelian republic in 1968 year, then the number of cases of the lung cancer (Qp) can make 60.0 cases in a year.

DOSE LOADS ON THE POPULATION OF COLA PENINSULA

The Murmansk region annual doze from a radon in air of premises is about 2,2 mSv. It should clearly see, that this value is enough rough valuation, owing to limited number of surveyed towns. On separate settlements a range of fluctuations from this average value is about 2 times decrease or increase (from 1.2 up to 3.7 mSv in a year). The excess number of the lung cancers for Murmansk region can be Qp= 27.8 cases per year.

CONCLUSIONS

1. The radiation conditions, formed by the expense of receipt of radon and its daughters products in the air of living accommodations and buildings of various purpose in settlements of Karelia and Cola peninsula, should be regarded as intense and creating for the population and its critical groups (in particular, the children) potential opportunity of irradiation higher then established normative limits.
2. Average annual ED of irradiation of population, stipulated by receipt from air of radon and its daughters, is for the inhabitants of various settlements 0.6 - 25 mSv in a year. These levels of irradiation change within the limits of 6- 120 % from value, considered by international organizations as not requiring fulfillment's of protective measures. At the same time, in the process of settlements survey separate houses are revealed, where according to results of measurements, radon concentrations 2 - 3 times exceeding national normative values are registered. The number of such houses in different settlements makes up 13 % from total number of buildings. In these cases protective measures should be accepted.
3. Annual mean ED value in surveyed towns of Karelia is 4.5 mSv, and for Cola peninsula - 2.2 mSv.
4. According to prognostic account, the possible lung cancer number, caused by the inhaling radon daughters, for the inhabitants of surveyed regions of Karelia, , makes up 9 persons on 100 000 of the population in a year, and for the inhabitants of Cola peninsula - 4 persons.

RADIATION CONDITIONS FROM RADON DWELLINGS OF VARIOUS PURPOSE

F.I.Zuevich

Research Institute of Industrial and Marine Medicine, St. Petersburg, Russia

INTRODUCTION

A specific feature of the mechanism of pollution of air environment is continuous flow of a radon in volume of a dwelling and, owing to it decay , accumulation of affiliated products, mainly determining a dose load on the person.

The intensity of radon allocation in volume of a dwelling depends basically on geophysical properties of spread under rocks, building material and time of air exchange .This determines specific character of formation of a radiating conditions in residential and industrial dwellings.

SOURCES AND FACTORS, INFLUENCING TO INTENSITY OF ALLOCATION OF A RADON IN VOLUME OF DWELLINGS

Main sources of allocation of a radon in volume of dwellings are:

1. Massif of rocks under buildings;
2. Building materials;
3. Technical and drinking water, natural gas.

The quantity of a radon, arriving from these sources, depends on a number of the reasons, determined by geological and geophysical properties of spread under rocks and by construction and architect features of dwellings and buildings.

The allocation of a radon from a massif of spread under rocks.

Process of receipt of a radon from a massif of rocks consists of two consecutive steps: the first step is allocation of a radon in emptiness of rocks (pores, cracks) thanking the phenomenon of effect Ra-226 decay, second - distribution of allocated in thepores radon under the laws of gas diffusion or convection.

The theory of distribution of a radon in pores was in detail developed in (1,2), where for various cases of radon distribution the theoretical formulas were deduced.

In general the differential equation of distribution of volumetric activity of radon at steady conditions will have a form:

$$K\frac{\partial^2 C}{\partial^2 n} - V\frac{\partial C}{\partial n} + q\rho k - \lambda C\varepsilon = 0 \qquad (1)$$

where: K - coefficient of diffusion;
C - quantity of a radon in 1 cm³ of pore air;
V - convection velocity;
q - quantity of a radon, formed for 1 s in 1 g of rocks;
ρ - volumetric weight of rocks;
k - emanation coefficient;
λ- constant of radon decay;
ε -porosity of rocks;
t - time.

As an example we shall consider the elementary case and, in particular, diffusion distribution of a radon in infinite, homogenious layer, leaving on a surface. The change of volumetric activity of radon with depth is described by the equation:

$$C_{Rn} = \frac{q\rho k}{\lambda} * \left(1 - H\sqrt{\frac{\lambda}{K}}\right) \qquad (2)$$

And flow of radon from 1 cm² of a rock surface (exhalation)

$$E = K\frac{\partial C}{\partial x} = \frac{q\rho k}{\lambda}\sqrt{\lambda K} \qquad (3)$$

THE ACCUMULATION OF SHORT LIVED AFFILIATED PRODUCTS OF RADON IN AIR OF DWELLINGS OF VARIOUS PURPOSE

Accumulation of products of radon decay in a general case can be expressed by the following equation:

$$N_n = N_{Rn} * \lambda_1\lambda_2....\lambda_{n-1} * (\frac{\exp(-\lambda_1 t)}{(\lambda_2-\lambda_1)(\lambda_3-\lambda_1)*...*(\lambda_{n-1}-\lambda_1)} + \tag{4}$$

$$+....+\frac{\exp(-\lambda_n t)}{(\lambda_1-\lambda_n)(\lambda_2-\lambda_n)*...*(\lambda_{n-1}-\lambda_n)}\}$$

As the initial volumetric activity of decay products , and also the correlations between them can be different, we shall consider character of accumulation of volumetric activity of radon decay products and their potential energy directly from a radon, i.e. when the initial volumetric activity RaA, RaB and RaC is equal to zero. In this case the equation (4) became:

$$N_a = \lambda_{Rn}\frac{N_{Rn} * (1-\exp(\lambda_a t)}{\lambda_a} \tag{5}$$

$$N_b = \frac{\lambda_{Rn} N_{Rn} * \{\lambda_a(1-\exp(\lambda_b t) - \lambda_b(1-\exp(\lambda_a t)\}}{\lambda_b(\lambda_a-\lambda_b)} \tag{6}$$

$$N_c = \lambda_{Rn} N_{Rn}(\frac{1}{\lambda_c} - \frac{\lambda_b \exp(-\lambda_a t)}{(\lambda_a-\lambda_c)(\lambda_a-\lambda_b)} - \frac{\lambda_a \exp(-\lambda_b t)}{(\lambda_c-\lambda_b)(\lambda_a-\lambda_b)} + \frac{\lambda_a\lambda_b \exp(-\lambda_c t)}{\lambda_c(\lambda_a-\lambda_c)(\lambda_c-\lambda_b)} \tag{7}$$

The quantity of accumulated radon decay products , expressed in potential energy units of alpha-decay, is equal in MeV l^{-1}

$$E = E_a + E_b + E_c = 13{,}68 * N_a + 7{,}68 * N_b + 7{,}68 * N_c \tag{8}$$

where N_a, N_b and N_c are calculated under the formulas (5, 6, 7).
The change of potential energy in time in relative units will be equal

$$\phi = \frac{E}{E_{eqv}} = \frac{13{,}68 * N_a + 7{,}68 * N_b + 7{,}68 N_c}{E_{eqv}} \tag{9}$$

The analysis of decay curve "ϕ" shows, that with rather good approximation the change in ϕ can be expressed by the following dependence:

$$\phi = 1 - \exp(-\lambda_e * t) \tag{10}$$

Where λ_e - empirical constant, s^{-1};
t - time of a radon presence of in volume of a dwelling, s.
Then the equation of accumulation of potential energy or equivalent equilibrium volumetric activity (EEVA) of a radon in a dwelling will have a form:

$$E = C_{Rn} * [1 - \exp(-\lambda_e * t)] \tag{11}$$

In dwellings, in which radon continually arrives, the change of volumetric activity is recorded by an equation:

$$v\frac{\partial C_{Rn}}{\partial w} + \lambda_{Rn} C_{Rn} = Q_w \qquad (12)$$

where C_{Rn} - volumetric activity of a radon in a point "w" of a dwelling, Bq m^{-3};
v - speed of air movement in a dwelling, m / s;
λ_{Rn} - constant of radon decay , s^{-1};
Qw - volumetric density of radon flow, Bq $m^{-3} s^{-1}$.

Using a boundary condition $C_{Rn} = C_{Rn}o$ at x=0, the solution of equation (12) at constant ventilation mode can be recorded in the following form

$$C_{Rn} = C_{Rn}o * \exp(-\lambda_{Rn} * t) + (Qw / \lambda_{Rn}) * [1 - \exp(-\lambda_{Rn} * t) \qquad (13)$$

Taking into account, that the time of air exchange in a dwelling cannot be more than two hours, $\lambda_{Rn} * t << 1$, the equation 13 can be recorded with sufficient for practical purposes accuracy:

$$C_{Rn} = C_{Rn}o + Qw * t \qquad (14)$$

Thus, the equation of accumulation of potential energy can be submitted as

$$E = C_{Rn}o * [1 - \exp(-\lambda_{Rn} * t)] + Qw * t * [1 - \exp(-0,5 * \lambda_{Rn} * t)] \qquad (15)$$

PARAMETERS, DESCRIBING A RADIATION CONDITIONS UNDER THE FACTOR "RADON" IN A DWELLING

In the basis of acceptance of the decisions is incorporated criterion not excess mean year EER of a radon equal 100 Bq m^{-3} for new housing accommodation and 200 Bq m^{-3} for existing. For valuation of these values, long-term measurements of a radon by extent till 6 months (measurements in current two seasons) and subsequent recalculation on EEVA of radon with accepted shift of balance equal 0,5 are recommended. I shall not be go in critics of this rule, but I offer, as alternate, following approach to valuation and forecast of a radiating conditions in dwellings of various purpose at different stages of its development from designing before delivery it in operation and while in service.

CRITERION of DECISIONS ACCEPTANCE

Stage of designing and organization of the use of land.

Parameter	Radon safe	Additional researches needed	Radon remedial measures needed
1. Content Ra-226 in soil, Bq kg^{-1}	< 20	$20 < A_{Rn} < 50$	>50
2. Diffusion coefficient, $cm^2 s^{-1}$	> 0,01	> 0,002	> 0,002
3. Volumetric Rn activity kBq m^{-3}	< 10	$10 < C_{Rn} < 40$	> 40
4. The relation C_{Rn} (1 m)/C_{Rn} (0,1 m)	1,2	1,1-1,0	>1,05
5. Exhalation, Bq $m^{-2} h^{-1}$	< 75	75 - 150	> 150

The exhalation of radon from a surface can be determined experimentally or by calculation using gradient of volumetric activity in soil pore air. Unfortunately, the estimates are rather complex and possible only on computers. The account of an exhalation of a radon is carried out under the formula (3), and we receive factor of diffusion from the solution of equation:

$$K = \frac{H1 * H2 * \lambda_{Rn}}{2 * \ln(1 - B(1 - \exp(-H2 * \sqrt{\frac{\lambda_{Rn}}{K}})))} \qquad (16)$$

Stage of a reception of a new living accommodation and valuation of existing.

The accumulation EEVA of radon in a dwelling is well described by equation (15), from which it is clear, that determining parameter is specific volumetric flow of a radon in a dwelling. Taking into

MEASUREMENTS OF Rn - 222 CONCENTRATIONS IN DWELLINGS IN AN AREA OF HIGH NATURAL RADIOACTIVITY

Günseli Yaprak and Selman R. Kınacı

Ege University, Institute of Nuclear Sciences, 35100 Bornova, IZMIR / TURKEY

ABSTRACT

An investigation was conducted on the levels of Rn- 222 concentrations in dwellings in Köprübaşı where there exits large uranium ore deposits. Considering the importance of the region in radioactive environmental programme of our Institute the radon concentrations of dwellings were measured by using LR-115 cellulose nitrate films as nuclear track detectors. The results have indicated that the range of radon levels in this area is 20-340 Bq/m^3 . The highest radon concentrations are observed in the stone buildings which were constructed with the material obtained from that area.

INTRODUCTION

Long term measurements by using LR-115 nuclear track detectors have been carried out to investigate the distribution of radon concentrations in dwellings in Köprübaşı located in vicinity of uranium ore deposits (1). One can think it might be a possibility of healt risk even for long exposure to low irradiation doses. This is fundemental when some population group are living in an area of high level of natural radioactivity. It follows that more information about radon concentration level in the atmosphere of the dwellings in Köprübaşı seems to be necassary for considering the importance of the region. Taking this point into account the radon concentration has been measured in about hundred houses of the region in radioactive environmental programme of our Institute.

EXPERIMENTAL AND RESULTS

Kodak- Pathe LR -115 type 2 cellulose nitrate film is used as SSNTD for the measurements of radon in dwellings in the vicinity of uranium deposits. These small passive and inexpensive detectors are convenient for making the long term measurements of alpha activity of indoor radon. LR- 115 type 2 film in this study was cut into 1.2* 1.2 cm pieces, numbered and attached with the tape on the bottom of a numbered plastic cup. These sampling cups were hung to living quarters of dwelling. After exposing for a month the films were collected and processed chemically. Etching conditions in this process are % 10 NaOH at 60 °C for 2 hours (2) using 25 ml etchant for each film (3) in a thermo-controlled water bath. The number of registered alpha tracks per film area is manually counted using an optical microscope. To avoid poor counting statistics on each film normally an area of 1 cm^2 is counted. After counting, the alpha track density was converted to units of Bq / m^3 radon. In our laboratory calibration 1 track/ mm^2 corresponds to an exposure of about 31.25 Bq/m^3

radon and its daughters during a month (4). The distribution of radon levels in this region is shown in figure 1.

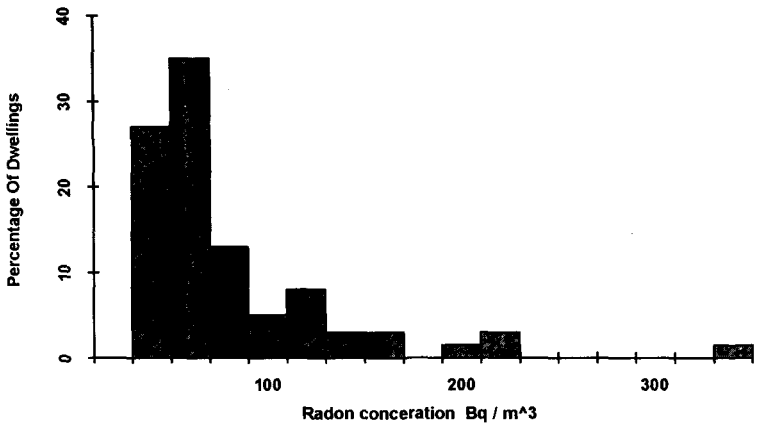

Figure 1. Radon consentration in Bq/m^3 according to persentage of dwellings

The results have indicated that the range of radon levels in this area is 20-340 Bq/m^3. The highest radon concentrations are observed in the stone buildings which were constructed with the material obtained from that area.

CONCLUSION

The survey of radon levels in Köprübaşı located in vicinity of uranium ore deposits indicated that a large persentage of the houses has Rn-222 concentrations below 100 Bq/m^3 as a small percentage of the dwellings is above 200 Bq/m^3. But these values are higher the correspoinding values for the dwellings in İzmir (4) in radioactive environmental programme of our Institute.

RADON CONCENTRATIONS IN TAIPEI METROPOLITAN RAILWAY STATION

Pao-Shan Weng and Che-Hui Hsu

Department of Nuclear Science
National Tsing Hua University
Hsinchu, Taiwan 300, R.O.C.

INTRODUCTION

For routine airborne radon monitoring, including use in field conditions, the technique based on electret ion chamber technology seems to be the most suitable choice in many applications (1). However, this simple and relatively inexpensive method has some specific drawbacks: poorer reproducibility at lower radon concentrations, some uncertainty in the use of manufacturer suggested gamma correction factors, and limited reusability (2).

A modified electret ion chamber method has been proposed (2), but it is mainly for water borne radon measurement. Therefore, we still applied the simple method recommended by the manufacturer to survey radon concentrations in Taipei Railway Station.

MATERIAL AND METHOD

Taipei City is the capital of Taiwan. Its metropolitan railway station was built with concrete elements, two stories underground, and equipped with mechanical ventilation system. The daily number of passengers is about 100,000, and during long weekend it may reach 300,000 per day.

Three types of instrument were used for a period of one-year survey between June 1994 and June 1995. For the radon survey the electret ion chamber was used with a commercial name of E-PERM. For the survey of radon progeny the electret ion chamber equipped with an air pump and filter system was used with a commercial name of E-RPISU. Since both instruments mentioned above cannot detect the instantaneous fluctuation in radon concentrations, a third instrument was added to the one-year monitoring program. It is a pulse type ion chamber equipped with temperature, barometric and humidity gauges (3). The ambient gamma exposure was measured with thermoluminescent dosimeters $CaSO_4$:Dy. All calibrations were performed inside a radon chamber installed at the Taiwan Radiation Monitoring Center.

RESULTS AND DISCUSSION

Radon concentrations at the platform which is located at second basement below the ground floor are shown in Fig.1 while those at the passengers' waiting area which is located at the first basement below ground floor are shown in Fig.2.

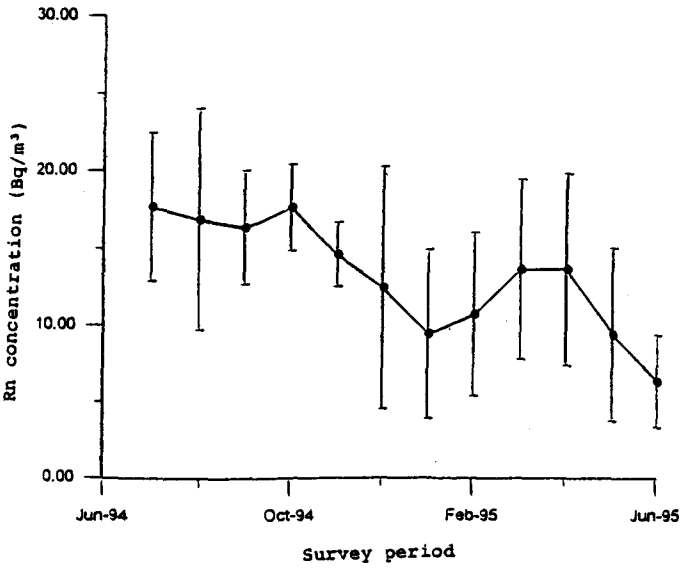

Fig.1 Yearly survey of ^{222}Rn concentrations at the platform.

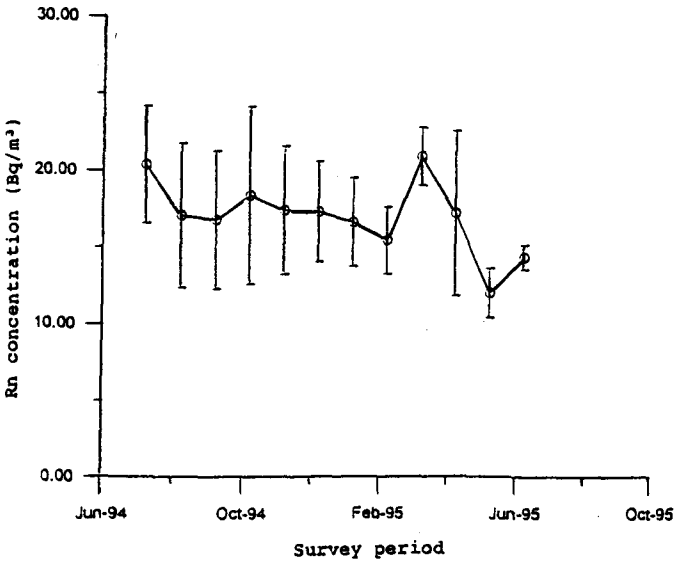

Fig.2 Yearly survey of ^{222}Rn concentrations at the waiting area.

The decrease in radon concentrations as a result of ventilation improvement can be seen in both Figs. 1 and 2. The equilibrium factors varied from 0.29 in hot and humid summer to 0.39 in cold winter with a yearly average of 0.35. The gamma background was rather low with an average energy of about 0.23 MeV.

The annual effective dose received by the Taipei Railway Station personnel is estimated to be about 87 uSv while the annual equivalent dose to lung is about 71 uSv.

ACKNOWLEDGMENTS

Financial support from the Atomic Energy Council of the Executive Yuan (Cabinet) is much appreciated.

BUILDING AND ENVIRONMENTAL FACTORS ASSOCIATED WITH ELEVATED RADON LEVELS IN KINDERGARTENS IN SLOVENIA

Janja Vaupotič[1], Ivan Kobal[1], Howard F. Nicholson[2], Burton C. Kross[2]

[1] "Jožef Stefan" Institute, Jamova 39, Ljubljana, Slovenia
[2] Institute for Rural & Environmental Health, 100 Oakdale Campus, Iowa City, Iowa, USA

INTRODUCTION

In the winter periods of 1990/91 and 1991/92, the 730 Slovenian kindergartens and play schools that together care for more than 66,000 children, instantaneous indoor radon concentrations were measured using alpha scintillation cells. In 528 (72%) of the kindergartens and play schools radon concentrations below 100 Bqm^{-3} were found. In 16 buildings (2.2%) the concentrations exceeded 800 Bqm^{-3} (1).

Parameters that can affect radon concentrations are geological location, structural characteristics, climate, building material, and the occupancy patterns within these buildings. However, the most important parameter affecting radon concentrations is source. Without source material, there can be no radon. In certain areas of Slovenia, uranium, radon's source material, is abundant (2).

Each building possesses its own dominant parameters for elevated radon concentrations. Sampling and evaluation provide the best opportunity for advising mitigation measures in buildings. New buildings can be constructed utilising radon resistant techniques. Possible building sites can be evaluated with soil testing for radon, and evaluation the porosity of the soil and drainage from the site.

METHODOLOGY

For radon measurements alpha scintillation technique (3) was applied. Grab samples were collected from one groundfloor playroom, closed overnight, at each building. At the same time a short questionnaire concerning construction characteristics and working regime was filled.

In an effort to further define the extent and possible centers of elevated radon concentrations Slovenia was divided into nine units (regions) on the basis of telephone codes and four geographic units for evaluation. The nine regions are: Ljubljana, Maribor, Celje, Kranj, Nova Gorica, Koper, Postojna, Novo mesto and Murska Sobota (1). The four geographic units are: Alps, Fore-Alps, Dinarides and Pannonian basin (4). For each unit the mean and median value was calculated. All analyses were performed using SAS (5) and SigmaStat (6) software packages.

RESULTS AND DISCUSSION

The distribution of radon concentrations in Slovene kindergartens is lognormal with a geometric mean of 58 Bqm^{-3} and geometric standard deviation of 2.5. Data from previous studies indicate that grab samples collected with alpha scintillation cells may over estimate continuos radon levels by as much as a factor of two (7), therefore the information presented here should be considered as the "worst case scenario".

The mean and median radon concentrations for four geographic units are plotted in Figure 1. The Alps (the Julian and Savinja Alps, Karavanke and Pohorje) occupy the northern part of Slovenia. The Julian and Savinja Alps are built predominantly of carbonate rocks, the Karavanken and Pohorje from metamorphic and volcanic rocks. The Fore-Alps occupy the

central part of Slovenia and are mostly built of clastic sediments. The Dinarides, a well known as "dinaric karst" region, represent southern parts of the country and are predominantly built of carbonates and flysch deposites. The Pannonian basin occupies the flat-lands and hilly regions in eastern Slovenia, built of alluvial deposit as sand, gravel and clay (4). Statistically significant differences were found between groups. The Dinaric unit was statistically different from both, the Pannonian basin and the Alpine unit, but did not vary statistically from Fore-Alps. A statistically significant difference existed between the Fore-Alps and the Pannonian basin, but no statistical difference existed between the Fore-Alps and Alps. There was no statistical difference between the Alps and the Pannonian basin.

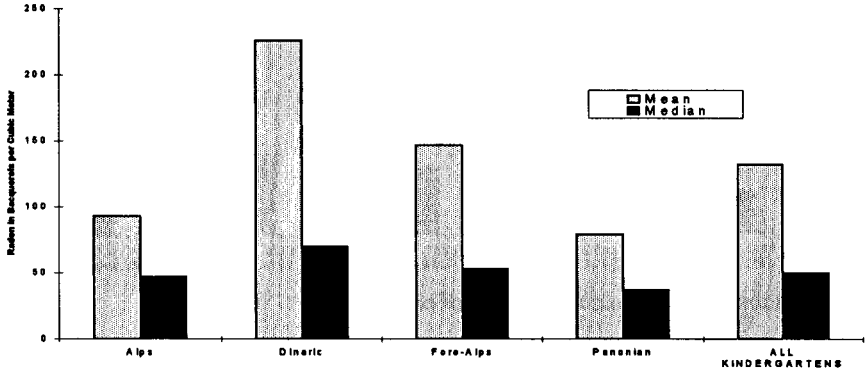

Figure 1. Mean and median radon levels in Slovene kindergartens by geographical regions

Radon concentrations in kindergartens within eight regions on the basis of telephone codes were below 200 Bqm^{-3} with an exception in Postojna region (the Dinarides), with the highest radon exposure risk.

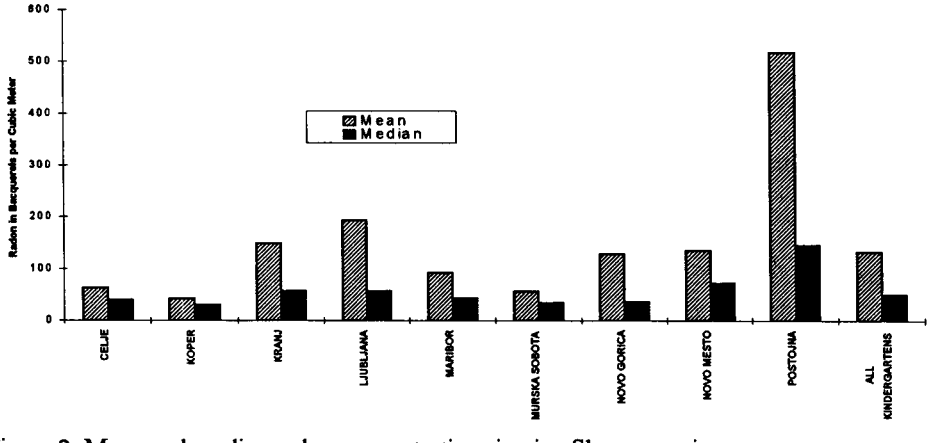

Figure 2. Mean and median radon concentrations in nine Slovene regions

The relationship between radon concentration and age of the building was looked but not found (Figure 3). The majority of the kindergartens are 20-30 years old single story buildings, built of bricks. In some older buildings, built of stone, higher radon levels were found and the mean reason was bad building construction. In years around 1960 fly ash bricks

were used as building material, but not extremely high radon levels in these buildings were found.

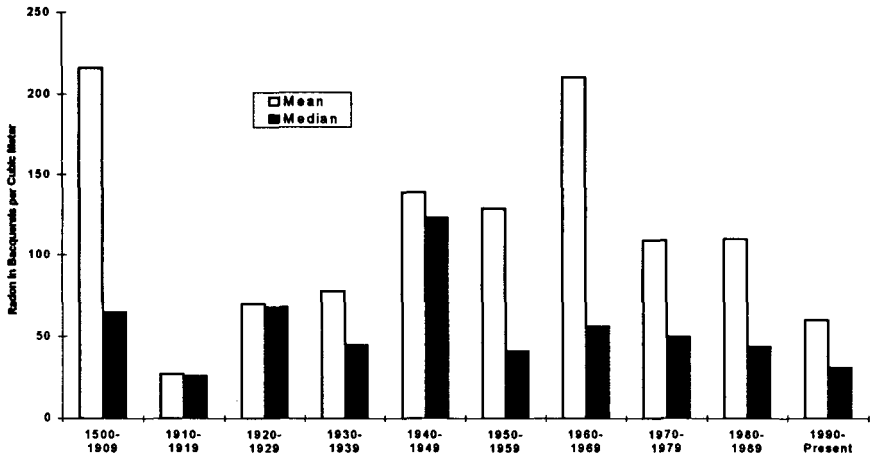

Figure 3. Mean radon levels in buildings by year of construction

CONCLUSIONS

What is important is that radon levels in Slovene kindergartens and play schools were evaluated using consistent techniques and conducted with trained personnel, so that proper evaluations could be made. Most important, all kindergartens and play schools were sampled for radon. Although geographic region, age, construction type and construction material can affect radon levels, sampling is the only technique which will determine actual radon levels within a particular building. Data from this study indicates that 5085 (7.68%) children attend a kindergartens and play school with radon levels which exceeded 400 Bqm^{-3}, the proposed Slovene Radon Action Level. 12,719 (19.2%) of kindergarten and play school children attended a kindergarten in which the radon level exceeded 150 Bqm^{-3}, the current US-EPA radon action level. In 16 buildings radon concentrations exceeded 800 Bqm^{-3}, affecting 1719 (2.59%) children (1).

Data from this study has been used to determine both need and method of mitigation in the buildings affected most by elevated radon levels. Mitigation has begun or been completed on five of the kindergartens effectively lowering radon concentrations to more acceptable levels.

MODELIZATION OF THE RADON EMANATION FROM NATURAL SOURCES IN THE SOIL

A.SABIR[1], H.MARAH[1], D.KLEIN[2], L.HLOU[1] and A.CHAMBAUDET[3]

1 Laboratoire de Physique Nucléaire Appliquée, Université IBN Tofail, Faculté des Sciences, Département de Physique, Kénitra Maroc.

Radon is a natural radioactive gas from the uranium family which is the main component of the annual natural radiation exposure of the population. It has been shown in several epidemiological studies that this gas, when inhaled, provokes lung cancer.
Part of the radon formed in the earth's crust can migrate to the atmosphere through cracks and fissures by transport mechanisms (diffusion and fluid convection). Different parameters such as the localisation of radon sources, the porosity, the humidity of the soil can influence this migration and therefore the radon emanation in the atmosphere.
To evaluate the radon emanation and hence the risk to populations, we have adapted an original mathematical model based on the method of distribute parcels (L.Hlou, These d'état, Faculté des Sciences, Kénitra, MAROC, 1994). This allows us to follow the migration, in time and space, of a quantity of radon produced in a unit volume as a function of the geological, morphological and structural characteristics of the site studied. Knowing the petrographic and pedologic parameters enables us to calculate the radon concentration in all points inside the soil of the site as well as the radon emanation in the atmosphere. It is therefore possible to calculate the radiological risk for populations brought to live on the site studied.
Different applications of this model have been realised in Morocco and in France to demonstrate its efficiency.

SOME INFLUENCING PARAMETERS OF THE RADON AND THORON DAUGHTERS CONCENTRATIONS IN DWELLINGS

Constantin Milu, Raluca Gheorghe

Institute of Hygiene, Public Health, Health Services and Management
Bucharest 35, Romania

INTRODUCTION

Man spents at least 60% of his life indoor and this fact imposes a careful investigation of his habitual environment. Indoor exposure rises up to 50% of the total radiation exposure of the public to natural sources (1).

It is also well known that inhalation of radon is the principal mechanism of human exposure to ionising radiation and that the exposure to high levels of radon short-lived decay products (radon daughters) is undesirable since it has been shown to cause lung cancer.

In Romania, during the 80's, several industrial wastes with high natural radioactivity have been used as building materials. At the same time, the energetic problems of those years obliged the population to a very drastically dwelling isolation in order to preserve the heat. These factors, in addition with other influencing parameters have been investigated.

METHOD

Measurements of indoor and outdoor radon and thoron daughters concentrations were performed in 119 Romanian dwellings, by air samping on a membrane filter, followed by repeated gross-alpha countings. Several constructive and physical parameters have been recorded: construction type (detached houses, block of flats), constructive solution design (brick work, prefabricated reinforced concrete), floor and room position, building materials used, heating systems, season, indoor and outdoor temperature, pressure and relative humidity, direction and speed of wind. Knowing the radon and thoron daughters concentrations, the Potential Alpha Energy Concentration (PAEC), the Equilibrium Equivalent Concentration (EEC), the equilibrium factor (F) and the effective dose for adults (ED) have been calculated.

RESULTS

The results obtained are presented in Tables 1,2 and 3.

Table 1. Dependence of the indoor Radon and Thoron daughter concentrations on constructive type, solutions and building materials

5th floor	0.67	SW-NE	14	12	760	749	60	56	NE	49.9	43.7	1.1	0.81
6th floor	0.20	NW-SE	16	12	760	760	80	77	SW	43.0	37.8	1.4	0.80

CONCLUSIONS

EEC (Rn) experimental values ranged from 3 to 130 Bq.m^3. The main determined influencing parameters were: ventilation rate, type of building material and indoor relative humidity. It was also pointed out that the contribution of the thoron daughters to the total ED is about 20% (2).

Radon measurements in the cave Vilenica P11-29

Peter Jovanovič, Institute of Occupational Safety, Ljubljana, Republic of Slovenia

Abstract
The cave Vilenica is about 1300 m long and 180 m deep. One third of the cave is open for the visitors. Radon and its daughter concentrations and also temperature and pressure have been measured at different times of the year and at different locations in the cave in order to estimate doses to visitors and guides. Radon concentrations ranging from few 100 Bqm^{-3} in the winter up to few 1000 Bqm^{-3} in the summer months. The dose rate for visitors and guides is 10 to 40 μSv/h, depends from the radon concentration.

1. Introduction

The Vilenica cave is situated near the town Sežana in the middle of the typical karst and it's probably the oldest show cave in Europe. First tourists visited the cave in the year 1633. Total length of the galleries is 1300 m. The part arranged for tourists is one gallery 450 m long and 94 m deep. Other part of the cave is accessible only to cave explorers with special equipment.

The Vilenica cave is one of caves, where a speleotherapy (1,2) will start in near future. Speleotherapy is a special kind of climatotherapy and is being used as an additional treatment for curing bronchial and asthmatic diseases of children and adults in last 40 years in many countries in Europe.

The objectives of this measurements are (i) to determine the physical parameters of the cave microclimate, important for the speleotherapy and (ii) to determine radon and progeny concentrations for dose estimation.

2. Methods

In the period from January to December 1995 monthly measurements of different parameters on the route for visitors have been investigated. Relative humidity, temperature and air flow were measured by standard digital devices. Concentrations of positive and negative ions were measured by ionometer Shomandl with the accuracy of about 10 %. Concentrations of different gases were measured by Dröger tubes. Radon and progeny concentrations were performed by radon gas monitor RGA-40 and working level monitor WLM-30 from Scintrex, Canada. Radon concentrations were measured also by track each detectors and charcoal canisters. Duration of measurements was three days for radon and progeny, measured by devices or charcoal canisters and one month or more by track detectors. All measurements were made in the middle of the cave at one place, "near the water", except radon concentrations, which were measured at 9 different places.

The visiting part of the cave has two different temperature regimes, first part about 200 m long with stronger influence of meteorological parameters from outside, where temperature changes throughout the year for few degree Celsius and second part about 250 m long with nearly the same temperature of 10 °C in all periods of the year. From September to December air velocities and temperature at 5 different places were measured, two in first and three in second part of the cave. The volume of the cave is about 200000 m^3, of the second part about 120000 m^3.

3. Results

Measurements of microclimatic parameters showed us no content of ozone, sulphur dioxide, nitrate, fluoride and carbon monoxide in cave. Only carbon dioxide was detected, its concentrations were in the range of 0.05 vol % to 0.4 vol %. Temperature in the first part of the cave changed from 2 °C to 10 °C, at the point, where second part started (temperature point) was between 7 °C and 10 °C, and at the lowest part, accessible for visitors, varied from 10,5 °C to 12 °C. Air pressure was changing in a measuring period for few millibar (3-7 millibar), only in December first decreased for 6 millibar and then increased for 15 millibar. Temperature on all places slowly increased with hight. On the bottom of the Hall of the Faires is a small entrance (1m^2) in a Fabris cave. Air flow at this place is obout 30 m^3/h. Only in December changes in air velocities from 0.01- 0.08 ms^{-1} were found. It was like a breathing with a period of 30 s.

In summer months we can suppose air velocities of 0.01 ms^{-1} or less on all places in the cave. In December was air velocity at the place "temperature point" in the range of 0.03-0.1 ms^{-1} and at the entrance between 0.2-0.3 ms^{-1}. If we assume effective cross section at the temperature point of 50 m^2, air flow in summer was 2000 m^3h^{-1} and ventilation rate was less then 0.01 h^{-1}. Calculated air flow and ventilation rate in December were between 6000-10000 m^3h^{-1} and 0.03-0.1 h^{-1}, respectively.

The effective cross section at the entrance is about 20 m^2. Air flow and ventilation rate in summer were the same like at the temperature point, in December air flow was between 10000-15000 m^3h^{-1} and ventilation rate in range form 0.05-0.1 h^{-1}. If we take into account equation from Wilkening and Watkins (3), $Q = \lambda V(C_{max}-C)/C$, and insert values

for radon concentrations, we obtain for air flow in December at the temperature point and at the entrance the value of 9000 m^3h^{-1} and 11000 m^3h^{-1}, respectively. Results are in good agreement with measured values of air flow.

Concentrations of positive ions were changing from 3000-11000 per cm^3 and negative ions from 3000-9000 per cm^3. The difference between concentrations of positive and negative ions was higher by higher radon concentrations.

Radon concentrations at different places in the cave were nearly the same in different measuring periods (Fig. 1), except at the place The dance Hall. This is a very big hall on the entrance in the cave. We didn't measure radon concentration in the hall but in small crack (about 30 cm^2). We suppose the crack lids to a big unknown hall with higher radon concentrations.

10 Annual average

Fig. 1. Radon concentrations in the Vilenica cave in the period Jan - Dec 1995

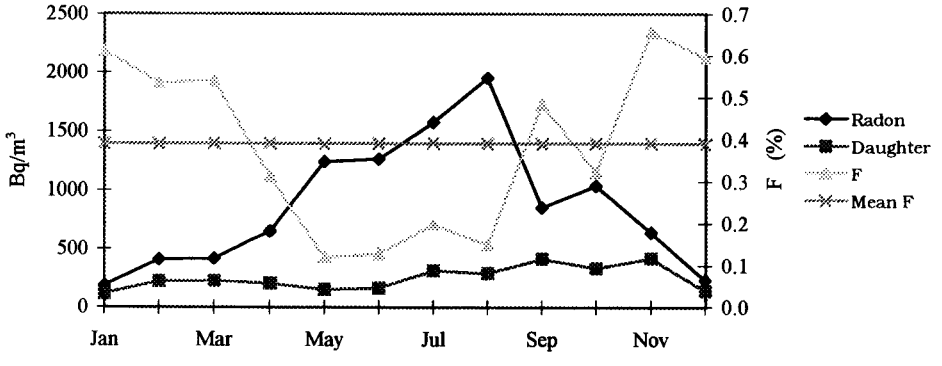

Fig. 2. Monthly radon and daughter concentrations and equilibrium factor in Vilenica cave at the place near the water

Higher values were measured on the bottom of the Hall of the Faires, where radon cames through the small entrance from the Fabris cave. This is a big cave with higher content of clay and higher temperature. This are main reasons for higher radon concentrations on the bottom of the cave, accessible for visitors, which has no clay only washed limestone. Radon concentrations at these place were 20-50 % higher then on other measuring places, depends from the period of the year. We suppose this is a main radon source.

Radon concentrations in cave were higher in summer then in winter, mean value was 980 Bqm^{-3}. The lowest values were in December and January. In first and last months of the year the wetter was changing, measured radon concentrations at different times could be different form presented values. In September it was very cold wetter in the time of measurements (less than 10 °C), what is a reason for lower radon concentrations. Radon concentrations in cave increased from January to August, and then decreased from September to December, like mean outdoor temperature. Different temperature gradient between the cave air and outdoor air produced higher or lower ventilation rate.

On the Figure 2 radon and daughter concentrations at the place "near the water" are presented. Radon progeny concentrations were nearly the same in the first half of the year, then increased about two times from July to November and then sharply decreased in December. Equilibrium factor between radon and daughter was about 4 times lower in summer then in winter months.

The measurements which have been made in Postojna cave (4) showed very low aerosol concentrations, between 2000-4000 per cm^3. The activity median aerodynamic diameter AMAD was 250 nm (σ_g=1.6). A quite high activity fraction (30%) was found in the nucleation size range between 4 and 80 nm. Unattached fraction f_p was between 10 and 15 %.

We didn't measure aerosol size distribution and unattached fraction in different periods of the year, but we suppose that in winter time fresh air brings more aerosols from outside into the cave. Because of higher ventilation rate in winter time the air in the cave is mixing faster and more radon decay products can claimed with aerosols what produces higher equilibrium between radon and progeny. This explains differences in equilibrium between radon and daughters; we will prove it with measurements next year.

4. Dose estimates

Our dose calculation based on three different models, ICRP 50 (5,6), Jacobi-Eisfeld (J-E) and James-Birchall (J-B). For AMAD and unattached fraction we take into account values from Postojna cave, fp=0.1 and AMAD 0.2 μm. The dose rate is 10 to 40 μSv/h, depends from the radon concentration. If we suppose 1000 to 2000 working hours per year and mean progeny concentration of 250 mWL, annual dose is about 20 mSv from J-E and 30 mSv from J-B model. If we suppose new dose convention 5 mSv/WLM, annual dose lies between 10-15 mSv.

In future we will measure unattached fraction and aerosol size distribution of radon daughters, for more precisely dose estimation and for understanding the differences in equilibrium factor.

RADON SURVEY IN KUWAIT HOUSES

H. Bem[1], T. Domański[2], Y.Y. Bakir[3] and S. Al-Zenki[3]

[1]Technical University of Lodz, 90-924 Lodz, Poland
[2]Institute of Occupational Medicine, 90-950 Lodz, Poland
[3]Radiation Protection Department, Ministry of Health, Kuwait

INTRODUCTION

Measurement of indoor radon levels in Kuwait houses is part of a project undertaken to estimate the average annual effective doses from different sources for Kuwait population. It is known that airborne ^{222}Rn in houses is a major contributor to this value (1). Among common sources of radon in dwellings, geological factors may play important role. Kuwait is situated on the northern coastal area of the Arabian Gulf. From geological point of view its surface soil is relatively uniform - desert type with prevailing smooth sand sheets with relatively low uranium and radium concentrations (2). The first pilot study of indoor Rn concentration showed surprisingly relative high concentrations with mean values above 40 $Bq \cdot m^{-3}$ (3). In this study results of a survey of indoor radon in 150 houses in different parts of Kuwait over summer period are presented. Among many methods developed for indoor radon measurement, the method using vials with activated charcoal adsorbant and liquid scintillation counting proved to be very reliable and especially useful for large scale surveillance (4) and therefore this method has been applied in this survey.

METHODS

Commercially available plastic liquid scintillation vials with charcoal PICORAD were purchased from Packard. In each household two vials were exposed in the slepping rooms for a standard time of 48 hr. The returned vials (within 1 to 7 days after the end of exposition) were eluted with 10 ml of liquid scintillation cocktail (5 g/1 PPO; 0.3 g/l POPOP in xylene plus 10 % of methanol) and after at least 8 hrs (to reach the maximal elution of Rn from charcoal to a scintillator) were measured in liquid scintillation counter Packard 2550 TR/AB for one hour in the channel 25-900 keV. Concentrations of Rn were calculated from the following formula:

$$C_{Rn} = K_1 \, I \, [1-\exp(-k_2 \, t_e)]^{-1} \, [\exp(-\lambda \, t_d)]^{-1}$$

where: K_1 - is the normalization constant that converts net counts per minute I to $Bq \cdot m^{-3}$,
K_2 - absorption constant,
λ - radioactive decay constant for ^{222}Rn,
t_e - exposure time in hrs,
t_d - delay time, which elapsed from the end of exposition to the start of counting.

The K_1 and K_2 constants were experimentally determined by exposure of vials for different times in the radon experimental chamber with constant radon concentrations, determined by scintillation detector REX-013. The: Lower Limit of Detection" (LLD), i.e. the lowest measurable concentration for used method with the confidence level α=0.95 has been achieved as 1.4 $Bq \cdot m^{-3}$ for the standard duration of exposure 48 hours and delay period 24 hours.

The arithmetic mean from two vials was taken for calculation of Rn concentrations. Usually deviation between two vials was below 30 % of the mean value, showing good reproducibility.

All experimental results for 150 houses were divided to the three groups: those for the ground and first floors, for higher floors (above first floor) and total results without distinction of the floors.

It has been found that obtained results very well correspond to lognormal distribution with parameters given in the Table 1.

Table 1. Parameters of lognormal distribution of ^{222}Rn concentrations in Kuwait houses.

Parameter of Study	Value of Parameter		
	Ground Floor & First Floor Above Ground	Higher Floors	All Flats Together
Number of Flats	89	61	150
Arithmetic Mean ($Bq \cdot m^{-3}$)	13.9	14.2	14.0
Arithmetic Standard Deviation ($Bq \cdot m^{-3}$)	16.7	9.0	14.0
Median ($Bq \cdot m^{-3}$)	10.1	11.4	10.6
Mode ($Bq \cdot m^{-3}$)	5.8	6.6	6.1
Geometric Standard Deviation (Dimentionless)	0.74	0.74	0.74
Minimum value of Concentration ($Bq \cdot m^{-3}$)	1.95	3.95	0.67
Maximum value of Concentration ($Bq \cdot m^{-3}$)	119.2	45.4	119.2

DISCUSSION

It is evident from the Table 1 that the average values (arithmetic and geometric) are well below the previously published values of 40 $Bq \cdot m^{-3}$ (3) and below the word average value also being equal to 40 $Bq \cdot m^{-3}$. However, this data well correspond to those for similar climatic and geological conditions, for example, for Cyprus (6). No significant differences have found for the two lowest floor flats and the flats from higher levels. It confirms the fact that radon entry from subjacent earth with low ^{222}Ra concentration is not a limiting factor.

The average concentration which has been found (14.0 $Bq \cdot m^{-3}$) corresponds to the average annual effective dose equal to 0.246 mSv if the average effective equilibrium factor (Rn daughters/Rn) F_{eff}=0.4 would be assumed. If the real effective equilibrium in Kuwaiti houses would be different, e.g.

F_{eff}=0.3 or 0.6, then the average annual effective dose should be respectively modified, i.e. proportionally changed. Therefore, the 'radon component' of the average annual effective dose for population of Kuwait, mentioned above, should be recognised as the provisional, temporary value until the study of average effective annual equilibrium factor would be conduced.

However, it should be recognised that the average radon concentration and the average annual effective dose relevant to that concentration is smaller than the analogical components evaluated for European countries where they lie between 1.0 mSv (for UK) and 6.4 mSv (for Finland).

Even if the effective equilibrium in Kuwaiti houses would be much higher than it has been assumed, i.e. F=0.8 against F=0.4 (assumed), then the relevant average annual effective dose would be higher, i.e. ~0.500 mSv instead 0.246. However, even that value (0.500 mSv) still remains much lower than mentioned values found for European countries.

Nevertheless, the separate regular study of reasons of relatively low concentrations of radon in Kuwaiti houses as well as study of effective equilibrium factor seems to very desirable.

INDOOR RADON LEVELS IN A PUBLIC SCHOOL AND SOME DWELLINGS FROM THE VILLAGE OF TEIÀ, CATALONIA (SPAIN).

C. Baixeras, Ll. Font, F. Fernández, C. Domingo

Grup de Física de les Radiacions. Universitat Autònoma de Barcelona, Spain

INTRODUCTION

The radiation dose from inhaled decay products of radon (^{222}Rn) is the dominant component of radiation exposure of the general population (1). Due to the fact that children are more sensitive to radiation than adults, it is of interest to determine the indoor radon levels at which they are exposed. The determination of radon levels in schools is important because children spend there an important fraction of their time. In this paper we present the indoor radon levels measured in a public school and in some of the houses where pupils inhabit. This study was carried out during winter in the village of Teià,, situated at 20 km far from Barcelona, which has only one public school and where the soil is composed mainly of granite rock. Moreover, an estimation of the upper limit of the annual effective radiation dose received by pupils is given.

EXPERIMENTAL METHOD

Indoor radon levels were measured with closed type dosimeters based on Makrofol ED etched track detector. The dosimeter consists of a hemispherical cup (internal radius r = 1.5 cm) of electrically conductive material as a diffusion chamber with a fibreglass filter, where all aerosol and radon daughters solid products are deposited. Therefore, only radon gas can diffuse through the filter. Makrofol foils are covered with aluminised Mylar. The dosimeters were exposed for 3 months in the period November 94 - February 95 and after collecting them, the detectors were etched electrochemically. The etching conditions for the Makrofol ED foils were obtained in a previous study which accounted for the diffusion chamber size (2). The optimal etching conditions found were: (a) chemical etching for 4 h, and (b) electrochemical etching (frequency: 3kHz, voltage: 1000 V_{rms}) for 1.5 h, at 40°C, using a mixture of 50% 6N KOH and 50% ethanol as etching solution. Tracks registered in exposed foils were counted in a 0.97 cm^2 surface area using a semiautomatic track density counting system set up in our laboratory (3). The sensitivity of the dosimeters was obtained by exposing several sets of dosimeters in the Radon Environmental Chamber at the National Radiological Protection Board (NRPB) Chilton Laboratory. The value of the sensitivity corresponding to the optimal etching conditions is (0.89±0.08) tracks.cm^{-2}/kBqm^{-3}h (4). The reliability of the dosimeter calibration was checked in an European Intercomparison Exercise (5) . Background track density of Makrofol ED plates is 7 ± 2 cm^{-2} . The Radon Minimum Detectable Concentration (MDC) was calculated using the Currie (6) relations for well known background (7) and its value is 4 Bqm^{-3} for a 3 month exposure.

DISTRIBUTION OF DOSIMETERS

In the village of Teià, there are two types of houses: those situated in the village centre and those placed in the residential area, where the school is built. Multiapartment dwellings almost do not exist. The school staff placed 10 dosimeters in the school building, distributed in ten classrooms, five from the ground floor and five from the first floor. In addition, 15 pupils were selected to collaborate in the study by placing two dosimeters in their homes: one in the living area and the other one in their bedroom. A questionnaire was handed out together with the dosimeters in order to collect various physical features of the dwelling and of the life style of the occupants. As a result of the small size of the study, there were no dosimeters lost and only 2 questionnaires were missing.

The distribution of the dosimeters is shown in table 1.

Table 1. Distribution of the dosimeters

	Houses	Dosimeters			
		Total	Living area	Bedroom	Other
Residential area	7	14	6(1)	6(1)	
Village	8	16	7(1)	7(1)	
School		10			10 (classrooms)

(1) We do not know the placement of 4 dosimeters due to the two questionnaires lost.

RESULTS

Table 2 shows the results obtained in the residential area, in the village and in the school. These results indicate that radon levels in the school are similar to those corresponding to the houses where pupils inhabit and thus, the fact of going to school does not affect the radon levels at which pupils are exposed to. Even though the number of data is small, the indoor radon levels obtained are similar to those measured in a previous winter survey carried out in the Barcelona area (50 Bqm^{-3}) (4), and also to the world arithmetic mean value (40 Bqm^{-3}) given in the UNSCEAR 1993 report (1).

Table 2 Results of indoor radon measurements in the period November 94 - February 95

	Range	**AM**	**GM**	**GSD**	**n**
Residential area	19 - 94	46	41	1.68	14
Village	8 - 126	52	37	2.53	16
School	20 - 95	48	43	1.66	10

Radon concentration values are given in Bqm^{-3}

AM: arithmetic mean; **GM**: geometric mean; **GSD**: geometric standard deviation; **n**: number of dosimeters

In addition to the dosimeters distributed in living areas and bedrooms, one dosimeter was placed in the basement of a village house. The radon concentration obtained there was 198 Bqm^{-3}, higher than all the other values found in living areas and bedrooms. This result can be a consequence of the lack of ventilation of the basement and also of the fact that the room is in direct contact with the granite soil, typical of this region. Moreover, the radon concentration values obtained in the ground floor of the

school building are higher than those obtained in the first floor (arithmetic means 61 and 46 Bqm^{-3}, respectively) confirming the soil as the most important radon source.

The results obtained constitute an upper limit to the indoor radon concentration annual average because radon measurements were performed in winter season when windows are kept mostly closed. Previous studies carried out in Barcelona confirm that winter concentrations are higher than summer concentrations (4). Thus, the estimation of the radiation dose from our results leads to an upper value for the annual dose that pupils receive. The effective dose was estimated for each pupil using the conversion factor given in the last UNSCEAR report (1) (3.6 nSv per $Bqm^{-3}h$ of radon exposure) considering an indoor occupational factor of 0.8 and assuming that pupils spend 5 hours at school , 10 in the bedroom and 4.2 in the living area. The mean value obtained was 1.2 mSv and the range 0.5 - 2.2 mSv. These values constitute an upper limit of the annual effective dose and are similar to the mean world values (1).

CONCLUSIONS

The indoor radon concentration values obtained in the public school of Teià and in 15 houses where pupils inhabit are similar and comparable to the mean world values.

An upper value of annual effective dose was estimated for each pupil taking into account the school, bedroom and living area radon levels and occupational pattern. The arithmetic mean was 1.2 mSv and the range 0.5 - 2.2 mSv.

ACKNOWLEDGEMENTS

This study was supported in part by the Spanish Consejo de Seguridad Nuclear.

The authors gratefully acknowledge the school management and teaching staff and the pupil families for their collaboration in the study.

Special thanks are given to Ms. Fermina Pérez for her help to carry out this work.

A PORTABLE APPARATUS FOR CONTINUOUSLY MEASURING Rn-222 EXHALATION FROM GROUND

Osamu Ariyada, Tatsuo Tanji, Michio Okino, and Sadamu Mochizuki

Muroran Institute of Technology, Muroran 050, Japan

INTRODUCTION

For the purpose of continuously measuring the rate of ^{222}Rn exhalation from the ground surface, an apparatus has been developed that consists of a radon collector, a 60-*l* cylindrical buffer tank, three kinds of filter and an ionization chamber of flow-through type.

The apparatus is capable of providing an evaluation of the ^{222}Rn exhalation rate that is sufficiently accurate for all practical purpose.

MEATHOD OF MEASUREMENT AND STRUCTURE OF APPARATUS

The means adopted for measuring the exhalation rate of ^{222}Rn, is an improved version of Wilkining's method.[1][2] The ^{222}Rn collector is of structure and dimensions as shown in Fig.1.

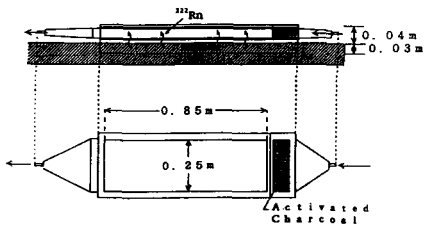

Fig. 1 Device for collecting ^{222}Rn exhalation

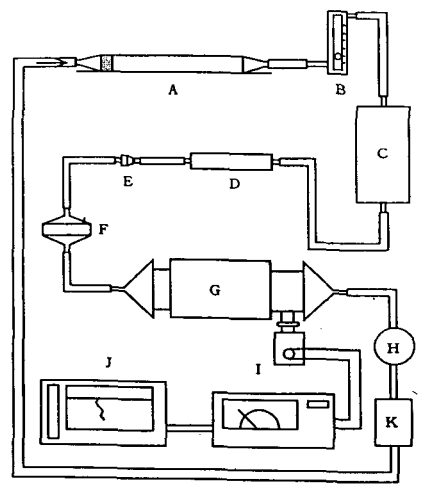
The measuring system is arranged as schematized in Fig.2. The ionization chamber(G in Fig.2) is cylindrical aspiration condenser with inner and outer cylinders measuring respectively 0.05 m and 0.2 m in diameter and 0.45 m in common length. The outer cylinder is maintained at a potential of -1 080 volts. The vibrating reed electrometer (I) is used to measure the ionization current.

The measurement proceeds with the respective components functioning in the following manner: The ^{222}Rn collector is placed on the ground to be measured: the sampling air is adjusted to flow at 6 *l*/min, which is a rate that will not let the radon exhaled from ground be forcibly entrained; this sam pling air contained ^{222}Rn and ^{220}Rn is then passed into the 60-*l* buffer tank(C) to eliminate ^{220}Rn, whose half-life is only 54.5 s and thus decays away during its stay in the buffer tank. Further downstream, before attaining the ionization chamber(G), the sampling airpasses through the silica gel desicator(D), the glass fiber filter(E) for eliminating the daughter nuclides of ^{222}Rn and ^{220}Rn, and the ion trap(F) for removing ions generated in the channels of the system by the radiations from ^{222}Rn and ^{220}Rn, as well from their daughter nuclides. The ionization current measured by the electrometer(I) is continuously recorded in analogical form, to be converted off-line into ^{222}Rn concentration byconsulting a calibration table, and the resulting data are then used for calculating the ^{222}Rn exhalation rate, asdescribed in the next section.



A: Radon collector, B: Flow meter, C: Buffer tank (60-*l* capacity), D: Silica gel desicator, E: Glass fiber filter, F: Ion trap, G: Ionization chamber, H: Pump, I: Electrometer, J: Recorder, K: Charcoal bed

Fig. 2 Arrangement of apparatus for measuring ionization current generated by ^{222}Rn exhalation from ground

DERIVING THE ^{222}Rn EXHALATION RATE FROM THE MEASURED IONIZATION CURRENT

For determining the relation between the measured ionization current and the concentration of entrained ^{222}Rn flowing through the ionization chamber, calibration measurements were made on radon gas exhaled from samples of sandy rock used for extracting titanium, containing in average 4 900 Bq/kg of ^{226}Ra.

Before proceeding on a calibration measurement, the initial zero point of ionization current was determined using Miranda's charcoal trap method.[3] Thereafter, the calibration proceeded as follows: Place a suitable quantity of the sandy rock sample in a spare 60-*l* tank; connect this tank and the ^{222}Rn collector(A in Fig.2) to the system; close off the system and leave it standing until establishment of radioactive equilibrium in the tank between radon and its daughter nuclides, with ^{220}Rn decay away; start up the pump(H) to circulate the sampling air through the system, and let system as a whole; adjust the pump speed to obtain a flow rate of 6 *l*/min; while continuing to circulate the sampling at this rate through the system, measure the ^{222}Rn concentration in the tank, applying Thomas' two-filter method;[4] plot the measured ^{222}Rn concentration against the corresponding reading of ionization current on the electrometer(I) to obtain a calibration plot; repeat this calibration measurement with the quantity of sandy rock parametrically varied, to gen-erate the calibration curve.

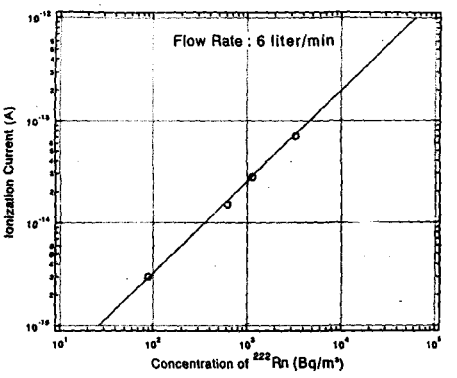


Fig. 3 Calibration plots relating measured ionization current to ^{222}Rn concentration

The calibration curve thus obtained is shown in Fig.3, relating the ionization current to the ^{222}Rn in the sampling air flowing through the ionization chamber at 6 *l*/min. Using the values of ^{222}Rn concentration determined by means of this calibration curve, the exhalation rate is calculated with the equation

$$E = C_{Rn} V_s / S$$

where E : Exhalation rate (Bq/m^{2}s)
C_{Rn}: Radon concentration (Bq/m^3)
V_s : Flow rate of sample air (m^3/s)
S : Covering area by collector (m^2).

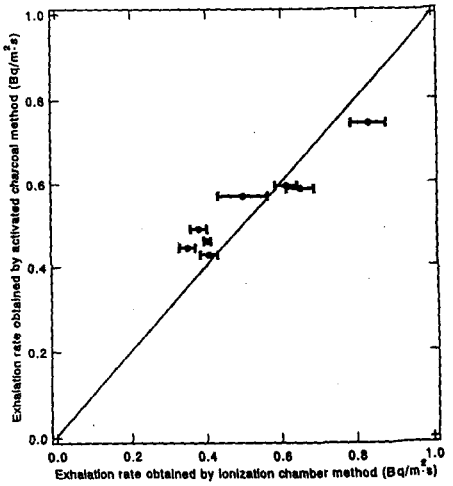

Fig. 4 Measured values of ^{222}Rn exhalation compared between present method and that using activated charcoal

COMPARISON BETWEEN VALUES OBTAINED WITH THE PRESENT AND WITH OTHER METHODS

The accuracy of measured values with the present method was evaluated through comparative measurements with corresponding values obtained using Megumi's activated charcoal method,[5] adopting as common sample parametrically varied quantities of river sand (for its uniformity of grain size) placed in a wooden box measuring 2 m x 2 m x 2 m. The measurements were performed inside a shed, to eliminate wind and other environmental effects.

The results obtained from the comparative measurements are plotted in Fig.4, from which a correlation coefficient of 0.91 has been derived. The plots of Fig.4 indicate a higher range of exhalation rate given by the ionization chamber compared with those by activated charcoal method.

OPERATING CHARACTERISTICS

The operating characteristics of this apparatus were determined from long-duration observations performed on the apparatus at different sites.

An example of the continuous record of exhalation rate is shown with atmospheric pressure and weather con-

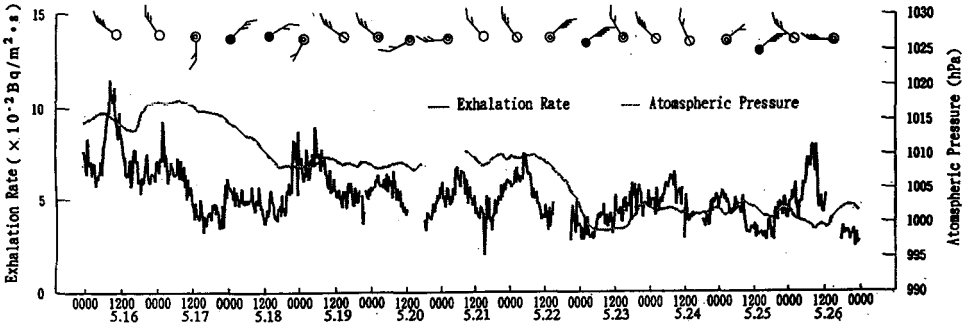

Fig. 5 An example of continuous record of exhalation rate.

ditions in Fig.5. From the observations it was confirmed that the apparatus operates stably in a period of long-duration and even in stormy weather.

CONCLUDING REMARKS

The basic experiments described above, substantiated by performance obtained in practical application in different sites, have yielded the following informations:

(1) The apparatus is capable of continuously recording measured data that provide an evaluation of ^{222}Rn exhalation rate with sufficient accuracy for all practical purposes.

(2) The apparatus operates stably even in stormy weather, and impairment of evaluation accuracy can be expected to be minimized, once a suitable formula -now being sought- is found for taking account of the difference between collector interior and ambient exterior brought by the storm in respect of such factors as the ground conditions, wind and air flow speed.

RADON EXPOSURE OF PASSENGERS IN THE PRAGUE METRO

Jozef Sabol

Czech Technical University, Faculty of Nuclear Sciences & Physical Engineering
115 19 Prague, Břehová 7, Czech Republic

INTRODUCTION

Although the world-wide average annual effective dose from natural sources is 2.4 mSv, in some locations and under some conditions elevated values up to 10 or 20 mSv may be encountered.[1] The additional contributions depend strongly on human activities and practices and show therefore enormous fluctuations. This is especially true with regards to the doses from indoor inhalation of the short-lived decay products of radon gas which are influenced by local geology, building design, and by building or surrounding materials as well as air ventilation. Generally, closed or poorly ventilated enclosures, such as cellars, tunnels, mines and other subterranean areas, are characterised by increased radon concentrations.

Of the three naturally occurring radioactive radon isotopes, namely ^{219}Rn (actinon), ^{220}Rn (thoron) and ^{222}Rn (commonly referred to simply as radon), the last one, owing to its relatively long half-life (3.824 d), is the most significant for human exposure.[2,3] The production of ^{222}Rn in the terrestrial materials depends on the activity concentration of its parent nuclide ^{226}Ra, a member of the ^{238}U series.

It is well known that radon-related exposures are actually almost entirely caused by the inhalation of their decay products rather than by the inhalation of radon gas itself. Consequently, from the radiological point of view, information concerning the concentration of radon decay products is of primary importance because it can be interpreted in terms of the appropriate radiation protection quantity, i.e., the effective dose. Since the quantity usually monitored is radon gas concentration (C_{Rn}), the parameter *EECR* (equilibrium equivalent concentration of radon) is commonly obtained using the equilibrium factor (F) which is defined as the ratio of *EECR* and C_{Rn}. Generally, the equilibrium factor is taken to be 0.4 for indoor exposure and 0.8 for outdoor exposure. For more accurate evaluation the factor F has to be derived from simultaneous measurements of both radon concentration and concentrations of its decay products. In intensively ventilated objects, the equilibrium factor may often be below 0.4.

CHARACTERISTICS OF THE PRAGUE METRO

The Prague Metro[4], whose first section between the *Florenc* and *Kačerov* stations was opened in 1974, is the most important public transport system in the capital of the Czech Republic now serving more than 1.2 million commuters each day. This share represents about 44% of all passengers using all Prague mass transport systems. At present, the Metro network consists of three lines A, B and C, with a total rail length of 45.1 km and 46 stations altogether. The busiest line is line C (42%), followed by line A (38%), while line B transports about 20% of all persons using the Metro which operates daily from 5:00 AM to midnight.

Some further characteristics of the Prague Metro network are illustrated in Fig. 1, which shows the depth profiles of individual lines and positions of the stations. The deepest station is station *Nám. míru*, 52 m below ground level. On the other hand, the deepest location in the tunnels is between the stations *Hradčanská* and *Malostranská*, about 68 m below the ground. As to the absolute value related to sea level, the lowest place is in the tunnel of line A beneath the River Vltava (about 19 m below its bed).

The inner spaces of tunnels, stations and other Metro areas are built using reinforced concrete, prefabricates and steel, and they are tiled with natural materials and, in some places, with marble or aluminium plates. These materials provide essentially a water-tight encasement for all inside areas. The Metro is intensively ventilated by means of powerful blowers and fans; the piston effect of the moving trains also contributes to the air exchange. The ventilation rate is typically 3-4 h^{-1}; the highest rate is in line C where the air in all underground areas is completely exchanged 6 times each hour.

INSTRUMENTATION

Radon measurements were carried out using AlphaGUARD[5], a portable radon monitor using an ionisation chamber with an active detection volume of 0.56 L. In order to overcome problems with long-tail output pulses as well as microphonic artefacts, this instrument uses a special digital signal processing technique. The pulses are counted, stored and converted into the corresponding radon concentration whereas 1 cpm corresponds to 20 Bq m^{-3}. One of two sampling intervals, 10 or 60 minute, can be selected. The data capacity of a non-volatile memory is 20 days at 10 min sampling or 4 months at 60 minute measuring intervals. The instrument can work

continuously for at least 10 days with an internal rechargeable battery. The monitor is suitable for continuous monitoring of ^{222}Rn concentrations covering the range from 2 Bq m^{-3} up to 2 MBq m^{-3}. The sensitivity for ^{220}Rn is only about 5% of that for ^{222}Rn.

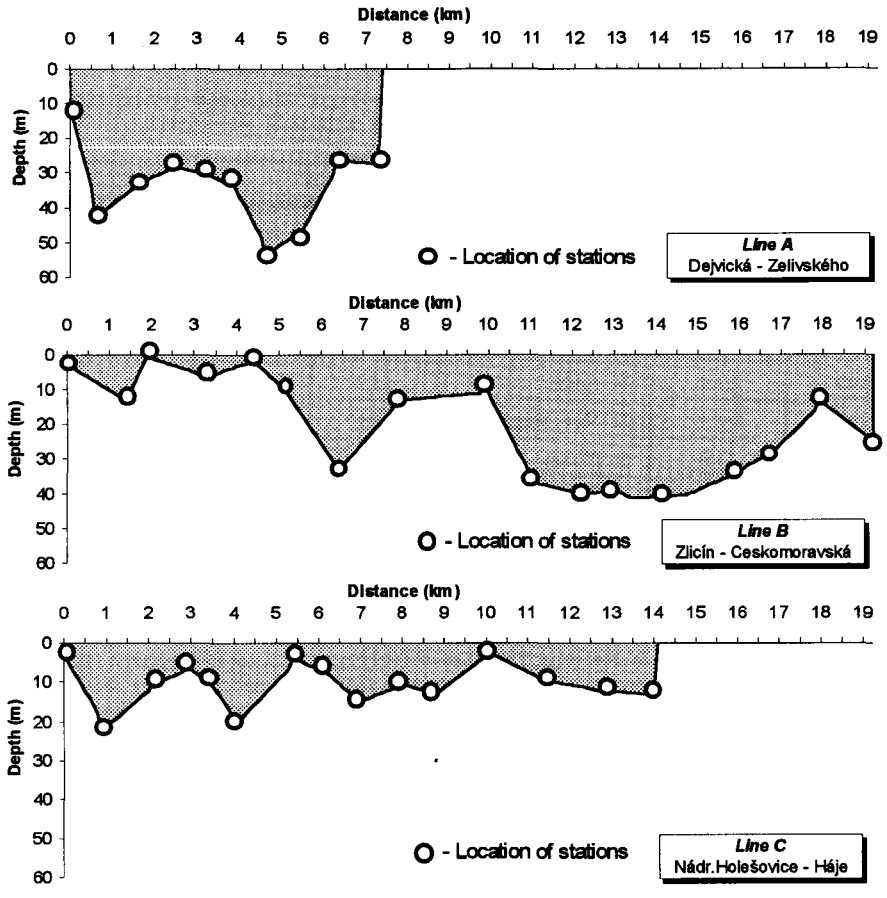

Fig. 1. Some characteristics of the Prague Metro (the distance, depth and position of the stations).

In addition to radon concentration in the air, this radon monitor at the same time also measures and records ambient temperature, relative humidity and atmospheric pressure. By combining simultaneous monitoring of the radon level and these associated environmental parameters, some interesting correlations can be observed..

The measuring results may be seen on a 2 line x 20 character alphanumeric display indicating the current values of all parameters. The data from the monitor can be transferred through the RS-232 output to a PC, where they are presented in the form of diagrams and can be evaluated further. These operations are performed by means of the available company software for the analysis of multiple parameters.

RESULTS AND DISCUSSION

The measurements of both airborne radon concentrations and gamma dose rate were carried out in the period of January - May 1995. The results of monitoring in the trains and the selected stations are summarised in Table 1 showing radon and gamma radiation levels given in appropriate units. Special attention has been

paid to line A which has several stations and tunnel sections at the greatest depth positions below the ground surface (Fig. 1).

Most of the measurements presented in this survey took 2-7 days and were carried out in winter 1994/95. The results given in Table 1 may be considered representative although some small variations may be expected in comparison to the average for the whole year.

CONCLUSION

Due to intensive ventilation, average radon concentrations in the Prague Metro are generally less than 30% of the concentrations found in Czech dwellings. The effect of shielding against cosmic radiation (soil and rock layers, lining and construction materials) results in a slight reduction of external penetrating radiation within the stations. In addition, the robust construction of the Metro trains also contributes to the decrease of dose rates found in the trains.

This paper summarises the results of radon concentration monitoring in the carriages and at some stations of the Prague Metro network. The measurements revealed that radon levels in the Metro are relatively low in comparison to those normally encountered in dwellings in the Prague region. On average, the radon concentrations in the air inside the carriages have been found to be about 11 - 12 Bq m^{-3} while the levels at most stations reached values between 10 and 15 Bq m^{-3}. The Metro is intensively ventilated by means of powerful blowers and fans; the piston effect of the moving trains also contributes to air exchange. The ventilation rate is typically 3-4 h^{-1}. The highest rate is in line C, where the air in all underground areas is completely exchanged 6 times within each hour.

These results demonstrate that Metro passengers receive about the same effective dose as passengers using surface transport. The doses from radon in the metro are only slightly higher than radon-related doses in the open air, while exposure due to external photon radiation seems to be a few percent lower than dose rates common in typical Czech houses.

INTRODUCTION

Radon and its short-lived decay products are greatly concerned by the world scientific community since such exposure constitutes nearly 50% of the effective dose received by the public in countries with temperate climates(UN93). Vigorous researches have been conducted to investigate many aspects of the indoor ^{222}Rn problem. The predominant source of indoor ^{222}Rn in China genera lly appears to be the soil adjacent to the foundation. The other major sources, potable water and building materials, occasionally contribute significantly to indoor radon concentrations, and may be the dominant source in some cases. Several investigations in the past decade were conducted to measure ^{222}Rn concentrations in public water supplies, in wells, thermal springs and underground thermal water in China. Radon concentrations in drinking water have been observed to range over an extremely large range. The highest ^{222}Rn concentration recorded so far is 11 MBq m^{-3} in a private well of Guo Village, Jiangxi province(Li81). The ^{222}Rn concentrations in domestic water from public water supplies of the Chinese major cities are depends on the types of water supplies. The purpose of this paper is to summaries the results of ^{222}Rn concentrations in public water supplies of Chinese major cities, each with population larger than one million, and to estimate the contributions of waterborne radon to indoor air radon concentration as well as the related doses received by the residents from waterborne radon.

METHODOLOGY

The investigation was conducted in nearly 100 Chinese cities, which either are the capital cities of each province, municipal city directly under the Central Government, or are cities with population larger than 0.4 million. Several sites were selected in each city, and at each site, two representative tap water samples were sampled from water tap with radon bubblers after allowing about 10 minutes water flow. Each sample, with a volume of 50 cm^3 water, was collected into 100 cm^3 radon bubbler. High pure nitrogen gas was used to degassing Rn dissolved in water and drove it from bubbler into scintillation flask for measurement in laboratories.

RESULTS

1. Radon Concentrations in Different Types of Water

Radon concentrations in different types of water have been observed to range over an extremely large range, as listed in Table 1. The average concentrations in 138 thermal springs, most of them are famous in China, and 93 underground thermal water wells are 118.2 and 36.3 kBq m^{-3}, respectively, The highest concentration found is 11 MBq m^{-3}, in a private well, Guo Village, Jiangxi Province. The ^{222}Rn concentrations in domestic water from public water supplies of about 100 Chinese cities are ranging from 0.035 kBq m^{-3}, in

Fuzhou, to 101.3 kBq m^{-3}, in Shenyang, with average of 7.82 kBq m^{-3}.

Table 1. Radon concentrations in different types of water (KBq m^{-3})*

Water Type	No. of samples	range	Mean+-1SD
Surface	6	0.035- 2.98	0.27+- 0.28
Wells	9	0.68 -11000	20.5 +- 14.8
Thermal spring	138	0.3 -2720	118.2 +-266.3
Underground thermal water	93	0.3 - 259	36.3 +- 29.0
Tap water		0.053-101.3	9.5 +- 13.1

* Data from Ch93, Ch84, Ch87, Fa93, Ji89, Li81, Wa91,Zh87, Zh89.

2. Radon Concentration in Public Water Supplies

Table 2 shows the ^{222}Rn concentrations measured in the public water supplies of 24 Chinese major cities, each with population larger than one million. The average ^{222}Rn concentrations in domestic water from public water supplies of the Chinese major cities, are in the range from average of the 24 major cities is 8.61 $\pm$ 13.3 kBq m^{-3}, For those cities with Surface public water supplies systems, for example, Shanghai, Tianjin, Guangzhou et al., the average radon concentration is 0.27 $\pm$ 0.28 kBq m^{-3}, ranging from 0.05 to 7 kBq m^{-3}. In some cities, the main sources of thier public water supplies are from well or underground water, the waterborne ^{222}Rn concentration are much higher with average value of 20.5 $\pm$ 14.8 kBq m^{-3}, ranging from 0.68 to 101.3 kBq m^{-3}.

Table 2 Radon concentration in public water supplies(kBq m^{-3})*

City	Mean+-1SD	City	Mean+-1SD
Beijing	14.8 +- 2.2	Zhengzhou	1.22+- 0.09
Haerbing	5.02+- 0.26	Xian	7.98+- 0.53

Aggregate water supplies			9.5+-13.1
Surface water supplies			1.0+-0.7
Underground water supplies			20.5+-14.2

* Some data from Reference Ch93.

3. Transfer Factor of ^{222}Rn from water to Indoor Air
An important question in assessing the impact of waterborne ^{222}Rn on indoor exposure is to know the transfer factor, f, of ^{222}Rn from water to indoor air. Transfer factor can be expressed as f= Ca/Cw, Ca and Cw are ^{222}Rn concentrations in air and in water, respectively. Several measurements on the values of f were made. One study measured indoor air ^{222}Rn concentrations in real conditions in bathrooms using underground thermal water by dual filter grab sampling method. The values of f were in the range of 2 10^{-3} to 26 10^{-3} and average and standard deviation were 7.2 10^{-3} +- 7.1 10^{-3}(Ch84). In another study, ^{222}Rn concentrations were measured in a room with volume of 15 m^3 by grab sampling. The average f values were 2.4 10^{-4} and 3.2 10^{-3} under window open and close conditions(Ch93).

4. Increment of ^{222}Rn Concentrations in Indoor Air Due to Water Use
We take 2 10^{-4} as typical value of the ratio of airborne to waterborne ^{222}Rn concentrations. The increments of radon concentrations in indoor air are 0.2, 4.1 and 1.9 Bq m^{-3} for the three different types of public water supplies listed in Table 2. These increments equivalent to 0.8%, 17% and 8% of the nation-wide average of indoor radon concentration, respectively. This suggest that the reference concentration, 10 kBq m^{-3}, adopted by UNSCEAR in its 1993 Report is reasonable. The estimated annual effective doses to the sesidents, are 2.3,177 and 734.3 10-6 Sv, respectively, by inhalation pathway, including doses from inhaled radon that becomes dissolved in tissues.

INTRODUCTION

In recent years there has been growing concern about radon levels indoors in China. Shenzhen is a coastal, subtropical city having a typical maritime climate with average annual rainfall of 1948 mm. The city is famous for its very fast economical and social development speed. These features make an opportunity to study ^{222}Rn variation and the controlling factors. Measurements of indoor ^{222}Rn concentrations in Shenzhen were carried out in two phases, 1986 and 1992.

METHODOLOGY

Many measurements were made in different types and different usage of buildings at widely distributed locations in both phases. Compared with the first phase, much more buildings were well fit up inside with plain or color painting or paper or marble stone and air-conditioned in the 1992 investigation. In the first phase, most of the measurements were conducted with a dual-filter environmental radon monitor having a decay volume of 15l, and the lower limit of detection(LLD) was 2.3 $Bq.m^{-3}$ for ^{222}Rn for 30-min counting. Another grab sampling technique used was a scintillation flask radon monitor with volume of 0.7l and the LLD was 3.6 $Bq.m^{-3}$, using mainly for checking or for rural area measurements. Integrated activated carbon detectors were also employed for comparison. All these instruments were calibrated with liquid radium sources. The in situ intercomparison showed that the results of these three methods agreed within +-24%[1,2] .

In the second phase of investigation, solid state nuclear track detectors were employed for measuring radon concentration in air. CR-39 chips supplied by Pershore Mouldings LTD, England, were placed in Karlsruhe diffusion chamber, which were covered with polyethylene filters. After exposure, chips were etched under the condition: 6.25N NaHO at 80^0 C for 4 hours. The LLD calculated is 5554 Bq h m^{-3} , equivalent to radon concentration of 7.0 Bq m^{-3} for one month exposure. Intercomparison test was made in a radon chamber and the results of CR-39, scintillation flask and electret passive environmental radon monitor(E-PERM) all agreed within +-13%[3].

RESULTS AND DISCUSSIONS

1. Outdoor and indoor radon concentration

In the first phase 222 dwellings were measured at sites selected[2]. The total sites were 176 in the second phase, having same site distribution with the first phase of investigation[4]. The arithmetic mean of outdoor radon concentration obtained in

second phase is 13.0 Bq m^{-3} , which is in good agreement with 1986's value of 13.7 Bq m^{-3}. The city-wide indoor radon average is 33.7 Bq m^{-3} . These values are higher compared with the province-averaged indoor and outdoor radon concentrations in China, being 23.6 and 10.7 Bq m^{-3}, respectively. Shenzhen is geographically located in a uranium-rich granite rock region, its soil contains higher radium, average being 84.7 Bqkg^{-1} , about 2.2 and 3.4 times of China's and world average, respectively. The facts may explain the higher radon value.

2. Radon in different types of building

The measured ^{222}Rn concentrations, extremes, arithmetic and geometric means, in several types of buildings and outdoors are given in Table 1. In the first phase, ^{222}Rn concentrations in detached houses and multi-family apartments are similar, however, the average in high-rise buildings is significantly higher than in other two types of dwellings. One of the reasons is that the air exchange rate is much lower in high-rise buildings, being central or separate mechanically air-conditioned, than in other types of dwellings. The same explanation can applied to 1992's results, in which arithmetic mean of radon concentration in multi-family apartments is raised to a level of 31.0 Bq m^{-3}, because more and more apartment, about 83% of the total dwellings investigated, set up air-conditioner in recent years. In the opposition, the 1992's mean value of radon in basement is significantly lower than that of 1986', because more basement space is used as cafeteria or department store, in which ventilation condition was improved.Radon concentrations in naturally ventilated detached houses and 1986's multi-family apartments, whose air exchange rates were about 2 h^{-1} and 15 h^{-1} for closed and open conditions, respectively, are about the same in the two phases and only slightly higher than outdoor radon values. Their values of ratio of indoor to outdoor radon are between 1.1-1.3, in the contrast with values between about 2.3-7.9 for other types of dwelling. This supports the UNSCEAR's prediction: indoor and outdoor radon concentrations for well-ventilated buildings should be essentially equal. It indicates that social and economic development, through indoor air ventilation, is one of the controlling factors of indoor radon concentration.

3. Dose estimation

Exposure to radon and its decay progeny comes mainly from the inhalation of the products of radon. Table 2 lists the annual effective doses in ventilated and unventilated dwellings, In the calculation the conversion coefficients relating average annual concentrations to effective dose and occupancy factors for indoor and outdoor given by UNSCEAR[1] are used.

Table 1. Measured ^{222}Rn concentration in different types of dwellings in Shenzhen (Bq m^{-3})*

Types of dwelling	Number of dwellings	Range	Arith. mean	Standard deviation	Geom. mean	Geometric standard deviation
High-rise buildings	147 (65)	1.5-14.2 (13.3-87.7)	31.1 (39.7)	22.9 (17.4)	25.2 (36.3)	1.96 (1.5)
Multi-family dwellings	19 (80)	3.3-52.5 (12.1-98.1)	15.5 (31.0)	11.8 (18.9)	11.8 (26.2)	2.16 (1.8)
Detached houses	50 (24)	4.1-54.0 (6.7-53.0)	17.8 (19.5)	11.8 (12.7)	14.4 (16.3)	1.93 (1.8)
Basement	6 (7)	77.7-142 (35.5-86.2)	108 (62.5)	26.3 (22.4)	106 (58.1)	1.27 (1.5)

* The values in the parentheses are results of 1992 investigation.

Table 2. Estimation of annual effective dose caused by ^{222}Rn and its progeny*

types of dwelling	Typical concentration (Bq m^{-3})	Effective dose rate (nSv h^{-1})	Annual effective dose (mSv) (I)	(I+O)
Ventilated	36	142	0.97	1.08
Unventilated	16	63	0.43	0.54
Basement	65	257	1.8	1.91
Outdoor	13	62		

* "I" and "O" stand for "Indoor" and "Outdoor", respectively. Outdoor contribution to annual effective dose is 0.11 mSv a^{-1}

INDOOR RADON MEASUREMENTS IN DWELLINGS OF GARHWAL HIMALAYA, NORTHERN INDIA

R.C.Ramola
Department of Physics
HNB Garhwal University Campus
Tehri Garhwal 249 001, India

Measurement of indoor radon and daughters concentration were performed in several houses in Garhwal Himalaya during 1993-95 with solid state nuclear track detector films (LR-115 Type II). The detector films were exposed for a period of three months to one year. The films basically measured total airborne alpha activity but may be calibrated in unite of EEC_{RN} (equilibrium equivalent concentration of radon with equilibrium factor F=0.45) in an environment with known radon and daughters concentrations. A numbers of dwelling in the area exhibited radon daughters concentrations (EEC_{RN}) exceeding the recommended level. The abnormal values are due to typical house construction (mud house) in the area. The houses are constructed with soil and local stone with a thin paste of mud. Behaviour and abnormality of radon in mud houses are discussed in details the corresponding annual effective dose has been calculated.

INTRODUCTION

Nearly one half of the total natural radiation exposure is due to the inhalation of radon and its progeny in air(1) which can result in a significant risk to the general public. The health effect of radon is well known in mine workers (2,3) but recent survey carried out all over the world (4-10) shows high concentration of radon in some dwellings could entail significant health risk. The daughter products of radon, which are solid under ordinary condition, attach themselves to atmospheric dust. During inhalation these particles may deposit in the lung and damage the tissue. It is therefore desirable and possibly necessary to monitor levels of radon in places where people are exposed to radon, particularly at sites where the geological formations are enriched with uranium. This paper presents the results of radon survey carried out in the houses of Garhwal Himalayas using LR-115 type II, plastic track detector.

CALIBRATION OF DETECTOR

The experiment on the calibration of LR-115 type II, plastic track detector was performed at Environmental Assessment Division, Bhabha Atomic Research Centre, Bombay. The detector films (2.5 cm X 2.5 cm) were exposed in bare mode in a calibration chamber of known radon concentration. The condition was kept similar to that in the field measurements. In all 12 samples were exposed and an average value was obtained as 3.12×10^{-2} tracks/cm^{2}d = 1 Bq/m^3.

EXPERIMENTAL TECHNIQUE

Track etch technique has been used for the measurement of radon activity in the dwellings. Small pieces (2.5 cm X 2.5 cm) the LR-115 were fixed on a glass slide which acts as a supporting material and these slides were suspended inside the houses at a height of about 2 meters from ground floor. The detectors are then removed after three months, etched in 2.5 N NaOH solution at 60 °C for two hours and were scanned under an optical microscope for track density measurements. The resulting values of track densities are converted in Bq/m^3 by using the calibration factor as discussed above.

RESULTS AND CONCLUSIONS

The results of indoor radon concentration in Garhwal Himalaya are given in Table 1. The choice of house was random and one room of each house selected for radon measurement. Most of the houses in the area are mud houses, constructed with local stone and soil.

Table 1. Radon concentration and equivalent dose in the dwellings of Garhwal Himalayas.

Place	Average Radon Concentration (Bq/m^3)	EEC_{RN} (Bq/m^3)	Dose (mSv/y)
Padiyargaon	199	90	7.9

Tehri	110	50	4.3
New Tehri	119	54	4.7
Nail	119	54	4.7
Chamma	109	49	4.3
Dikholgaon	76	34	3.0
Thanegaon	64	29	2.5
Sabligaon	72	32	2.8
Khanda Srikot	178	80	7.0
Srinagar	75	34	2.9
Chauras	69	31	2.7
Kotdwar	33	15	1.3
Malideval	133	60	5.2
Serain	82	37	3.2
Rajgaon	118	53	4.7
Uppu	48	22	1.9
Dang	54	24	2.1

The results reveal that radon concentration in mud houses are relatively higher than that in the normal buildings. This variation may be due to the building material and mode of construction of the mud houses. The ground floor of such houses allows more radon to diffuse inside the room because of higher porosity of the material used. The emanation of radon from building material (stone and soil) is also higher than the normal building material and may contribute additional radon inside the room. As such high radon concentration is recorded in mud houses.

The radon concentration is expressed in terms of equilibrium-equivalent radon concentration (EEC_{RN}) by using the following relation:

$$EEC_{RN} = F.A_{RN}$$

Where F is the equilibrium factor (F=0.45) and A_{RN} is the measured radon activity. The dose equivalent received by bronchial and pulmonary regions of human lungs have been calculated using a conversion factor 1.0×10^{-5} mSv per $Bq.h/m^3$ (4).

The calculated dose for indoor radon values were found to be four to six times higher than the recommended value (4). The total relative life time risk of lung cancer from inhaled radon and daughter concentration in the study area was calculated as 0.52 per Bq/m^3. This indicates that the lung cancer risk for a population exposed throughout an average life time to the calculated mean EEC_{RN} is more than half of normal lung cancer. These abnormal recorded values in the area finds a scope for the further study in the areas with identical geographical and geological conditions. A detailed study is already in progress in other areas of Garhwal Himalayas.

INDOOR RADON CONCENTRATION AND GAMMA DOSE IN HUNGARIAN DWELLINGS

I. Nikl

"Frédéric Joliot Curie" National Research Institute for Radiobiology and Radiohygiene, H-1775 Budapest, Hungary

INTRODUCTION

The first measurement of indoor dose in Hungarian dwellings were made in 1979. From this date the system is working as a passive dosimetry network. The indoor radon concentrations were measured during 1985-1986 at the sites of the network. The number of the sites are 123 which is rather low.

The aim of the nation-wide survey during 1993-1994 was to obtain results of indoor dose and radon concentration in represantative dwellings and in thi base to determine the average dose equivalent to the population. The effect of wall materials and geographical situation were also examined.

One thousand of dwellings were selected as a representative sample which means 1 in 3.800 of the housing stock. The sites cover uniformly the territory of the country (1 site/km^2).

Method used are $CaSO_4$:Tm TLD's for the measurement of dose and electret ionization chambers for the measurement of radon activity concentration. Exposure duration is one year. The detectors were distributed personally and were collected through postal service. The lost of detectors is 8 per cent.

RESULTS

1) Radon concentration and exposure

The arithmetic mean of indoor radon concentration is 128 $Bq.m^{-3}$, the median value is 81 $Bq.m^{-3}$. The concentration of radon in groun floor dwellings are higher than in dwellings above it. The lowest radon concentration is in prefabricated multi-family houses.

The frequency distribution of indoor radon concentration is nearly log-normal. 17 per cent of the dwellings have radon concentrations above 200 $Bq.m^{-3}$ and 2 per cent of the houses exceed 600 $Bq.m^{-3}$.

Taking into account the arithmetic means of the radon concentration in dwellings with different wall materials, their position to the soil (ground floor and above it) and the population density the weighted mean is 107 $Bq.m^{-3}$ radon. The estimated annual effective dose is 1,3 mSv, supposing that the occopancy in dwellings is 5.000 hours/year, F factor is 0,4 and the other parameters are the same as in the Recommendation of ICRP 65 (3).

2) Indoor dose rate and exposure

The arithmetic mean of indoor dose rates is 127 $nGy.h^{-1}$, the median value is 133 $nGy.h^{-1}$, including the secunder cosmic rays and terrestrial radiations. The arithmetic mean of the dose is the lowest in dwellings in prefabricated multifamily houses compare with other buildings. The weighted mean is 109 $nGy.h^{-1}$. Based on this result the estimated annual effective dose indoors from terrestrial sources and cosmic rays is 0,43 mSv using the same parameters as for radon and Sv/Gy factors according to the UNSCEAR 1993 Report (4).

3) Annual effective dose to adults from terrestrial and cosmic rays and from radon inhalation in dwellings

The sum of the estimated effective dose based on the weighted means is 1,73 mSv for 5.000 hours yearly occupancy and is 2,4 mSv for 7.000 hours. It can be seen that about 75 per cnt of the indoor exposure is because of radon inhalation.

(3) Mendeleev's Metrological Institute, St.Petersburg,Russia,

(4) Protontunnelstroj, Protvino, Russia

The problem of radiation exposure of population from radon gas in indoor air is well-known now and the national regulations on this factor are adopted in many countries [1]. But from our point of view existing regulations don't take into account the special group of population - childrens and tine adgers whose organizms are significally more sensitive to this factor. In this report we present some preliminary data on radiation exposure of childrens in schools and kindergardens from natural radon gas in t.Serpukhov(Moscow region) during 1993-1994 y.y.. Presenting this report we hope to attract attention of IRPA-96 Congress scientists to discuss the question about the necessity of new regulation on radon gas factor for childrens and tineadgers. The 5-th International Symposium in Salzburg, 1991, Natural Radiation Environment, tooke more attention for radon gas concentration in dweling, but only one publication concerned the above mentioned problem [2]. Me have measured the concentration of radon gas and it's DDP (daughter disintegrated products) in 36 kindergardens and schools in July 1993 practically simultaneously with the goal to choose objects for the following investigations. The results of DDP concentration (Crd) measurements are shown in Table 1.

Table 1. The number of rooms due to Crd, %.

Crd, Bq/cub.m	**0...40**	**40...100**	**100...150**	**150...200**
Number,%	**67**	**28**	**4**	**1**

For the more detail observation we choose three buildings with different radon gas concentrations. The procedure of measurement consists of determination of momentary radon gas concentration, momentary DDP concentration Crd and two - days integrated radon gas concentrations one time per month during one calendar year. The obtained data are given in Table 2.

Table 2. Momentary daughter concentration Crd, Bq/cub.m.

(The upper line represents month of measurements)

Dat	De	Fe	Fe	Ap	Apr	May	Jun	Jl	Au	Au	Oc	Nov
Crd	25	19	40	98	112	125	123	53	58	34	37	102

The mean Crd values per year are: for building 1 - 65 Bq/cub.m, for building 2 - 31 Bq/cub.m, for building 3 (background) - 11 Bk/cub.m. The mean equlibrium coefficient per year between radon and it's DDP for all investigated buildings was equal 0.6. But for the definition of the effective total dose it's more important to know the Crd daily variations. These data are shown in Tabl.3 for building 1.

Table 2. The daily variation of momentary DDP concentration Crd,

Bq/cub.m.(The upper line represents the hours of measurements)

H	11	12	13	14	15	16	17	18	19	20	21	22
Crd	92	73	62	79	78	65	58	38	40	43	38	56
H	23	24	1	2	3	4	5	6	7	8	9	10
Crd	53	88	77	53	35	39	52	50	50	67	124	131

Now there is the possibility to take into account the real children exposure during the maximum daily time from 8 a.m to 6 p.m.(Tabl.4).

Tabl.4. Exposure of children in daily time (1840 hours), mSv/y

Buildings	Dose from DDP	External gamma dose	Summary dose
N 1	1.35	0.26	1.61
N 2	0.65	0.24	0.89
N 3	0.32	0.22	0.54

These data must be compaired to "normal" effective population dose per year (8500 hours) from radon gas 1.26 mSv/y [3].

Summary:

- the using of only integral methods for the determination of mean value C per year is not enough. It's nesessary to have the additional data on the daily varyations of it to correct the estimation of effective dose.

- from our point of view it is nesessary to have the special regulation on children exposure from the radon factor.

MAJOR SCIENTIFIC TOPIC NUMBER ..... (see page 7)

ABSTRACT (See instructions overleaf)

Beside well known sources of radon at the Žirovski vrh Uranium mine there are also other disposal sites with technologically enhanced natural radioactivity, distributed in several non-uranium mining districts of Slovenia. The deposited material, such as uranium waste rock and mill tailings, roasted mercury ore residues, waste coal residues, fly-ash, bauxite waste, could be classified according to the levels of uranium content as low activity radioactive wastes or at least as materials with restricted use.

Environmental concentrations of radon and radon daughters were measured in the nearby surroundings of disposal sites, simultaneously at different mine districts of the country, mainly by continuous alpha spectrometry. It was found that the highest radon levels - far exceeding a value of 100 Bq/m^3 - are not related to uranium production but rather to coal and mercury mining. The results were evaluated taking into account site specific features, including size and position of radon sources, and topographic and climatic characteristics of environment. Typical alpha spectra were also recorded and values of equilibrium factor at sampling points near ^{222}Rn sources were estimated. The data obtained are important base for future restoration of all contaminated sites.

RADIATION EXPOSURE OF THE MOLDAVIAN POPULATION FROM RADON AND THORON PROGENY

Olga Iacob , C. Grecea , L. Clain

Institute of Public Health and Medical Research Iasi,RO-6600

INTRODUCTION

The aim of this paper is to provide un updated, completive review of the data available for assessing the Moldavian population exposure from radon and thoron progeny inhalation and the potential risk of radiation-induced lung cancer. According to our last estimate (1), the short - lived decay products of radon and thoron make the most significant contribution to exposures from natural radiation background (2.5 $mSva^{-1}$).

METHODS

The radon and thoron daughters concentrations have been measured in 348 typical Moldavian dwellings from urban and rural areas using the active method by sucking air through filter and counting the deposited activity by means of a ZnS alpha scintillation counter. Measurement and calculation procedures have been described previously (2).

The exposure of individuals resulting from radon and thoron progeny inhalation has been expressed in terms of effective dose (E), the new indicator of the total detriment due to the stochastic effects in the exposed individual and his descendents, as defined by ICRP in Publication 60 (3).

The annual effective doses have been derived from the average Equilibrium Equivalent Concentration (EEC) of radon and thoron using the dose coefficients adopted in the UNSCEAR 1993 Report (4) and assuming the average occupancy factors of 0.75 indoors and 0.25 outdoors.

The radiation-induced risk estimates have been performed from the annual collective effective doses by applying the risk factor of $5x10^{-2}$ per Sv for fatal cancers for a population of all ages and both sexes,recommended by ICRP Publication 65 (5).

RESULTS AND DISCUSSIONS

Table 1 shows the arithmetic means and the range of values for both EEC of radon and thoron and the resulting annual effective doses. The average value of the equilibrium equivalent concentrations of radon have been estimated at 8.7 Bqm^{-3} in block of flats and at 28.0 Bqm^{-3} in detached houses. The highest value found has been of 564 Bqm^{-3}, in a rural house. It is evident from estimates given in table 1 that EEC of radon levels are about three times higher in detached house than in block of flats. The explanation is that in detached houses the major source of indoor radon is the subjacent ground but, in the upper storeys of tall block of flats, the building materials might be expected to be the main source.

The resulting annual effective dose of an individual living in a detached house is 1656 µSv on average while in a flat, un individual receives only 514 µSv.

Table 1. Equilibrium Equivalent Concentrations (EEC) of radon and thoron in dwellings and the resulting annual effective doses

Source of exposure	Location	EEC (Bqm^{-3}) Average	EEC (Bqm^{-3}) Range	Annual Effective Dose (μSv) Average	Annual Effective Dose (μSv) Range
^{222}Rn daughters	Detached house	28.0	10.2-564	1656	603 -33340
	Block of flats	8.7	3.8- 19.4	514	225 - 1147
^{220}Rn daughters	Detached house	1.3	0.2- 6.4	273	42 - 1345
	Block of flats	0.6	0.1- 2.8	126	21 - 589

Regarding thoron progeny inhalation, the annual effective doses are of 273 μSv and 126 μSv for detached house and block of flats, respectively.

The population-weighted averages of EEC of radon and thoron, the corresponding annual effective doses as well as collective doses and risk estimates, are given in Table 2.

Table 2. Radiation exposure of the Moldovian population from radon and thoron progeny inhalation

Source of exposre	Location	EEC* (Bqm^{-3})	Annual effective doses per capita (μSv)	Annual effective doses collective (man Sv)	Potential annual no of lung cancer
^{222}Rn daughters	indoors	20.2	1195	6214	311
	outdoors	4.6	90	468	23
Total radon			1285	6682	334
^{220}Rn daughters	indoors	1.0	200	1040	52
	outdoors	0.2	5	26	1
Total thoron			205	1066	53
TOTAL radon+thoron			1490	7750	387

*) population - weighted average

The values are of 20.2 Bqm^{-3} indoors and 4.6 Bqm^{-3} outdoors for EEC of radon and of 1.0 Bqm^{-3} and 0.2 Bqm^{-3} for EEC of thoron indoors and outdoors, respectively.

From these values and applying the dose coefficients, the annual effective dose per capita from inhalation of radon progeny was estimated at 1285 μSv and at 205 μSv from thoron progeny inhalation. From the total of 1490 μSv, more than 90 per cent are received indoors.

Taking into account the annual collective effective dose of about 7750 manxSv it is possible to estimate that 387 lung cancer

each year in Moldavian population (5.2 mill. inhabitants) may be attributable to radon and thoron short-lived decay products inhalation.

Radon and thoron progeny are the dominant source of human exposure to ionising radiation contributing about 60 per cent of the total dose from natural background of Moldavia, as Fig.1 illustrates.

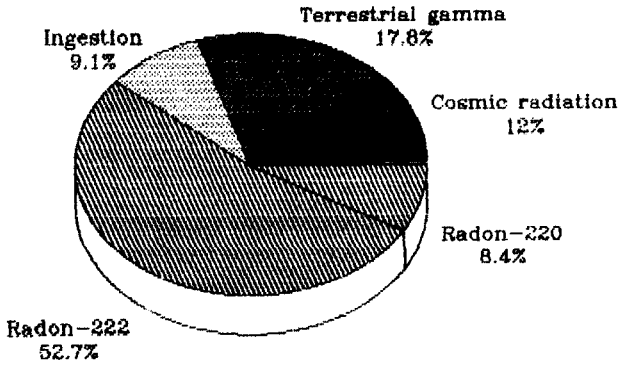

Fig.1 Contribution of natural radiation sources to annual effective dose

CONCLUSIONS

1. The population-weighted averages of EEC of radon and thoron are of 20.2 Bqm^{-3} and 1.0 Bqm^{-3} indoors and of 4.6 Bqm^{-3} and 0.2 Bqm^{-3} outdoors.

2. The annual effective dose per capita due to radon and thoron progeny inhalation are of 1285 μSv and 205 μSv, respectively.

3. The resulting annual collective dose of about 7750 manSv may be responsable for 387 potential lung cancers induced annually in Moldavian population.

PRESENTING AUTHOR (IF DIFFERENT)

MAJOR SCIENTIFIC TOPIC NUMBER 1.1 (see page 7)

ABSTRACT (See instructions overleaf)

Continuous measurements of the potential alpha-energy of thoron progeny have been carried out in 23 dwellings in the south-east of Germany over time periods from two month to over one year. Mean values of the equilibrium equivalent concentration of thoron decay products were found to range from 0.1 to 1.0 Bq/m^3 with an overall average of 0.5 Bq/m^3.

Results show that there is a seasonal variation of the concentration with a minimum in summer. This can be attributed to increased ventilation in this time period.

Exposure from thoron progeny was compared to the exposure from radon progeny which was measured simultaneously. The contribution to the annual effective dose equivalent of the inhabitants by inhalation of radon progeny is about 5%.

739-1,Uchio,Okayama 701-02,Japan

1. Introduction

Naturally occurring radon is estimated to be one of the most significant environmental radioactive substances(1). The main sources of natural radioactive radon are ^{222}Rn and ^{220}Rn. This paper presents investigations of ^{220}Rn daughters in the environment. The earth's crust contains trace amounts of ^{232}Th which decay to ^{220}Rn. ^{220}Rn is an alpha particle emitter. Its half-life is 56 s; and upon decay it emits a single alpha particle of energy 6.29 Mev. ^{220}Rn gas molecules leave the soil and enter the atmosphere. The concentrations of ^{220}Rn and their decay products vary according to the time because their information is due to different decay constant. It is set free in the atmosphere where it brings about a series of radioactive products which are rapidly fixed on the aerosol of the air. Although ^{220}Rn levels can be inferred from ^{220}Rn daughter measurement, measuring ^{220} directly avoids the problem of uncertainty in the extent of equilibrium between ^{220}Rn and its daughters.
^{212}Pb which reached its equilibrium state with its daughters in the air was measured around small uranium mines in Japan. Environmental. ^{212}Pb concentrations rose suddenly and reached a value ten times as high as usual values. These phenomena were observed many times during the past six years. We called these phenomena ^{212}Pb storms. Meteorological conditions lead to the variations of ^{220}Rn progeny concentrations(2-5). These phenomena have been studied in the point of meteorology.

2. Method

Kamisaibara village was selected as the investigation site. This village is situated in the central sector of the Chugoku mountains in Okayama Prefecture, Japan(35° 18′ N, 113° 35′E. about 710 m above sea level). This district is studded with small uranium mines which are of the sedimentary type. The geological structure of this area is comprised of quaternary gravel and the surface layer of this area is composed of granite. The location of the Kamisaibara region is shown in Fig. 1. Three monitoring stations were selected in this area. The monitoring stations were set up in the Toge, Akawase and Tennoh. Atmospheric ^{212}Pb and meteorological parameters were measured from January 1990 to December 1994. The meteorological parameters which were measured :atmospheric temperature, atmospheric pressure, precipitation, relative humidity, wind velocity, net exchange radiation. ^{212}Pb concentrations were determined by obtaining

an aerosol sample on an air filter, followed by measurement of the alpha activity on the filter after the end of sampling. To collect atmospheric aerosols, a high volume air sampler was used for a period of over 3 hours at suction speed 250l/min. After standing 7 hours at the end of air sampling, ^{212}Pb exists in equilibrium with ^{212}Bi and ^{212}Po. ^{212}Bi half-life is 60.6 min; and upon decay it emits an alpha particle of energy 6.05Mev. ^{212}Po half-life is 0.30μs; and upon decay it emits an alpha particle of energy 8.78 Mev. These alpha particles were detected by the use of a ZnS(Ag) detector(150 mm φ). The counting of alpha particles on the filter was carried out a period of over one hour. Eight samples were collected in one day.

3. Results and discussion

The yearly variations of atmospheric ^{212}Pb were presented in Fig. 2. The yearly mean values and the standard deviations are shown. In 1994, the yearly mean value was slightly high. The yearly fluctuations were small. The seasonal variations of atmospheric ^{212}Pb are presented in Fig. 3. The maximum mean value was shown in autumn and the minimum value was shown in winter. One reason for this may be that usually this district was covered with snow in winter. The mean values and the standard deviations at every station for five years are shown in Fig. 4. The mean values were slightly different.It may be presumed that these differences were caused by the environment of the setting point.The yearly maximum values for every station are presented in Table 1. Environmental ^{212}Pb concentrations rose suddenly and it reached a value ten times as high as the usual value. The maximum concentrations of ^{212}Pb for five years were shown at 594 mBq/m^3 on 28 Apr. 1992 in Akawase, 608 mBq/m^3 on 3 Nov. 1994 in Tennoh.The relationships of the maximum values for two cases and meteorological conditions at that time were investigated. In the case of the maximum values of ^{212}Pb concentrations at Akawase and Tennoh, atmospheric pressure was about 940 hPa/h. These values were equal to the approximate monthly mean value . Atmospheric pressure was not large affected to the maximum ^{212}Pb concentrations. As the maximum values of ^{212}Pb show, the relative humidities range from 90 to 95%. These values are the highest values in the month. These facts shows that the relative humidity strongly affected ^{212}Pb concentration. The relative humidity was positively correlated to ^{212}Pb concentration. Although the relative humidity reached above 90% in the case of precipitation, ^{212}Pb concentration was low. In daily fluctuation, the relative humidity was similar to that of ^{212}Pb concentrations. In general wind speed strongly affected ^{212}Pb concentration. As ^{212}Pb reached maximum value, wind velocity ranged from 0.3 m/s to 0.5 m/s. As the ^{212}Pb concentration reached maximum value, net exchange radiation ranged from -0.20 to -0.25 MJ/m^2/h. Net exchange radiation was inversely proportional to ^{212}Pb concentration.

MAJOR SCIENTIFIC TOPIC NUMBER ..... (see page 7)

ABSTRACT (See instructions overleaf)

Indoor concentrations of short-lived radon decay products (Rn-d) can reach levels over 1000 times that of outdoor levels and such elevated levels pose a significant risk of fatal lung cancer. High Rn-d levels indoors are generally dominated by ingress of soil gas of high Rn concentration and by ventilation characterized by poor outdoor air exchange - building materials and water making only minor contributions (with recognizable exceptions).

When considering the buildup of Rn and Rn-d in a building the source is Ra-226 in a soil-gas compartment which is successively (serially) connected to compartments of the building. There are losses from each compartment to the outdoor air which acts as a sink and to surfaces which act as sinks for the Rn-d; in the soil-gas compartment surfaces remove the Rn-d quantitatively.

The ventilation fluctuates and can coarsely be categorized into 'stagnant' situations and into wind activated situations. Modelling these situations, and changeovers thereof, provides an insight into the relative importance of the various parameters, such as the effect of the (?poorly known) soil-gas compartment.

Stagnant situations generally provide the higher concentrations whereas changeover situations can produce peak concentrations of short duration. Accurate short-term measurement of the activity ratios of Rn and individual Rn-d can indicate what ventilation situation prevails.

Applications of modelling are the more accurate prediction of longterm exposures from short term measurements, ventilation analysis and assessment of the potential for remedial action.

ABSTRACT (See instructions overleaf)

CALIBRATION AND QUALITY ASSURANCE FOR THE MEASUREMENT OF RADON

Volker Genrich, Genitron Instruments, D-60488 Frankfurt (Germany)

In many countries measurement of 222-Rn in air is performed as a part of governmental radiation protection activities. In such screening programs, there is need for exact national primary standards. Additionally reliable secondary references should be available as regular quality assurance for radon measurement services. The author reports on his experiments in

- ☐ qualifying a new type of radon monitor, to be used as a reference machine for the calibration of other active and passive radon measurement systems
- ☐ cross-checking a set of five monitors in 15 different radon calibration facilities around the globe (International Calibration Experiment ICE'94)
- ☐ qualifying the instrument under US-EPA's RMP program and for the Federal Russian GOSSTANDARD as radon reference equipment
- ☐ establishing a "quick" field calibration procedure for routine QA, based on the NIST radon standard SRM 4968 and a portable calibration chamber

ABSTRACT (See instructions overleaf)

Radon is a natural radioactive gas. It is a chemically inert, highly radioactive daughter of uranium, thorium and actinium decay. A part of the radon formed in earth's crust (natural source) and in radioactive wastes storage sites (artificial source) can migrate to the atmosphere through cracks, fissures by transport mechanisms (diffusion, fluid convection). Thus, radon occurs naturally in every place and not in uranium mines only. It may pose a health risk for the population, because it is the first component of the average annual radiation exposure to the population.

For the past 10 years, we have been developing complementary techniques in the detection of radon and its decay products (proportional counter, silicon detector and solid state nuclear track detectors). A methodology has been developed to analyze the radon concentration in large and varied areas in using. This analysis is effected in time or in space. Thus, the measurements reveal the distribution of radon emanation and the range of variation. The method is used routinely for the following purposes: in homes in the aim of radioprotection, in geological applications for prospecting, studying the movement of the earth crust and analyzing the effect of alpha pollution in the environment.

ABSTRACT (See instructions overleaf)

Indoor concentrations of short-lived radon decay products (Rn-d) can reach levels over 1000 times that of outdoor levels and such elevated levels pose a significant risk of fatal lung cancer. High Rn-d levels indoors are generally dominated by ingress of soil gas of high Rn concentration and by ventilation characterized by poor outdoor air exchange - building materials and water making only minor contributions (with recognizable exceptions).

When considering the buildup of Rn and Rn-d in a building the source is Ra-226 in a soil-gas compartment which is successively (serially) connected to compartments of the building. There are losses from each compartment to the outdoor air which acts as a sink and to surfaces which act as sinks for the Rn-d; in the soil-gas compartment surfaces remove the Rn-d quantitatively.

The ventilation fluctuates and can coarsely be categorized into 'stagnant' situations and into wind activated situations. Modelling these situations, and changeovers thereof, provides an insight into the relative importance of the various parameters, such as the effect of the (?poorly known) soil-gas compartment.

Stagnant situations generally provide the higher concentrations whereas changeover situations can produce peak concentrations of short duration. Accurate short-term measurement of the activity ratios of Rn and individual Rn-d can indicate what ventilation situation prevails.

Applications of modelling are the more accurate prediction of longterm exposures from short term measurements, ventilation analysis and assessment of the potential for remedial action.

ABSTRACT (See instructions overleaf)

Indoor concentrations of short-lived radon decay products (Rn-d) can reach levels over 1000 times that of outdoor levels and such elevated levels pose a significant risk of fatal lung cancer. High Rn-d levels indoors are generally dominated by ingress of soil gas of high Rn concentration and by ventilation characterized by poor outdoor air exchange - building materials and water making only minor contributions (with recognizable exceptions).

When considering the buildup of Rn and Rn-d in a building the source is Ra-226 in a soil-gas compartment which is successively (serially) connected to compartments of the building. There are losses from each compartment to the outdoor air which acts as a sink and to surfaces which act as sinks for the Rn-d; in the soil-gas compartment surfaces remove the Rn-d quantitatively.

The ventilation fluctuates and can coarsely be categorized into 'stagnant' situations and into wind activated situations. Modelling these situations, and changeovers thereof, provides an insight into the relative importance of the various parameters, such as the effect of the (?poorly known) soil-gas compartment.

Stagnant situations generally provide the higher concentrations whereas changeover situations can produce peak concentrations of short duration. Accurate short-term measurement of the activity ratios of Rn and individual Rn-d can indicate what ventilation situation prevails.

Applications of modelling are the more accurate prediction of longterm exposures from short term measurements, ventilation analysis and assessment of the potential for remedial action.

STOCHASTIC MODEL OF RADON DAUGHTER DEPOSITION AND CLEARANCE IN HUMAN BRONCHIAL AIRWAYS

Werner Hofmann[1] and Laszlo Koblinger[2]

[1]Institute of Physics and Biophysics, University of Salzburg, A-5020 Salzburg, Austria
[2]KFKI Atomic Energy Research Institute, H-1525 Budapest, Hungary

INTRODUCTION

Morphometric measurements of human airway casts have revealed that the human bronchial tree is an asymmetrically dividing network, exhibiting individual variations of airway dimensions within a given airway generation (1). Thus, a statistical correlation exists between the linear dimensions of a given parent airway and those of the asymmetrically dividing daughter branches (2). This statistical relationship, however, is constrained by correlations among various geometrical parameters, i.e., the human lung is not a fully stochastic system. From a statistical analysis of these morphometric data, the following geometrical parameters could be obtained for each airway generation or bifurcation: (i) probability distributions for diameters and lengths, ratios of parent cross section to the combined cross section of both daughters, ratios of major to minor daughter diameters, and branching angles for major and minor branches; (ii) correlations of diameters and lengths; and (iii) the probability of terminating the bronchial region as a function of both diameter and generation number (2). Since the original lung morphometry refers to total lung capacity (1), airway diameters and lengths were scaled down to functional residual capacity (3).

STOCHASTIC BRONCHIAL DEPOSITION AND CLEARANCE MODEL

The stochastic deposition model used in the present study refers to the transport of inhaled particles through this stochastic lung structure by selecting randomly the sequence of airways for each individual particle, applying Monte Carlo techniques (4). For the computation of particle deposition within a selected airway bifurcation, however, the average deposition behavior of many particles is assumed, i.e., deposition probabilities are calculated by the commonly used deposition equations (4). In other words, the stochastic deposition model used here reflects the effects of a stochastic airway system on particle transport and deposition. In this model, deposition is computed for individual airway bifurcations (consisting of half of the parent and the major and minor daughter lengths) in a given lung lobe, considering the filtering effect of nose or mouth (5). The stochastic deposition model has been validated by comparison with total and regional deposition data in human test subjects for a wide range of particle sizes (6).

In the present study, a bronchial mucociliary clearance model has been implemented into the above described stochastic deposition model, based on the following assumptions: (i) the average mucus velocity in the trachea is assumed to be 5.5 mm min^{-1} (7); (ii) at a given airway bifurcation, average mucus velocities in the asymmetrically branching daughter airways are proportional to their respective diameters (7); (iii) mucus transport is delayed at central bifurcation zones (delay time Δt is uniformly distributed between 0 and 30 min) (8); and, (iv) the slow bronchial clearance fraction, f_s, with a half-life of about 10 days, decreases in a linear fashion with the particle's diameter, d, according to the equation: $f_s = 0.77 - 0.12\ d\ (\mu m)$ (9).

RESULTS

Experimental data on particle retention in the lungs after shallow bolus inhalation for 1.7, 3.2. and 6.7 μm geometric diameter particles are plotted in Figure 1 (10) (note: the volumetric front depth of 55 cm^3 refers to a bolus inhalation time of 3.78 s during a 4 s inspiration time, with an initial dispersion of 0.1 s). Except for the first four hours, in which the stochastic clearance simulations predict a higher retention than has been observed in the experiments, the agreement between experiment and model predictions is quite satisfactory, considering potential effects of inter-subject variability in lung dimensions and structure.

In the simulations presented here, bronchial deposition patterns, normalized to the number of particles entering the trachea are computed for 0.2 μm unit density particles under resting breathing conditions, i.e., for a tidal volume of 1000 cm^3, a cycle time of 4 s (2 s inspiration, 2 s expiration, no breath-hold period), and uniform inhalation during the 2 s inspiration time. The initial activity of the inhaled radon decay products is 9 Bq (^{218}Po), 6 Bq (^{214}Pb), and 4 Bq (^{214}Bi/^{214}Po), representing typical decay product ratios in domestic environments (8).

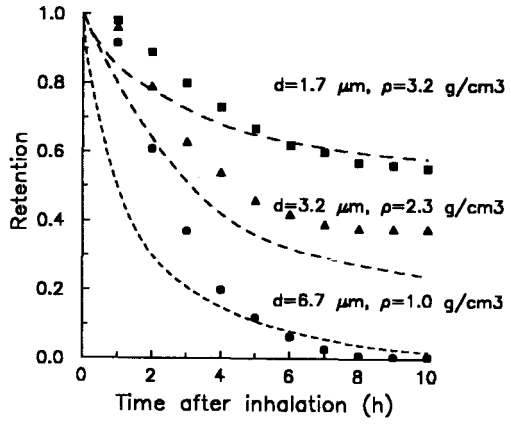

Figure 1. Particle retention as a function of time after shallow bolus inhalation for three different particle sizes. The symbols denote the theoretical predictions, while the fits to the measured data (10) are represented by the broken lines.

The subsequent upstream transport of the deposited radon progeny by mucociliary clearance is simulated for the same pathway which was selected upon inspiration, considering their radioactive decay. The transit times of the deposited particles in different bronchial airway generations, illustrating the effect of mucucs clearance, together with the initial deposition pattern are displayed in Figure 2. Because of the presumed relationship between mucus velocity and airway diameter, the decrease of diameters in peripheral bronchial airway bifurcations leads to increasing transit times. In the most distal genenerations, however, transit times decrease again due to the decreasing number of bronchial airways in these generations (note: in contrast to the commonly used symmetrical models, still 0.6 % of all airways in bifurcation 20 are terminal bronchioles).

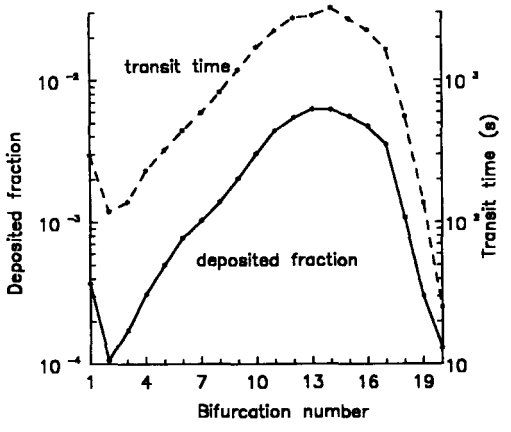

Figure 2. Initial deposition pattern for 0.2 μm unit density particles under resting breathing conditions, and the transit times of these particles in individual bronchial airway bifurcations due to mucociliary clearance.

The total number of radioactive decays, illustrating the combined effect of deposition, clearance and radioactive decay, and the number of radioactive decays per unit surface area, representing the radiation dose distribution, are plotted in Figure 3 as functions of the bifurcation number for both alpha-emitting radon progeny (only attached ^{218}Po nuclides have been considered here). Because of their relatively short half-lives,

the distributions of both nuclide transformations reflect the transit time distribution. On the other hand, the distribution of the number of nuclear transformations per unit surface hardly changes with penetration into the bronchial tree due to the larger total surface area in peripheral airway generations. Above about bifurcation 13, there is no further increase in total surface area due to a decreasing fraction of bronchial airways and the surface activities, therefore, drop parallelly to the decay pattern.

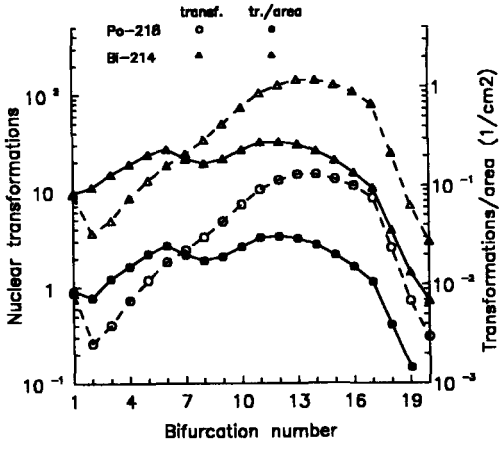

Figure 3. Number of nuclear transformations and number of decays per unit surface area in individual bronchial airway bifurcations for inhaled radon progeny with initial activities of 9 Bq (^{218}Po), 6 Bq (^{214}Pb), and 4 Bq (^{214}Bi/^{214}Po).

CONCLUSIONS

The results of the stochastic deposition and clearance calculations presented here reflect primarily the intra-subject variability of the human lung morphometry. In other words, the random walk of individual particles within a given bronchial bifurcation during inspiration and, if deposited, during mucociliary clearance has not yet been considered due to the lack of pertinent experimental information. Future incorporation of the random location of target cells in bronchial epithelium into the present stochastic deposition and clearance model will allow us to quantitate the effect of individual biological variability in cellular dose.

THE NATIONAL STANDARD FOR ^{222}Rn ACTIVITY MEASUREMENTS DEVELOPED AT ENEA IN ITALY

P. De Felice, G. Sciocchetti, P. Baldassini, E. Soldano, G. Cotellessa

Istituto Nazionale di Metrologia delle Radiazioni Ionizzanti,

INTRODUCTION

The growth of interest in radon measurements and the increasing importance of laboratory quality assurance programmes have caused a growing request of calibration of radon measuring instruments. To this purpose radon calibration equipment and testing facilities have been developed in many countries and recommended sampling and measurement protocols are being studied by national and international standardisation organisations.
In Italy, the Istituto Nazionale di Metrologia delle Radiazioni Ionizzanti of ENEA, the Italian Primary Standard Institute for ionising radiation quantities, has developed a set of equipment to satisfy the national request of radon calibrations. These equipment are traceable to the ENEA national standard of ^{222}Rn through an interrupted chain of transfer instruments. The ^{222}Rn national standard is derived from the national standard of ^{226}Ra and it is made by a ^{222}Rn Reference Measurement System (RMS) and a ^{222}Rn Transfer System (TS). The ENEA ^{222}Rn standard has been compared with other ^{222}Rn national standards in the frame of two EUROMET (European collaboration in measurement standards) intercomparisons carried out in 1992 and in 1994 (1). The system of experimental equipment developed at ENEA and the relation to the national standard are reported in figure 1. This paper briefly describes this system of experimental equipment.

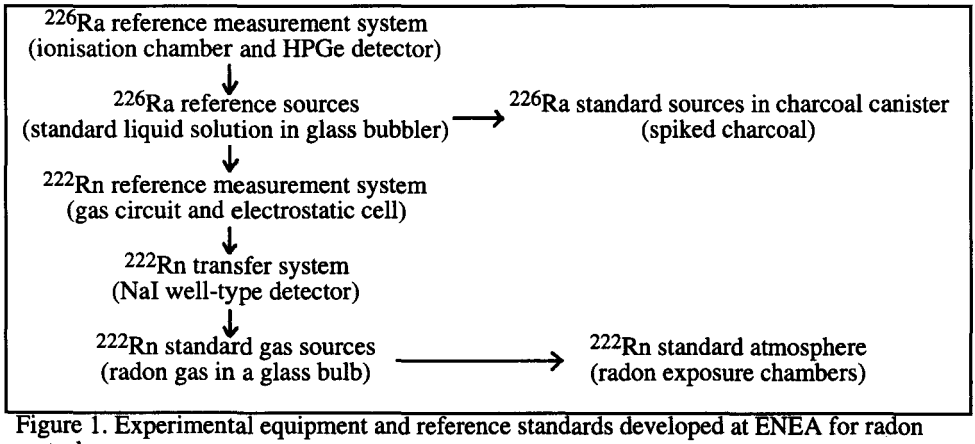

Figure 1. Experimental equipment and reference standards developed at ENEA for radon metrology.

THE ^{222}Rn REFERENCE MEASUREMENT SYSTEM

The ^{222}Rn RMS is used to relate the activity of ^{222}Rn gas samples to the activity of a ^{226}Ra reference source by the physical separation of the ^{222}Rn produced in the ^{226}Ra decay and its transfer into a counting chamber.
The ^{226}Ra reference source consists of a 5 kBq liquid standard solution (0.8 M HCl, 3.8 mg of BaCl2 per gram of solution) with volume of about 40 cm^3 sealed in a glass bubbler. The reference source was calibrated at ENEA by the ^{226}Ra reference measurement system. This

system is used to maintain the national ^{226}Ra standard and it is based on a well-type ionisation chamber used for activity measurement of gamma-ray emitting nuclides (2). The ^{226}Ra calibration factor of the ionisation chamber was determined by a ^{226}Ra standard source, traceable to the 1934 Hönigschmid international mass standard of radium and supplied by the National Institute of Standards and Technology. The ionisation current was corrected for the contribution of ^{210}Po the activity of which was determined by HPGe X-ray spectrometry. The combined standard uncertainty of the activity of the ^{226}Ra reference source was 0.63% (1s).

The ^{222}Rn RMS is a gas transfer and circulation system made of a gas input/output unit, a radioactive source section, a circulation and dehumidification unit and an electrostatic cell with a Si detector. The overall volume of the circuit is 3.88 dm^3, the volume of the electrostatic cell alone being 3.72 dm^3. The activity of ^{222}Rn gas sources in spherical glass bulbs (35 cm^3) is measured in the RMS by a particular procedure that does not require volume determinations or any assumption of total radon removal from the liquid ^{226}Ra solution (3). The radon gas, either from gas samples or from the ^{226}Ra reference source, with ^{222}Rn in equilibrium with ^{226}Ra, is transferred from the source section into the whole circuit by slowly flushing and continuously circulating a carrier gas through the circuit. The ^{218}Po count rate of the electrostatic cell is used for monitoring the radon activity in the circuit. Under reproducible extraction conditions the cell response is proportional to the overall radon activity in the circuit and hence it is used to relate the activity of radon gas samples in glass bulbs to the activity of the ^{226}Ra reference source. The conbined standard uncertainty of the efficiency value of the RMS is 0,98% with the main contribution coming from the calibration of the ^{226}Ra solution (0.63%) and the reproducibility of the transfer procedure (0.75%).
Unfortunately the direct calibration of radon gas samples with the RMS is based on a destructive procedure for the gas sources itself.

THE ^{222}Rn TRANSFER SYSTEM

The ^{222}Rn Transfer System (TS) was developed at ENEA for the non-destructive calibration of ^{222}Rn gas sources.

The ^{222}Rn activity of gas sample bulbs (1 to 10 kBq) is determined by measuring the source photon emission rate by a NaI(Tl) well-type detector. The NaI(Tl) crystal has an external diameter of 10.5 cm and a thickness of 14.5 cm. The well diameter is 7.5 cm and the well height is 10.5 cm. The well is suitable for containing the 35 cm^3 glass bulb. Similar systems have been developed and described by other authors (1-4). The count rate in the gamma energy window from 148 to about 1360 keV is measured to determine the ^{222}Rn activity. This energy window includes the photon emissions produced in the decay of ^{222}Rn daughters and their sum peaks. The NaI(Tl) detector was calibrated by using a set of gas sources that, after counting on the TS, were calibrated by the RMS.

The additional component of uncertainty introduced by the TS on the calibration of ^{222}Rn gas sources in glass bulbs is just due to the TS-response reproducibility (0.2%). The combined standard uncertainty in the calibration of these sources is then about 1.2% (1s).

As the TS is used at ENEA for routine calibration of radon gas sources, including the sources used for filling the radon chambers, the stability and the reproducibility of the system response is carefully checked by use of a solid ^{226}Ra sealed source. The TS has been also characterised in terms of several additional parameters such as the working range and the linearity of the system response (5).

STANDARD SOURCES FOR INSTRUMENT CALIBRATION

The calibration service provided by ENEA include the preparation of standard sources for radon measurements. In particular the following sources are available (figure 1):

- ^{226}Ra liquid solutions in glass ampoules or glass bubblers;
- ^{226}Ra standard sources in charcoal canisters;
- ^{222}Rn gas sources in 35 cm^3 glass ampoules.

The sources in charcoal canisters are prepared by spiking a charcoal matrix with a ^{226}Ra standard solution. The spiking procedure was specifically developed at ENEA for the preparation of reference materials for gamma-ray spectrometry (6). The ^{222}Rn gas sources in glass bulbs are utilised for the calibration of several radon measuring instrument equipped with a counting chamber, such as scintillation cells or ionisation chambers, by directly transferring the radon gas from the bulb into the counting chamber. In other cases the instrument calibration is carried out in standard atmospheres created in suitable exposure chambers.

THE ENEA RADON CHAMBERS

In order to allow the calibration of the different measuring equipment utilised in the environmental radon surveillance, two radon chambers were developed at ENEA (7-8). These radon chambers have different volumes (0.1 m^3 and 1 m^3, respectively) and different possibilities of climatic parameters control. Both the exposure chambers are equipped with suitable instruments for monitoring the radon concentration and the climatic parameters. The calibration of the ^{222}Rn monitor instruments has been carried out by transferring known amount of radon gas from glass bulbs into the radon chambers.

The 1 m^3 chamber is working at ENEA since 1985. Standard atmospheres are created in this chamber with control of the following parameters: temperature, relative humidity, activity concentration of ^{222}Rn and its decay products, aerosol size distribution and concentration. The facility can operate both in static and dynamic condition. Under static condition a known radon activity is transferred into the chamber from a standard gas source. At dynamic condition the radon concentration is maintained constant at a given level by continuously flushing the carrier gas through an external ^{226}Ra source. This radon chamber is utilised for the calibration of radon measurement systems that require the control of climatic parameters and for the calibration of devices, such as continuous and integrating passive monitors, for which the simple transfer procedure described above is not applicable.

The 0.1 m^3 chamber is working since 1992 and it is used for the calibration of nuclear track detectors and other small volume devices. In this chamber ^{222}Rn activity concentrations higher by an order of magnitude, with respect to those routinely used in the 1 m^3 chamber, can be obtained.

CONCLUSIONS

A complete system of experimental equipment utilised for calibration of radon monitoring devices has been developed at ENEA. The system is based on the ^{222}Rn national standard developed and maintained at ENEA. The work in progress concerns the completion of the calibration of the radon chambers and the development of new national standards related to radon monitoring such as the radon-in-water and the radon flux-density standards.

A new project consists in the development of a radon chamber with volume of about 50 m^3 for calibration of radon daughters measuring instruments and for intercomparison exercises to be organised by ENEA for the quality assurance of the laboratories belonging to the national radioactivity surveillance network.

TIME INTEGRATED MEASUREMENT OF POTENTIAL ALPHA ENERGY (PAE) DUE TO SHORT LIVED DECAY PRODUCTS (SLDP) OF RADON 220 and 222 IN THE ENVIRONMENT

S. BERNHARD ; C. GIBAUD ; JF. PINEAU ; F. SARRADIN ; Y. VAUZELLE

ALGADE/COGEMA group, 87250 BESSINES, FRANCE

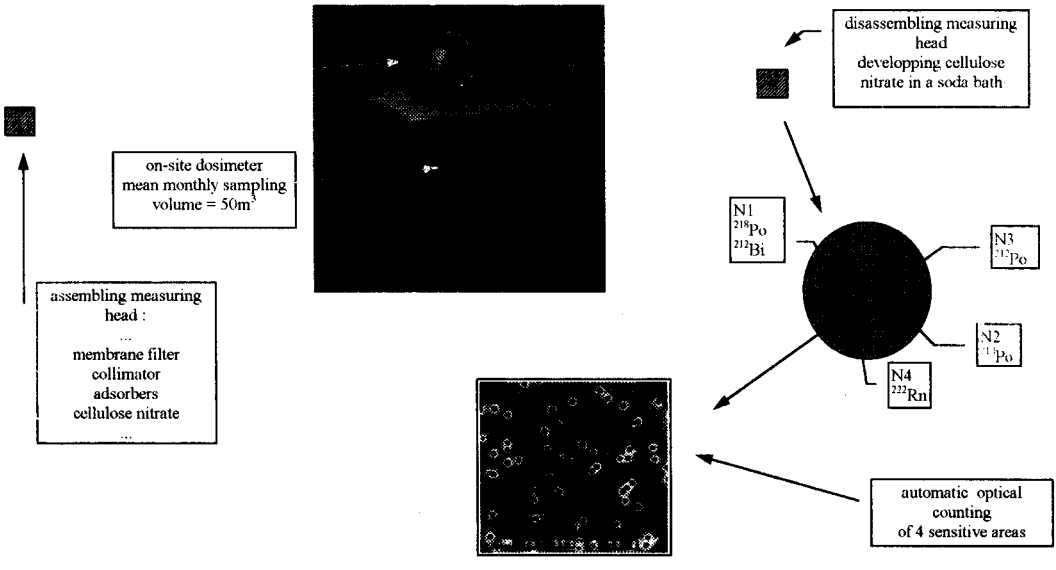
INTRODUCTION

The on-site alpha dosimeter, which provides time-integrated measurement of PAE due to SLDP of ^{220}Rn and ^{222}Rn in the environment is a derivative of the well-known individual alpha dosimeter used since 1983 for the monitoring of workers in french uranium mines It includes a sampling unit and an interchangeable measuring head, and while sampling on the incorporated membrane filter, the detection of alpha particles from SLDP of ^{220}Rn and ^{222}Rn is carried out following energy discrimination using a solid state nuclear track detector, of the type KODAK LR115 .

In practical terms, we can give as an « use range » of measurement for the on-site dosimeter an interval between 5 nJm^{-3} and 5.10^4 nJm^{-3} ($PAE^{222}Rn$) for a monthly sampling of 50 m^3 . The setting-up of calculation for the uncertainty estimation for one single measurement result, including the whole measurement chain, shows that for this interval the total relative standard deviation is less than 40% .

It's good metrological performance, the great density of informations it can provide, and the simplicity of use make this device a usefool tool : not only to make small investigation of PAE monitoring in houses, in radium waste storage environment or to study specically night/day PAE ratio nearby uranium site for example, but also to follow up with a dosimeter network the evolution of the radiological impact of uranium or thorium facilities . At present, more than 150 on-site dosimeters are in use in France, Africa and others .

SIMPLIFY DIAGRAM OF USING PRINCIPLES



PAE CALCULATION FROM RAW OPTICAL DATA

Knowing the physical constant ratio of ^{212}Bi desintegration (α:36% and β/α:64%)

$$PAE_{(thoron)} = K\,(8.7\,N3 + 6.08\,N3/2) / \rho V \quad in\ nJm^{-3}$$

$$PAE_{(radon)} = K\,(7.7\,(N2 - a\,N4) + 5.99(N1 - N3/2 - b\,N4)) / \rho V \quad in\ nJm^{-3}$$

with ρ : ***combination of collection and detection efficiency***
V : ***sampling volume***
a, b : weighting factors of radon contribution
K : International System unit factor

METROLOGICAL FEATURES OF ON-SITE DOSIMETERS

Range measurement

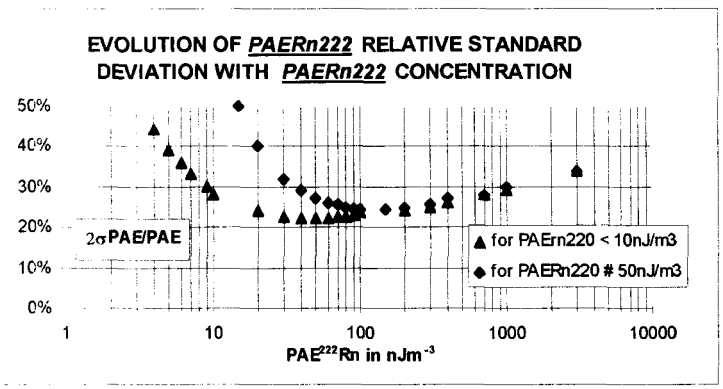
Theoretical aproach use to estimate the uncertainty of one single measurement results based on the simple propagation of statistical errors is a bit complicated by the fact that we have got some linked parameters . Nevertheless this calculation is essential to have got a good estimation of the lower end range measurement of the system .

The global formulae presented below represents the basis of this calculation and has been used to obtain the simplified curves which show the expexted evolution of relative standard deviation with PAE results .

$$\sigma_f^2 = \left(f_x' \sigma_x\right)^2 + \left(f_y' \sigma_y\right)^2 + \left(f_z' \sigma_z\right)^2 + \Lambda + 2 f_x' f_y' \operatorname{cov}(x,y) + 2 f_x' f_z' \operatorname{cov}(x,z) + 2 f_y' f_z' \operatorname{cov}(y,z) + \Lambda$$

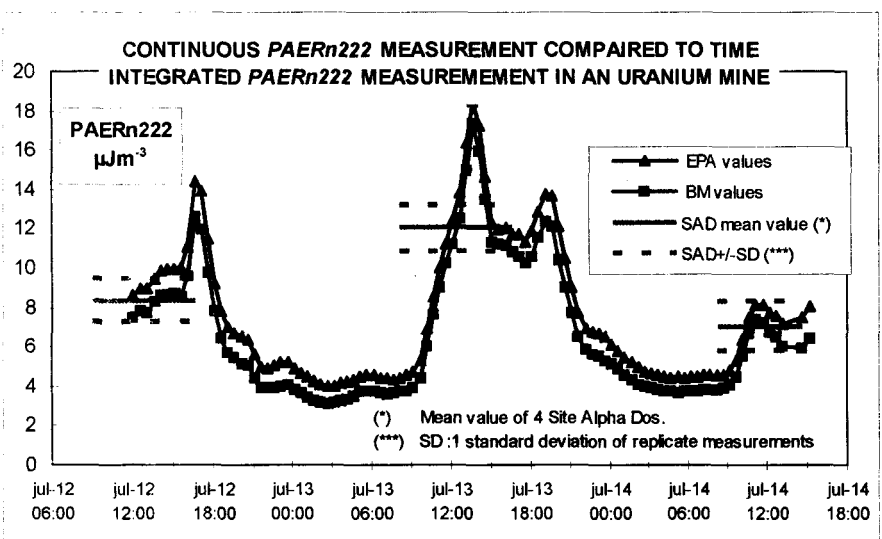
where the variable parameters will be in our case :

- the number of tracks N1, N2, N3, N4 counted on each sensitive areas
- the experimental collection efficiency
- the calculated by monte carlo algorithme detection efficiency
- the real-time measured sampling volume



Calibration

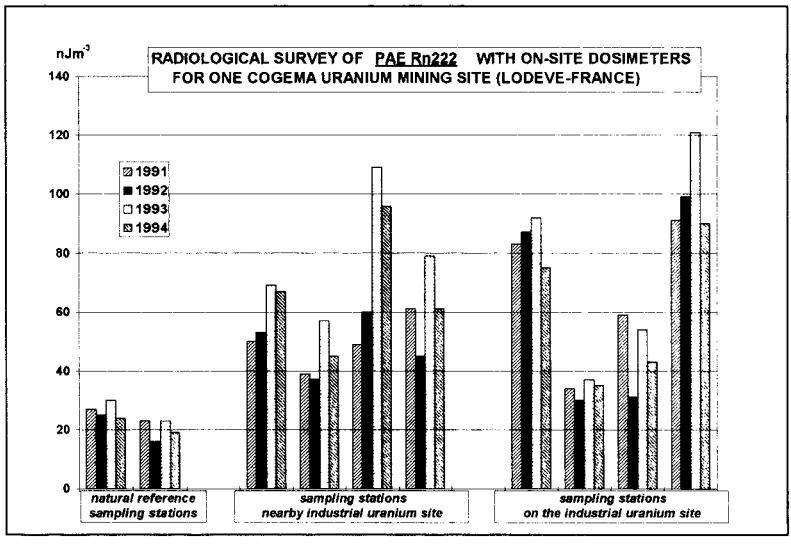
In addition to internal calibration, we try to compair our methods and results with other ones to follow an always possible time-drift . Some results of the last International Intercomparison we have participated concerning PAE measurements with Uranium mines conditions are presented below :



EXEMPLES OF USES

radiological following of uranium mining site

For example in south of France,there is a dosimeter network of about 10 devices measuring PAE around and on one of COGEMA's uranium mining site . Then we can follow since few years the radiological impact on the environment and by the way we can have a very good estimation of PAE exposure of the defined critical group . The diagram below is just a small example of results obtained among all dosimeters installed today.



specific application

In order to have more informations not only about the monthly but also night/day fluctuations of PAE and consequently to better estimate the real impact for the public, we have installed in this way for about 1 year 3 dosimeters sampling at different times during the day . In the same time, one continuous radon monitor (BARASOL) has been set , then permitting us to calculate with PAE and radon concentation the time-integrated equilibrium factor for specific periods .

The diagram below shows seasonaly, monthly, mean night and day fluctuations of PAE in a valley just nearby a radon source, an uranium tailing .

ABSTRACT (See instructions overleaf)

WMC (Olympic Dam Corporation) is a copper and uranium producer in the arid region of South Australia. To date, two mathematical models have been used to determine the incremental impact of the operations on the natural environmental radon daughter concentrations. The models are based on measured sources of radon and radon daughters from the process and measured meteorological conditions. Although the modelling approach is scientifically sound, it is limited because it does not take into account field measurements of radon daughter concentrations.

A method has been developed which combines real time environmental radon daughter concentration measurements from a number of sites around the operations and real time meteorological data to assess the impact. The method essentially determines if a particular site is affected by the operations by considering the wind direction. When there is no impact at a monitoring site, as determined from the wind direction, then that site is considered to be measuring a background level. The background levels from the unaffected sites are then averaged and subtracted from affected sites to determine the impact.

This paper will present the new method which confirmed the results of the modelling, thereby giving more confidence to the existing impact assessment process.

SIMULTANEOUS AND AUTOMATIC DETERMINATION OF Rn-222 DAUGHTERS AND Pb-212 CONCENTRATIONS IN THE ATMOSPHERE USING TWO α SCINTILLATION COUNTERS

ABSTRACT : The method using a monitoring instrument having two α scintillation counters is devised for determining short-lived ^{222}Rn daughters and ^{212}Pb in the atmosphere simultaneously and automatically every 3h. Both levels of these concentrations measured by this method are the same as those observed elsewhere on land.

INTRODUCTION

There are a few reports on simultaneous measurement of ^{222}Rn and/or short-lived ^{222}Rn daughters (the term 'short-lived ^{222}Rn daughters' will hereafter be denoted by '^{222}Rn daughters') and ^{212}Pb in outdoor air using scintillation counters. Druilhet and Fontan [1] measured ^{222}Rn, ^{222}Rn daughters and ^{212}Pb continuously. Nishikawa [2] measured ^{222}Rn daughters and ^{212}Pb continuously. It is very difficult to estimate errors of their concentrations obtained by these method. Fujinami [3] measured ^{222}Rn daughters and ^{212}Pb every 6 h. An interval of 6 h is too long to estimate diurnal variation of their concentrations.

We devise a method using a monitoring instrument having two α scintillation counters for determining ^{222}Rn daughters and ^{212}Pb in the outdoor air every 3 h. This method enables us to measure them automatically for 6 months.

MEASURING INSTRUMENT AND CALCULATION

We remodel a ready-made instrument (Fuji Electricity Co. Ltd., type NAD 23803) for measuring the α-rays of ^{222}Rn daughters and ^{212}Pb daughters. A block diagram of the remodelled instrument is shown in Fig. 1. Air is drawn through a filter of cellulose (Advantec Toyo Co. Ltd., type HE-40T) from an intake at 2 m above the air-ground interface (the first position in Fig. 1). Effective area of the filter for the suction is 0.0023 m^2. After sucking the air for 3 h at a rate of 15 m^3h^{-1}, the part of the filter through which the air is drawn moves from the first position to the second position, the part situated at the second position moves to the third position, and the part situated at the third position moves to the fourth position (see Fig. 1). Then, the α-rays of the radionuclides collected on the filter are measured using two scintillation counters (ZnS and photomultiplier). Since the movement of the filter requiers 2 min, the first measurement starts 2 min from the end of the suction (the first position in Fig 1). This measuring time is 58 min. 7 h from the end of the suction, the second measurement is made for 1 h (the fourth position in Fig. 1).

The distance between the filter and the

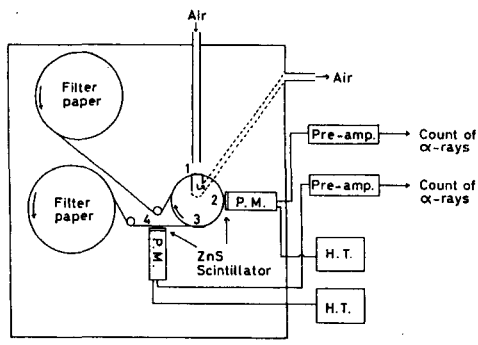

Figure 1. Schematic diagram of measuring instrument.
1 : First position
2 : Second position
3 : Third position
4 : Fourth position

counter is 2 X 10^{-3} m.

In the second measurement, ^{212}Pb is in radioactive equilibrium with its daughters. Therefore, ^{212}Pb concentration A_{Pb} (Bqm^{-3}) is represented by

$$A_{Pb} = \lambda_1\{\varepsilon qG(T_c, T_3, T_4)\}^{-1}C_2 \quad (1)$$

with

$$G(T_c, T_3, T_4) = \frac{\lambda_2}{\lambda_1(\lambda_2-\lambda_1)}(1-e^{-\lambda_1 T_c})(e^{-\lambda_1 T_3}-e^{-\lambda_1 T_4}),$$

where λ_1, λ_2 are the respective decay constants of ^{212}Pb and ^{212}Bi (s^{-1}), ε is the total efficiency for the α-rays, q is the flow rate of air passing through the filter (m^3s^{-1}), T_c is the collecting time (s), T_3 is the time interval from the end of the sampling to the start of the second measurement (s), T_4 is the time interval from the end of the sampling to the end of the second measurement (s), C_2 is the count of the α-rays obtained by the second measurement.

In the first measurement, ^{222}Rn daughters are assumed to be in the radioactive equilibrium in the outdoor air. ^{222}Rn daughters concentration A_{Rnd} (Bqm^{-3}) is represented by

$$A_{Rnd} = \lambda_3[\varepsilon q\{F_1(T_c, T_1, T_2)+F_2(T_c, T_1, T_2)\}]^{-1}(C_1-C_2') \quad (2)$$

with

$$F_1(T_c, T_1, T_2) = \frac{(1-e^{-\lambda_3 T_c})(e^{-\lambda_3 T_1}-e^{-\lambda_3 T_2})}{\lambda_3}$$

and

$$F_2(T_c, T_1, T_2) = \frac{\lambda_4\lambda_5}{\lambda_3(\lambda_4-\lambda_3)(\lambda_5-\lambda_3)}(1-e^{-\lambda_3 T_c})(e^{-\lambda_3 T_1}-e^{-\lambda_3 T_2}) - \frac{\lambda_3^2\lambda_5}{\lambda_4^2(\lambda_4-\lambda_3)(\lambda_5-\lambda_4)}$$
$$X(1-e^{-\lambda_4 T_c})(e^{-\lambda_4 T_1}-e^{-\lambda_4 T_2}) + \frac{\lambda_3^2\lambda_4}{\lambda_5^2(\lambda_5-\lambda_3)(\lambda_5-\lambda_4)}(1-e^{-\lambda_5 T_c})(e^{-\lambda_5 T_1}-e^{-\lambda_5 T_2}),$$

where λ_3, λ_4 and λ_5 are the respective decay constants of ^{218}Po, ^{214}Pb and ^{214}Bi (s^{-1}), T_1 is the time interval from the end of the sampling to the start of the first measurement (s), T_2 is the time interval from the end of the sampling to the end of the first measurement (s), C_1 is the count of the α-rays obtained by the first measurement, C_2' is the count of the α-rays estimated from the second measurement, which is due to ^{212}Pb daughters during the first measurement. C_2' is calculated on the assumption that the ratio of ^{212}Bi concentration A_{Bi} (Bqm^{-3}) to the ^{212}Pb concentration is 0.7 in the outdoor air (A_{Bi}/A_{Pb} ranges from 1.0 to 0.4 [4] in the outdoor air, we adopt the average of these two values) and that ^{212}Bi is in radioactive equilibrium with its daughters.

There are many reports on the deviation from the radioactive equilibrium among ^{222}Rn daughters. Even if the ratios of the ^{214}Pb and ^{214}Bi concentrations to the ^{218}Po concentration are 0.5 and 0.3 respectively, the average concentration of these three radionuclides is only +20 % as compared to the concentration calculated by the assumption of the equilibrium.

EXAMPLE OF RESULTS OBTAINED BY THE MEASUREMENT

The measurement is made at Kamisaibara-mura (35°18'N, 133°35'E) in Japan. The ^{222}Rn daughters concentration ranges from 0.29 to 9.61 Bqm^{-3} and the ^{212}Pb concentration does from 0.006 to 0.433Bqm^{-3}. The average values of the ^{222}Rn daughters and ^{212}Pb concentrations are 3.23 and 0.125 Bqm^{-3} respectively. These values are observed elsewhere on land for the

^{222}Rn daughters and ^{212}Pb concentrations. The ratio A_{Pb}/A_{Rnd} ranges from 0.008 to 0.089, and its average value is 0.032 (the ratio of the average value of A_{Pb} to the average value of A_{Rnd} is 0.039). This average value is a little smaller than the world average of a few available values [5, Annex D, Table 23], which is 0.04. The ^{222}Rn concentration in the Table 23 shows the ^{222}Rn daughters concentration defined in this article.

We show here an example of the results measured for a week, but this instrument permits us to measure the ^{222}Rn daughters and ^{212}Pb concentrations automatically without exchange of the filter for 6 months.

MEASURABLE ZONE

Figure 2 shows the zone where the ^{222}Rn daughters and ^{212}Pb concentrations can be measured simultaneously with this instrument. This zone is enclosed with the strait lines I and II and the curved line III. If the ratio A_{Pb}/A_{Rnd} is larger than the strait line I (2.67×10^{-4}), the contribution of the ^{222}Rn daughters to the second measurement can be neglected. The strait line II indicates merely the lower limit of detection of ^{212}Pb. The curved line III indicates the ratio A_{Pb}/A_{Rnd} estimated from the following equation,

$$C_1-C_2' = 3\sqrt{C_1+C_2'+(C_2'-C_2'')^2}. \quad (3)$$

where C_2'' is the count of the α-rays estimated from the second measurement, which is due to ^{212}Pb daughters during the first measurement. C_2'' is calculated on the assumption that ^{212}Pb is in radioactive equilibrium with its daughters. Considering the variations of the ^{222}Rn daughters and ^{212}Pb concentrations, this zone includes 14 points out of 16 in UNSCEAR Report [5, Annex D, Table 23] where the ^{222}Rn daughters and ^{212}Pb concentrations were measured. Therefore, this method enables the simultaneous measurement of these concentrations over considerably vast extent of land. And, having high sensitivity, this instrument is useful to measure simultaneously the low concentrations of the ^{222}Rn daughters and ^{212}Pb in the open air.

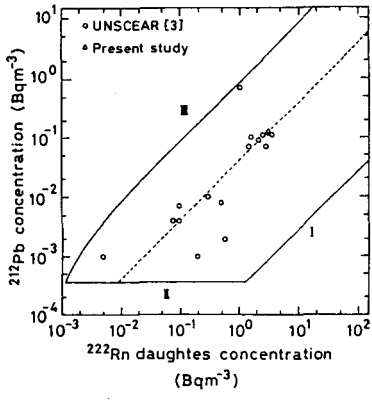

Figure 2. Zone where simultaneous measurement of ^{222}Rn daughters and ^{212}Pb is possible.
----- : A_{Pb}/A_{Rnd} = 0.04

INTRODUCTION

Recently the ICRP recommended that steps be taken to reduce radon not only in the home environment but also in the workplace (1). Although nation-wide surveys of radon concentrations have been often carried out in dwellings, very few have been conducted in the workplace. If we consider that workers spend more than 1/3 of their day on the job, workplace surveys are just as significant as those in dwellings. Radon concentrations in several offices were measured with passive devices. Due to the use of air conditioner and the habits of workers, radon concentrations during the actual working period may differ from the averaged radon concentrations throughout a day. Most offices make use of one of two types of air conditioners. With the first, air is re-circulated in the room. Radon concentration remains stable whereas radon progeny concentrations may vary drastically. With the second, outside air is partially injected into indoors and consequently the radon concentration as well as radon progeny may vary due to the effect of fresh air entry. For the dose assessment, determination of parameters such as equilibrium factor(F) and unattached fraction(f_p) is also needed as well as radon concentrations. Therefore, the equilibrium factor and unattached fraction were continuously measured in two places with an active device. The results of these measurements in workplaces were presented in the present paper.

MATERIALS AND METHODS

Radon measurements with passive devices were carried out at five offices which were located near Shinjuku station in Tokyo. Two devices were placed at each site. One provided the average radon concentration over a 24 hour period. The other provided the average radon concentration during working hours. An electrostatic integrating radon monitor developed by T. Iida et al. was used in this survey (2). Although CN film is used in the ordinary monitor, CR-39 was chosen for its stable sensitivity. Its detection limit is below 1 Bq m^{-3} for an exposure time of 2 months. Since most of ^{218}Po atoms are positively charged, they are collected on the negative electrode of the monitor (-300V) (3). In order to control the period of applying a voltage to the monitor, a weekly timer was incorporated into the monitor. The voltage applying period was set from 11:00 to 19:00 taking into consideration the air exchange rate of the monitor (4). The monitor with the timer measure the average radon concentration from 9:00 to 17:00, Monday to Friday. CR-39 were replaced every 2 months for more than 1 year.

So as to measure the equilibrium factor and unattached fraction, an active device developed by S. Tokonami et al. was used (5). This device consists of three parts: an unattached progeny monitor, an attached progeny monitor, and a radon gas monitor, all connected in series. When air is introduced into the device, unattached radon progeny is collected on a metal wire screen (JIS 300 mesh, openings: 118.2 cm^{-1}, wire diameter: 3.75×10^{-3} cm), and its activity is detected simultaneously by a silicon semiconductor detector (6,7). Remaining unattached and whole attached progeny are collected on a fiberglass filter(Whatman GF/F). ^{218}Po concentration and equilibrium equivalent radon concentration(EER) of the unattached and attached fractions were determined by the build-up method (8,9). Radon gas flows into a cylindrical vessel(decay chamber: inner volume of 7 liters) through a drying column filled with $CaCl_2$. Since radon progeny formed in the decay chamber are positively charged, they are collected on the detectable surface of a silicon semiconductor detector with an electric field(-4500V). The radon concentration is estimated from the net count of the collected ^{218}Po. This device can simultaneously provide the equilibrium factor and unattached fraction every 30 minutes. The minimum detectable concentration, derived from counting data in which the relative standard deviation is assumed to be 50%, is 3 Bq m^{-3} for radon concentration and below 1 Bq m^{-3} for both ^{218}Po concentration and EER.

RESULTS AND DISCUSSION

Figure 1 shows the average radon concentrations in the five offices. The radon concentrations varied

nd some relative high radon concentrations were observed. From these limited measurements, it was found that he radon concentrations during working hours were almost the same as those for all day average. Since re-circulating air conditioners were used in each of the offices, it is possible that the radon concentrations were stable whereas radon progeny concentrations varied. Thus the equilibrium factor and unattached fraction during the working period would more than likely be different from the daily average. By using an active device, the authors obtained data for the equilibrium factor and unattached fraction. The measurements were done in the laboratory of Waseda University, Tokyo. The radon concentrations were almost constant all day. However, the equilibrium factor and unattached fraction varied widely when the air conditioner was operated. When the air conditioner was turned off, the arithmetic mean of the equilibrium factor and unattached fraction were 0.6 and 0.05, respectively (5). When it was turned on, the arithmetic mean of the equilibrium factor and unattached fraction were 0.25 and 0.11, respectively (5). As other researchers have pointed out, a negative correlation can be found in the relationship between the equilibrium factor and the unattached fraction (10,11). Since the effects of the equilibrium factor and unattached fraction on dose are counterbalanced, determination of the radon concentration may be more significant than that of these parameters (10,11).

From other measurements carried out in Chiba over a period of 50 days with an active device, it was found that the radon concentrations during the working period were different from the daily average. Table 1 shows the variation of average radon concentrations in a week. The average concentration ratio between the working period and all day was 0.57 on weekdays whereas 0.84 on weekends. Table 2 and 3 show the variation of average equilibrium factors and unattached fractions, respectively. The equilibrium factors during the working period were larger than those during all day. On the other hand, the unattached fractions during the working period were smaller than those during all day. When compared with the radon concentrations, however, the difference was not so significant.

CONCLUSION

Radon measurements in workplaces were carried out. The radon concentrations during the working period and during all day were determined. A difference between the two was not found. The radon concentrations were almost stable whereas the equilibrium factor and unattached fraction varied since air conditioners were used in each office. If the relationship between the equilibrium factor and unattached fraction is taken into consideration, their effect on dose is counterbalanced. When the radon concentrations varied drastically, the equilibrium factor and unattached fraction showed only a slight variation. These findings suggest that for dose assessment, determination of the radon concentration is more significant than that of other parameters.

et Techniques, 16 route de Gray, 25030 Besançon cedex, France

ABSTRACT

In this paper we propose an evaluation of detection efficiency for the LR 115 alpha particle detector. This evaluation is based on the consideration that the trach etch rate is proportionnal to the ionization rate at a given point of particle's trajectory. A good correlation is obtained when comparing both modelized and experimental detection efficiencies. It is put forward that detection efficiency depends upon the used measurment device (optical or spark counting).For LR 115, spark counting seems to be a much sensitive method when performing radon dosimetry.

INTRODUCTION

To explain the track etching phenomenon in LR 115, the conical model [1] uses the notion of constant etching rate during etching, both for the undamaged zone (V_b) and for the damaged zone(V_t). If this hypotheses seems us reasonable for the V_b it do not seem realistic for the description of V_t. The energy loss of an alpha particle varies when it is slowed down and the resulting damage density is not linear along the travelled distance into the detector material. This consideration suggests us that the track etch rate V_t does vary during the etching process. We will deduce the detection efficiency expressed as a n energetic sensitivity area and the mean critical angle for alpha particles registered in LR 115 and propose some limitations for its use in the field of dosimetry.

HYPOTHESES OF THE MODEL.

-We consider that the dissolution rate V_t (E;x) in cellulose nitrate in the vicinity of a point x of ionizing particle's trajectory with energy E is proportionnal to the ionizing rate J (E;x) at this point:

V_t (E;x) = K J (E;x); K being a proportionality factor for the ratio of these two rates.

-A track only will be visible if the etching process reaches the colourless substrate on which the cellulose nitrate sensitive fim is deposited.

-Ionization rate varies as a function of energy of the incident particle and consequently with its depth or position, x. Nevertheless, as indicated in Figure 1, for energies E greater than 4 MeV, this rate remains quasi-constant. In such a case, we will suppose that V_t (E>4MeV;x) = Cste.

For the experimental determination of K, we first measure the dissolution rate V_b of the non-damaged material using sodium hydroxyde with a molar concentration 2.5 M and an etching bath temperature of 60°C. The obtained value is $V_b = 3.4\ \mu m.h^{-1}$.

To follow the evolution of the specific alpha track etch rate V_t, we irradiated a set of 11 LR 115 films under normal incidence (90°), with alpha énergies of 4 MeV. The etching conditions were the same as indicated above but we used etching steps ranging from 80 to 130 mn.

In these conditions, the etched length along the trajectory L of the particle only exceeds the detector thickness (begins to be visible under an optical microscope) after a time t_d = 100 mn. The mean etching rate then is: V_t (E=4MeV;x) $= h/t_d = 7.2\ \mu m.h^{-1}$. h is the detector thickness (h=12μm).

For cellulose nitrate, the computer code TRIM91 [2] gives J (E=4MeV;x) = 176.74 keV. With these values one obtains $K = 0.0409\ \mu m^2\ h^{-1}\ keV^{-1}$.

RESULTS

1) Calculation of V_t (E;x).

In Figure 2 we present the variation of V_t (E=6MeV;x) in cellulose nitrate along the track axis of length R_6. An energy of 6MeV is choosen in order to cover the energetic detection range of the detector. The best fit for V_t (E=6MeV;x) was obtained using a 9 degree polynomial expression P(x) whose parameters are:

a_0=4.22; a_1=0.49; a_2=0.03; a_3=-0.06; a_4=1.32 10^{-2}; a_5=-1.38 10^{-3}; a_6=7.96 10^{-5}; a_7=-2.61 10^{-6}; a_8=4.55 10^{-8}; a_9=-3.28 10^{-10}.

The V_t (E;x) du to an alpha particle with energy E (range R) lesser than 6 MeV and with an incidence angle θ is obtained from P(x) with the forcoming boundary limits:

$$\Rightarrow L < h/\sin\theta: \quad (R_6 - R) < x < R$$

$$\Rightarrow L = h/\sin\theta: \quad (R_6 - R) < x < (R_6 - R + L)$$

2) Minimum time necessary to etch a track or to open a track.

The model enables the determination of the minimum time needed to to prduce a given track to be performed.

Figure 3. Pénétration of an alpha particle with incidence θ when the substrate is not reached (a) ; when the end point of the alpha particle is out of the detector (the track is open) (b).

Cas(a): The alpha particle is thermalized in the thickness of the detector. The range R is then such that R sinθ < h. The polynomial of V_t (E;x) is used with the boundaries $(R_6-R)<x<R_6$. The time t_p needed to etch a track to its end is:

$$t_p = \int_{\alpha}^{\beta} \frac{1}{V_t(E;x)} dx$$

where $\alpha = (R_6 - R)$ and $\beta = R_6$. Further, the dissolution (enlargement) of the undamaged material will be controled by the constant V_b.The minimum time necessary to obtain an open track is then:

$$(t_p)_{\min} = t_p + \frac{h - R\sin\theta}{V_b}$$

Cas(b): The particle passes through the detector and its range R is such that $R \sin\theta > h$. The condition on x being now $(R_6 - R_i) < x < R_6 - R + h/\sin\theta$, the minimum time needed to create an open track will be:

$$(t_d)_{\min} = t_p - \int_{\alpha}^{\alpha + h/\sin\theta} \frac{1}{V_t(E;x)} dx$$

Table 1 presents calculated values of the times needed to open a track with various energies and incidence angles. These values are in good agreement with those obtained by several experimenter [3,4].

Table 1. Calculated values $(t_d)_{min}$ for various energies E and incidence angles θ.

3) Sensitivity area of the detector

The sensitivity area of the LR 115 detector is determinated by means of the described model (Table 1). All the $(t_d)_{min}$ which are greater than 2h will correspond to non-detectable energies. The so defined sensitivity area is comprised between 2 MeV and 4.5 MeV. To test this result, 11 detectors were used. Irradiations were performed under normal incidence (90°) with an américium (241-Am) source having an initial alpha energy of 5.5 MeV. Energies between 0.5 and 5.5 MeV were obtained by changing the distance from the source to the detector in air. The etching time is equal to 2h. The sensitivity area determinated with an optical microscope is comprised between 1.2 and 4.6 MeV (Figure 3). The poor agreement observed at weak energies can be explained: it is du to the measurement tool. Indeed, for optical reasons, an open track is not necessarely observable under an optical microscope. Spark counting performed on LR 115 detectors irradiated in the same conditions provide a sensitivity area from 1.8 to 4.8 MeV, in better agreement with our predictions.

Figure 3. Experimental sensitivity area of LR 115 (optical microscope)
Figure 4. Critical angles calculated for LR 115

4) Calculation of critical angles.
From the model we deduce the variation of the critical angle θ_c as a function of energy (Figure 4). θ_c varies from a value of 80° to a value of 60° passing by a minimum value of 45° as energy ranges in the calculated sensitivity area. From this result, we deduce a calculated mean critical angle:

MEASUREMENT OF THE POTENTIAL ALPHA ENERGY CONCENTRATION IN AIR BY SEPARATE REGISTRATION OF THE RADON DECAY PRODUCT 214-Po USING NUCLEAR TRACK ETCHED DETECTORS

B.Dörschel[1], B.Burgkhardt[2], T.Kubsch[1], A.Kupschus[2], E.Piesch[2], J.Reinhard[1]

INTRODUCTION

Long-term measurements of the activity concentration of ^{222}Rn in air can be easily performed using a solid state nuclear track detector within a diffusion chamber. The radiation exposure of the human respiratory tract is, however, mainly characterised by the potential alpha energy concentration W_p of the radon daughters. The measurement of this quantity over the same period of time is very difficult. Some authors applied the double chamber method, using one detector within a chamber closed by a diffusion filter and another detector within an analogeous chamber, but without the filter (1,2). The results found from the relationship between W_p and the activity concentration of both alpha active decay products (^{218}Po and ^{214}Po) depend strongly on the exposure conditions, e.g. on the equilibrium factor and the fraction of unattached radon daughters. The aim of our studies was to find a new approach to estimating the potential alpha energy concentration on the basis of its relation to the activity concentration of ^{214}Po only.

CONCEPT OF MEASUREMENT

The actual radon daughter concentration in air is affected by the dilution as the result of ventilation as well as the deposition on wall surfaces. The latter effect is different for radon daughters attached on aerosols and unattached daughters, resp. Taking into account realistic values for the attached fraction and the deposition rates the radon daughter concentrations c_1 (^{218}Po), c_2 (^{214}Pb), c_3 (^{214}Bi), c_4 (^{214}Po) can be calculated from the ^{222}Rn concentration c_0 by means of a recursion formula. Inserting the results into the definition equation for the potential alpha energy concentration W_p, the functions

$$\frac{W_p}{c_0} = f\left(\frac{c_1 + c_4}{c_0}\right) \tag{1}$$

and

$$\frac{W_p}{c_0} = f\left(\frac{c_4}{c_0}\right) \tag{2}$$

can be calculated (3). The results are shown in Fig. 1. Determining the activity concentration of radon on the one hand, and that of ^{218}Po and ^{214}Po or of ^{214}Po only on the other hand, the potential alpha energy concentration can be derived from these curves.

Measurements of ^{222}Rn and the total activity concentration of both alpha active decay products are frequently performed by means of the double chamber method. However, because of the marked steepness of the corresponding curve (I) in Fig. 1 a very high uncertainty of W_p results. Therefore, we proposed a new concept detecting ^{214}Po only. Then curve (II) in Fig. 1 is relevant which is much more flat. Therefore, more precise results for W_p can be expected. The superiority of this new method has been theoretically shown in our recent studies, especially in such cases where the unattached fraction of the radon daughters is relatively high (3-5). It needs, however, a method for the separate long-term measurement of the activity concentration of ^{214}Po.

For this purpose, the application of nuclear track detectors with a suitable energy response function is useful. From the alpha energy spectrum in air followed that such a detector should be sensitive only to alpha particles slowed down to energies within a window between 6.1 MeV and 7.4 MeV. This limitation is needed in order to avoid tracks from radon daughters plated out on the detectór surface. The aim of our studies was to optimize the energy response of a Makrofol DE detector for that purpose.

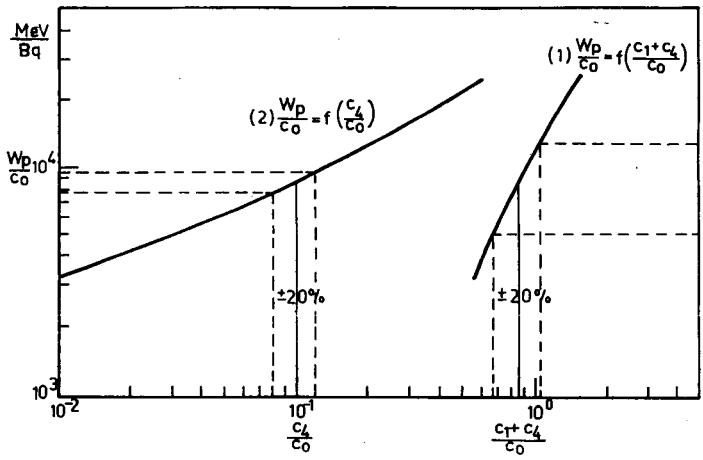

Figure 1. Potential alpha energy concentration as a function of the radon daughter concentrations after eq. (1) and (2)

EXPERIMENTAL AND THEORETICAL BASIS

The detector material used was Makrofol DE with a thickness of 475 µm. During the irradiations the detectors were covered by a protecting Mylar foil with a thickness of about 2 µm.

For irradiations with high energy alpha particles a source has been prepared by electrodeposition of thoron daughters. The alpha particles with an initial energy of 8.8 MeV have been slowed down in the irradiation chamber by variation of the air pressure to fall into the interesting energy interval between 5.8 MeV and 7.7 MeV.

The main task was to investigate whether the energy window characterised by two thresholds can be generated. For that some theoretical considerations were performed. Etchable tracks are formed only when the restricted energy loss REL_{350} of the alpha particles along their paths exceeds the critical energy loss for the detector material. The REL_{350} value depends strongly on the alpha energy and varies, therefore, considerably along the alpha particle trajectories (see Fig. 2).

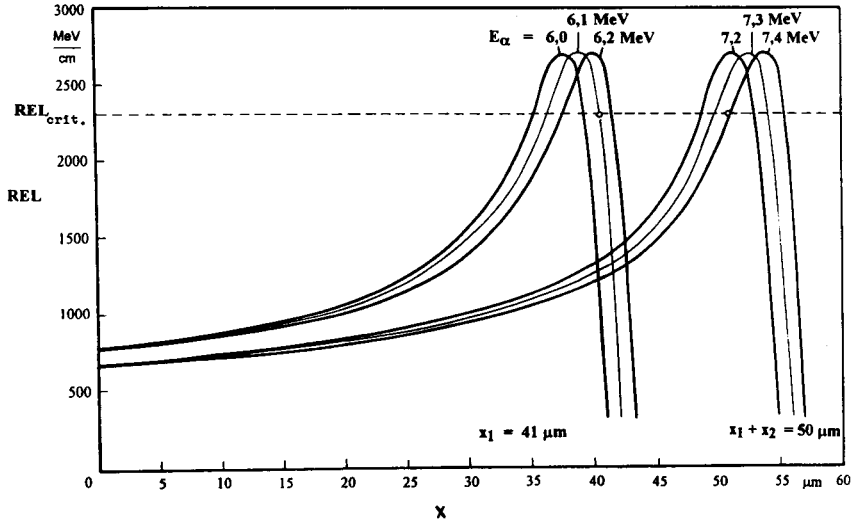

Figure 2. Restricted energy loss REL as a function of the depth x within the detector (including 2µm Mylar) (Parameter: Initial alpha energy E_α; Calculation using the program STOPOW 2000 (6))

The critical REL_{350} value has been found to be about 2300 MeV/cm in separate experiments. To avoid a formation of etchable tracks by alpha particles with energies lower than 6.1 MeV a detector layer (below the Mylar foil) of about 39 µm has to be removed by a chemical etching process. Over-etched tracks caused by lower energy alpha particles may not contribute to the detector reading during a further processing of the detector by electrochemical etching. The treeing process with strong enlargement of the tracks takes place only

if a sharp tip is formed at the end of the chemical etching, i.e. not for over-etched tracks. Figure 2 shows that at a depth x_1 of 41 μm the 6.1 MeV alpha particles are just ready to produce electrochemically etchable tracks. On the other hand, the energy loss of alpha particles with initial energies above 7.4 MeV may not exceed the critical value for track formation at a depth of $x_1 + x_2 = 50$ μm. That means, the detector layer removed during the electrochemical etching must be about 9 μm up to the end of this etching step. Because the formation of electrochemically etched tracks is influenced by the applied field strength it has been expected that the exact thresholds and the shape of the alpha energy window depend on the field strength, too.

RESULTS

The etching was carried out using a mixture of 80% ethanol and 20% KOH at 40°C. During the chemical pre-etching a detector layer of 39 μm was removed. The electrochemical etching was performed at an electric field strength of 51 kV/cm and a frequency of the high voltage of 3 kHz for 1 hour. After that a chemical post-etching followed for 0.5 hours. During this process the tracks are enlarged without changing the energy response of the detector. This last step makes, however, the detector evaluation easier. The total detector layer removed during the electrochemical etching and chemical post-etching was about 14 μm. The maximum track diameter amounted to 200 μm. The resulting energy response of the detector is shown in Fig. 3.

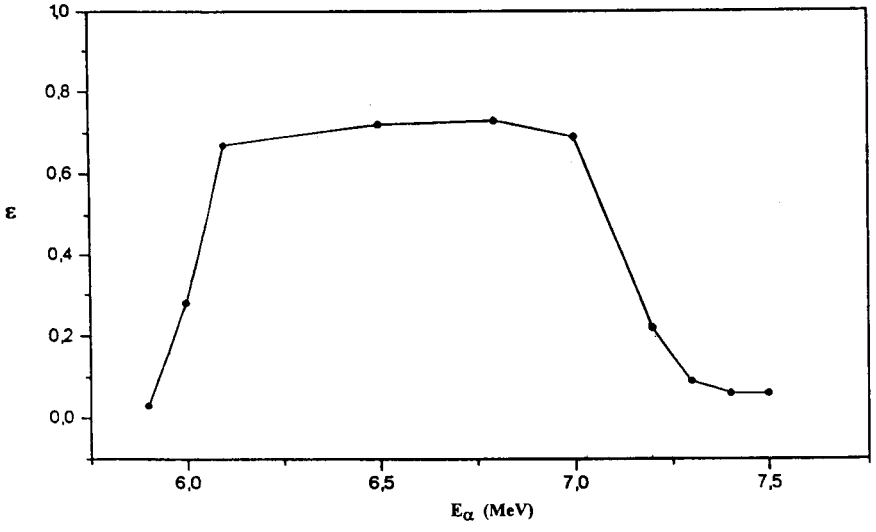

Figure 3. Registration efficiency ε as a function of alpha energy E_α

CONCLUSIONS

The results of our studies confirmed that, using Makrofol-DE detectors treated by a combined chemical and electrochemical etching, the energy window needed for a separate detection of ^{214}Po can be generated. The activity concentration c_4 of ^{214}Po results from the detector reading, i.e. the track density within a defined period of exposure. The calibration factor which links both quantites can be found by an experimental calibration using a reference measuring device for ^{214}Po. On the other hand, the calibration factor can also be calculated. The corresponding relationship was derived in a former paper (3). The most important quantity needed for the calculation is the critical angle of track detection as a function of the alpha energy. The precise determination of this function will be the objectives of our next work. Using the c_4 value and the radon concentration c_0 determined by means of a traditional method, e.g. using the diffusion chamber, the potential alpha energy concentration W_p can be determined..

A test of the method under practical conditions is planned, e.g. in living rooms or at special working places.

RECENT PROGRESS IN SAMPLING AND MEASUREMENT OF RADON AND THORON DECAY PRODUCTS

Martin Pohl and Henning von Philipsborn
University of Regensburg, D-93040 Regensburg

Abstract: **A new approach to sampling and measuring the unattached fraction of radon decay products is presented. Two methods of electrostatic sampling with polystyrene plates charged by friction or with copper plates connected to a high voltage source are compared to conventional sampling on wire mesh screens. A good correlation between Po-218 alpha activities for the three sampling methods for different radon concentrations and aerosol conditions was found. For total beta activities correlation between the methods is less obvious.**

INTRODUCTION

The alpha-decay of Rn-222 and its recoil result in about 90% positively charged Po-218 ions. They have a high mobility, characterized by the diffusion coefficient, which controls the processes of aerosol attachment and deposition on surfaces. The diffusion coefficient of charged and uncharged Po-218 and Pb-212 has been studied with electric fields in diffusion chambers (1, 2). Despite the fast neutralization of the ions, collection is possible with a sufficiently high voltage. The efficient mean life time of free Po-218 ions due to decay, recombination and attachment is typically 12 s (3). Therefore it is possible to determine the Po-218 concentration by collecting the free ions. Likewise Pb-214 may be positively charged, but its amount is unknown, which makes the determination of the Pb-214 concentration by collecting the ions less certain. The recoil energy of the beta decay of Pb-214 to Bi-214 is not sufficient for ionization and thus there are no Bi-214 ions.

All radon decay products quickly attach to aerosol particles or deposit on surfaces. Airborne radionuclides are divided into an "attached" and an "unattached" fraction. Molecular clusters up to 1 nm in size are formed with water molecules and trace gases. The fraction with a thermodynamic diameter below 2 nm is defined as "unattached", the larger one as "attached".

Unattached radionuclides have a higher diffusivity and may be deposited on wire mesh screens. An alternative method is a collection on negatively charged plates, which attract the positively charged radon decay products. The unattached fraction is attracted much more effectively than the attached fraction, due to its much higher mobility. In the following the activity collected on charged plates is compared with the activity on wire mesh screens under different radon concentrations and aerosol conditions.

MATERIALS AND METHODS

The alpha activity was determined by alpha spectroscopy with a 30 cm^2 surface barrier silicon detector in a vacuum chamber and a multichannel analyzer (EG&G, D-81677 München), and by a hand-held alpha spectrometer Alpha Analyzer with a 2" diameter silicon detector (SAIC, San Diego, CA 92121 USA). The beta activity was measured with the Living Level Monitor LLM 500 (Münchener Apparatebau, D-82024 Taufkirchen) with a 11 x 11 cm^2 proportional detector (4).

The attached fraction was sampled with glass fiber filters MN 85/90 (Macherey-Nagel, D-52348 Düren). The unattached fraction was deposited on wire mesh screens (Bucher, D-81669 München) with a mesh width of 0.04 mm and a wire diameter of 0.028 mm (147 mesh/cm = 374 mesh/in). Both have an effective diameter of 10 cm and are mounted in cardboard diskettes, which fit into the LLM. The wire mesh screen was fixed in front of the glass fiber filter on an air sampler (vacuum cleaner). The distance between the wire mesh screen and the glass fiber filter was 4 mm to avoid penetration by alpha-recoil-atoms. After 1 min of sampling at 250 L/min with the air sampler and 10 s transfer time, the filter and the screen were evaluated in the LLM within 1 min for beta activity and equilibrium equivalent radon concentration (EER). Additional screen samples were measured for alpha activity on the front side. 250 L/min through a 10 cm diameter screen yield a subcritical face velocity of 50 cm/s, for which the particle diameter for 50% collection efficiency is about 2 nm.

Collector plates for electrostatic collection are polystyrene plates (PS) of 130 x 200 x 2 mm^3 charged by friction, "Philion Plates" (5), or Cu plates of 100 x 100 x 0.6 mm^3, charged by a

high voltage source. The PS plates were charged by rubbing with wood or wool. With charge saturation on the PS by appropriate rubbing, -20 kV are reproducibly achieved and confirmed by measurement with a "field mill" Static Monitor 140 C (John Chubb Instrumentation, Cheltenham, GL51 8PL, UK). The voltage on the plate decreases faster at higher radon concentrations. The Cu plate was connected to a constant voltage source of -16 kV. No significant differences between PS plates and Cu plates were found, so in the more results from the Cu plate are described, because they are assumed to be more convincing. After sampling for 1 min and transfer time of 10 s Cu plates were measured 1 min for beta and for alpha activity. Using large-area collectors and large-area detectors improves overall efficiency approx 100-1000 fold, relative to wires connected to a voltage source and an electrometer discharge first used by E. Rutherford in 1900 in the laboratory, and by J. Elster and H. Geitel in 1901 in the open air.

The samples were taken in a radon lab (46 m^3), where uranium minerals were stored in air tight containers. The radon concentration was changed by opening and closing containers. The aerosol concentration was changed by burning candles and incense and filtering the air with an air cleaner Breatheasy (12 m^3/min) (Biltwell, Mississauga, Ontario L5C 2Z2). The radon gas concentration was varied between 500 and 12000 Bq/m^3.

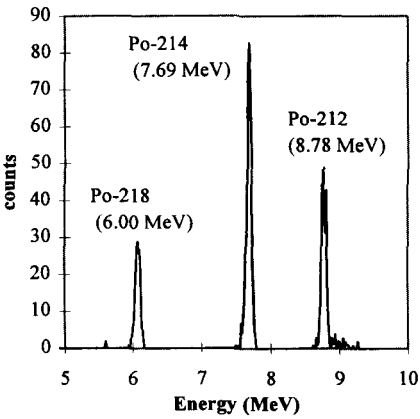

Fig. 1. Alpha spectrum of a Philion Plate, exposed to ambient air for 25 min; 3.7 h count with a 30 cm^2 silicon detector in a vacuum chamber

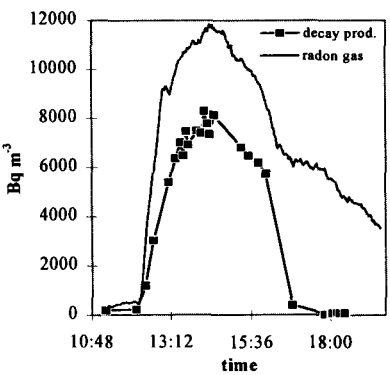

Fig. 2. Concentration of radon gas and EEC of radon decay products in the radon test room

RESULTS AND DISCUSSION

A problem with alpha measurements is the self-absorption in samples like glass fiber filters. Peaks in alpha spectra become very broad with crosstalk between Po-218 and Po-214 peaks. A problem with wire mesh screens is the dependence of the front to back ratio and screen losses on environmental parameters. Fig. 1 shows the alpha spectrum of a Philion Plate, which was exposed to ambient air for 25 min and measured with the 30 cm^2 silicon detector for 3.7 h in the vacuum chamber. The result is a neat spectrum of Po-218 and Po-214 from the radon decay series and of Po-212 from the thoron decay series. All decay products are on the surface of the plate, so there is no self-absorption like in glass fiber filters. Therefore it is possible to count the plates in open air with the SAIC Alpha Analyzer for Po-218 and Po-214 activities without crosstalk. The spectrum on a Cu plate is of similar appearance.

For fast measurements with good counting statistics, high radon levels were used. Fig. 2 shows the variation of radon gas, measured with an instrument Megarad, and of attached radon decay products EER, collected on glass fiber filters and measured with a LLM 500. The radon gas concentration was raised by opening a container with uranium minerals at 12:11. High aerosol particle concentrations of different size distributions were produced by burning candles from 12:45 to 14:40 and incense from 15:15 to 16:10. From 16:10 to 19:00 the air cleaner was put into operation. There is almost no thoron, so measurements were not disturbed by thoron decay products.

After sampling, the Cu plate and the screen were counted for alpha activity with the SAIC Alpha Analyzer and for beta activity with the LLM 500. In fig. 3 the alpha counts in 1 min of the Po-218 peak on the Cu plate and the screen are shown. Pairs of values, measured at nearly the same time are plotted in fig. 4. The numbers indicate corresponding values. There is a good correlation between the activities sampled on the screen and on the Cu plate. This confirms, that there is a fairly constant fraction of Po-218 ions within the unattached fraction for

different aerosol and radon gas conditions. It also shows that the collected activity on the Cu plate or the friction charged polystyrene plate is a fair quantity for the unattached fraction under different aerosol and radon gas conditions.

The Po-214 activity was very low and showed no correlation for both methods of sampling. This is explained by the fact that there is almost no unattached and no charged fraction.

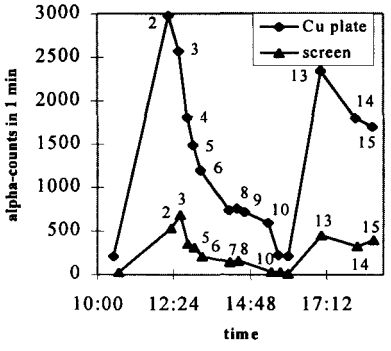

Fig. 3. Alpha counts of Po-218 on the Cu plate (1 min exposition at -16 kV) and on the screen (250 L of air sampled), measured with the SAIC alpha analyzer. Numbers refer to fig. 4

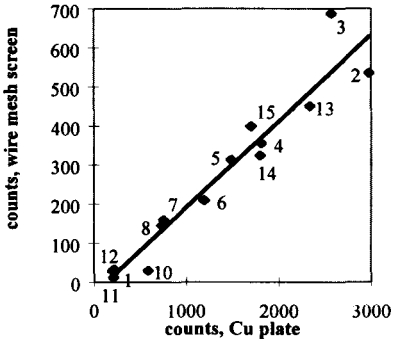

Fig. 4. Alpha counts of fig. 3, plotted as pairs, to show the correlation between the Po-218 activity on the screen and on the Cu-plate. Numbers indicate the points, taken from fig. 3

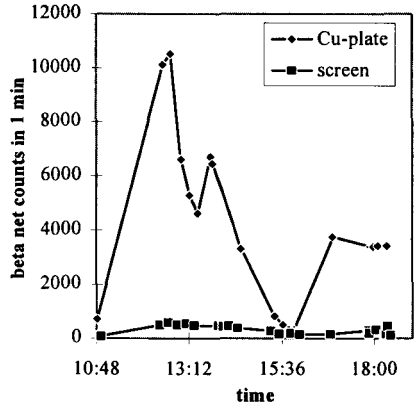

Fig. 5. Beta activity on the Cu-plate and the screen, measured with the LLM 500.

In Fig. 5 total beta counts are shown. There is no obvious correlation between the two series of measurements. The Cu plate shows a wider range of activities for different conditions. This leads to a vague exponential correlation between the two sampling methods. There are several reasons for not having a good correlation. First of all, decaying Po-218 adds to the beta activity. In addition, the correlation between the charged and the unattached fraction of Pb-214 is not known and depends on parameters like humidity and trace gases. Both charged plates sample only the charged unattached fraction, screens sample charged and uncharged, and partly the attached fraction.

CONCLUSIONS

The comparison of the wire mesh screen method with the two types of charged plates - Cu plates and the Philion Plates - gives the following results: A charged plate is a good sampling device for the unattached fraction of Po-218. Despite the very fast neutralization rate of the Po-218 ions, it is possible to collect them by this method, which is simpler and more efficient than wire mesh screens. Because of the sufficiently high voltage the ions are collected before recombination. The determination of the volume, from which Po-218 is sampled, and possible influences of water vapor are still under investigation.

ABSTRACT (See instructions overleaf)

Continous and simultaneous measurements of radon, the attached, unattached radon daughters and aerosol particles were performed in a house under normal living conditions which include ordinary living habits and the normal natural ventilation rate in Japan.

Radon concentration was measured by use of a radon monitor which is composed of an electro-precipitation chamber and a ZnS(Ag) scintillation counter. Concentrations of individual daughter(RaA,B and C) were also measured by a continuous-radon daughter monitor, which has air filtration and gross alpha three counting systems. The unattached atoms of radon daughters were measure with another radon daughter monitor with wire screens substituting for the filter.

The experimental data through one annual cycle were focused on the temporal variation and the influencing factors of equilibrium factor. The equilibrium factor of the house was with the range from 0.35 to 0.45 in monthly mean. The present results showed that there are a high correlation between the equilibrium factor and the unattached fraction of radon daughters and the relation is in agreement with the theoretical prediction, which describes a mass balance of indoor radon daughters.

APPLICATION OF PASSIVE TYPE RADON DETECTORS TO FIND FISSURES IN BANKS CAUSED BY THE SOUTHERN HYOGO PREFECTUAL EARTHQUAKE IN JAPAN

INTRODUCTION

Innumerable fissures were formed widely in Hanshin area in Japan by the former southern Hyogo prefectural earthquake occurred on Jan.17, 1995. It is an urgent necessity for the science of disaster prevention to find these fissures simply and non-destructively. There are thousands of holding reservoirs in the Hanshin area and it is expected that some bank of reservoirs might have fissures inside the bank. In this study, as a preliminary investigation, we applied passive type radon detector Pico-Rad (U.S. Packard Instrument Co. Ltd.) (1, 2) with hemispheric plastic cover over them around the fissure along on the bank of two reservoirs to examine whether there is possibility to find fissures using the characteristics of ^{222}Rn migration. At the same time, we measured the total exposure rate on the ground with NaI(Tl) scintillation surveymeter (Hamamatsu Photonics, SS-γ), radioactivity of soil by sampling method (and low back ground germanium detector) and water contents of soil as supplementary factors of the investigation.

One of the reservoir, Taniyamakami-ike, is located at the north of the Awaji-shima island at a distance of about 4 km from the seismic center of this earthquake. On the whole, ^{222}Rn exhalation rates were high on a line of 2 m below the edge of the bank and got lower in proportion to the distance from this line. Those top of the bank had middle values among the lines. The mean ^{222}Rn exhalation rate was 4.7 mBq m^{-2} s^{-1}, and in these data we found some singularly high ^{222}Rn points.

The other reservoir named Hosho-ike is located at northwestern Nagaokakyo city of Kyoto prefecture and the Komyoji active faulting runs from north to south parallel with the bank about 120 m to the west. In this bank, a fissure about 50 m in length and 0.1 m in width was taken shape. ^{222}Rn exhalation rates were relatively high on the top of the bank compared with on the slope of the bank. The mean ^{222}Rn exhalation rate of 5 points which were measured on the fissure was 16 mBq m^{-2} s^{-1}, and that which were measured on about 1 m to the east from the fissure was 4.9 mBq m^{-2} s^{-1} and in case about 1 m to the west was 4.2 mBq m^{-2} s^{-1}.

From these results we concluded that there is a possibility to find fissures inside the bank using the characteristics of ^{222}Rn migration. Our future objective is to find fissures inside banks non-destructively.

PRINCIPLE AND METHODS

^{222}Rn ($T_{1/2}$=3.8 d) originates from the decay of ^{226}Ra ($T_{1/2}$=1600 y) that distributes widely in the soil. Typical processes of the ^{222}Rn transport below the ground surface are molecular diffusion and/or convective flow, and also the macroscopic flow in channels or fissures as this case. So if there is any fissure in the bank, it is expected that high ^{222}Rn concentration will be observed above the fissure.

In this survey we used Pico-rad detectors for the measurement of ^{222}Rn concentration. It is a compact ^{222}Rn detector using the adsorption of ^{222}Rn to the activated charcoal and ^{222}Rn concentrations are evaluated by LSC counting. The detectors are passive collection devices requiring no power. It is come onto market by U.S. Packard Instrument. Some of the detectors were covered with hemispheric plastic cover to get higher ^{222}Rn

activity and to evaluate area exhalation rates.

Besides there are a lot of papers related to the radiological survey using the terrestrial gamma ray (3), we had not been certain about applying these method to the investigation because our object is the fissures which were made recently not the fault. But for the present we measured the total exposure rate on the surface of the earth with NaI(Tl) scintillation detector (Hamamatsu Photonics, SS-γ), radioactivity of soil by sampling method (and low background germanium detector) and water contents of soil as supplementary factors of the investigation. Measuring methods and conditions of the survey of the Taniyamakami-ike and Hosho-ike are shown in Table 1.

Table 1 Measuring methods and conditions of the survey on the Taniyamakami-ike and Hosho-ike.

	Taniyamakami-ike reservoir	Hosho-ike reservoir
Measuring date (weather)	15-17 Oct., 1995 (clear and cloudy)	17,18 Apr., 1995 (clear)
Pico-rad detectors used	**No. 1-95** set on the ground with the hemispheric plastic cover **No. 96-100** set at 5 cm high above the ground without cover	**No. 1-21** set on the ground with the hemispheric plastic cover **No. 22-24** set in the fissure without cover **No. 25-26** set at 5 cm high above the ground without cover
Arrangement	lattice (interval 2 m)	across (5 lines) and along the fissure
Total sampling time	23~25 hr	about 19 hr
Supplementary measurements	**Total exposure rate** (NaI(Tl) scintillation detector, 56 points) **Radioactivity of soil** (sampling, Ge detector, 9 points) **Water content of soil** (sampling, 28 points)	**Total exposure rate** (NaI(Tl) scintillation detector, 8 points) **Radioactivity of soil** (sampling, Ge detector, 1 point) **Water content of soil** (sampling, 21 points)

RESULTS AND DISCUSSION

1) Taniyamakami-ike reservoir.

The 9 points (on the same line across the bank) mean radioactivity and s. d. of ^{214}Bi, ^{208}Tl and ^{40}K about 10 cm below the ground surface were 23 ± 2 Bq kg^{-1}, 33 ± 3 Bq kg^{-1}, 1140 ± 40Bq kg^{-1}, respectively. We did not find any characteristic feature in this line on the three radioactivity of soil and also on the ^{214}Bi/^{208}Tl ratio. The atmospheric ^{222}Rn concentration measured at 5 cm high above the ground (No. 96~100) was 9.2 ± 3.2 Bq m^{-3}. Figure 1 shows a horizontal distribution of ^{222}Rn concentration inside the hemisphere (No. 1~96). The mean total exposure rate on the ground surface measured by SS-γ was 100 ± 10 nSvh^{-1} (58 points, max. 137, min. 65 nSvh^{-1}). On average, ^{222}Rn exhalation rates were high on a line of 2 m below the edge of the bank and low nearby the bed and at the back slope. Those top of the bank had middle values among the lines. The mean ^{222}Rn concentration was

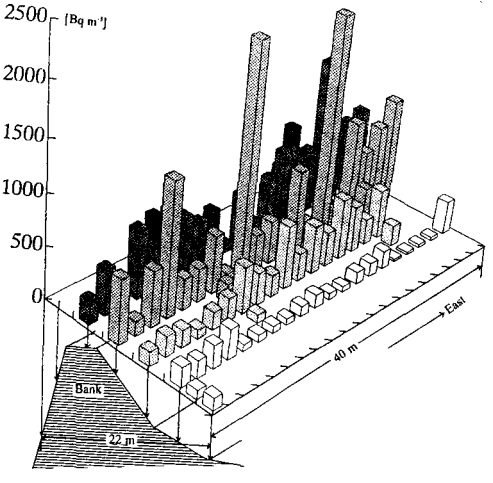

Figure 1. Horizontal distribution of ^{222}Rn concentration around the fissure in the bank of Taniyamakami-ike.

290 Bq m^{-3} (corresponding to 4.7 mBq m^{-2} s^{-1}), and in these data we found some high ^{222}Rn points that concentration was over one thousand Bq m^{-3}. We expect that there are some buried fissures around below this line. The mean water content of soil and its s. d. at about 10 cm deep of 28 points was 14±12% (max. 58, min. 1.1 %) and we did not find the correlation of ^{222}Rn concentration with water content of soil.

2) Hosho-ike reservoir.

The radioactivity of ^{214}Bi, ^{208}Tl and ^{40}K 10 cm below the ground surface were 7.9, 14, 560 Bq kg^{-1}, respectively. The mean total exposure rate on the ground surface measured by SS- γ was 70 $nSvh^{-1}$ (6 points, max. 100, min. 57 $nSvh^{-1}$). These values are within the range of that of the normal natural environment. The atmospheric ^{222}Rn concentration measured at 5 cm high above the ground (No. 25, 26) was 11± 10 Bq m^{-3}, and ^{222}Rn concentration measured in the fissure at 0.3～0.5 m deep (No. 22～24) varied widely from 40 to 4200 Bq m^{-3}. Figure 2 shows a horizontal distribution of ^{222}Rn concentration inside the hemisphere. ^{222}Rn concentration were relatively high on the top of the bank compared with the slope of the bank.

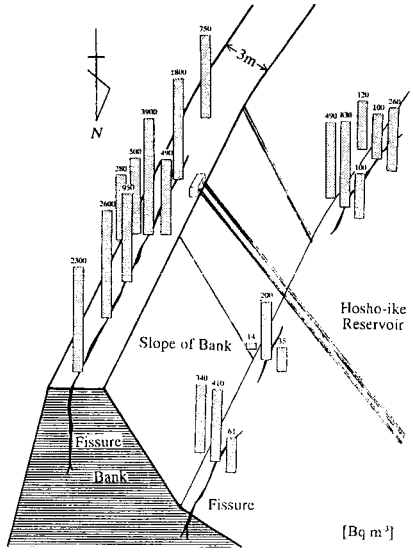

Figure 2. Horizontal distribution of ^{222}Rn concentration around the fissure in the bank of Hosho-ike.

The mean ^{222}Rn concentration of 5 points which were measured on the fissure was 1000 Bq m^{-3} (16 mBq m^{-2} s^{-1}), and that which were measured on about 1 m to the east from the fissure was 300 Bq m^{-3} (4.9 mBq m^{-2} s^{-1}) and in case about 1 m to the west was 260 Bq m^{-3} (4.2 mBq m^{-2} s^{-1}). The mean water content of soil at about 10 cm deep of 21 points was 11.4 % (max. 18.5, min. 5.6 %) and there was no correlation of ^{222}Rn exhalation rates with water content of soil. (After the survey, repair work is now in progress on the Hosho-ike reservoir. About 7 m fissure was found in the cross section of the bank (Photo 1)).

Above mentioned two results showed that it is effective for the survey of new fissures to apply ^{222}Rn gas method rather than the radiological survey using gamma-ray.

diffusion, deposition, laminar flow, radon daughters, unattached fraction

INTRODUCTION

To study the plate-out of the first three unattached radon daughters (^{218}Po, ^{214}Pb, ^{214}Bi), we have to know the diffusivities of these particles. One way to determine these diffusivities is to use the so-called two-filter method (4, 17). By theoritical calculation and experimental measurement of the penetration fraction of a radon daughter through a circular cross-section tube, with filters at each end, we can determine its diffusivity. There are, however, uncertainties in this method and the aim of this work was to re-analyse the theories used to calculate the penetration fraction and to employ experimental conditions which avoid errors in determining these diffusivities.

TWO-FILTER METHOD APPLIED TO RADON DAUGHTER DIFFUSIVITIES MEASUREMENTS

A known concentration of radon (^{222}Rn) is introduced into the tube. Due to the upstream filter, the initial radon daughter concentrations are zero. The radon daughters are then formed by radioactive decay, transported by convection and deposited on the tube walls by brownian diffusion. Those which are not deposited on the tube walls and have not decayed are collected on the outlet filter and form the penetration concentration.

THEORETICAL STUDY

Published work (2, 5, 9, 12) on radon daughter penetration through a tube is limited to studies of the first radon daughter and a number of assumptions were made to allow an analytical determination of the penetration fraction. By using a computer program, we can study the penetration fractions of the first three radon daughters and take into account phenomena neglected in the analytical theories.

We used the TRIO EF program (10), a fluid-mechanics code, based on the finite-element method, developed by the CEA Nuclear Reactors Direction.

VALIDATIONS

Our program was validated by :

- diffusive deposition of non-radioactive aerosols in laminar tube flow (3, 6, 7, 16)
- diffusive deposition of aerosols with in-flight formation (1, 8, 14, 15)
- study of diffusive deposition of aerosols with in-flight formation and radioactive decay: comparison with results of a finite-difference method (13).

There is a good correlation between our results and those in the literature ; TRIO EF can thus be considered to provide good modelling of these diffusion and decay phenomena.

^{218}Po DIFFUSIVITY CORRECTION

The analytical theories (1, 3, 6, 7, 8, 14, 15, 16) used for the two-filter method do not make allowances for phenomena that can be taken into account with TRIO EF, i.e. :

- loss of radon daughters by radioactive decay - leading to a penetration fraction decrease ;
- Poiseuille flow development : this effect creates a radial velocity field component directed to the tube centre and also enhances the penetration fraction
- downstream filter effect on flow : this effect creates a radial velocity field component directed to the tube wall, and also reduces the penetration fraction

These effects result in correcting of the penetration fraction by around 5-20% depending on tube length, tube radius and mean axial velocity. This leads to correction of the ^{218}Po diffusion coefficient determined by the two-filter method by around 5-25%. Sasse (13) found a correction of around 10-20%.

^{214}Pb AND ^{214}Bi DIFFUSIVITIES

We computed the second and third radon daughter penetration fractions using this program. These penetration fractions are different and this will be explained in our poster by using concentration profiles of the three species.

This program can also help us to determine ^{214}Pb and ^{214}Bi diffusion coefficients.

EXPERIMENTAL STUDY

The experimental measurements can give rise to errors in determining radon daughter diffusivities. We tried in our work to reduce the number of factors that could result in such errors.

RADON CONCENTRATION ERRORS

The ^{226}Ra source used to produce radon should have a constant emanation factor, which we verified.

We also ensure that we do not have any ^{220}Rn (from impurities in the ^{226}Ra) by allowing it to decay in an upstream volume and verify that there are no ^{220}Rn daughters.

The radon concentration measurements must be very precise. We use a gross alpha counting method calibrated with a reference radon monitor. We also correct the radon concentration for temperature and pressure variations.

DEPOSITION ERRORS

Deposition must be due only to brownian diffusion and we take care to avoid thermophoresis and electrostatic deposition.

RADON DAUGHTERS DIFFUSIVITIES ERRORS

Trace gas can affect radon daughter diffusivities and thus we measure both trace gas concentration and relative humidity and keep these constant as far as possible.

The radon concentration affects the air ionisation rate and thus the radon daughters neutralisation rates and their diffusivities. We thus divid our measurements into those with low and high radon concentrations.

RADON DAUGHTERS MEASUREMENTS ERRORS

Radon daughter concentrations are usually obtained with a total alpha three-count method developed by Thomas (18) which results in uncertainties at low radon daughter concentrations. We use a more precise method optimised by Nazaroff (11).

SAMPLING TIME ERRORS

In the theoretical study, the radon concentration is assumed to be constant and uniform throughout the tube. This is not true in the experiments and we have to use a sampling time which is much greater than the time needed to have this condition. This time can be computed with our program.

Experimental results are now being obtained for comparison with the computer program and to have more precise diffusivity values for the three radon daughters.

CONCLUSION

In this work, we have re-analysed the two-filter method for determining radon daughter diffusivities.

We used a computer program which takes into account phenomena neglected in analytical determinations. Making allowances for these phenomena leads to corrections of around 5-25% for ^{218}Po diffusivity. This program can also help us to determine the other radon daughter diffusivities.

In our experiments, we considered various parameters that can affect diffusivity determination.

Corrections from using theoretical and experimental approaches should give us much more accurate values for the first three radon daughter diffusivities.

ABSTRACT (See instructions overleaf)

The measurement of radon and radon progenies as well and the calibration of their detection systems require the production and measurement of well-defined aerosols in size and concentration. In the German radon reference chamber carnaubawax is used for the production of standard aerosols due to their unique chemical and physical properties. The aerosol size spectra are measured on-line by an aerosol measurement system in the range of 10 nm to 1 μm aerodynamic diameter and compared with theoretical calculations from molecular dynamics for the first time.

The experimental set-ups will be described for the study of adsorption of radioactive ions on aerosols as function of their size and concentration, the results presented and further adaptions for an aerosoljet (for example measurement of short-lived neutron-rich isotopes) introduced.

A LABORATORY FOR STUDYING RADON MITIGATION METHODS IN HIGH-RISE OFFICE BUILDINGS IN HONG KONG

John K.C. Leung, L.C. Hung, M.Y.W. Tso

Radioisotope Unit, The University of Hong Kong,
Pokfulam Road, Hong Kong

ABSTRACT

A territory-wide survey of indoor radon level in 1993 showed that 17% of offices in Hong Kong have radon concentrations above 200 Bq m^{-3} compared with 4% for dwellings. Consequently, the Radioisotope Unit Radon Analysis Laboratory (RURAL) is being built for studying radon mitigation methods applicable to high-rise office buildings. The laboratory consists of three rooms; the main exposure room is built of concrete and is surrounded by the buffer room; and all controls and operations are done inside the control room.

The exposure room can, with the aid of the buffer room, simulate any environmental conditions that can be faced by a real building. The pressure, temperature and humidity can be adjusted to any meteorological conditions that can be found in Hong Kong. Pressure differential and temperature differential can be adjusted to simulate the arrival of fronts, troughs or typhoons. Aerosol concentration and distribution inside the exposure room are controllable as well as the ventilation conditions.

Various mitigation methods will be tested under different conditions. Passive methods include application of radon barriers to building structures and active methods include the use of air cleaners; techniques to increase radon daughters plateout or reduce their attachment to aerosols; and various modifications to the ventilation systems. Mitigation techniques involving modifications to the building strictures and building services will also be developed with the help of the RURAL.

INTRODUCTION

Building materials containing naturally occurring ^{232}Th and ^{238}U, which decay to ^{220}Rn and ^{222}Rn respectively, are the major sources of indoor radon, especially in poorly ventilated environment (1). Some European and U.S. countries have proposed regulations to control the use of building materials in order to minimize their hazards to the people. Hong Kong is a densely populated city, most people spend a lot of time, both living and working, in high-rise concrete buildings; and owing to the hot and humid weather, the use of air-conditioning systems with limited air change rate is very common. According to the territory-wide indoor radon survey conducted in 1993, 17% of offices in Hong Kong have radon concentrations above 200 Bq m^{-3} compared with 4% for dwellings. Moreover, the contribution of ^{220}Rn in Hong Kong is significant, since the predominant geological material is decomposed granite that has a higher content of ^{232}Th. According to another previous survey conducted in 1986 (2), the hazard of ^{220}Rn is almost half of that of ^{222}Rn. Because of the potential high radon dose, there is a necessity to build the RURAL to investigate radon mitigation methods under situations in Hong Kong.

STRUCTURE OF RURAL

The RURAL consists of three rooms, the Exposure Room, Buffer Room, and Control Room. The total area is 8 m x 5 m, and the overall height is 3 m. A schematic diagram of the RURAL is given in Fig. 1.

The Exposure Room is the room where indoor environment of high-rise building is simulated, and where most of the measurements will be done. Its is 3.5 m x 2.4 m x 2 m (L x W x H) and is built of 10 cm thick concrete. The Exposure Room is completely isolated from outdoor environment by the Buffer Room which completely encloses it. The floor of the exposure Room is also isolated from the floor of the Buffer Room by raising the Exposure Room with supports underneath it. Entrance to the Exposure Room is through double air-tight doors which minimize disturbance to the exposure condition.

The Buffer Room is 5 m x 5 m x 3 m (L x W x H) and is built of bricks. Its main function is to simulate all sorts of meteorological conditions external to the Exposure Room. Hence by changing the pressure and temperature inside both the Exposure Room and Buffer Room, the arrival of fronts, troughs or typhoons can be simulated and their effects to indoor radon concentration can be studied. Entrance to the Buffer Room is again guarded by double air-tight doors. All the walls, ceiling and floor of the Buffer Room are coated with polyurethane paint which reduces the generation of radon from the building material of the Buffer Room thus keeping the radon concentration at the low outdoor level.

The Control Room is where all controls and operations take place. Sample of air in the Exposure Room can be taken here through ducts connected to the Exposure Room. The room also contains a stainless steel radon exposure chamber (3) where radon related experiments are done.

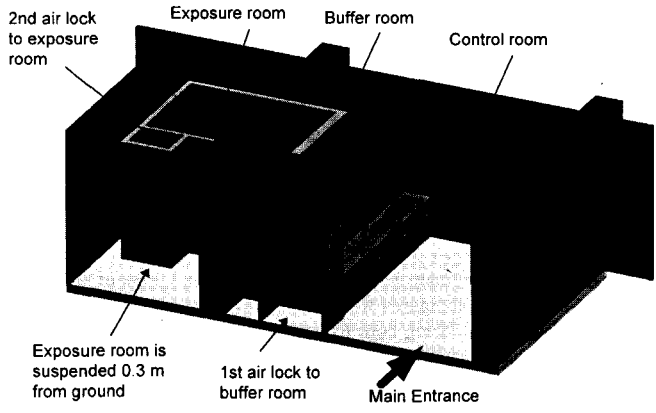

Figure 1. The RURAL (Radioisotope Unit Radon Analysis Laboratory)

FEATURES OF RURAL

The followings are brief descriptions of major equipment installed in the RURAL.

1. Aerosol generator

To create a steady concentration of monodispersed aerosol, a high output atomizer (model 3076, TSI Inc., USA) and a diffusion dryer (model 3062, TSI) are installed. The aerosol particle size can be altered by changing the concentration of solute in the solution of the atomizer. Typical particle size ranges from 0.02 m to 0.3 m. By adjusting the injection duration and interval, a wide range of aerosol concentration can be achieved.

2. Aerosol measurement

The size distribution of the aerosols are measured by two equipment. The Scanning Mobility Particle Sizer (SMPS) from TSI selects particle size with an electrostatic classifier (model 3071A, TSI) and then measure their concentrations with a condensation nuclei counter (model 3052A, TSI). The SMPS can measure the size distribution of aerosols from 5 nm to 1 μm. Above 1 μm, the aerosols are measured by a laser optical particle counter (model LASAIR 510, PMS) which has eight particle size channels from 0.5 μm to 10 μm.

Activity size distribution of ^{222}Rn daughters is determined by six wire screens-filter-detector assemblies (3). By varying the number of the 400 mesh stainless steel wire screen on each assembly, different sizes of aerosol particles will be collected on the six filter papers. By stripping the recorded activities on the filter papers by an iterative nonlinear algorithm (4), the activity size distribution in the range 0.002 μm - 0.5 μm can be obtained.

3. Ventilation measurement

Ventilation and air flow in the Exposure Room is monitored by a SF_6 tracer gas monitor (model 5302, B&K). The monitor detects SF_6 based on the photoacoustic infra-red absorption method.

4. ^{220}Rn & ^{222}Rn gas measurement

The gas inside the exposure room is continuously pumped through two Radiation Systems (model AB-5, Pylon Enc.) with scintillation cells, connected by a long delay tube. The first AB-5 measures the concentration of ^{220}Rn and ^{222}Rn, and the second measures that of ^{222}Rn alone after most ^{220}Rn decays inside the delay tube. In both AB-5 systems, the ^{220}Rn and ^{222}Rn daughters are first removed by a filter paper and only gas that decays inside the scintillation cells are recorded. The continuous radon concentration in the second AB-5 system is calculated by an algorithm (5) which takes into account of activities of previously deposited ^{222}Rn daughters and which also corrects for different humidity and flow rates. Concentration of ^{220}Rn is obtained by noting the difference in activities of the two scintillation cells.

5. Radon daughters measurement

The ^{220}Rn and ^{222}Rn daughters are sampled intermittently by a filter and Si detector assembly. The energy spectra of the radon daughters collected in the filter paper are recorded in a multichannel analyzer. Alternatively, three-count method (6) and five-count method (7) are used to determine the daughter activities and working levels. Unattached fraction of ^{222}Rn daughters are measured by computing the collected activities

on 2 filter papers, one of them is preceded by a single 400 mesh wire screen that collects the unattached daughters.

6. Radon Chamber (3)

The chamber is made of stainless steel and has a volume of 1.46 m^3. It is connected to the Exposure Room where samples of air can be taken for conducting experiments. Similar to the Exposure Room, radon gas and radon daughter concentrations, aerosol size distribution, activity size distribution, etc. in the chamber can be controlled and monitored.

METEOROLOGICAL CONDITION

According to information provided by the Hong Kong Royal Observatory, the mean atmospheric pressure is 101.3 kPa, ranging from 95.3 kPa to 105.3 kPa, being maximum in winter during the cold fronts, and minimum in middle of the year during troughs and typhoons. The mean temperature ranges from 8 °C to 32 °C, being hottest in July and August, and coldest in January.

The exposure room can, with the aid of the buffer room, simulate any environmental conditions that can be found in Hong Kong. The designed pressure can range from 96 kPa to 103 kPa and temperature from 10 °C to 35 °C. The ventilation systems in both the Exposure Room and Buffer Room contain pressure sensors which automatically maintain the pressure by varying the input and output air flows. Similarly, the air change rate can be controlled and maintained automatically.

MITIGATION METHODS

It is well known that some paints or wall papers are effective radon barriers and provide an economic passive method to reduce indoor radon level. In addition to that, the RURAL is designed to study active mitigation methods such as controlling the ventilation system. Since change in pressure and temperature will result in change of radon exhalation rate, so by quantifying this change with respect to temperature and pressure differential between the two sides of the walls or between interior and exterior of the walls, the reduction of indoor radon can be accessed. Plate out of radon daughters can be increased by use of air cleaners or ionisers (8). Devices using similar principle will be installed and tested in the ventilation system. The air flow pattern in wall surface is also known to affect deposition rates of radon daughters, hence air flow system will be studied and adjusted to provide maximum reduction of suspended radon daughter concentration.

Radon-220 daughters attract less attention in other countries but they are certainly important contributors to the total radon dose in Hong Kong. Mitigation methods aiming to reduce ^{220}Rn exhalation and working level will be studied.

CONCLUSION

Rather standard mitigation methods have been developed in western countries for the detached or semi-detached houses but little was done for high-rise buildings. In places such as Hong Kong where the population density is high and ^{220}Rn and ^{222}Rn exhalation from local building materials are also high (9), the population exposure to radon is significant. Though indoor radon can be removed efficiently by increasing ventilation, there are many situations where this is not economically feasible, such as inside commercial buildings, so other methods have to be used and these may involve modifications to the building structures and building services.

With the help of the RURAL, reduction of indoor ^{220}Rn and ^{222}Rn hazards in high-rise buildings under situations in Hong Kong can be investigated. It is hoped that appropriate mitigation methods can eventually be developed.

ABSTRACT (See instructions overleaf)

The deposition of radon progeny in respiratory organs depends on the size of the radon progeny. In this study, the apparatus for continuously measuring size distribution of radon progeny has been developed. This apparatus consists of 10 ZnS(Ag) scintillation counters and 10 screen type diffusion batteries. In the diffusion batteries, various numbers (from 0 to 100) of 500-mesh wire screens are installed in series. The range of measurable particle diameter is from 0.016 to 1.6μm. Measurement can continue automatically for about 10 days, if the data are required every two hours.

Size distributions of radon progeny were measured in a tunnel where radon concentration was high. Simultaneously size distributions of aerosol particles were also measured using condensation particle counter and electrostatic classifier. The size distributions of radon progeny obtained by this apparatus agreed well with the calculated ones from aerosol data.

In outdoor air in Tokyo, the similar measurements were carried out for about two months. Activity median diameter of radon progeny were in the range of 0.095 to 0.34μm. The representative value of activity median diameter was 0.17μm. This was almost the same as 0.2 μm, which was reported in UNSCEAR 1988 REPORT.

PRESENTING AUTHOR (IF DIFFERENT)

MAJOR SCIENTIFIC TOPIC NUMBER 5.1. (see page 7)

Short-term measurements (5 min. sampling) of radon-222 and its decay products concentration, and also of the concomitant meteorological parameters have been performed on a waste-rock pile (Crosses, Saxony) during the week 17-21 August 1994. As could be expected from measurements made directly above the source, the equilibrium factor is low (mean value at 0.5m-1.5m,0.13-0.16), while the daily radon concentration (152-136 $Bq.m^{-3}$) and the daily potential alpha energy concentration (0.122-0.136 $\mu J.m^{-3}$) are relatively high. The relationships binding these radiological parameters to the state of atmospheric stability has been investigated. The concentrations of radon and its daughters increase with the stability of the atmosphere. On the contrary, the equilibrium factor variations are not completely explained by the state of atmospheric stability. Other parameters such as wind velocity and dry deposition of radon decay products might be taken into account. The complexity of studying the outdoor equilibrium factor resides in the fact that, besides the necessity to integrate numerous explanatory phenomena, the equilibrium factor value above a finite area source is also influenced by the presence of radon from the regional background.

VARIATIONS OF Rn-222 CONCENTRATION IN THE BRATISLAVA AIR

K.Holý[1], R.Bohm[1], A.Polášková[1], O.Holá[2]

[1]Comenius University, Faculty of Mathematics and Physics, Bratislava, Slovakia

INTRODUCTION

^{222}Rn is produced by alpha decay of ^{226}Ra in soil. A small fraction of totally produced ^{222}Rn escapes from soil particles into soil air. Then ^{222}Rn is transported predominantly by molecular diffusion into outdoor atmosphere. The radon concentration in the outdoor atmosphere is not stable. It varies irregularly depending on meteorological conditions. However, there were found out regular daily and seasonal variations of ^{222}Rn concentration in outdoor atmosphere. These variations were measured in numerous works and results are summarized f.e. in work of Gesell (1). A simple model described the annual variations of ^{222}Rn concentration was published by Minato (2). A mathematical analysis of daily course of ^{222}Rn concentration in outdoor atmosphere was realized by Garzon et al. (3).

Some results of our study of ^{222}Rn variations in outdoor atmosphere of Bratislava are shown in this report.

METHODS

The ^{222}Rn concentration in the outdoor atmosphere has been studied at our department since 1987. Up until the end of 1991 the method of measurement of radon concentration in the outdoor atmosphere was as follows. Radon was concentrated from the air volume of 10 l on an active carbon and after its transfer radon was measured by means of the scintillation chamber of Lucas-type (4). A sampling was realized every morning at 9 o'clock in the hight of 1,5 m above the ground surface. Since Februar of 1991, radon in the outdoor atmosphere has been monitored continueously by a large volume scintillation chamber which volume is 4,5 l (4).

RESULTS

We obtained about 80 000 data of ^{222}Rn concentration (February 1991 - August 1995) by continual monitoring of radon in the outdoor atmosphere of Bratislava. This large number of data with great variability have to be processed statistically to reveal some regularities. Table 1. gives the arithmetic means of ^{222}Rn concentrations averaged throughout the years 1991-1995.

Table 1. ^{222}Rn concentrations [Bq.m^{-3}] - years 1991 - 1995.

18.00 - 20.00	7,17	5,54	4,07	3,35	4,27	3,72	4,96	5,54	5,59	6,83	6,52	7,03	5,38
20.00 - 22.00	6,85	5,74	4,21	4,05	4,95	4,99	6,51	6,77	6,41	7,65	6,69	6,51	5,94
22.00 - 24.00	7,21	6,05	5,03	4,22	5,28	5,31	6,84	7,62	7,01	8,18	6,79	6,44	6,33
Mean	7,16	5,83	4,58	4,01	4,79	4,82	6,19	6,96	6,53	7,41	6,62	6,82	5,98

The results averaged in this way enable us to demonstrate the average daily courses of ^{222}Rn concentration for individual months and average annual courses for various time intervals.

The average daily course of ^{222}Rn concentration calculated on the basis of all measurements reaches a maximum between 4 and 6 a.m. and a minimum between 2 and 4 p.m. The ^{222}Rn concentration reaches its average daily value at 9: 30 a.m. and at 9 o'clock in the evening.The ratio of the maximum and minimum values in the average daily course of ^{222}Rn concentration amounts to 1.67. The daily variations of the ^{222}Rn cocentration are ascribed to variations of atmospheric stability and vertical mixing (5).

The average annual course of ^{222}Rn concentration calculated on the basis of continual measurements during the years 1991 - 95 reaches the maximum value in October and the minimum value in April. Further we can see in Table 1, that the average annual course of ^{222}Rn concentration calculated from all the data is in good agreement with the average annual course of ^{222}Rn concentration calculated on the basis of measurements made between 8 and 10 p.m.

Nearly five years lasting continual monitoring of the ^{222}Rn concentration in the outdoor atmosphere enables us to make an analysis of mean daily waves for different months of the year. According to Garzon et al. (3), the average daily course of the ^{222}Rn concentration in the outdoor atmosphere can be expressed by the following equation :

$$\frac{C(t)}{\bar{C}} = 1 + A_1 \cos\left(\frac{2\pi}{24}t + \Phi_1\right) + A_2 \cos\left(\frac{2\pi}{12}t + \Phi_2\right) \qquad (1)$$

where C(t) is the average ^{222}Rn concentration at the time t, $\bar{C}$ is the monthly average of the ^{222}Rn concentration, A_1 is the first harmonic amplitude, A_2 is the second harmonic amplitude, Φ_1 is the first harmonic phase, and Φ_2 is the second harmonic phase.

In this equation, the first harmonic term describes the turbulent dispersion process originated by solar heating. The second harmonic term describes the influence of the diurnal instability interval varying with the season. The values of the parameters in Eq.(1) are summarized in Table 2. They were obtained by the Fourier's analysis of the average daily courses of the ^{222}Rn concentrations.

Table 2. Results of Fourier analysis of the mean daily waves.

Month	A_1	A_2	A_1/A_2	Φ_1	Φ_2
1	0,08	0,04	1,87	298,2	173,3
2	0,11	0,04	2,78	295,9	117,5
3	0,22	0,05	4,75	302,8	162,4
4	0,32	0,08	4,16	303,6	158,5
5	0,36	0,06	5,58	315,7	186,6
6	0,43	0,06	7,69	309,4	174,2
7	0,45	0,08	5,91	309,9	175,2
8	0,46	0,07	6,93	306,7	167,4
9	0,35	0,08	4,74	305,9	156,7
10	0,22	0,06	3,75	312,5	116,3
11	0,05	0,03	1,49	307,3	142,4
12	0,06	0,05	1,23	263,1	145,7
Mean	0,26	0,06	4,24	302,6	156,4

Further we were looking for correlations between Φ_2 and the hourly difference between the sunrise and the sunset ΔH, and for correlations between A_1 and the intensity of solar radiation, so as it was done in Ref.(3). We determined the followed expression for Φ_2 and A_1 :

$$\Phi_2 = (34,8 \pm 23,3) + (9,2 \pm 1,7)\Delta H \qquad (2)$$

where ΔH was calculated for the 15 th day of each month and taken as the monthly average value,

$$A_1 = (-0,053 \pm 0,024) + (0,00069 \pm 0,00005)Q \qquad (3)$$

where the global solar radiation Q was calculated according to an equation published in (6), for the 15 th day in a month at 12 a.m. of the local time.

The phase Φ_1 of the first harmonic term is practically constant for all the months and its average value is equal to (302,6°±13,6°).

The amplitude A_2 of the second harmonic term shows only small variations during the year. Therefore we did not search for any correlation for A_2 and we calculated an average value :

$$A_2 = 0,056 \pm 0,015$$

CONCLUSION

In Table 3., there are compared the results of analysis of our measurements with results of analysis done by Garzon et al. (3) for data from various places in the world .

Table 3. The values of Φ_1 , Φ_2 and A_2 for the monthly mean waves at various places in the world.

	Φ_1	Φ_2		A_2
		$\Phi_2 = a_2 + b_2 \Delta H$	r^2	
Oviedo	276,8±3,7	-116,3+19,5ΔH	0,94	from 0,05 to 0,1
Socorro	278,2±9,7	-155,7+23,1ΔH	0,75	
Toulouse	276,4±8,4	12,1+10,6ΔH	0,98	
Brazaville	271,4±10,7	-1494+133,7ΔH	0,41	
Bratislava	302,6±13,6	34,8+9,2ΔH	0,90	0,056±0,015

The amplitudes and phases of the harmonic terms determined by Fourier's analysis of mean daily courses for different months have the same behaviour as those from Oviedo (3). The amplitude A_1 of the first harmonic term is well correlated with the global solar radiation fallen down on the Earth's surface.

The phase Φ_1 is constant and its value found out for Bratislava is about 10 % higher than its average value given in Ref.(3).

The expression of Φ_2 determined by us approaches mostly to the relation that is valid for data from Toulouse. The average value of the amplitude A_2 is between 0,05 and 0,1. This is in the range of the values found out also for the other places.

INTRODUCTION

In the present work, we proposed to estimate the contribution of the thermal power plants (TPP) relying in fossil fuel to the modification of the natural radioactive background and implicitly to the population's exposure in two urban centers - district residences - Timisoara and Deva.

In the range of natural radioelements released in the atmosphere we considered as critical, ^{210}Pb and ^{210}Po for the following reasons:

- radiolead is one of the long lived daughters of ^{222}Rn in secular equilibrium with its daughter ^{210}Bi. It is a beta active hard element, generator of ^{210}Po, an alpha active element with high energy. ^{210}Pb, and ^{210}Po are in the group of very high radiotoxicity; ^{210} Bi high radiotoxicity;
- during the technological process of coal combustion of thermal power plants, there take place an accumulation of radiolead in the fly ash by a concentration rate of about 3 to 50.

MATERIALS AND METHODS

Two thermal power plants were taken into account: Timisoara Sud TPP, a power industrial of the city of Timisoara being partially set working; Mintia TPP, placed at a distance of 11 km from Deva, one of the greatest industrial units in Romania.

Within the framework of the study were performed radiochemical determinations of ^{210}Pb and ^{210}Po concentrations in atmospheric depositions (wet and dry cumulated), aerosols, food chain (drinking water, bread and milk) and processed food (daily menu).

Cumulated wet and dry atmospheric depositions were sampled monthly and analyzed quarterly. Aerosols were collected twice in a year by aspiration on membrane filter, with 40 to 60 m^3 aspired air volume.

The food chain were investigated twice in a year, by samples taken from centralized distribution sources. Processed food were investigated once in a year, by daily menus taken from representative sources.

All samples were mineralized with nitric and fluorohydric acid. After the concentration through coprecipitation of the microcompounds the critical radionuclides were wholly separated by spontaneous electrochemical deposition on pure nickel disks.

The radiochemical recovery output was 65% for ^{210}Pb and 80% for ^{210}Po.

Beta activity of the disks were measured after 30 days, using a NK-350 counting equipment with anticoincidence GM counter (background 4 cpm, counting efficiency 19.4%). Alpha activity of ^{210}Po were measured using a RFT 20026 counting equipment with ZnS scintillation detector (background 0.72 cpm, counting efficiency 18%).

RESULTS AND DISCUSSION

The data of the analyses are registered in tables 1 to 4

Table 1 indicates the total quantity of powders falling out on the soil surface. There are presented the quarterly and yearly values expressed in gm^{-2} . It shows a relatively moderated level of powdering in Timisoara and a level of about two times increased in Deva. In both cases there is a minimum value in the third quarter, in rest the powdering level is near constant.

Table 1 Powdering degree (total and quarterly values) in Timisoara and Deva

Investigated locality	Powdering degree (gm^{-2})				
	I^{th} quarter	II^{nd} quarter	III^{th} quarter	IV^{th} quarter	Total
Timisoara	20	20	14	18	72
Deva	50	47	22	40	159

Table 2 refers to the concentration of ^{210}Pb and ^{210}Po in atmospheric depositions. There are presented quarterly values in Bqm^{-2}. Both of the nuclides present higher levels in Deva, with increasing factors depending on the time of deposition .

Table 2. ^{210}Pb and ^{210}Po content in atmospheric deposition

Investigated locality	QUARTERLY CONTENT (Bqm^{-2})							
	^{210}Pb				^{210}Po			
	I^{th} q.	II^{nd} q.	III^{th} q	IV^{th} q.	I^{th} q.	II^{nd} q.	III^{th} q	IV^{th} q.
Timisoara	2.96	1.18	2.35	2.49	3.14	0.65	2.04	2.14
Deva	10.49	4.52	3.55	4.39	7.35	3.8	2.78	3.28

Table 3 presents the estimated total exposure levels through atmospheric deposition, with the necessary informative elements. It shows a near five times higher global (^{210}Pb and ^{210}Po) exposure level in Deva in comparison to Timisoara.

Table 3. Estimated global exposure levels

Informative elements	Investigated localities	
	Timisoara	Deva
Total deposition of ^{210}Pb (Bqm^{-2})	8.98	22.95
Total deposition of ^{210}Po (Bqm^{-2})	7.97	17.21
Total surface of deposition (ha)	$1.3\ 10^4$	$5.99\ 10^3$
Number of inhabitants	$3.34\ 10^5$	$8.05\ 10^4$
Global exposure level (kBq man year)	6.59	29.87

Table 4 presents the average value of internal irradiation levels for the population of the considered localities, by ingestion of processed food due to natural uranium, ^{210}Pb, ^{210}Po, ^{226}Ra.

Table 4. Internal irradiation of population by ingestion of processed food

Investigated locality	Effective dose ($\mu Sv\ y^{-1}$)				
	U_{nat}	^{210}Pb	^{210}Po	^{226}Ra	Total
Timisoara	2.9	59	4.14	2.75	68.79
Deva	1.8	155	3.15	3.05	163

CONCLUSIONS

1. ^{210}Pb and ^{210}Po from the fly ash of the TPP spread in the atmosphere under the form of sedimentable powder and fall out on the soil surface either through free falling, or in association with impurities or rain. Their concentrations in the aerosols was significant less in the atmosphere.
2. The population's exposure levels to ^{210}Pb and ^{210}Po was estimated to 6.59 KBq $man^{-1}year^{-1}$ in Timisoara and to 29.87 $man^{-1}year^{-1}$ in Deva; the levels of internal irradiation due to ingestion of processed food to 63 $\mu Sv\ y^{-1}$ in Timisoara, 158 $\mu Sv\ y^{-1}$ in Deva. The estimated data suggests the opportunity of some epidemiological studies upon the population living in the area of influence of these thermal power plants.
3. The monitoring of the ^{210}Pb and ^{210}Po content in atmospheric deposition constitutes an available indicator in finding out the modifications of the natural background induced by thermal power plants.

EFFECTS OF WEATHER ON THE AMBIENT GAMMA RADIATION LEVELS IN HONG KONG

M.C. Wong, H.Y. Mok and H.K. Lam

Royal Observatory Hong Kong, 134 A Nathan Road, Kowloon, Hong Kong

ABSTRACT

A nuclear power station was recently constructed in the People's Republic of China some 50 km to the northeast of Hong Kong. A radiation monitoring network equipped with high pressure ionisation chambers was set up in Hong Kong to continuously monitor the ambient gamma radiation level over the territory. The network consists of ten field stations and one central station. Ambient gamma radiation levels at each station are transmitted to the central station via radio link and dedicated telephone lines once every minute. An alarm level can be set to each high pressure ionisation chamber to generate an alarm at the central station when the ambient gamma radiation level exceeds a preset threshold.

In the past few years, abnormal increase in ambient gamma radiation level was observed in some rainy days and onset of the winter monsoon. It was found that the ambient gamma radiation levels might increase by more than 100% of the background level on some of these occasions. These increases were primarily due to increases in the amount of natural airborne radionuclides, such as radon daughters. In rainy conditions, the downpour brought natural airborne radionuclides higher up in the atmosphere down to the ground while during the onset of the winter monsoon, the cool stable layer of air in the lower atmosphere tends to limit the dispersion of natural airborne radionuclides, resulting in increased ambient gamma radiation level.

INTRODUCTION

A nuclear power station was recently constructed in the People's Republic of China some 50 km to the northeast of Hong Kong. A radiation monitoring network (RMN) was set up in Hong Kong to continuously monitor the ambient gamma radiation levels over the territory and to provide an alarm should an abnormal increase in the radiation level be detected. The network consists of ten field stations (Fig. 1) and a central station. Each field station consists of a High Pressure Ionisation Chamber (HPIC), one high volume air sampler, one radioiodine sampler and one set of total deposition collector. The HPIC continuously monitors the ambient gamma dose-rates at the field station. Data in units of microgray per hour (μGy/h) are transmitted to the central station by both radio and dedicated phone lines at one minute intervals. An alarm threshold can be set for each field station. When the ambient gamma radiation level exceeds the threshold, an audio and visual alarm will be generated at the central station. The central station will then automatically send a command to that field station to turn on the high volume air sampler and the radioiodine sampler to collect air samples. The air samples and the total deposition samples will then be collected by staff on emergency duties for detailed isotopic analysis in a laboratory.

Studies of the RMN data showed that the average ambient radiation levels in Hong Kong varied from place to place from 0.09 μGy/h at Ping Chau to 0.14 μGy/h at Tsim Bei Tsui, amongst which about 0.03μGy/h originated from cosmic radiation. Shown in Fig. 1 is the average ambient dose-rates at the ten stations in 1994. The spatial variation of the ambient radiation levels is mainly due to the differences in the geology of the stations where the HPICs are located.

Since the operation of the nuclear power station in 1992, there was no incident at the nuclear power station which would result in accidental release of radionuclides. However, abnormal increases in the ambient radiation levels were detected by the RMN in rainy days and during onset of the winter monsoon.

SEASONAL VARIATIONS IN THE AMBIENT RADIATION LEVEL IN HONG KONG

Since the operation of the RMN in 1987, it has been observed that there is a marked seasonal variation in the ambient gamma radiation levels at each of the field stations. For all ten stations, the ambient gamma dose-rates in winter were higher than in summer. The differences varied from 3.6% at Tsim Bei Tsui

to 13 % at King's Park. Figure 2 shows the monthly average ambient gamma dose-rates of King's Park in 1994. Isotopic analyses of the air particulate samples collected at the station showed a similar seasonal variation in the activity concentrations of radon daughters e.g. Pb-212 and Pb-214 (also shown in Fig. 2). The main reason for the higher activity concentrations of radon daughters and subsequently higher ambient gamma dose-rates in winter was believed to be the prevalence of the northeasterly monsoon. The winter monsoon affected the ambient radiation level in two ways. Firstly, the airstream which originated from mainland China carried along with it an abundance of natural terrestrial radionuclides. Secondly, the stable layer of air in the lower atmosphere that appeared after cool northeasterly winds became established locally tended to limit the dispersion of natural radionuclides. Both effects would result in an increase in the ambient radiation levels. This is exemplified by the gamma dose-rate readings recorded at Yuen Ng Fan (YNF) on a cloudy but rainless day on 7 November 1995. Fig. 3 shows a 24-hour trend plot of the one-minute ambient gamma dose rate at YNF together with the wind field and surface temperature recorded by the nearest automatic weather station at Sai Kung, about 7 km west of YNF, over the same period. The figure shows that winds changed from moderate easterly to light northeasterly at about 4 a.m. as a result of the arrival of a surge of the winter monsoon. At the same time, the ambient gamma dose-rate started to rise slightly from 0.12 μGy/h to 0.13 μGy/h and remained at that level until early afternoon. The change in wind direction could have brought more natural radionuclides from mainland China to the territory resulting in a rise in the ambient gamma dose-rates. Just after midday, winds picked up significantly from the north and temperature started to fall from about 25 to 20 degrees Celsius at around 4 p.m. The fall in surface temperature created a cool layer of air at the lower atmosphere thus trapping the radionuclides. This was evident from the T-Φ diagram (insert in Fig. 3) which showed an inversion at the surface level up to about 500 meters after the arrival of the monsoon. This resulted in a further rise in the ambient gamma dose-rates in the evening of that day.

In contrast, during the summer months the airstreams are mostly of maritime origin which contain less terrestrial radioactivity. Thus a lower ambient radiation level would be expected.

EFFECTS OF PRECIPITATION ON THE AMBIENT RADIATION LEVEL IN HONG KONG

Short-term abnormal increases in ambient gamma radiation levels have also been observed in rainy days. The ambient gamma radiation levels typically increase by 30 to 50% of the background but have been observed to increase by up to 100% of the background level in occasions of heavy rain. Figure 4 shows a trend plot of the one-minute average ambient gamma dose-rates recorded by the field station at King's Park on 23 September 1994. It also shows the 24-hour trend plot of the hourly rainfall recorded at the Royal Observatory Headquarters, about 1.5 km from King's Park on the same day. The abnormal rise in the dose-rates which happened twice on that day was in phase with the two episodes of heavy rain. The downpour brought natural airborne radionuclides higher in the atmosphere down to the ground resulting in increased ambient radiation level.

CONCLUSION

Studies of RMN data showed that the ambient gamma radiation levels in Hong Kong are significantly affected by weather conditions. Precipitation has the largest effect which in some cases may result in abnormal rises in the ambient radiation level by up to 100%. The primary reason is that the heavy precipitation would result in a higher activity concentrations of radon daughters at the ground level and hence higher ambient gamma dose-rates. During the onset of winter monsoons, the northerly winds originating from China carry with them an abundance of natural terrestrial radionuclides. Furthermore, the cool stable layer of air in the lower atmosphere in winter tends to limit the dispersion of natural airborne radionuclides. These two factors would result in increased ambient gamma radiation levels in the winter months.

CHARACTERISTICS OF RADIATION FIELD IN LIVING SURROUNDINGS AND IN NATURAL ENVIRONMENTS

Youichi Hiruta, Tatsuo Tanji, Michio Okino, Toru Nagato, and Sadamu Mochizuki

Muroran Institute of Technology, Muroran 050, Japan

INTRODUCTION

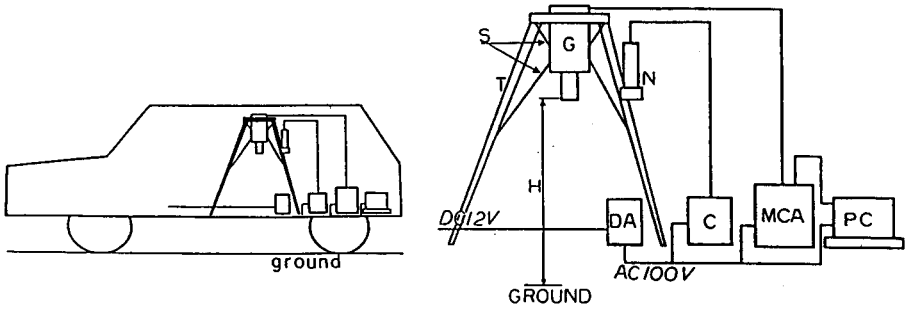
Levels of environmental radiation vary upon the environmental conditions and have own characteristics locally. Therefore it is very important to survey the distribution of environmental radiation levels anywhere for assessing its variation thereafter[1)2)].

For the porpose of grasping of environmental radiation fields in Hokkaido, a survey on the distribution of environmental gamma rays was made, using a portable spectrometer fitted with a high purity Ge semiconductor detector installed in a car - a car-borne survey -, during the period from Apr. 1994 to Aug. 1995. In addition to car-borne survey, in-situ monitorings were performed at spots sporadically .

In this paper, we will present the results obtained from the survey in Hokkaido Island, Japan.

METHOD OF MEASUREMENT AND INSTRUMENTS USED

Measuring method adopted for this survey was a car-borne survey in which measurements were made with the measuring systems installed on a car and made on cruising. Detectors used for gamma ray detection were a portable high purity Ge semiconductor detector and an NaI(Tl) scintillator detector. Figure 1 shows a schematic diagram of the measuring system installed on a car. During this survey we used the same car to be available the



T:Tripod G:HPGe detector N:NaI detector DA:DC/AC inverter C:Controller MCA:Multi-channel analyzer PC:Personal computer S:Hanging spring H:Height from the ground surface(=80 cm)

Fig.1. Schematic diagram of the measuring systems.

same conditioning not to vary the shield effect by car. Two detectors were set on a tripod to be fixed in the same position during the survey. Height of the detectors were 80 cm above the ground. Power from the cigar lighter of the car was supplied to the measuring systems through a DC/AC inverter.

Cruising speed of the car was kept 40 through 50 km/h. Every cruising of 40 or 50 km, spot monitoring was made. Measured intervals and spots were plotted on a map manually. The output from the high purity Ge semiconductor detector was stored on floppy disks by a personal computer. The output from the NaI(Tl) scintillator detector was printed out by its own printer.

TERM AND AREA FOR SURVEY

The survey over Hokkaido Island was taken place five times of cruising during the term from early spring in 1994 to summer in 1995. The areas covered were the proximity of Muroran City(i.e. proximity of Institute), northern part of Hokkaido, eastern part, south-western part, central part, and partially duplicated. Figure 2 shows the survey routes over Hokkaido.

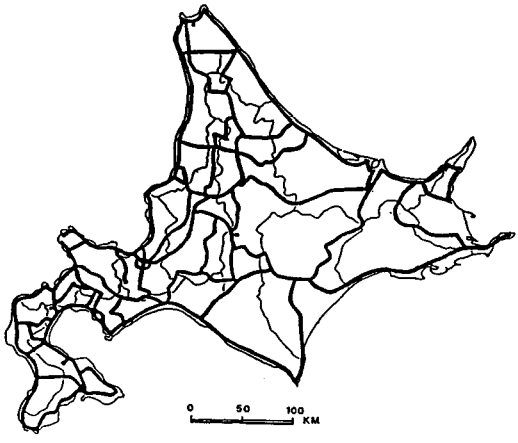


Fig. 2. Map of the survey routes over Hokkaido.

ANALYSIS OF DATA

Data obtained directly from the detectors are energy spectra of counts on gamma events. We used the method of the HASL-258 by Beck et al.[3] to discriminate nuclides of the gamma sources from the obtained spectra and summed up classifying into uranium-series, thorium-series, potassium-40, and fallout nuclides. The shield effect by car was 26 %.

RESULTS AND DISCUSSIONS

Figure 3 shows an example of the analyzed result obtained from the survey on eastern part of Hokkaido mainly. The lower part of the figure, lines denote the values of exposure rate in air in μR/h due to uranium-series, thorium-series, potassium-40, respectively, and dots denote the total values of dose rate in nGy/h. The upper part of the figure shows ratio among three groupes of nuclides mentioned above.

The figure shows not only remarkable variation on total absorbed rate against difference of area but also remarkable variation on constitutive ratio among uranium-series, thorium-series and potassium-40. In the figure, exposure rate of thorium-series varys remarkably as variation of location where measurement was made, but those of uranium-series and potassium-40 vary a little. Therefore amount of thorium-series seems to contribute mainly to the variation of the total absorbed dose rate.

Figure 4 shows a summary of the analyzed results on total absorbed dose rate in nGy/h over Hokkaido Island obtained from

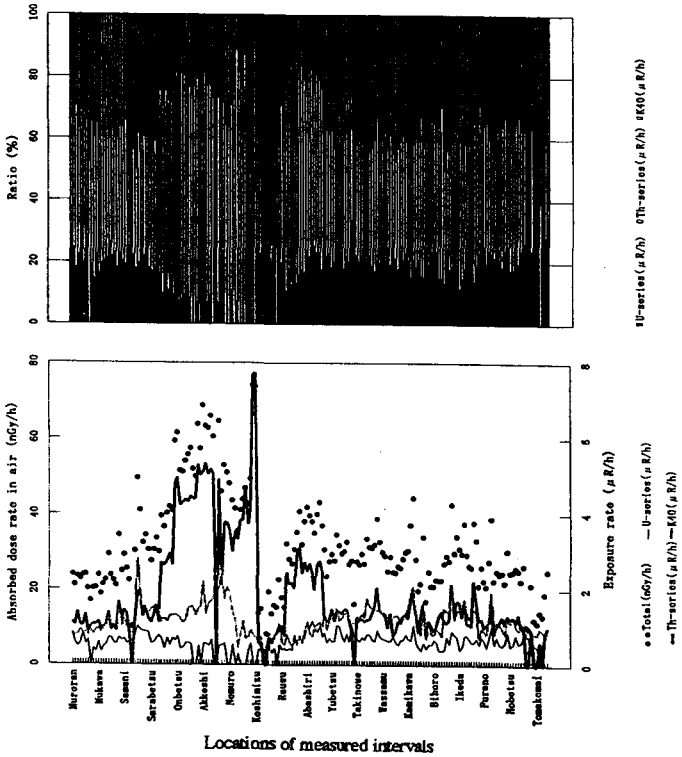

Fig.3. An example of the analyzed result as the analyzed results, obtained mainly from the survey on eastern part of Hokkaido.

the survey carried out during the period from Apr. 1994 to Aug. 1995.

Higher total absorbed dose rates were measured sporadically in some areas over Hokkaido Island, i.e. in northern part, in eastern part, and in south-western part of it. In these areas radiation due to thorium-series were higher than other districts. And also in some areas along survey routes, remarkable jump-up or jump-down of total absorbed dose rate was sporadically found.

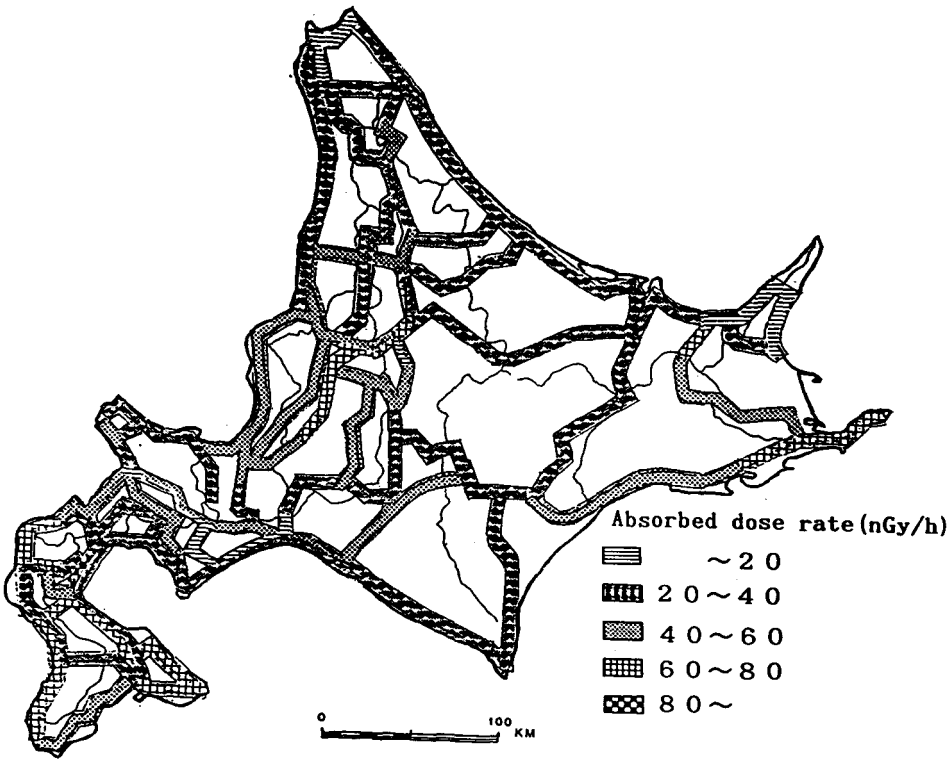

Fig.4. Summary of the analyzed results on total absorbed dose rate in nGy/h over Hokkaido Island.

CONCLUDING REMARKS

A survey on distribution of environmental gamma-rays was made along the almost all main roads in Hokkaido Island, using a portable spectrometer fitted with a high purity Ge semiconductor gamma ray detector installed in a car - a car borne survey -, during the period from Apr. 1994 to Aug. 1995. The values of absorbed dose rates in air due to gamma rays were found to distribute from 20 to 106 nGy/h, and mean dose rate was calculated to be 38.2 nGy/h.

The variation of total absorbed dose rate was seemed to be originated mainly in the variation of dose rate due to gamma rays radiated from the nuclides of thorium-series. Higher total absorbed dose rates were measured in some districts over Hokkaido Island, i.e. in northern part, in eastern part, and in south-western part of it. In these districts radiation due to thorium-series were higher than other districts.

^{238}U SERIES ISOTOPES AT DIFFERENT SOIL DEPTHS AND DISEQUILIBRIUM OVER VARIOUS GEOLOGY AND SOIL CLASSIFICATIONS ALONG TRANSECTS IN SELECTED PARTS OF IRELAND.

I.R.McAulay and A.Hayes,
Physics Department, Trinity College Dublin, Ireland.

Abstract - Sampling of soils was carried out along linear transects in selected regions of the country, a technique known as Transect Sampling. This was a controlled rather than a random sampling technique. The transects were located in regions which were previously known to contain high levels of the ^{226}Ra isotope, from the ^{238}U series. The soil sampling was carried out at selected sites along these transects. At each transect site, two different soil depths were examined and the soil samples collected were identified as the top and bottom soil samples. This transect data set, consisting of the isotope activity levels and the influencing variables transect geology and soil types, provided a data base for investigation.
Comparisons were made between the soil isotope activity levels measured at different soil depths. An examination of the ^{238}U decay series showed the existence of disequilibrium. Relationships between the disequilibrium data and the associated geology and soil types were investigated.

INTRODUCTION

Previous surveys of radioactivity in soil in Ireland had shown that radium concentrations were considerably higher than average in a small number of regions (1 - 2). Comparison of these regions with a geological map indicates that some of the high values for radium in soil activities might be associated with certain categories of underlying geological strata.

To investigate the existence of such an association, it was decided to take a series of soil samples at selected sites along a number of linear transects. These transects were laid down with the assistance of geological maps in such a way that they crossed a number of geological strata within regions where previous surveys had shown greater than average concentrations of radium in soil samples. The sites were selected so that each lay within the boundaries of a geological stratum as indicated on the map and the number chosen gave a good coverage of the different strata lying along the transect. Because of the uneven distribution of underlying geological strata, the sites were not evenly spaced. The length of the transects was between 30 and 50 km and was chosen to cover several different geological strata in each case.

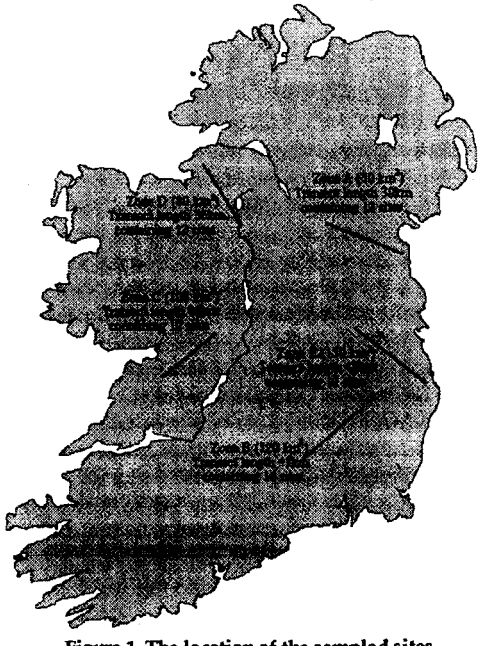

Figure 1. The location of the sampled sites

Figure 2. A section of the Geological map of Ireland showing the location of the first transect in the north-east in county Louth

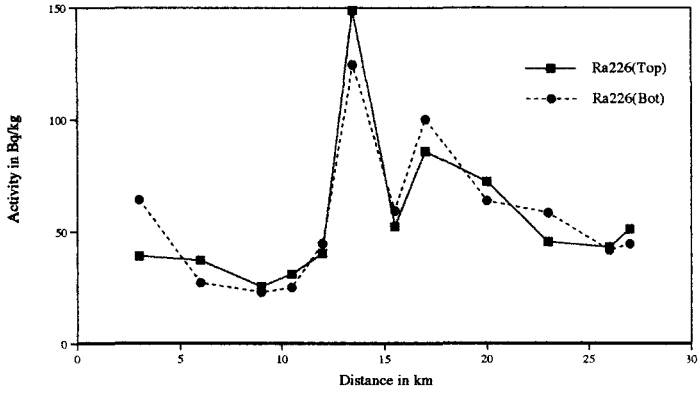

Figure 3. ^{226}Ra top and bottom activity levels at the Louth transect

SOIL SAMPLING

The selected transects are shown in figure 1 and details of the first transect are shown superimposed on the geological map in figure 2. Two soil samples were taken at each site, one of surface soil and one of soil from below the agricultural horizon which was assumed to be at a depth of 25 cm beneath the surface. The surface soil sample was made up by taking equal quantities of soil from 12 randomly located points within an area of approximately 1000 m^2. These sub-samples were mixed, dried and ground to a fine consistency (particles > 1 mm diameter) after removing stones and pebbles of greater than about 1 cm diameter. The deep soil sample was taken at a single location at each site and was obtained by removing soil from the bottom of a hole dug at the location. The uranium content was determined by measuring the ^{234}Th activity from the principle gamma ray in the prepared sample and the radium concentration was found using the 186 keV gamma ray emitted in the decay of ^{226}Ra.

The results from the first transect are shown in figure 3. It is clear that there is no significant difference between the samples obtained from surface soil and those taken below the agricultural horizon. The figure also indicates that the ^{226}Ra activity levels show variations related to the nature of the underlying strata.

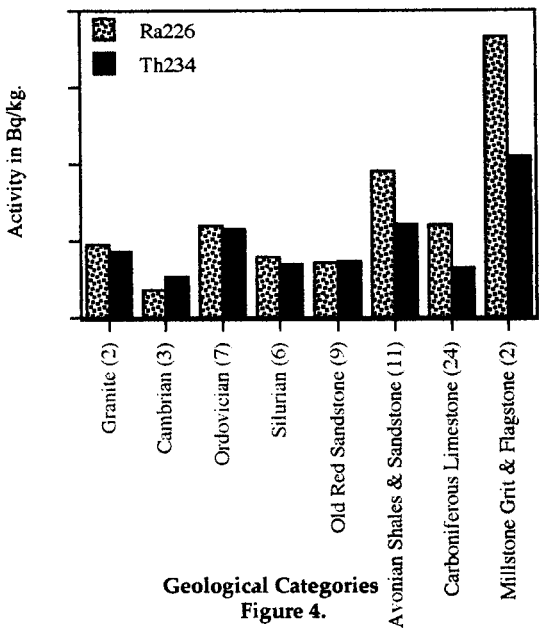

Figure 4.

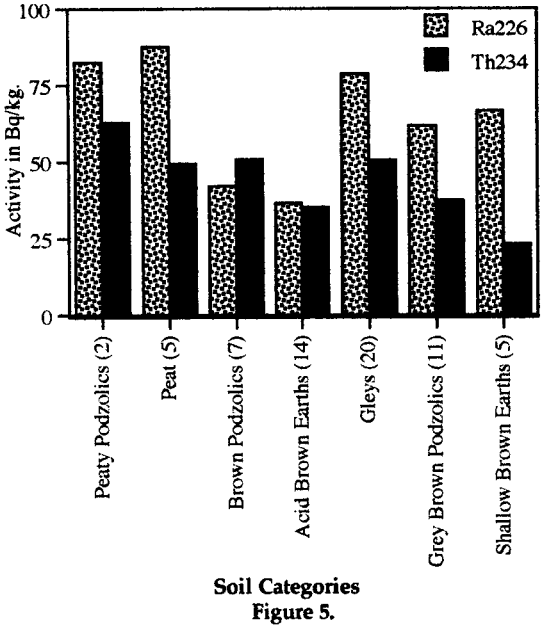

Figure 5.

Ra/U Disequilibrium over the Geological and Soil Categories of all transects

DISCUSSION OF RESULTS

The mean activities for ^{226}Ra and ^{234}Th for all transects are shown on figures 4 and 5, as a function of geological category and soil category respectively. The numbers shown in brackets for each category represent the number of sites within that category for which measurements were made. Although there are some indications that radioactive disequilibrium exists for a number of the different categories shown, the number of sites is rather small for several of the classifications used. However, for those categories within which there are more than about six samples and a difference in activities of greater than about 15 Bq/kg between ^{234}Th and ^{226}Ra, the measured activities support the hypothesis that a radioactive disequilibrium exists. The results indicate that the disequilibrium is particularly well confirmed for soils overlaying carboniferous limestones and avonian shales and sandstone. The disequilibrium is in the direction of an excess of ^{226}Ra and, when considered as a function of soil category, is most marked for gleys and grey brown podzolics.

It is concluded that geological and soil maps can, at least in the conditions that pertain in Ireland, be a useful indicator of areas in which radioactive disequilibrium may occur in soil. Measurements of soil radioactivity may also be used as indicators of changes in underlying geological strata on a relatively small scale. Further work will be carried out to investigate possible associations of these results with high values of radon in the domestic environment for the areas surveyed.

ABSTRACT

A representative survey to evaluate the exposure to natural radiation in dwellings was conducted in Italy from 1989 to 1994. The survey was coordinated by ANPA (former ENEA/DISP) and Istituto Superiore di Sanità, and it was carried out in collaboration with 19 Regional Laboratories. Beside radon concentration, absorbed dose rate in air was also measured. For gamma measurements, whose results are reported in the present paper, ENEA collaborated, too. Thermoluminescent dosemeters (TLDs) were used as detectors. Four TLDs were exposed for six months in a bedroom of each surveyed dwelling. Particular attention was devoted to calibration and treatment procedures of the dosemeters (annealing, transport dose etc.), according to detailed protocols. Intercomparison exercises were conducted for all the Laboratories involved. The national and regional averages were calculated from the results in the actual sample (4234 dwellings) taking into account the sampling scheme. The national average absorbed dose rate in air was around 105 nGy/h, after the subtraction of the cosmic ray contribution. This value is located in the high range of the national average values of other Countries given in the 1993 UNSCEAR Report. Using the dose factors assumed in the same report, the estimated effective dose due to indoor gamma exposure at home results about 0.4 mSv/y. Appreciable differences exist among the average dose rates measured in various Italian Regions. The highest values were found in Central Italy where natural building materials with high uranium and thorium content are widely used.

INTRODUCTION

In the period 1989-1994, a representative national survey was conducted in Italy, to evaluate the indoor exposure to natural radiation, both radon and gamma radiation. The characteristics of the survey, its organisation, the sampling criteria and the general policy adopted have been described elsewhere (1,2,3). Although it is well known that radon is the main source of indoor exposure (4), measurements of outdoor gammas carried out during the seventies and indoor gamma measurements conducted in the eighties, pointed out the existence of areas where the exposure rate was particularly high (5,6). These areas are characterised from the geological point of view by the existence of effusive and explosive materials (recent volcanitis); moreover, building industry generally makes use of local materials which significantly contribute to the indoor exposure (6).

MATERIALS AND METHODS

As described in ref. 3, 19 Regional Laboratories participated in the survey. Standardised measurement protocols were used in order to assure comparability and to minimise uncertainties. Detailed information on the procedures for gamma measurements are reported elsewhere (7) and are summarised here. Thermoluminescent dosemeters were used, in particular LiF sintered chips from the same batch doped with Mg and Ti or Mg, Cu and P. Two dosemeters

were positioned in one room of each dwelling, usually the main bedroom, and exposed aside the radon detectors for six months. Each dosemeter was made of two chips enclosed in a light-tight plastic sachet of 100 mg cm^{-2} thickness. As far as quality assurance procedures are concerned, intercalibration exercises were carried out, exposing dosemeters both to a reference Cs–137 gamma beam (see Fig. 1), with a dose of 500–1500 μGy, and to environmental radiation in high background room, where the dose rate (~320 nGy/h) was measured by means of a ionisation chamber.

RESULTS AND DISCUSSION

Gamma measurements were carried out in 18 Regions. The national distribution of absorbed dose rate in air detected indoors is shown in Fig. 2. A cosmic ray contribution of 32 nGy/h has been subtracted from TLD results. This contribution has been estimated applying a building shield factor of 0.8 (4) to the measured value of 40±9 nGy/h (6), which is compatible with the value calculated taking into account latitude and altitude. The national average value is 105 nGy/h (3), with an estimated overall uncertainty of about 10%, which takes into account both statistical and systematic errors. The world population weighted average assessed by UNSCEAR is 83 nGy/h (4). This value was obtained from surveys of different statistical significance, whose averages are generally lower than the Italian one, e.g. 71 nGy/h in Austria, 60 nGy/h in UK and 37 nGy/h in USA, while only few values are equal or higher, such as 103 nGy/h in Australia, 105 nGy/h in Portugal and 110 nGy/h in Sweden. Regional averages in Italy are quite different, with the lowest figures in Emilia–Romagna, Toscana, Veneto and Puglia (40–50 nGy/h), and the highest ones in Lazio and Campania (>210 nGy/h). For the dose assessment, an average occupancy factor at home equal to 0.6 – obtained from the survey questionnaires (3) – was applied to the average dose rate in air. The estimated gamma radiation contribution to the effective dose at home resulted around 0.4 mSv/y.

CONCLUSIONS

The average absorbed dose rate in indoor air, obtained through the Italian national survey, is about 105 nGy/h, which is rather high when compared with the values obtained in other national surveys. The regional averages show a large variability over the Italian country: the highest values have been detected in those Regions, such as Lazio and Campania, where local building materials with high uranium and thorium content are widely used. These data stress the importance of studying natural building materials, as both gamma radiation and radon sources, in order to reduce the presence of radioactivity indoors. In authors' opinion, a regulation to limit the radioactivity content and the radon exhalation rate for building materials of future dwellings should be promulgated.

THE ADDITIONAL EXPOSURE DUE TO THE USE OF UNCOMMON BUILDING MATERIALS IN ROMANIA

INTRODUCTION

Beginning with 1981, the district ionizing radiation hygiene laboratories, charged by the Ministry of Health with the surveillance of the work places and the environment, have signaled the attempt of the industry to introduce new highly radioactive materials in the building products. Phosphogypsum, by products of the phosphate fertilizer industry, and slag and ash, wastes of the coal-fired power plants, are the most important of them.

In order to establish radioactivity levels and limits for the building materials and the exposure due to their use, some studies have been elaborated by the specialized laboratories of the Ministry of Health. As a result, admissible limits for the building material radioactivity have been chosen the maximum values obtained for the building materials commonly used, are presented in Table 1.

The additional exposure and fly ashes have been assessed by two ways:

1) The measurements of the potential alpha energy concentrations, PAEC (mWL) and equilibrium equivalent concentrations (Bq/m^3) for radon level were carried out in a flat with internal walls of phosphogypsum. The measurement results were compared both with those obtained for the flat without internal walls and those obtained for the houses from Romania (50% of the country).

2) For the same flat of the experimental house, annual effective dose were calculated.

MATERIALS, METHODS AND RESULTS

Samples of phosphogypsum obtained from the main producers of phosphate fertilizers and samples of the fly ashes collected on filters came from 18 coal-fired power plants were analysed by the high resolution gammaspectrometry method using a 4096 MCA Canberra systems equipped with Ge(li) detectors. Results are presented in Table 2.

An experimental detached house (basement, ground floor, garret) was built with usual building materials (concrete 15 cm thick and aerated concrete bricks 30-35 cm thick for walls, concrete 20 cm thick for floor and ceiling, the flat of ground floor having the internal walls of phosphogypsum (7 cm thick).

In order to estimate the contribution of the Rn level in the flat, PAEC or EEC levels were determined by Nazaroff's method [1] occasionnally doubled by Sima's method [2]. The annual effective dose given by the building materials have been estimated on the basis of the data delivered by UNSCEAR Reports 1982 and 1993 [3,4] and W van Dijk [5].

The results are presented in Table 3. The exposure generated by the phosphogypsum only partly used in a flat is very high compared to both ground floor values (4-5 times higher) and the mean value obtained for the houses in Romania (2-3 times higher).

CONCLUSIONS

As a result of these studies, the Ministry of Health included two articles regarding the use of the building materials in the "Regulations concerning the radioprotection of the population and environment"

a) "The natural radioactive elements in building materials should correspond to the raw materials from which are derived, the intentional addition of the natural and artificial radioactive elements being prohibited"

b) "The use as building materials of the sterile, slag and by-products of the fertilizer industry, with a natural or artificial content higher than the value of the products commonly used in the building industry is forbidden"

The use of phosphogypsum as building material for social dwellings was banned in any way (no mass proportion was addmitted). In the case of the potential building materials containing fly ash, each solution should be analysed and licensed by the Ministry of Health on the basis of the Ra-226, Th-232 and K-40 radionuclide concentrations of the products and dose assessements.

INTRODUCTION

Thermoelectric power generated by coal represents about 30% of the electric power production in Romania (1). The combustion of coal results in release to environment of naturally occuring radionuclides. These are reasons for the research about the radiological impact of coal-fired power plants on the surrounding zones and population living there.

With that end in view we selected ten representative modern and older coal-fired power plants in Romania with a total installed capacity of 2.5 Gw.

MATERIALS AND METHODS

This work performed during 1984-1994, involved the measurement of activity concentrations of natural radionuclides in coal (235 samples) bottom and fly-ash (820 samples) originating from the power plants. Soil, vegetation and snow samples (910) have also been collected at 20 locations from the surroundings of each thermal power plant within a 5 Km radius from the stack. All the samples were counted for their natural radioactivity content using gamma ray spectrometry techniques and radiochemical methods (2,3).

RESULTS AND DISCUSSION

In the investigated power plants they burn brown coal, lignite and/or mixture of different kinds of coal : brown coal, lignite, pit coal, pitch coal, bituminous coal. The activity concentrations measured in the coal samples varied over two orders of magnitude (Table 1). The natural radionuclide concentrations in fly ash are significantly higher than the corresponding concentrations in the coal (Table 1).

The normalized discharged activities for the investigated power plants are much higher than those estimated in the UNSCEAR 1988 Report for typical old and modern plants (Table 2). Firstly, accounting for this is the low ash retention efficiency of the particulate control devices of power stations, especially for the older ones,and secondly,the high ash content of the coal: 26-60%. The low quality of coal leads to the higher coal consumption; thus the combustion of up to 20.10^9 Kg of coal is required to produce 1 Gwa of electrical energy.As a result,the activities of radon-222 and of radon-220 released per Gwa have been assessed at 25 to 770 GBq (2,3).

Table 1. Activity mass concentrations of natural radionuclides in coal and ash samples ($Bq.Kg^{-1}$)

Radio-nuclide	Brown coal	Lignite	Mixture of coal	Bottom ash	Collec-ted fly - ash	Escaping fly - ash

^{40}K	310	274	305	526	500	547
	230-590	182-490	30-615	158-1000	160-1200	160-1300

x - Arithmetic average ; xx - Range

Table 2. Estimates of annual atmospheric discharges per unit energy generated (GBq per Gwa)

Radionuclide	Coal - fired power plants (10)	
	Modern (7) [x]	Old (3) [xx]
^{238}U	0.19 - 50	28 - 281
^{226}Ra	0.07 - 47	28 - 201
^{210}Pb	0.17 - 86	52 - 300
^{210}Po	0.50 - 85	60 - 330
^{232}Th	0.04 - 17	10 - 65
^{228}Th	0.06 - 22	13 - 80
^{40}K	10.50 - 236	200 - 915

x - Fly-ash removal efficiency 96-99.5%
xx - Fly-ash removal efficiency 60-80 % ; in 1993,the worst of these plants was modernized.

Mesurements in soil, snow and vegetation had clearly shown the presence of increased concentrations of the natural radionuclides in the surroundings of the coal - fired thermal power plants,particularly for the oldest and most poorly controlled ones (Table 3).

Table 3. The average activity concentrations of natural radionuclides in soil,vegetation and snow (Bq kg^{-1})

Natural radionuclide	Soil (560 samples)		Vegetation	Snow
	the upper 5cm layer	the 5-15 cm layer	175 samples	175 samples
^{238}U	33 ± 30	26 ± 25	51 ± 46	$(4.2\pm3.1).10^{-3}$
^{226}Ra	38 ± 30	30 ± 27	30.8 ± 7.5	$(2.6\pm2.0).10^{-2}$
^{232}Th	36 ± 17	29 ± 16	83 ± 61	$(2.5\pm1.5).10^{-3}$
^{40}K	535 ±180	420 ±170	451 ±100	$(4.5\pm3.8).10^{-1}$

The resulting normalized collective effective doses (Table 4) have been estimated taking into account: the activity released per electrical energy unit; the population density; the wind rose and the deposition (dry and wet) velocity; the effective stack height (ranging from 55 m to 220m) (4,5).

Table 4. Estimates of normalized collective effective doses (manSv per Gwa)

Coal-fired power plants	Inhalation during the cloud passage	Irradiation due to deposited activity		Total
		Internal	External	
Modern	0.06-2.39	0.17-2.31	0.009-0.101	0.24 - 4.8
Old	10.4-34.5	7.2 -31.0	2.4 - 10.5	20 - 76

CONCLUSIONS

1. The population living in the neighbourhood of a inadequately controlled coal fired power plant is exposed to enhanced levels of natural irradiation.

2. The mass of $384x10^6$ Kg fly ash annually released to the atmosphere from ten coal - fired thermal power plants was considered to be the main cause of disturbance of natural radiation background and of enhancement of population doses.

THE PRESENCE OF ^{226}Ra IN THERMAL SPRINGS OF CROATIA AND HEALTH RISK FROM MINERAL WATER CONSUMPTION

Gordana Marović, Jasminka Senčar and Zdenko Franić

Institute for Medical Research and Occupational Health, Zagreb
Department of Radiation Protection
Ksaverska cesta 2, P.O.Box 291, HR-10001 Zagreb, CROATIA

INTRODUCTION

The presence of ^{226}Ra in water and possible health effects require particular attention considering the great radiotoxicity of ^{226}Ra, its long half-life ($T_{1/2}$= 1.622 yrs) and its high potential for causing biological change (1). Numerous studies have shown that many thermal water springs around the world contain relatively high levels of natural radionuclides, in particular ^{226}Ra which may present a possible risk of increased exposure to ^{226}Ra in the general population (2).

The purpose of this study was to determine ^{226}Ra concentrations in thermal water springs in the Republic of Croatia at six sampling sites, mostly spas and health resorts. These thermal waters have been used for medical and bathing purposes, for therapy, rehabilitation and recreation, and also for drinking for its good mineral composition.

Radium contamination in the samples of thermal waters was measured in order to estimate the radiation doses received by the population - patients or tourists during a stay in the spa, and to calculate the radiation dose originating from drinking spring waters. Equivalent dose received from a medical drinking cure over a four week period was estimated and compared to the dose received from ingestion of public system tap water over a year.

The Republic of Croatia is one of the richest countries in hot springs in the world and many health resorts are based on thermal and mineral water springs. Considering popularity of the spas and habit of the Croatian population to use beneficial effects of these springs it is of interest to estimate to what extent is radioactivity of thermal and mineral waters absorbed by bathing and drinking practices.

MATERIAL AND METHODS

The samples were collected several times over the period of last four years at six locations of selected thermal water springs, most popular tourist spas and health resorts, majority of which are clustered in North-western Croatia.

In all samples ^{226}Ra was determined by alpha spectrometric measurements after radiochemical separation. The counting time for each measurement was 60000 s or longer.

RESULTS AND DISCUSSION

Values of the average ^{226}Ra concentrations measured at six locations of selected thermal water springs are given in Figure 1 showing deviations from the average values in the observed period.

In the spas in which waters were used for bathing and drinking, ^{226}Ra activities measured in the samples of thermal waters did not exceed maximal permissible level of 1000 Bqm^{-3} for drinking water (3). In Croatia, health-based acceptable level of exposure from drinking water is based on the latest IAEA recommendation taking 1000 Bqm^{-3} as the maximum permissible level for ^{226}Ra in drinking water which is a derived concentration (DC) for a group of individuals (3). Guideline activity refers exclusively to ^{226}Ra concentration in municipal drinking water supplies and there is no regulation that would refer to the occurrence of ^{226}Ra in other water categories, such as thermal and mineral waters, and to possible contribution by routes of exposure other than ingestion. In other words, natural mineral water has not been included in the existing Croatian legislation on drinking water and has not been taken into consideration as a distinct category of water although the analyses show that ^{226}Ra concentrations contained in thermal and mineral waters are higher than in other categories of water in Croatia.

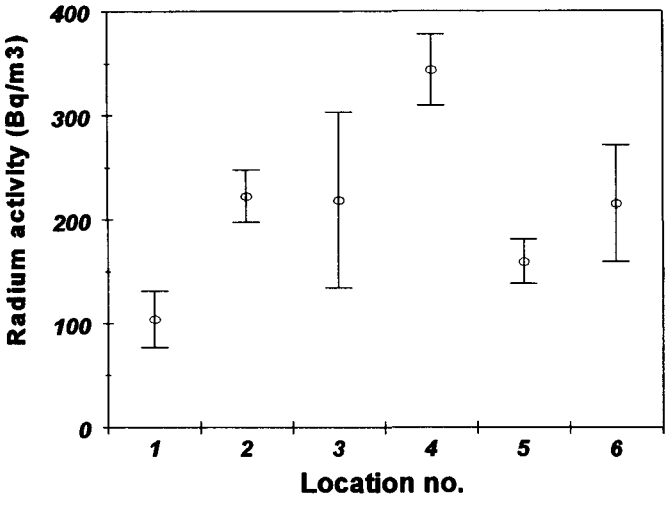

Figure 1. Average ^{226}Ra concentrations measured at six thermal springs

According to the study by Marović and co-workers ^{226}Ra concentration measured in the tap water in several major urban centres of Croatia was 2.1 ± 1.4 Bqm^{-3} (4).

In selected spas all waters have been used for medical and bathing purposes, and also recommended for drinking cure. The water from location no. 1 (Figure 1.) known for its good mineral content, is bottled and commercially sold in the country and abroad.

Considering relatively high ^{226}Ra content in thermal waters of the spas and health resorts of Croatia and on the assumption that a drinking cure contains 1 L of mineral water daily for one week, a possible influence on body burden from drinking this water would be higher than from consumption of the tap water over a year.

Estimating the dose due to consumption of spring waters with increased radium content, it has to be emphasized that these waters are applied as medicinal waters for definite periods and in given amounts. Therapeutical application usually takes daily doses of 0.2-1 litres for several weeks.

Table 1. The effective dose received from a medical drinking cure

Effective dose over four weeks (mSv)		
Sampling location no.	**0.2 L/day**	**1 L/day**
1	$1.28 \cdot 10^{-4}$	$6.41 \cdot 10^{-4}$
2	$2.74 \cdot 10^{-4}$	$1.37 \cdot 10^{-3}$
3	$2.70 \cdot 10^{-4}$	$1.35 \cdot 10^{-3}$
4	$4.24 \cdot 10^{-4}$	$2.12 \cdot 10^{-3}$
5	$1.97 \cdot 10^{-4}$	$9.83 \cdot 10^{-4}$
6	$2.65 \cdot 10^{-4}$	$1.33 \cdot 10^{-3}$

The assumed received dose is compared to that received by consuming only tap water over a year. The effective doses received from a medical drinking cure, that is 0.2 L/day of thermal water over the period of four weeks (Table 1) were estimated to be 1.3 times higher than the dose received from drinking 2 L/day tap water over a year ($3.37 \cdot 10^{-4}$ mSv). The doses received from 1 L/day of thermal water over a four-week period estimated to be as were much as 2 to 6 times higher, than the dose received from drinking tap water over a year.

According to ICRP recommendations (5) the limit for public exposure should be expressed as an effective dose of 1 mSv in a year. Since the doses obtained in our study are well below the recommended dose of 1 mSv the practice of using thermal waters (bathing and drinking for medical therapy, recreation and rehabilitation) should not be restricted provided that other sources of exposure are taken into account and controlled.

INTRODUCTION

This work is a contribution to the national programme for the supervision of the food radioactivity and provides data on natural radionuclides in wheat, maize and potatoes.

These foodstuffs are major part of Romanian population diet (32%) therefore they are being cultivated on over half an area of main crops in Romania.

MATERIALS AND METHODS

During 1984-1994 there were taken from the territory of districts Suceava,Botosani,Neamt,Iasi,Bacau,Vaslui,Vrancea and Galati, samples of wheat grains, corn and potatoes. We made up 900 average samples which represented about 30% from all the area of these crops in Moldova.

The taking of samples (in the harvest time) and their analysis were carried out by standardized methods in Romania. The samples of 1 Kg of grain respectively peeled potatoes were dried, calcinated and wet ashed. Arising acid extracts were utilized for the assay of natural radioelements: uranium-238, thorium-232, radium-226, polonium-210 and potassium-40. Uranium-238 and thorium-232 were calculated after determining the content of natural uranium and thorium by the method based on their separation and purification on a strong basic anion exchange resin and spectrophotometric measurement in the form of their Arsenazo III complex. Radium-226 was determined through its decay descendent radon-222, and by alpha rays measurement in a scintillating chamber. The assay of polonium-210 was done by electrochemical deposition and alpha counting of polonium-210 deposited on the nickel disc in a low background ZnS (Ag) scintillation counter. Potassium-40 was found by calculation after the photometric dosing in flame emission mixture of potassium natural isotopes.

RESULTS AND DISCUSSION

Natural radioactivity levels due to uranium-238,radium-226 polonium-210,thorium-232 and potassium-40 which were determined in wheat grains, maize and potatoes are presented in Table 1.

There is no significant difference between the yearly determinations values in the investigating period of eleven years

with but few exceptions. The samples prelevated in 1984-1987 have had increased values for uranium-238 and radium-226. We suppose that the intensive use of chemical fertilizers in that period is responsible for this. During the eighties, a mean quantity of 40 Kg $P_2 O_5$ per hectare was used in Romania for wheat, and about 150 Kg $P_2 O_5$ per hectare for potatoes (1,2). The measurements of the uranium-238 and radium-226 content performed in our country, showed values of up to 580 Bq/Kg fertilizer respectively 351 Bq/Kg fertilizer for the superphosphate (1,3).

Table 1. The activity concentrations (mean and limits) of the natural radionuclides in some foodstuffs

Food product	^{238}U mBq/Kg	^{226}Ra mBq/Kg	^{210}Po mBq/Kg	^{232}Th mBq/Kg	^{40}K Bq/Kg
Wheat (grains)	39 6.1-84.5	155 10-455	135 11-370	12.3 1.6-33.2	79 35-152
Maize	32 2.4-69.8	72 10-268	89 10-372	8.2 0.8-18.9	68 30-115
Potatoes (peeled)	24 6.1-115	30 9-120	51 15-138	1.7 0.4-2.05	121 35-285

One can see from our data the high variability of natural radioelements values in the samples of food products, very likely due to the various activities of the soil in the sampling zones (4).

Potatoes from Suceava, Botosani and Neamt districts, showed somewhat higher local activities for all the five nuclides with the highest uranium-238 content.

The values are generally comparable to those found in the other zones of Romania and are situated between the variation limits of concentration values determined and reported for the other countries in areas of normal natural radioactivity (1,5,6, 7,8).

The annual ingestion of natural radioelements per capita was assessed for each of the three food-products, taking into account the yearly average consumption. Yearly average consumption of food products per capita in natural units represents the quantities of food products effectived for human consumption irrespectively of the consumption type (gross or processed), of supply source (food stores, free market, consumption from own resources of agricultural producers, etc) as well as the consumption place (households, restaurants, canteens, etc) (2,9).

The relative contributions of three major dietary categories to the total diet intake are listed in Table 2.

In the previous studies (8,9) there were determined natural radioelements in samples of different food products (representing components of human diet), menus and drinking water. The annual ingestions of natural radioelements was calculated and were used in Table 2 for the data comparing. One observes that the cereals products and the potatoes have the greatest contribution to ingestion of radium-226 and polonium-210.

Table 2. The annual ingestion of natural radionuclides (Bq y^{-1}) (region Moldova - Romania)

Food product	^{238}U	^{226}Ra	^{210}Po	^{232}Th
Wheat *	1.69	7.21	9.65	0.62
Maize *	1.42	3.02	6.80	0.43
Potatoes	1.31	1.30	2.64	0.09
Total dietary ingestion in Moldova (8,9)	6.2-11.2	12.4-20.7	24.8-40.1	1.6-4.4

* - Cereals products in equivalent flour

CONCLUSIONS

1. The natural radioactivity of the analysed foodproducts generally varied in the order: wheat grain maize potatoes excluding potassium-40, which was higher in potatoes.

2. The contribution of wheat and maize(equivalent flour) and potatoes, which are the main components of Moldavian diet, to the total dietary intake of natural radionuclides is over 60 %.

NATURAL RADIONUCLIDE CONCENTRATIONS OF CEMENTS IN IZMIR AND DOSE ASSESSMENTS

A. Tanbay, G.Yener
Ege University, Institute of Nuclear Sciences, 35100 Bornova-İzmir/Turkey

ABSTRACT

The growing demand of electric power and the large domestic deposites of lignite coal have made coal-fired plants grow in number in Aegean Region of Turkey. Some of this coals like Yatağan lignites are known to have high uranium concentration (315-405Bq/kg for coal, 746-1076Bq/kg for collected fly ash). The stockpiles of fly ash of these power plants are readily available for industrial uses as in the case of cement production. Therefore to assess the doses arising from building materials especially from cement in the cities of Aegean Region a project has been started beginning from Izmir.

The traces of radium, potassium and thorium in 45 cement samples which are collected from building constructions in Izmir have been analysed by gamma spectrometry. The mean concentrations of Ra-226, Th-232 and K-40 were determined. The indoor radionuclide doses were calculated using the mean concentrations found in the measurements of this work. The results were compared with those given for other countries.

INTRODUCTION

In Turkey as well as many other countries one can observe increasing interest in industrial and extractive wastes as substitutes for natural products in building industry. They usually have higher content of naturally occuring radioactivity than traditionally applied raws.

Knowledge of the radioactivity levels of materials used in the building construction is useful in the assessment of indoor radiation exposure of the population. This is also useful for the development of standarts and guidelines for the use and management of these materials for building low background laboratories.

EXPERIMENTAL

The materials were obtained randomly from local building material suppliers and manufacturers. Different brand names were sought. All samples were oven-dried at 105° C for 16h. and then sealed in 100g. portions in cylindrical polyethylene boxes. They were kept for 1 month to attain radioactive equilibrium between radium and radon for high energy γ-spectrometric analysis. The natural radioactivity of the building materials was determined from their Ra-226, Th-232 and K-40 contents. The eU, eTh and % K contents were determined from 1.76MeV Bi-214, 2.62MeV Tl-208 and 1.46MeV K-40 lines, respectively, with a method given elsewhere (Killeen, 1979). The sample and the standard γ-spectra were taken for 4000s. with the spectrometer consisting of NaI(Tl) crystal, 4096 channel Ortec .7010 analyzer and related electronic components.

The activity concentrations of the radionuclide in the samples were given by (Chung-Keung Man et al. ,1989)

$$A_i = [(C(E_i) - B(E_i))/(m\,f\,t\,P(E_i))] \qquad (1)$$

A_i : is the activity concentration of radionuclide i.
$C(E_i)$: is the net γ-counts above continum at the characteristic energy E_i
$B(E_i)$: is the background counts at E_i
m : is the mass of sample in kg.
f : is the branching ratio of the γ-emission at the energy considered.
$P(E_i)$: is the absolute efficiency at energy E_i

To compare specific activities of these materials a common index is required to obtain the total activity. This index called radium equivalent activity (Ra_{eq}) is based on the fact that 0.37Bq/g of Ra-226, 0.26Bq/g of Th-232 or 4.8Bq/g of K-40 produce the gamma dose rate (M.R. Menon et al. 1987).

$$Ra_{eq} = A_{Ra} + (A_{Th} \times 1.43) + (A_K \times 0.077) \quad (2)$$

where A_{Ra}, A_{Th}, A_K are activities of Ra-226, Th-232, K-40 respectively in Bq/g. A criterion formula corresponding to a maximum of 0.37 Bq/g is

$$H = A_K / 4810 + A_{Ra} / 370 + A_{Th} / 259 < 1 \ (A \text{ in Bq/kg}) \quad (3)$$

If the value of H is less than 1, the result signifies that the radiation hazard is about the same as that existing in a cave in the ground. The dose rate D, within a building is estimated from the emperical relation

$$D(\text{mrem/year}) = 1.16C_K + 11.45C_{Ra} + 17.8\,C_{Th} \quad (4)$$

where C is concentration in pci/g (K. Mamont-Ciesla et al. ,1983)

RESULTS AND DISCUSSION

The natural radioactivity in a variety of cement samples has been measured by gamma ray spectrometry . The concentrations of Th-232, Ra-226 and K-40 measured in a selection of cement samples available in İzmir are listed in table-1. The natural radioactivity of cement samples varies considerably depending on their origion. In the last columns radium equivalent concentration and dose rate are given. It can be seen that the Ra-equivalent and H values of samples measured in cement samples are lower than the limits given by Eq.2-3. The gonods, the active bone marrow, and the bone surface cells are considered by the UNSCEAR as the organs of interest. For this reason, many dosimetry models can be found in the literature for these organs. The maximum permissible gonadal dose from gama radiation due to the radioactivity in building materials amounts to 112 mrem/year. For comporison, the dose from the terrestrial radiation in İzmir (Turkey) varies from 34.41 to 89.73 mrem/year. These values can be compared with similar measurements performed by researchers other countries, they are also listed in Table 2.

Table 1. Natural Activity Concentration in Bq/kg of Cement Samples in İzmir

Sample	*eU (Ra-226)*	*eTh (Th-232)*	*%K*	Ra_{eq}	$C_K/4810 + C_{Ra}/370 + C_{Th}/259$	*Estimated gonadal dose mrem/year*
tc*	108.0	39.7	363.5	192	0.51	61.9

DETERMINATION OF CONCENTRATIONS OF SELECTED RADIONUCLIDES IN SURFACE SOIL IN THE STATE OF KUWAIT

F. Bou-Rabee[1] and H. Bem[2]
[1]Radiation Safety Unit, Kuwait University P.O.Box 5969, Safat 13060, Kuwait
[2]Institute of Applied Radiation Chemistry, Technical University of Lodz, 93-590 Lodz, Poland

INTRODUCTION

Exposure from radioactive nuclides of terrestrial origin has remarkable input to the total effective dose equivalent for human population. The substantial part of this exposure is external irradiation, which depends on activity mass concentration of primordial radionuclides in surface soil, mainly ^{238}U, ^{232}Th series and long-lived ^{40}K. From geological point of view the surface soil of Kuwait is relatively uniform: desert type with prevailing smooth sand sheets and one cannot expect the big differences in surface concentration of natural radionuclides, except of coastal deposits. However, Kuwait territory was heavily contaminated during the Gulf War due to large quantities of released crude oil and the atmospheric discharges from incomplete oil combustion from the burning of oil wells. Although oil and natural gas contain only trace quantities of the naturally occurring long-lived radionuclides, because of the large scale of atmospheric discharge the emitted activities were apprised as : 6.7 G Bq- ^{238}U, 10 GBq - ^{226}Ra and 5 GBq- ^{232}Th (1). In addition, the use of uranium tipped antitank shells during the Gulf war was another source of possible uranium contamination of the surface soil of Kuwait. Therefore continuous background radionuclide concentration measurements were initiated as a part of a program for assessment of radiation doses from natural sources for Kuwait population.

METHODS

The location of the 69 sites where soil samples were taken are shown in Fig. 1. These locations are non random and are positioned in the Kuwait City, its vicinity, along major highways and in the special geological formations. The several samples were also collected from the Gulf War battle-field (Mutla area). Three samples from the uninhabited islands: Guruh, Maradin and Kubar were also analyzed. The soil samples (top 5 cm) were collected from 100 sq. cm surface- three samples from each site. All samples were dried at 110° C and 1.5 kg fraction which passed through 12 mesh sieve was placed in the plastic Marinelli beaker and stored for three weeks to allow build up of radon and its daughters. The samples were counted using high purity Ge detector and the spectra were analyzed using Sampo-90 program. The detector was calibrated by adding the mixed radionuclide standard - QCD 1 (Amersham) to soil sample followed by homogenization of sample.

Concentrations of ^{238}U were determined directly from 92.6 keV and ^{40}K from 1461 keV peaks. In identifying ^{226}Ra the five principal γ-rays were analyzed: 295, 325, 609, 1120 and 1765 keV from ^{214}Pb and ^{214}Bi radionuclides. Also for analyzing of ^{232}Th five γ-lines: 239, 583, 727, 911 and 969 keV from its daughters. ^{208}Tl, ^{212}Bi and ^{228}Ac were used. Additionally the concentration of ^{137}Cs deposited after nuclear bomb tests were also determined.

RESULTS AND DISCUSSION

The calculated average concentrations of measured radionuclides are as follows:

^{232}Th ---	10.0 ± 3.5 Bq kg^{-1}	ranged from 0.57 to 16.3 Bq kg^{-1}
^{238}U ---	13.4 ± 5.2 Bq kg^{-1}	ranged from 7.0 to 30.7 Bq kg^{-1}
^{226}Ra ---	11.8 ± 4.4 Bq kg^{-1}	ranged from 2.25 to 22.8 Bq kg^{-1}
^{40}K ---	329.3 ± 111 Bq kg^{-1}	ranged from 4.4 to 496.5 Bq kg^{-1}
^{137}Cs ---	2.8 ± 2.6 Bq kg^{-1}	ranged from 0.1 to 9.9 Bq kg^{-1}

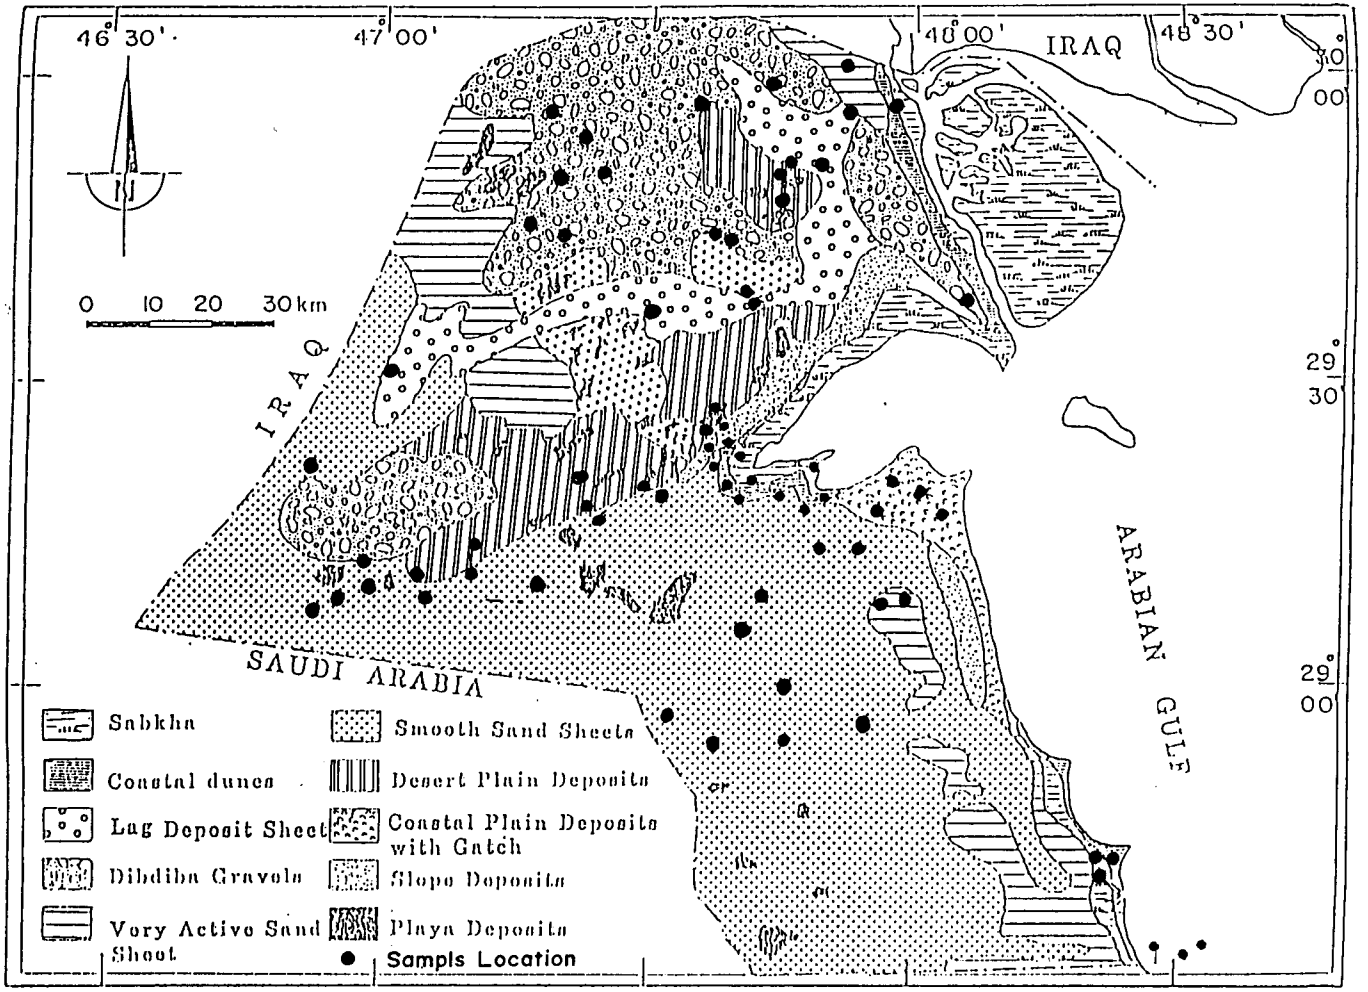

Fig.1. Surface deposit distribution in Kuwait and location of background soil samples

The highest concentrations of ^{238}U were observed in the samples from coastal area (Ras Al-Zoor) and from the island soils. The same samples showed very low ^{232}Th, ^{226}Ra, and ^{40}K values. No significant differences in uranium concentrations for Mutla area and other places have been found. The average concentration of ^{232}Th and ^{238}U in Kuwait surface soil were lower than the world average value of 40 $Bq\text{-}kg^{-1}$ (2) since the large area of Kuwait is covered with desert sandy soil. In the most cases daughter radionuclides of uranium and thorium series were found in a radioactive equilibrium except of those from Ras Al-Zoor and islands-samples.

On the basis of these measurements and dose rates per unit concentration in soil, adopted from UNSCEAR (3,4) the average absorbed dose rate in air (at 1m height) from gamma field of ^{232}Th, ^{238}U series and ^{40}K radionuclide was estimated on 0.234 mGy per year for Kuwait territory.

ACKNOWLEDGMENT

This study was supported by a grant SG042 from Kuwait University.

RADIATION EXPOSURE OF POPULATION DUE TO CARELESS USE OF RADIOACTIVE RAW MATERIALS IN THE URALS

I.V.Yarmoshenko, A.A.Ekidin, A.V.Vozhakov
Institute of Industrial Ecology, Ekaterinburg, Russia

HISTORY and BACKGROUND

In the middle of the forties a deposit of thorium monacyte sand was found in the Urals. Thorium monacyte is a physically and chemically resistant mineral, practically insoluble in water. The formula for monacyte is $(Ce,La,Y,Th)P_2O_5$. The monacyte sand contains high concentrations of long-live natural nuclide ^{232}Th. Characteristic ThO_2 concentration in sand is about 3-9%.

During 1949-64 in village Ozerny located in 70 km to the north-east from Ekaterinburg a concentrating mill processing thorium containing monacyte sand for the purposes of nuclear and military industry was functioning. In summer the mill processed local staff and in winter the staff brought from another places. The territory of railway station Kostousovo was used for loading and storage of staff and as a result of this the territory of temporary monacyte sand storage was subjected to technogenic radioactive contamination.

After the concentration mill has ceased its operation the careless use of thorium monacyte sand for private and public construction, for paving the roads along with natural dispersion of sand took place. Thus in the village and at the railway station some centres of technogenic radioactive contamination by natural radionuclides has been formed.

One of the reasons of careless use of radioactive raw materials was the absence of objective information on the character of the staff.

OBJECTIVES

Our main objective was to single out all cases of radioactive contamination for planning the rehabilitation and deactivation measures and for calculating the accumulated exposure dose for population of village Kostousovo. It was assumed besides, that the main ways of population exposure beyond the natural radioactive background was the external gamma-irradiation and inhalation receipt of ^{220}Rn (thoron) along with its daughter products in houses built with the use of thorium-containing materials. It was also necessary to ascertain the level of natural radioactive background for comparing it with the additional irradiation.

METHODOLOGY

For revealing the centres of radioactive contamination the method of continuous pedestrian sampling point by point with distance 5 m (scale 1:5000) at the territories of common use (streets, vacant lots, railway station), in private gardens, along the external fronts of buildings and indoors - ceilings, walls, stoves was conducted. Scintillation radiometers were used.

The measuring of equivalent equilibrium concentration (EEC) of thoron was conducted by aspiration method implying aerosol adsorbtion on filter with further measuring of alpha-activity on the filter. Besides the equivalent volume activity of ^{222}Rn (radon) is revealed, being an important share in population exposure. The obtained results of seasonal samplings were converted to mean annual activity by the methodology tested and applied in the Urals. This methodology accounts for typical value of equilibrium factor and relation between seasonal and annual concentrations. For the purposes of evaluating the ^{232}Th supplies the samples of soil were taken in the areas with elevated gamma-irradiation. To estimate the specific activity of long-live radionuclides in air and water we conducted air- and water- sampling.

RESULTS

The whole territory of village and 235 private and public buildings were tested for radiation exposure dose rate. 16 places of concentration of radiologically contaminated staff were found along with 25 cases of using thorium-containing materials for building purposes.

Total contaminated territory is about 10200 m^2 The most extensively contaminated spot is at the former loading site of the concentration mill (8000 m^2), now it is a vacant lot. Other contaminated centres are located in the vicinity of, or directly in residence zone; their square is from 1 up to 1.300 m^2. Total Th concentration at the contaminated territory is about 1.6 Ci. Such Th concentration was formed as a result of spreading of about 300 tons monacyte sand (5% concentration) by a thin layer of 1 sm.

The range of radiation exposure dose rate in the middle of the most contaminated site was from 0.8 up to 1.0 mR/h, and Th specific activity in ground samples reaches 600 kBq/kg.

In all 25 tested houses the elevated rate of exposure dose (up to 150 μR/h) is caused by non-controlled use of monacyte sand as building material. As a result such parts of buildings as the fundamentations, wall plasterer, stove grout and garret fillings were radioactively contaminated. The total Th content in building materials do not exceed 0.15 Ci.

These materials also served the source of thoron emanation . The volume activity of thoron in contaminated buildings was 2.5-15 Bq/m^3, whereas the mean value for the village in non-contaminated buildings equals to 1.7 Bq/m^3 and doesn't exceed 2.5 Bq/m^3. The mean value of indoor volume radon activity in the village is 77 Bq/m^3. There was no difference in radon concentrations in "clean" and contaminated houses in the village.

The air and ground-water samplings don't show the elevated level of contamination (exceeding the background).

DISCUSSION, DOSES

It was estimated that the natural background radiation is rather high at this territory. Mean outdoor exposure dose at the territory of the village is equal to 20 μR/h, and indoors - 23 μR/h. Indoor radon concentrations are also rather high.

Basing on the results of estimating the external dose of gamma-irradiation in private houses in village Kostousovo the collective exposure dose was calculated. Population of the village is 430 people. Taking into consideration that population spends indoors about 7000 hours per year this dose equals to 56 cSv/year. Besides, 77% (43 cSv) of this dose is formed by the sources of natural gamma-irradiation, whereas 23% (13 cSv) - by technogenic concentrations of natural radionuclides (addition). Maximum individual effective dose by gamma-irradiation is a private house is 16.2 mSv/year.

The collective exposure dose formed as the result of inhalation penetration of thoron and daughter products is equal to 32 cSv/year. Besides, 81% of this dose (26 cSv) is caused by exhalation of thoron from the building materials and soil with natural concentration of ^{232}Th, and 19% (6.0 cSv) - by Th exhalation from building materials with elevated concentration of natural radionuclides (addition). Maximum individual effective dose in a private house constitutes 3.8 mSv/year. In the result of penetration of radon and daughter products the annual collective dose (59 cSv) is formed.

The structure of collective exposure dose H for population of village Kostousovo is shown in table 1.

Table 1.

The structure of collective exposure dose H for population of village Kostousovo

	H_{Tn}	H_{Rn}	H_{γ}	$H_{Tn}+H_{Rn}+H_{\gamma}$
Total, cSv/year	32	59	56	147
Excess, cSv/year	6,0	-	13	18
Excess, %	19	-	23	12

In the most contaminated private house there are living 7 persons. The structure of annual individual effective dose E is shown in table 2. This house was built in 1970. The accumulated for 25 years over-background individual exposure dose constituted almost 0.5 Sv.

Table 2.

The structure of annual individual exposure dose E for inhabitants of most contaminated house in village Kostousovo

	E_{Tn}	E_{Rn}	E_{γ}	$E_{Tn}+E_{Rn}+E_{\gamma}$
Total , cSv/year	5.3	1.4	16.2	22.9
Excess, cSv/year	4.7	-	15.2	19.9
Excess,%	89	-	94	87

CONCLUSION

Careless storage of radioactive staff at the railway station Kostousovo has led to its non-controlled use in building construction and thus to contamination of the territory by long-live natural radionuclides and daughter products. About 10200 m^2 of the territory and more than 10% of houses were subjected to contamination. As a result the external gamma-irradiation and indoor ^{222}Rn concentrations have increased.

Annual collective dose has increased by 19% through inhalation of thoron and daughter products, by 23% through external gamma-irradiation , an increase of 12% is registered in cumulative exposure dose. In case of extreme radioactive contamination of private house there was registered an 11-fold increase of the individual effective exposure dose.

Basing on the results of investigations some rehabilitation measures were proposed.

DOSE MEASUREMENT AND ITS PROBLEMS ON THE HIGH BACKGROUND RADIATION AREA(HBRA) IN CHINA

[5]Laboratory of Industry Hygiene, Beijing, China

INTRODUCTION

As a part of China-Japan cooperative research on radiation epidemiology, we carried out dose-assessment study in the HBRA since 1991 to 1994. Particularly, we have examined quantitatively on the characteristics of distribution of the numerical measurements and analyzed the variables concerned, using different kinds of dosemeters in order to obtain the information with regard to accuracy of the data for dose estimation. We selected for the dose measurement, 陽東県 and 陽西県 as the HBRA and 恩平県 as the CA.

INHOMOGENEOUS SPATIAL DISTRIBUTION OF RADIATION EXPOSURE IN THE HBRA

Average dose rates for indoor and outdoor in different hamlets of the HBRA measured by NaI (Tl) scintillation survey meter (TCS-166) are shown in **Figure 1.** It was remarkable that indoor dose rates were about 2 times higher than those of outdoor, although the ratios of the dose rates between indoor and outdoor in the CA were not so remarkable, rather almost similar. Further study showed that the dose rates of indoor had a good correlation with the dose rates of the house wall, and decreased with increase of the distance of the measured site from the house wall. These results strongly suggest that levels of radionuclides containing house wall will be deeply concerned with the radiation dose exposed. Thus, we have performed radionuclide analysis of the building materials such as bricks, tiles and soil samples using Ge-semiconductor diode detector. Nuclides of Th-232 decay products in the HBRA were 3-4 times higher than those of the CA. Similarly the decay products of Th-232 in the HBRA were about 2 times higher than those of U-238. These results were verified the data obtained by Chinese investigators. We have further measured personal doses with PDMs and TLDs for 24 hours and 2 months respectively. It was obvious that there were good correlation between personal radiation dose rates and indoor dose rates. Personal dose rates largely depends upon exposure dose rates originated from radionuclides in building materials of house.

VARIATION OF THE EXPOSED PERSONAL RADIATION DOSE RATES WITHIN A HAMLET

We have examined variation of the indoor dose rates of 32 different houses within a hamlet of 牛根 . We observed there were fairly large variation of the indoor dose rates with different houses in a same hamlet, presumably due to the different housing conditions such as levels of

radionuclides of the building materials and spatial location in a hamlet. It should be noted that this range of variation on the indoor dose rates was almost comparable with those of distribution of different hamlets in the HBRA as shown in **Figure 2.** Further we have examined variation of personal dose rates measured by 96 TLDs as well as PDMs in a hamlet of 麻地. Fairly wide range of variation for personal dose rates within a hamlet demonstrated in **Figure 3.** This wide range of distribution for personal dose rates is considered to be due to, at least, two kinds of independent factors;
1) different levels of indoor dose rates with houses and 2) different personal behavior which is reflected as an occupancy factor.

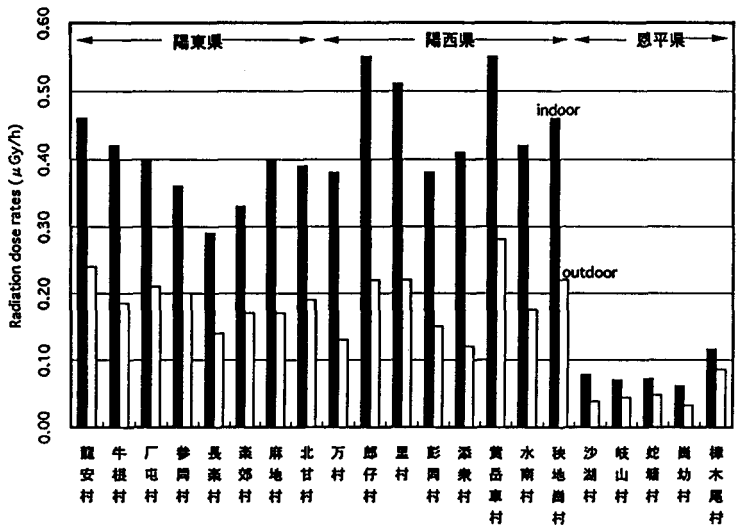

Figure 1. Variation of the mean environmental radiation dose rates on the HBRA (measured by TCS-166).

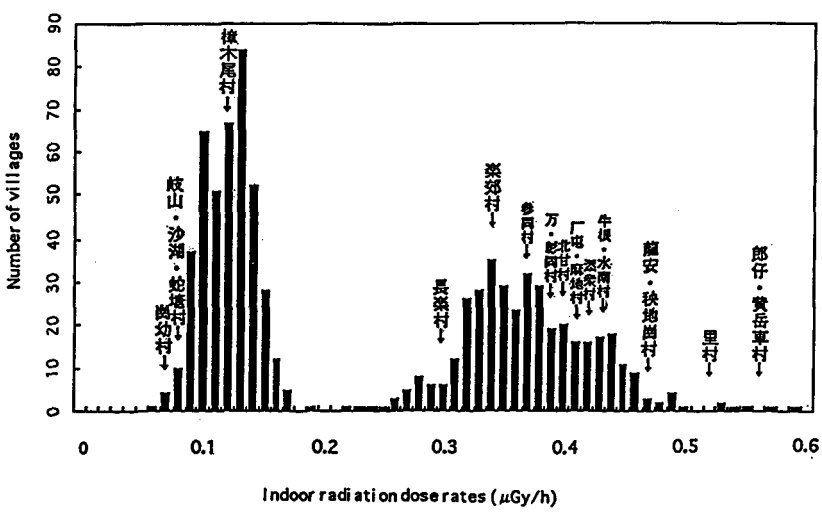

Figure 2. Frequency distribution of indoor radiation dose rate on HBRA (measured by survey meter).

VARIATION OF OCCUPANCY FACTORS CONCERNED AND ESTIMATION OF PERSONAL DOSE RATES

We have three models for personal dose measurement. They are two direct methods using electronic pocket dosimeter(PDM-101) and thermoluminescence dosimeter(UD-200S) and indirect method. The different approaches will be undertaken; direct methods and indirect method by using occupancy factor. In direct approach to estimate personal dose rates with hamlet population, since the difference between indoor dose rate and outdoor dose rate is so large, personal exposed dose rate depends upon their living life style which is related to occupancy factor i. e., ratio of the resident time on indoor per one day. This relation will be shown as following equation;

$$Dp=Di(q) + Do(1-q), \quad q=(Dp-Do)/(Di-Do)$$

where Dp, Di, Do and q are personal dose rate, indoor dose rate, outdoor dose rate and occupancy factor, respectively. Thus we can estimate personal dose rate if the values of Di, Do and q are given.

Coefficient q value of occupancy factor could be estimated by different two ways;
1) Indoor occupant time is available by direct measuring using the method of questionnaires and 2) Effective occupancy factor which is estimated from equation mentioned above and known values of Dp, Di and Do.

As it is impossible to measure the personal dose rate directly for everyone and them we will estimate indirectly using the measured environmental radiation dose rates. Further study to elucidate a nature of occupancy factor in various conditions is needed. And we should be carefully applied the occupancy factor for estimation of personal dose rates in hamlet population.

A TERRITORY-WIDE SURVEY OF INDOOR GAMMA DOSE RATE AND ITS RELATION TO INDOOR RADON LEVEL IN HONG KONG

M.Y.W. Tso, J.K.C. Leung and C.W. Ho

Radioisotope Unit, The University of Hong Kong, Hong Kong

ABSTRACT

A territory-wide survey of indoor radon level and indoor gamma dose rate was conducted in 1993. This paper reports the result of the indoor gamma dose rates and assesses the relationship between gamma dose rate and radon concentration in various types of buildings in Hong Kong. The TLDs and passive radon detectors were exposed simultaneously for about six months.

The overall arithmetic mean gamma dose rate is 0.22 $\mu Gy\ hr^{-1}$ with a standard deviation of 0.04 $\mu Gy\ hr^{-1}$. The modal gamma dose rate in high radon level rooms (>100 $Bq\ m^{-3}$) is 0.28 $\mu Gy\ hr^{-1}$ and in low radon level rooms (<100 $Bq\ m^{-3}$) is 0.22 $\mu Gy\ hr^{-1}$. The correlation between gamma dose rate and radon level is ventilation dependent and the regression coefficient ranges from 1.5×10^{-4} to 1.8×10^{-4} $\mu Gy\ hr^{-1}$ per $Bq\ m^{-3}$. Other factors that affect the indoor gamma dose rate and its relation to radon level are also discussed.

INTRODUCTION

Measurement of building materials and subsequent use of mathematical models to estimate the exhaled radon have shown that building materials, in particular the concrete, are the main contributors of indoor radon in high rise buildings (1). In 1993, a territory-wide survey of indoor radon level and gamma dose rate was jointly conducted with the Environmental Protection Department of the Hong Kong Government. Apart from knowing the population exposure due to radon and gamma irradiation, the survey also provides information on correlation between them.

METHODS

The whole territory of Hong Kong was divided into 19 districts and according to the land use and population in each district, a total of 1774 sites were measured. The sites were classified into residential and non-residential. Solid state track detectors consisting of CR39 chips were used to measure radon. Design, fabrication, calibration and readout of the radon detectors were all done in the University. On the other hand, the TLD badges for measuring gamma dose were borrowed from the China Institute of Radiation Protection in Taiyuan, China and they have to be returned to Taiyuan for reading out the TL signals. Each TLD badge contained five LiF chips and the badges were sent to Hong Kong by air and returned to Taiyuan by air again after the exposure. In order to determine the exposure of the badges during the freights, four background TLD badges were shipped with the batch. Immediately prior to deployment of the TLDs, the first background TLD was annealed at 240 °C and returned immediately to Taiyuan by air with the second un-annealed background TLD. The exposure of the whole batch of TLDs during the freight to Hong Kong and during the period before deployment was then given by the difference of the two background TL values. Similarly the exposure of the batch during the return freight was determined by annealing the third background TLD prior to be returned to Taiyuan. The fourth background TLD was kept inside a lead shield on arrival to Hong Kong. It was returned with the batch and its TL reading was used to compare with the known gamma dose inside the lead shield determined by a pressurized ionization chamber.

Each TLD badge was fixed to the bottom of a radon detector so that both could be hung from the ceiling of the sampling site. Because only 1000 TLDs were available, some radon detectors did not have associated TLD badges. Despite of this, the distribution of TLDs among the different types of buildings was similar to that of radon detectors. As a precaution and as a measure of the reliability of the detectors, some sites were given 2 detectors so that variation in sensitivity of the detectors could be determined. As a result, in addition to losses, the final number of sites that have simultaneous measurement results of radon level and gamma dose rate is only 664.

The cosmic ray contribution at each measurement site was not determined individually. But from a previous gamma dose rate measurement conducted in the sea, the cosmic ray contribution in Hong Kong was found to be 0.035 μGy hr^{-1} (2). The cosmic ray transmission factor in high-rise buildings similar to those in Hong Kong was found by Cui et al (3) to be 0.66 and 0.72 for floor 1 to 3 and floor 4 to 13 respectively. Using an average transmission factor of 0.69, the indoor gamma dose rate due to cosmic ray is about 0.024 μGy hr^{-1}. This value was considered as the background and was subtracted from all the gamma dose rates.

Over 80 science students from The University of Hong Kong and a few other part-time workers participated in the survey. They visited occupants of the buildings during the months January to February 1993, installed the radon detectors and TLDs and recorded particulars about the exposure environment. After about half a year, self addressed envelops were sent to the occupants asking them to return the detectors. The CR39 chips were etched in 6.25 N NaOH at 70 °C for 16 hours. Track density was counted manually using an optical microscope. The TLD badges were sent back to Taiyuan for readout of the gamma dose.

RESULTS

664 sites have measurement data for both gamma dose rate and radon concentration and they are plotted in Fig. 1. It is evident that the radon level increases with gamma dose rate. But because of the small fraction of radon generated inside the building material that is exhaled into the room and the uncertain gamma dose contribution from the cosmic ray, the relation can only be scarcely described. Similar analysis were made for sites having different ventilation conditions. It is found that the scattering of data points in the plots are similar and the corresponding slopes of the radon concentration weighted regression lines are 1.5 x 10^{-4}, 1.7 x 10^{-4} and 1.8 x 10^{-4} μGy hr^{-1} per Bq m^{-3} respectively for poor, good and intermediate ventilation. Poorly ventilated homes have higher radon concentrations for the same gamma dose rate and therefore they have a smaller value of slope.

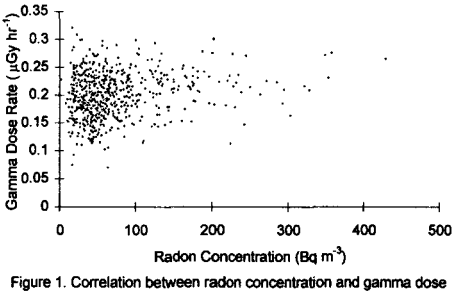

Figure 1. Correlation between radon concentration and gamma dose

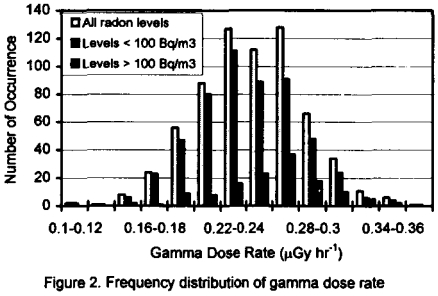

Figure 2. Frequency distribution of gamma dose rate

The frequency distribution of gamma dose rate is plotted in Fig. 2. Distributions of gamma dose rate for low radon concentration (<100 Bq m^{-3}) and high radon concentration (>100 Bq m^{-3}) were also plotted to illustrate the relation between radon concentrations and gamma dose rates. The arithmetic mean gamma dose rate for all measurement sites is 0.22 μGy hr^{-1} with a standard deviation of 0.04 μGy hr^{-1}. For low radon and high radon sites, the means and standard deviations of gamma dose rates are 0.22; 0.04 μGy hr^{-1} and 0.24; 0.04 μGy hr^{-1} respectively.

Attempts were made to find out the effects of other factors (apart from ventilation) that affect radon level but not the gamma dose rate. Wall covering materials and floor covering materials are the two most significant ones. But the floor only occupies about 1/6th of the total exhaling surface, therefore floor covering materials will not be considered. The two wall covering materials most commonly used in Hong Kong are emulsify paint and wall paper. A plot of gamma dose rates against radon levels for dwellings with low ventilation and painted walls is shown in Fig. 3. In the analysis that follows, only sites that have low ventilation were selected. Other ventilation were not considered because the ventilation effect will overshadow all the effects of the other factors. A similar plot for wall paper showed that the dependence of radon level on gamma dose rate is more

pronounced for painted walls than or wall paper covered walls. The greater deviation exhibited for wall paper is probably due to the fact that diffusion coefficient of wall papers for radon are more diverse than of emulsify paints.

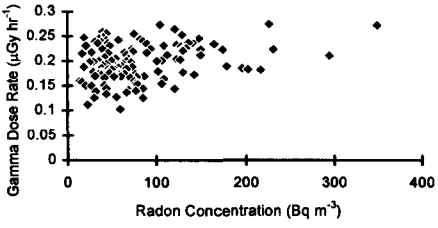

Figure 3. Correlation between gamma dose rate and radon concentration for rooms painted with emulsify paint and under closed window conditions.

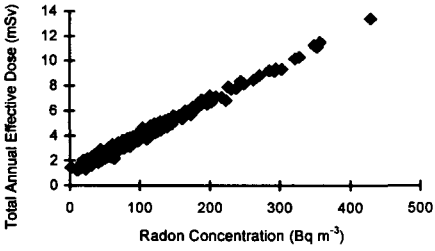

Figure 4. Total effective dose (radon + gamma) in houses of different radon concentrations.

For the case of emulsify paint, it is noted that the mean radon concentration in these sites increases quite rapidly with gamma dose rate. The arithmetic mean radon concentrations are 59, 67, 89 and 136 Bq m^{-3} respectively for gamma dose rate ranges in 0.1-0.15, 0.15-0.2, 0.2-0.25 and 0.25-0.3 μGy hr^{-1}. For wall paper covered walls, they are 84, 78, 131 and 236 Bq m^{-3} respectively for the same gamma dose rate ranges. The higher mean radon levels for wall paper covered walls are due to the fact that they are mainly found in offices and the majority of offices have central ventilation resulting in higher indoor radon levels. Of the buildings that have painted walls and low ventilation, only 15 % are offices. But of buildings that used wall paper, 56 % are offices.

The type of building material will certainly have effects on the radon-gamma relationship. But in Hong Kong, the majority of buildings are built of concrete. In our sampling sites, there are only about 3 % brick houses, 2.5 % fly ash concrete buildings and 0.2 % stone houses. Hence, their numbers are too small to allow any meaningful analysis of the radon-gamma relationship.

Variation of radon-gamma relationship at different floor levels was investigated. But it was found that there was neither a trend for indoor radon level nor gamma dose rate for different heights of a building even though walls in lower floors are usually much thicker than in upper floors. Hence plots of the radon-gamma data points at different floor levels look similar to Fig. 1.

The total effective dose at each site was computed by adding the radon dose and gamma dose at that site. Radon dose was obtained by using a dose conversion factor of 0.061 mSv/(Bq m^{-3}) given in ICRP Publication 50 (4). The equilibrium factor was taken as 0.43, 0.30 and 0.29 for poor, intermediate and good ventilation sites respectively. These values were obtained by a subsequent survey of equilibrium factors in 1994. The total effective dose against radon concentration is plotted in Fig. 4. Clearly the radon dose dominates over the gamma dose.

CONCLUSION

There are indications that indoor radon level increases with gamma dose rate which is directly related to the radionuclide contents in the building materials. But indoor radon levels are affected to a much greater extent by other factors such as ventilation and wall covering materials. When the total effective doses are concerned, radon level is by far the dominating contributor.

ACKNOWLEDGMENT-- The authors would like to thank the Environmental Protection Department of the Hong Kong Government for the support to the surveys.

INTRODUCTION

Hokutolite is a radioactive rock discovered at Peito hot spring, Taiwan and is famous for high content of Ra and daughter nuclides (1,2). Hokutolite is found along the river stream flowing from the source of spring water and the main chemical composition is recognized to be the sulfate of lead and barium. Radioactive elements containing in the hot spring water are incorporated into lattice structures of hokutolite during its formation. The radioactive analysis of hokutolite is necessary to understand the relationship between the growing condition of hokutolite and radioactivity and also important for radiation protection.

EXPERIMENTAL

Sampling and sample treatment

Survey of hokutolite was carried out in October, 1993 with a NaI scintillation survey meter along the river flowing from the orifice of the spring water. Hokutolite was found at about 300 m downstream from the source and high radiation was distributed as spots on the surface of rocks exposed in the river. The high radiation spots were sampled using a burin together with the underlying rock that supports the hokutolite. The mineral specimen was cut perpendicular to the surface, along the growing direction of hokutolite, into pieces with about 2 cm in width.

Hot spring water was also collected at the source and brought back to a laboratory. After addition of Ba and Pb to the water, concentrated sulfuric acid was added to make precipitate of $BaSO_4$ and $PbSO_4$ and the precipitate was recovered by filtration.

Measurement of radioactivity with an imaging analyzer

A two-dimensional radioactive distribution of hokutolite along the growing direction was measured with an imaging analyzer, BAS 1000 (Fuji Photo Film Corp.). The cut surface including the underlying rock was contacted with an imaging plate placed on a thick lead block and the sample was covered in lead grains during exposure.

Measurement of gamma spectra of hokutolite

To examine radionuclide concentrations in hokutolite along the growing direction, hokutolite was scraped off successively from the surface to the inner part with a chisel and the activity was measured with a Ge detector (ORTEC). Activities of ^{226}Ra and ^{228}Ra were determined by ^{214}Bi (609 keV) and ^{228}Ac (911 keV).

Chemical composition analysis

Hokutolite of the whole was ground to a powder and subjected to X-ray diffraction analysis to determine a ratio between $BaSO_4$ and $PbSO_4$ from lattice constants. The powder was then dissolved in HI solution with heating at 210 °C for 3 h in a sealed decomposition vessel and concentrations of Ba and Pb were determined by ICP-AES and ^{232}Th by ICP-MS.

RESULTS AND DISCUSSION

An illustration of the cut surface of hokutolite along the growing direction is shown in

Fig. 1. The hokutolite had a whitish color and was clearly distinguished from the underlying rock. The thickness of growth was about 6 mm at the maximum. Three-dimensional distribution of the radioactivity is also shown in Fig. 1. A part of the imaging picture of the hokutolite was divided into 50 x 50 mesh screen (0.16-0.64 mm^2/mesh) and the intensity of the activity in each mesh was obtained as PSL (Photo-Stimulated Luminescence) per unit area. The resolution of the imaging analyzer is 0.2 mm and the PSL is proportional to the intensity of radioactivity. The mountain located in the center of the three-dimensional distribution is hokutolite and left side of the mountain is the surface of hokutolite contacted with river water and right side towards the underlying rock. An intrusion of hokutolite into cracks of the underlying rock was observed and the mountain showed several peaks. The imaging pictures show that non-radioactive fine particles are incorporated into hokutolite during its growth (3). The mole ratio of Ba/Pb = 1.9 was determined by X-ray diffraction analysis and 2.4 by ICP-AES, and are similar to values previously reported (4,5).

The activity ratios of $^{228}Ra/^{226}Ra$ in the hot spring water and the whole hokutolite were listed in Table 1. The hokutolite (A) is the same sample shown in Fig. 1 and was located out of the river water, while the hokutolite (B) in the water. Lower activity ratio in the whole hokutolite than the spring water is reasonable because the activity ratio decreases with time: the hokutolite near the underlying rock has lower activity ratio compared to the surface where the activity ratio would be the same as that of the spring water. The faster decay of ^{228}Ra than ^{226}Ra decreases the activity ratio in the whole hokutolite. An equilibrium $^{228}Ra/^{226}Ra$ activity ratio of 0.095 was expected for hokutolite that had been formed at a constant growth rate for a long time within the river water having $^{228}Ra/^{226}Ra$ activity ratio of 26.3. However, the observed activity ratio for the hokutolite (A) was significantly lower than the expected one and even for the hokutolite (B)

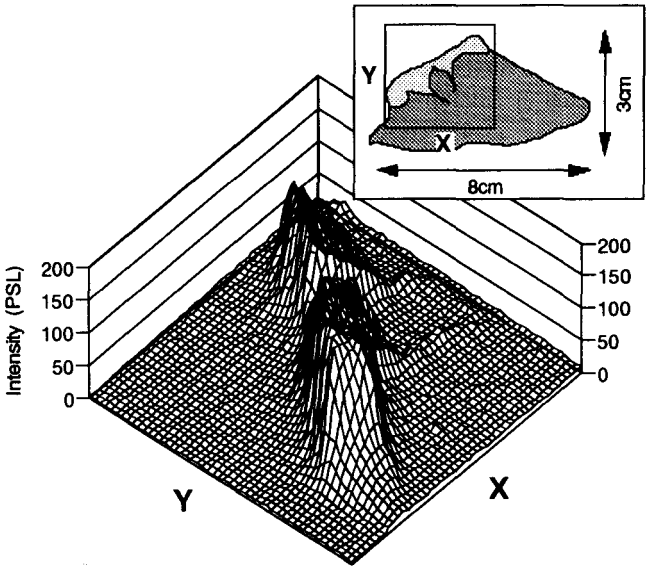

Figure 1. An illustration of the cut surface of hokutolite and its three-dimensional distribution of radioactivity measured with an imaging analyzer.

Table 1. Activity ratio in the spring water and hokutolite.

	Spring water	Hokutolite (A)	Hokutolite (B)
Activity Ratio $^{228}Ra/^{226}Ra$	26.3	0.027	0.178

that gives an unrealistic growing period within the river water, about 2,000 years. This would suggests that these hokutolite had been out of the river water for a certain period.

A change of $^{228}Ra/^{226}Ra$ activity ratio from the surface along the growing direction is shown in Fig. 2. The activity ratios were seemed to become constant at distance over 2.5 mm from the surface, suggesting an existence of ^{232}Th in the hokutolite and a radioactive equilibrium between ^{232}Th and ^{228}Ra. The average activity of ^{228}Ra from 2.5 to 5.5 mm is 1.52±0.34 Bq g^{-1} and the activity of ^{232}Th determined by ICP-MS was 1.55 Bq g^{-1}, supporting the radioactive equilibrium between ^{232}Th and ^{228}Ra over 2.5 mm. The decline in activity ratio from the surface to 2.5 mm could be attributed to decay of ^{228}Ra incorporated into hokutolite and the activity ratio at the surface would suggest an elapsed time after the hokutolite had isolated from the river water. A growth rate of the hokutolite was simulated and 0.17 mm y^{-1} gives a best fit as shown in Fig. 2. The elapsed time for the hokutolite after isolation was calculated to be about 60 years. The activities of ^{226}Ra and ^{228}Ra in hokutolite are summarized in Table 2. Higher activity ratio than the present work was reported for thin hokutolite deposited on the surface of sands and pebbles (1), indicating the older age of the present hokutolite. The concentration of ^{226}Ra in hokutolite is a few orders of magnitude higher than that in usual rocks.

ABSTRACT (See instructions overleaf)

This paper reports the results of environmental radiation background level monitored in Jilin Province from 1983 to 1993. The activities of U, Th, ^{226}Ra, ^{40}K are 2.3 , 0.1 , 1.1 , 0.3 ($\times 10^{-2}$ bq L^{-1}), in food they are 3.7 , 2.4 , 14, 7, 81.5 ($10^{-2} \cdot Kg^{-1}$) respectively. Rn activities indoor and outdoor are 8.7 , 5.8 (Bq m^{-3}) respectviely. Population weighted average of air-intaking dose of ionization component of universe ray is 3.2×10^{-8} Gy · h^{-1}. Air-intaking dose of γ radiation of the ground surface indoor and outdoor are 7.7 , 9.8 (10^{-8} Gy · h^{-1}) γ respectively. 1.47 msv (H) is obtained for natural background.

RADIATION EXPOSURE OF THE POPULATION IN THE VICINITY OF COAL-FIRED POWER PLANTS

ABSTRACT

Our investigation included 4 coal-fired power plants (CPP). All 4 CPPs are located near inhabited places and the depots of ash and slag are 2-5 km away from the CPPs. The measuring of the exposition dose rate was performed using the highly sensitive ionizing chamber under high pressure "in situ" 1 m above ground and termoluminescent (TLD) dosimeters on 4 measuring points (2-5 km in front of the CPP, on the ground of the CPP, at the depots of ash and slag and 2-5 km behind the CPP). The average annual radiation dose on 5 locations in the surroundings of the CPPs is approximately 1 mSv.

INTRODUCTION

It is known that all types of coal contain at least 1-2 ppm uranium and 3-4 ppm thorium which correspond to 12.2-24.4 Bq/kg uranium-238 and 12.21-16.8 Bq/kg thorium-232 as well as the products formed by their radioactive decay (1, 2). These concentrations are somewhat less in comparison to the content of natural radionuclides in the earth's crust (3). However, some types of coal contain considerably higher amounts of natural radionuclides (hard coal). Besides this, combustion of coal in CPPs leads to the concentration of natural radionuclides, during which the enrichment factor for ash and slag can amount from 5 to 10 (4-6). It was therefore interesting to examine the contribution and influence of CPP on the environment and total irradiation dose of the population (7-9).

MATERIAL AND METHODS

Exposition dose rates of gamma radiation were measured "in situ" at 1 m above the plain surface of ground. Measurements were made at four locations (2-5 km in front of the CPPs along the most frequent wind direction, on the grounds of CPPs, at the depots of ash and slag and 2-5 km behind the CPPs along the most frequent wind direction).

Three instruments were used for measuring exposition doses of gamma radiation:
- highly sensitive, pressurized ionization chamber (0.35 MPa argone + 1.4 MPa nitrogen), with low detection limit of 0.258 nC/kgh and resolution of 0.00258 nC/kg, manufactured by "SILENA",
- termoluminescent dosimeters (TLD) from the Institute for Nuclear Science, Vinca (each box contained 3 TLD tablets).

RESULTS AND DISCUSSION

A comparison of gamma radiation exposure dose rates at four locations for all the CPPs examined is given in Table 1 and 2. Table 1 shows that the highest values for CPP 1 were detected on depots of ash and slag (11.44 E-4 nC/kgs), while the other three locations had almost identical values. Exposition doses of gamma radiation in CPP 2 showed approximately equal values in all locations, while the highest exposition dose was measured 3-5 km behind the CPP and amounted to 8.60 E-4 nC/kgs. Approximately equal values were detected in all locations measured in CPP 3. The exposition dose rates for CPP 4 ranged from 7.17 E-4 (depot) to 9.13 E-4 nC/kgs (3-5 km behind the CPP).

	Annual dose:	0.93	0.96	0.96	0.97

* along the most frequent wind direction

An analysis of results indicates that the highest irradiation doses for all CPPs were measured during the period from January to March, while the lowest from March to June. It was obvious that the doses on depots of ash and slag as well as on the grounds and behind CPPs, in the direction of winds, were higher than at other locations. The total annual doses were highest at locations 3-5 km behind CPPs (except for CPP 3, where the highest annual dose was detected on the grounds of the CPP). The relatively lower doses detected close to the electrofilters are probably due to the absorption of radiation from metal constructions located between the dosimeters and the electrofilter contents, because it was not technically possible to set the dosimeters into the electrofilters.

Differences in values of doses detected between the spring-summer and autumn-winter seasons are most probably a consequence of a difference in the intensity of production of CPPs and repair work usually carried out in the spring-summer period. Table 2 gives a comparison of the exposition dose rates of gamma radiation at four locations measured for all the CPPs examined.

CONCLUSION

The basic problem of technologically induced increase of natural radioactivity caused by CPPs is the increase of the basic radiation rate in the surrounding area and higher exposure of the local population to radiation.

For coal with elevated or high uranium contents, a question is raised whether such depots should be considered as uranium strip mines or not. The potential for the discovery and application of coal with higher natural radioactivity is increasing as well as the need for coal. Therefore, it is necessary to devote much more attention to environmental pollution with radioactive material from coal-fired power plants in both research and scientific work as well as to legally regulate the technologically induced increase of natural radioactivity.

NEW DATA ON NATURAL RADIOACTIVITY OF SOME ROMANIAN FRESH WATER SOURCES

Elena Botezatu , L. Clain

Institute of Public Health and Medical Research,Iasi,RO-6600

INTRODUCTION

As water is an important factor of transfer of the natural radioelements towards the human organism, the main objective of the present research is to measure the natural radioactive content of fresh water in the Moldova region. The natural radioelements of utmost interest in finding out the radioactive water content are uranium,thorium,radium-226 and potassium-40.

MATERIALS AND METHODS

During 1982-1989 there were taken, from the territory of Moldova, 767 water samples of which 348 originated from ground water sources (individual or catchments) and 419 from surface waters (1). Between 1990 and 1994 we went on with the measure of the natural radioactive content of the fresh water in Moldova region (740 samples). We wanted to have data on the possibly changing values as a result of the new water sources findings and of the modifications in water processing stations. In selecting the sampling points, i.e. wells and micropower stations, the direction of a ground water table was followed, so that the differences in value should be due only to dissolved radioelements. As far as the potable water originating in the surface sources is concerned, the samples were taken from the central municipal and town water supply systems. The taking of samples and their analysis were carried out in conformity with the current standards (1).

RESULTS AND DISCUSSION

The variation domains with water supply sources originating from surface layers and the ground water are presented in Table 1.

Table 1. Activity concentration of natural radionuclides in drinking water samples (mBq l^{-1})

Radionuclide	Water source		AMAC *
	Ground water	Surface water	
^{238}U	0.6 - 37.2	0.36 - 18.0	257
^{232}Th	0.05- 9.3	0.035- 8.0	40
^{226}Ra	1.1 - 21.0	0.75 - 9.5	88
^{40}K	15.0 -720.0	58.0 -670.0	13420

* AMAC - Admitted Maximum Activity Concentration STAS 1342-91

On should remark that neither of the analysed samples exceeded the specific activity admitted in Romania for fresh water, in any of the natural radiolements under investigation.The mean activity concentrations of natural radionuclides in fresh water samples, for the three time periods of survey,are shown in Table 2.

Table 2. Average activity concentrations (mBq l^{-1}) of natural radioactivity in drinking water samples (according to water source type)

Number of samples by water source and investigation period		Radionuclide

III 119	143	0.7±0.2	0.1±0.04	0.8±0.2	52.9± 10

* - Water category

We succeeded in evidencing three categories of fresh water, according to the average content of natural radioelements, such as in Table 2.
1st category-fresh water with a high natural radioactive content, with a tenth order mean.
2nd category-fresh water with an average natural radioactive content, with unitary order mean.
3rd category-fresh water with a reduced radioactive content,with a subunitary mean.
The highest values for U, Th and Ra were mostly found in fresh water originating from ground table,about 23 % of samples being included in the 1st category. The fresh water originating from surface layers has a dimineshed natural radioelements content, due to treatment operations (floculation,settling,filtering, etc), 71% of the samples belonging to the category of average natural radioelements content and 29% to the 3rd category with the lowest natural radioactive content. During 1990-1994, the mean values for the four radionuclides were not by far different from those of 1982-1989, but the samples percentage distribution in the 2nd and 3rd categories is different. This may be explained by the rock radioactivity that the ground water passes through (2,3). In the case of the surface waters, it is possible that it might be due to the water processing improvement. The thorium concentration of drinking water is smaller than that in uranium, probably because of the much lower solubility of thorium in water. For each of the three categories the ingestion of natural radioelements per capita was assessed, considering a daily consumption of 2 litres (Table 3). We have obtained values which ranged within those reported by literature for the areas with

normal radiation background but higher than the average (4,5).

Table 3. The annual ingestion of natural radionuclides (Bq y^{-1})

Radionuclide	Drinking water <10 year old	Drinking water adults	Dietary intake in Moldova	Dietary intake in areas of "normal" background
^{238}U average	0.8	2.04	7.5	5
range	0.16-3.46	0.42-8.82	6.2-11.2	-
^{232}Th average	0.29	0.73	2.2	2
range	0.01-1.98	0.04-5.04	1.6- 3.4	-
^{228}Ra average	0.83	2.12	14.1	15
range	0.33-2.22	0.84-5.70	12.4-16.2	-

The contribution of drinking water to the total intake by ingestion varies over a wide range. Comparing the assessment values with those for food ingestion one can notice that natural radioactivity intake through water is much smaller (6).

CONCLUSIONS

1. The concentrations of uranium, thorium, radium and potassium activity in potable water in Moldova are lower than the admitted specific activity for the areas with a "normal" background.

2. Fresh water originating from ground water table has a higher natural radioelements content than that originating from surface water.

3. During 1990-1994 period the mean values for the four radionuclides were not different from the other periods, but water processing improvement and the finding of newer sources, probably influence the samples percentage distribution in those three categories.

RADIOACTIVE POLLUTING POTENTIAL OF COAL-FIRED POWER PLANTS FROM ROMANIA

G.N.Sandor[1],T.Peic[1],Rodica Peic[1]

Research and Design Institute for Rare and Radioactive Metals,
3638 Petru Groza,Bihor,Romania

ABSTRACT

Between 1993-1995,26 coal-fired power plants(CFP) were investigated.Water,coal,filter fly-ash,disposed ash and bottom-ash(slag) samples were collected.All samples were analysed for their natural radioactive element content (^{238}U and ^{232}Th series,and K-40) and at the sampling points the gamma dose rates were measured.

The escaping fly-ash, produced ash(fly-ash and slag) and the coal consumption per GWa were assessed as the associated activities of radionuclides.The mass radon flux density for coal,filter fly-ash,disposed ash,and slag samples were measured on lab specimens as well as the surface radon flux density for same building materials with ash content and were assessed the effective anual doses due to living is houses constructed with such materials.

INTRODUCTION

Coal is burned in furnaces operating at up to 1,800^{0}C in order to produce thermal and electrical energy,requiring $3 \cdot 10^9$ kg of coal to produce 1GWa of electrical energy (1).In the UNSCEAR 1982 Report (2) it is estimated the average concentration of ^{40}K,^{238}U and ^{232}Th in coal to be 50,20,20 Bq kg^{-1}, respectively.In a more recent paper from China (3) these concentrations are appreciably higher:104,36 and 30 Bq kg^{-1} for the same radionuclides.

Owing mainly to the elimination of the organic content of the coal,there is about an order of magnitude enhancement of the concentrations from coal to ash.So,the natural radionuclide concentrations in ash and slag from CFPs are signifinatly higher than the corresponding concentrations in earth's crust.Arithmetic averages in escaping fly-ash are 265 Bq kg^{-1},200 Bq kg^{-1},240 Bq kg^{-1} and 70 Bq kg^{-1} for ^{40}K,^{238}U,^{226}Ra and ^{232}Th,respectively (2).

METHODOLOGY

For estimation of radioactive pollutig potential of CFPs water(raw,industrial,recirculating),coal,filter (collected) fly-ash,slag and disposed ash samples were collected.The comsumption,produced ash and escaping fly-ash per GWa were assessed as well as the associated activities of radionuclides.

All samples were analysed for their radionuclide content using radiochemical or gamma spectrometric methods,respectively thermal neutron activation associated with gamma ray spectrometry for ^{238}U.

At the sampling points the gamma dose rates were measured using portable gamma rate meters having a sensivity of 0.01μSvh^{-1}(1μSv=100μR).

RESULTS AND DISSCUTION

All waters used in CFPs had U nat and ^{226}Ra concentations under the limits for drinking water(0.021 mg Unat/dm^3,0,088 Bq ^{226}Ra/dm^3(4),by themselves being not a radioactive pollution source.

The arithmetic averages of radionuclide contents of the 43 coal samples(bitumonous coal,lignite,brown coal) were at the level of reported averages in coal,being 36.3 Bq kg^{-1} for ^{238}U(range:6-112),44.4 Bq kg^{-1} for ^{226}Ra (range:2-112),19.7 Bq kg^{-1} for ^{232}Th(range:1-44) and 267 Bq kg^{-1} for ^{40}K(range:30-500).The mean ash content of coals varied between 20 and 62% and the caloric power between 1,200 and 5,500 Kcal kg^{-1}.

The activity concentrations of natural radionuclides of residual materials from CFPs are shown in Table 1.

It can be seen, than the highest activity concentrations were found in collected fly-ask and these value were taken into account for the computation of radioactive pollution potential by escaping fly-ash, although it is this know that the activity concentrations in this fraction are higher (2).

Using laboratory experiments(5) the mass radon flux density (Em) of coal, collected fly-ash, slag and disposed ash samples was measured.The results of these experiments are shown in Table 2.

The highest values for Em were measured for coal samples and the lowest ones for slag samples.

Also, were estimated the annual coal consumption, produced ash and atmospheric discharge by escaping fly-ash per GWa of electic energy generated by 19 CFPs which have had produced electric energy.The results of these estimates are shown in Table 3.

Activity concentrations of natural radionuclides in residual materals from CFPs

Table 1

ASH (no of sample)		Activity concentration ($Bq\ kg^{-1}$) ^{238}U	^{226}Ra	^{232}Th	^{40}K
Collected fly-ash	Average	100.0	129.3	49.6	421
(27)	Range	25-223	50-221	3-86	96-885
Disposed ash	Average	88.6	107.7	41.9	403
(27)	Range	17-230	21-227	5-86	83-1,097
Slag	Average	68.5	79.0	33.7	317
(20)	Range	6-161	15-159	3-84	71-852

Mass radon flux density (Em) vs. nature of sample

Table 2.

Nature of sample	No. of samples	Em (10^{-3} Bq $g^{-1}s^{-1}$) Average	Range
Coal	42	3.45	0.56 - 12.13
Collected fly-ash	26	1.59	0.11 - 4.70
Disposed ash	27	1.18	0.43 - 2.59
Slag	20	0.26	0.03 - 0.82

Estimates of annual coal consumption,ash production and atmospheric discharge per unit electrical energy generated

Table 3.

CFPs	Total installed power		Coal consumption 10^9 kg(GWa)$^{-1}$		Normalized Ash production 10^9 kg(GWa)$^{-1}$	Escaping fly-ash 10^6 kg(GWa)$^{-1}$	
19	GW						
Modern[a]	8.64	Range	4.5 - 20.4	(6)	1.56 - 8.16	4.5 - 304	(6)
		Average	11.73	3	4.33	64.2	7

a) Equipped with electrofilters

Using the values of activity concentrations of collected fly-ashes and the amounts of atmospheric discharges were assessed the activities of normalized discharges.The results of these estimates are shown in Table 4.

Estimates of the activities of annual atmospheric discharges per unit energy generated (GBq/GWa)

Table 4.

CFPs	Fly-ash removal efficiency %		^{238}U	^{226}Ra	^{232}Th	^{40}K
Modern	95 - 99.8	Average	8.4	10.0	3.65	32.2
(19)		Range	0.3-33.1	0.5-36.4	0.14-19.1	1.3-127.1

The total amount of disposed ash from ash dumps(from 26 CFPs) was estimated as being $230 \cdot 10^6$ t, and the total activity of natural radionuclides from these ones as being 21 TBq for ^{238}U, 29TBq for ^{226}Ra, 11TBq for ^{232}Th and 83 Tbq for ^{40}K and the activity of radon gas emanated in a year as being 93 TBq.

The gamma background in coal-fired power stations ranged between 0.04 and 0.12 $\mu Sv\ h^{-1}$, sometimes being slighty enhanced in comparison to the natural background of the areas.On the ash dumps the gamma dose rates ranged between 0.07 and 0.25 $\mu Sv\ h^{-1}$ being 2-3 times higher than the gamma background of the vicinities.

Two building materials with ash content in comparison with a normal one were investigated.The activity concentrations of natural radionuclides of these materials are shown in Table 5.

Activity concentrations of natural radionuclides in some building materials

Table 5.

Building material (ash content %)	^{226}Ra Bq kg^{-1}	^{232}Th Bq kg^{-1}	^{40}K Bq kg^{-1}	Density kg m^{-3}
Building material 1 (70)	123	52	141	660
Building material 2 (38)	40	13	52	1,780
Building matreial 3 (0)	27	11	242	660

Using laboratory specimens the surface radon flux density (E) was measured and were calculated the external, internal and total effective doses for a reference room build up from each material used 100%, the ventilation rate 1, residence time 4380h/y, equilibrum coefficient 0.4, conversion factor of equivalent equilibrum radon concentration in effective dose (mSv h^{-1} per Bq m^{-3}) of 9nSv and Ackers' conversion factors (6) .The results of these measurements and computation are shown in Table 6.

Annual effective dose due to bulding materials

Table 6.

Building material (ash content %)	E Bq m^{-2} h^{-1}	Annual effective dose (mSv) External	Internal	Total
Building material 1 (70)	1.14	0.397	0.024	0.421
Building material 2 (38)	0.62	0.119	0.013	0.132
Building material 3 (0)	0.80	0.118	0.017	0.135

It can be seen from Table 6 that the major contribution to the total effective dose is given by the external effective dose.At the same time, it is evident that in certain conditions building materials can be used without an additional risk for the public.

CONCLUSIONS

The main conclusions that resulted from this research are:

Coal-fired power plants are a potential radioactive polluting source for the environment due to atmospheric discharges of escaping fly-ash as well as by the presence of ash dumps, the activity concentrations of natural radionuclides in ashes being higher than in earth's crust.

Building materials with coal ash content can be used, in certain conditions, without additional risk for the public.

WORKING LEVELS IN THE COAL FIRED POWER PLANT IN CROATIA

Jadranka Kovač

Institute for Medical Research and Occupational Health,
HR-10000 Zagreb, Croatia

INTRODUCTION

The exposure from man-made natural sources is called *technologicaly enhanced natural radiation* - TENR (1). One of the first sources of uranium and thorium which was detected not being connected with the nuclear industry, was found during energy production using fossil fuels. As the combustion of coal increases, so will the magnitude of environmental and human health hazards associated with trace elements and radionuclides mobilized by the coal fuel cycle. The large fraction of coal ash that does not find commercial application is usually dumped in the vicinity of the coal fired power plant (CFPP). The coal ash may contain enhanced levels of the natural radionuclides in the uranium and thorium series, especially fly ash. Among the decay products are the radon isotopes, ^{222}Rn, ^{220}Rn and ^{219}Rn, which are noble gases and thereby pose special problems in assessing the radiological hazard of fly ash. For that reason, investigations of the hazards were undertaken in the CFPP in Croatia, because the anthracite coal used for combustion has an average 10% sulphur and a variation of uranium.

EXPERIMENTAL PROCEDURES

In the seventies the uranium content in coal was between 500-1200 $Bqkg^{-1}$ (2). After 1980 it declined to an average 250 $Bqkg^{-1}$ due to opening of an different vein in the coal mine. This requested a thorough monitoring programme which included measurements of activity concentration of radionuclides in coal and ash samples, and measurements of working levels (WL).

WL is defined as any combination of short-lived radon daughters in one liter of air that will result in the emission of 1.3×10^5 MeV of potential alpha energy. Under conditions of secular equilibrium 3.7 $kBqm^{-3}$ (100 $pCiL^{-1}$) of ^{222}Rn produces 1 WL (3).

WLs were measured as "grab samples" using method developed by Scott (4).

RESULTS AND DISCUSSION

In the CFPP seven locations have been chosen, because of long-time occupational exposure, and five on-site in places with natural air flow. All WL values are an arithmetic mean of three measurements.

Tables 1 and 2 summarize the estimated WL values, together with occupancy time limit.

Table 1. WL OF OCCUPATIONALLY EXPOSED PERSONS INSIDE THE CFPP

Work place	mWL (1977)	Occupancy time limit	mWL (1983)	Occupancy time limit
Conveyour belt (coal)	8.0	42 h/week* unlimited	7.0	42 h/week unlimited
Conveyour belt (coal)	15.0	24-42 h/week	6.0	42 h/week unlimited
Below the automatic control (ash hooper)	80.0	21 h/week	12.0	24-42 h/week
Below the automatic control (ash hooper)	60.0	42 h/week	12.0	24-42 h/week
Waste pile fresh	80.0	21 h/week	-	-
Waste pile old	-	-	60.0	42 h/week
Bottom ash	80.0	21 h/week	20.0	24-42 h/week

* 42 h/week was taken as the occupancy time limit to comply with the US general population standards, since the workers in the CFPP were never considered as people occupationally exposed to radiation.

Table 2. WL ON-SITE IN PLACES WITH NATURAL AIR FLOW

Work place	mWL (1977)	Occupancy time limit	mWL (1983)	Occupancy time limit
Area around the steam generator building	6.0	unlimited	6.0	unlimited
Under the stack	5.0	unlimited	6.0	unlimited
Near the furnice	5.0	unlimited	6.0	unlimited
Office building (500 m from the CFPP)	3.0	unlimited	-	-
10 km fom the CFPP	3.0	unlimited	6.0	unlimited

The WLs have shown great variations between two measurements, depending on the radioactivity of the coal and combustion products present at the time of the measurements in the CFPP. The highest WL was besides the bottom ash and fresh waste pile, where even an occupancy time limit should be considered.

Table 3 summarizes the estimated WL values measured in 1990.

Table 3. WL MEASURED ON-SITE AND OFF-SITE CFPP IN 1990.

Location	mWL
Coal storehouse	6.0
Below the automatic control (ash hooper)	11.0
Area around the steam generator building	6.0
Slag and ash pile	6.0
Štrmac	6.0
Vozilići	5.0
Stepčići	5.0
Luka Plomin	4.0
Rabac	3.0

As we expected, the highest values were obtained on-site of the CFPP.

Locations 5 - 9 were at different directions and distances from the CFPP, chosen in dependency on wind-rose (Table 4).

Table 4. ALTITUDES, DISTANCES AND DIRECTIONS FROM THE CFPP

Location	Altitude (m)	Distance (km)	Direction
Štrmac	120	3	SW
Vozilići	100	5	NW
Stepčići	80	2	W
Luka Plomin	10	1	SE
Rabac	0	20	S

The most interesting case is the location Štrmac, where a hamlet was built on a ninety years old tailing site, where already the third generation of same families are dweling in the same houses. At the location Rabac, which is at the sea shore, the WL is slightly lower, due to the lower ^{226}Ra content of the sea.

CONCLUSION

This paper introduces WL measurements in the industry where TENR is present. The CFPP is a specific case with the apperance of natural radioactivity which was very similar to open pit uranium mining. The appearence of places with an increase of natural radioactivity in non-nuclear industries have left the legislator, at present without a ready solution in Croatia, how to systematize occupationally exposed workers, especially after the Chernobyl accident, when the public become sensitive to radiation of any origin.

A FAST AND VERY SENSITIVE LSC PROCEDURE TO DETERMINE PB-210 IN ENVIRONMENTAL SAMPLES

Introduction

Pb-210, which has a half-life of 22,3 [1] years, as a member of the Uranium-Radium decay chain causes a significant contribution to the internal radiation dose and belongs with other members of this chain to the natural occurring radionuclides which show a very high dose factor for incorporation. But unfortunately this nuclide cannot be measured sensitive and fast enough in natural samples because of its low γ- (E = 46,539 keV [2], also low transformation yield of about 4 % [2]!) and β - energies (max. energies 17 keV and 61 keV [3] respectively).
This paper describes a method with both aims: lowest detection limit and short waiting time for the results. To reach this, after a radiochemical cleaning Pb-210 is detected in a liquid scintillation counter by its beta decay.

Methods

After drying the sample material at 105° C plant samples were reduced to small pieces and ashed at 450° C. To remove the remaining carbon fractions HNO_3 must be added to the ashes as often as necessary.
Soil samples must be sifted so that only fractions smaller than 2 mm remain. For the further procedure 40 ml HNO_3 and 10 ml HF were added to samples up to 5 g ash mass and evaporated to dryness. This step must be repeated two times. The remaining material must be treated with 2 ml $HClO_4$ for three times and evaporated to dryness.
From now on plant and soil samples are treated uniformly. The next step in sample preparation is a radiochemical cleaning. Thereby the ash is dissolved under warming in 100 ml HBr and extracted with 75 ml Trioctylamine/Toluene. The organic phase must be washed with 0,1 M HBr. For the reextraction of the lead 50 ml HCl must be added and the watery phase is mixed with 50 ml $CHCl_3$. The organic phase is discarded. After adding 50 ml HNO_3 the solution is evaporated to dryness. At this point lead is completely separated from all other elements except bismuth. Therefore radiochemical cleaning must be continued [4].
For that purpose the evaporate is dissolved in 0,02 M HCl and put on an anion exchange resin (DOWEX 1X8) column (3,5 x 0,8 cm) with a velocity of 1 ml/min. The anion exchange resin must be in the chloride form. This method elutes lead, the bismuth fraction remains on the column. The eluted fluid is evaporated to dryness taken up in 10 ml of 0,1 M HNO_3 and added to 10 ml of a scintillation cocktail (Quickszint 400 from Zinsser).
The chemical yield for lead was determined for each sample by atomic absorption spectrometry (AAS).
To detect Pb-210 by its low energy beta radiation, we used a liquid scintillation counter Quantulus 1220 from the Finnish company LKB-Wallac with an active shield.

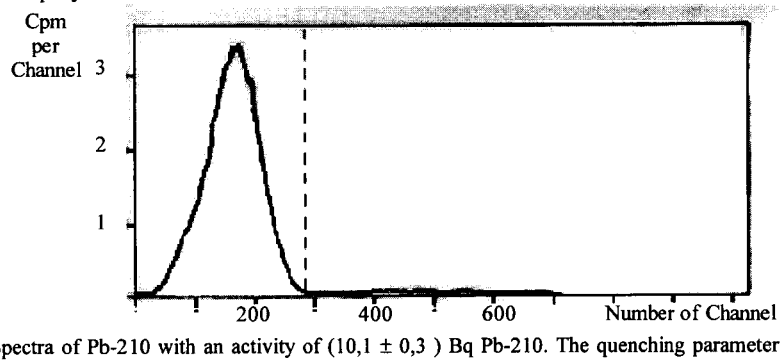

Figure 1: Spectra of Pb-210 with an activity of (10,1 ± 0,3) Bq Pb-210. The quenching parameter SQP(E) is 653. The counting window of Pb-210, which was fixed later is also drawn.

The time between separation of Pb-210 and start of the measurement was 3 h 55 min. In this period there is a build-up of Bi-210 and therefore the counts from channel 300 to 600 only come from this nuclide. Shorter waiting times are not desirable because of the effect of the chemoluminescene.

Fixation of the counting window for Pb-210 and the effect of quenching

In figure 1 the window for Pb-210 in the spectrum is marked. It reaches from channel 1 to an upper limit which is dependent to the effect of quenching. Quenching occurs when the sample is coloured, because the transmission of light pulses of the scintillator molecules to the photo cathode is weakened in the scintillator sample cocktail by absorption and so the spectra is shifted to lower energies. The quenching parameter SQP(E) which is detected by the LSC-Quantulus itself by a formula is a parameter for that effect. To get the dependence of the counting window for Pb-210 and the quenching parameter a preparation with different coloured samples was made. The result is a linear function between UC and SQP(E).

$$UC = a_1 \cdot SQP(E) + b_1 \qquad (1)$$

with: UC: upper channel of the window of Pb-210
$a_1 = 0{,}661$
$b_1 = -147{,}3$

With each SQP(E) given by the LSC counter the suitable upper channel of the counting window can be calculated.

The role of Bi-210 and Po-210 in the spectrum

Immediately after separation, Bi-210 grows up again and disturbs the detection of Pb-210. Also Po-210 grows up, but this nuclide with its great half-life in comparison of the time after separation can be neglected.
To correct the spectrum of Pb-210 in the counting window from the counts which belong to Bi-210 it must be shown, that the ratio from counts of Bi-210 inside the window to those outside of it is constant with time.
After the measurement of a pure spectrum of Bi-210 this ratio could be fixed as the constant value of $0{,}2958 \pm 0{,}0009$.
When Pb-210 in a sample material is now detected the counts outside the detection window of Pb-210, which all belong to Bi-210 can be measured. With the constant ratio mentioned above it is possible to subtract this fraction from the counts in the detection window.

Counting efficiency for Pb-210

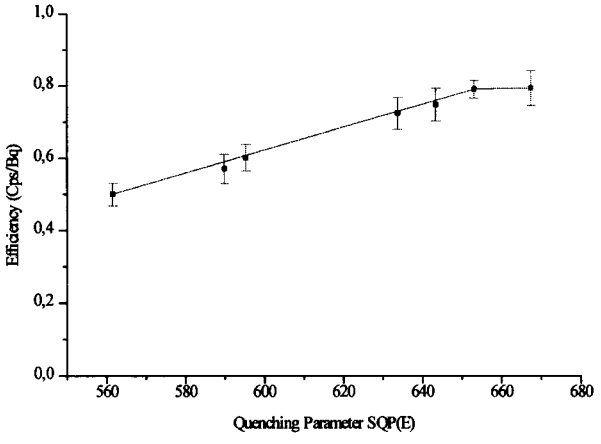

Figure 2: Relation of the counting efficiency for Pb-210 and the quenching parameter SQP(E) (1σ confidence level).
The quenching parameters normally are higher than 653, so that the counting efficiency is constant and $\eta = (0{,}80 \pm 0{,}04)$ Ips/Bq.

Influence of Pb-212 on the spectrum of Pb-210

Pb-212 from the thorium decay chain and its daughters cover a wide range of the measured spectrum by determination in LSC Quantulus. Pb-212 with a half-life of 10,64 h [3], Bi-212 ($T_{1/2}$= 60,6 min), Po-212 ($T_{1/2}$= 305 ns) and Tl-208 ($T_{1/2}$= 3,07 min) therefore also cause a counting rate in the window of Pb-210. But if the ratio of counts inside the window of Pb-210 belonging to Pb-212 and its daughters, to that outside the window is regarded, a constant value over time is obtained. This value, however, is only constant for times after separation which are greater than 4 hours. Then it amounts to 0,349 ± 0,002. This time is also sufficient to eliminate the possible presence of Pb-214 ($T_{1/2}$ = 26,8 min)
With known ratios of counting rates from Bi-210 and Pb-212 (and daughters) in- and outside the window of Pb-210, chemical yield and efficiency for Pb-210 the activity of Pb-210 in the sample can be calculated.

Detection limits and comparison with other possibilities of the measurement of Pb-210

To compare the single methods, detection limits are calculated for a 1000 min measurement and Pb-210 in watery solution. The formulas for detection limit calculate the 3σ confidence level.

Table 1: Comparison of detection limits of the different detector systems for Pb-210 in watery solution; time of measurement: 1000 min, no Pb-212 in the sample material.

		Detection limit (mBq/sample)
high purity Ge detector	100 ml Dose (content 100 ml)	662
	LSC-vial (content 8 ml)	234
NaJ detector	LSC-vial (content 20 ml)	340
LSC Quantulus		**7,4**
gasfilled counter	detection via Bi-210	3,2
α-spectrometry	detection via Po-210	0,3

Table 2: Comparison of sample preparation time

	duration of time in days for			
method	sample preparation	radiochemical cleaning	time between end of analysis and begin of measurement	sum
high purity Ge det.				
not ashed	0	0	0	0
ashed	2	0	0	2
NaJ, ashed	2	0	0	2
gasfilled counter	2	2	5	9
LSC Quantulus	**2**	**2**	**0**	**4**
α-spectrometry	altogether ca. 120 days			

Taking into account also the detection limits mentioned in table 1, the LSC Quantulus has a very low detection limit and the time between drying of the sample and begin of detection for Pb-210 is short.
To compare the results of this method with a high purity Ge detector, soil samples have been measured and the results harmonise within the error bars.

Conclusions

A new method for the detection of Pb-210 has been presented. This nuclide is measured by an LSC Quantulus, which has an extremely low underground counting rate. Therefore very low detection limits can be reached. Pb-210 can be detected after a waiting time of only 4 hours after separation from the daughter product Bi-210. This time is necessary because of the chemoluminescene and the possible presence of disturbing Pb-212.

THE EVOLUTION OF THE EARTH'S BACKGROUND RADIATION LEVEL OVER GEOLOGIC TIME

P. Andrew Karam CHP and Stephen A. Leslie Ph.D.
Department of Geological Sciences, The Ohio State University, Columbus, U.S.A

INTRODUCTION

The earth currently has a background gamma radiation level of 0.28 mSv/yr due to radionuclides such as U, Th, Ra, and ^{40}K (1), and humans are exposed to approximately 0.40 mSv/yr from ^{40}K in their bodies. An additional dose of 2.90 mSv/yr is derived from radon (2.0 mSv/yr), building materials (0.28 mSv/yr), cosmic radiation (0.27 mSv/yr) and various anthropogenic sources (1). Owing to the low penetrating power of alpha radiation, radon does not expose the whole body to ionizing radiation. Of the natural sources of gamma radiation the nuclides K, U+progeny, Th+progeny are Large Ion Lithophiles (LILs) and are preferentially partitioned into the continental crust. Since the amount of crust has increased with time, LIL abundance at the earth's surface has increased over geologic time. These elements are all radioactive with half-lives of less than the age of the Earth (except for ^{232}Th), and are now present in lower activity concentrations in the continental crust than at any time in the geologic past.

Prokaryotic life is thought to have evolved between 3.5 and 4 billion years ago (Ga), giving rise to eukaryotic life as early as 2.1 Ga (2) . It is further thought that primitive organisms resembled current life in terms of radiation repair mechanisms, potassium content, and basic biochemistry, based on remarkable similarities in basic chemical compositions of modern primitive and advanced life forms (3).

This paper examines the evolution of the background radiation field in which primitive organisms evolved in terms of internal dose (from internal ^{40}K) and external geologic dose (from gamma emitters in the crust of the earth), and how this may relate to dose-response in modern organisms.

GEOLOGIC AND INTERNAL DOSE

Crustal evolution was not uniform throughout time. Taylor and McClennan (4) suggested that the major epoch of crust formation occurred between 2.8 and 2.6 Ga. The oldest crust known dates from about 3.8 Ga. Ocean chemistry at this time is suggested to be similar to that of today's oceans (5).

LILs are partitioned into the molten phase of magma and discharged into the crust in magma intrusions or erupted as lava. These elements concurrently decay towards stable end products. Since the surface gamma radiation field from these elements is proportional to their activity concentration (6), competing mechanisms determine surface radiation levels from geologic sources (Fig. 1). Using Taylor and McClennan's (4) model for crust formation and assuming that LIL concentration was equal to the percentage of crust formed (i.e. LILs had one half of their current concentrations when the crust was 50% formed) then, at the time that life evolved, surface gamma radiation levels due to contact with the continental crust were similar to those at present, rising to approximately twice current levels at the time that eukaryotic life evolved. Therefore, life would have been exposed to up to four times current levels of external gamma radiation due to contact with the continental crust. In addition, based on a current ^{40}K concentration in seawater of 11 Bq/gm (7), organisms in the water column at that time would have received comparable doses from ^{40}K beta and gamma radiation.

Potassium is essential to life and is not evenly distributed in organisms. Most cells selectively maintain a K concentration approximately one order of magnitude greater than that found in extracellular fluids (8,9). Average K content in human muscle is approximately 155 moles/m^3, compared to an average interstitial fluid content of 4 mol/m^3 (9). Single-celled organisms appear to maintain a similar concentration factor, most at higher internal concentrations. For example, *Acetabularia mediterranea* (a single cell plant) contains 400 mol/m^3 K in its cytoplasm, 355 mol/m^3 in vacuoles, and 10 mol/m^3 in external solution (9). Our model uses the K content of human muscle, which appears to be a conservative estimate, as the basis for internal dose estimates through geologic time.

Radiological dose is measured in terms of energy deposited per unit of mass. Although a single-celled organism has much less potassium than a human, it also has far less mass. Therefore, we assume that the dose due to internal potassium activity remains constant at all scales. Many single-celled organisms are smaller than the mean free path of photons or beta particles in the cell. However, many early organisms were colonial (stromatolites, algal mats, etc). We assume that the thickness of these colonies is greater than the stopping distance of ^{40}K betas in water (approximately 0.7 cm) and that, as a result, the beta decay energy is deposited in the colony with each member receiving an approximately equal share.

Humans currently receive approximately 0.40 mSv/yr from internal ^{40}K. The majority of this dose is due to the 1.33 MeV beta decay (~89%) with the balance resulting from the 1.46 MeV gamma (~11%). The specific

activity of potassium currently is 31.6 Bq/gm. Three half-lives ago (approximately 4 Ga), K had a specific activity of 253 Bq/gm giving a yearly dose of 3.20 mSv.

There is currently a component of dissolved uranium to which we are exposed via drinking water. The short range of an alpha particle results in the deposition of a high percentage of its energy within the cell. However, uranium is insoluble under the reducing conditions which existed during the Archaean and is not likely to have contributed much dose to organisms at this time.

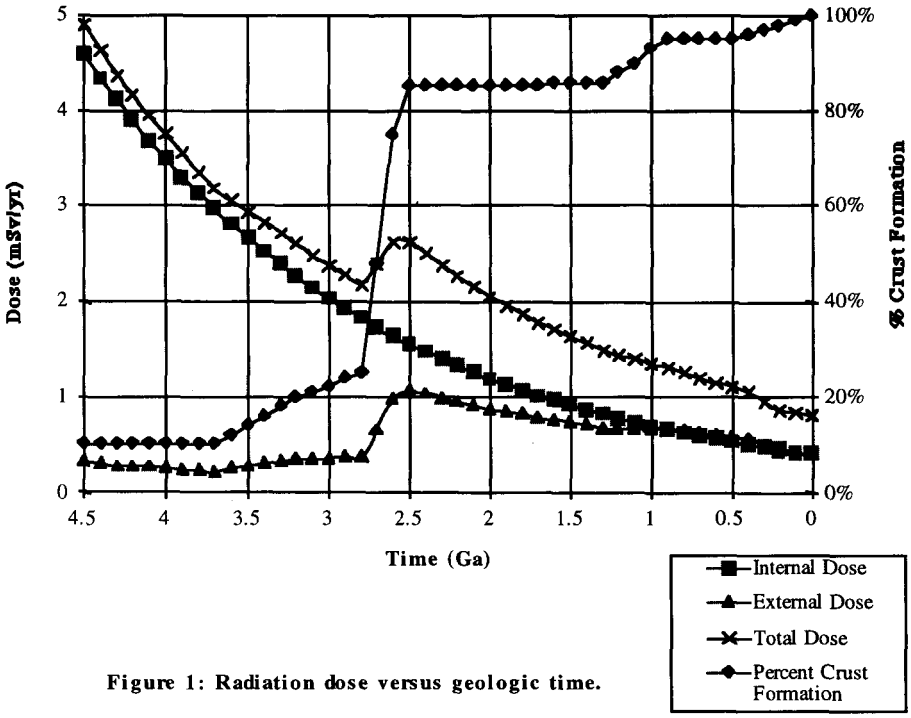

Figure 1: Radiation dose versus geologic time.

ULTRAVIOLET RADIATION

Kasting and others suggested (10) ozone did not exist during the Archaean due to a lack of free oxygen and could not have shielded the earth from ionizing UV radiation. The portion of the UV spectrum most likely to penetrate to the surface is the most energetic (10), UVC (200-280 nm). A high flux of UVC is thought to have sterilized the surface of the earth until a protective ozone layer developed. In addition, penetration of UVC through shallow pools of water or into shallow portions of the ocean may have further increased the ionizing radiation dose to organisms. During the Archaean, solar luminosity was approximately 70% present levels (11). This corresponds to a lower solar surface temperature, giving a UVC flux of 50-70% present levels. Therefore, the UVC flux reaching the earth at this point in time was much less than at present.

While free oxygen did not exist at this time, the earth's atmosphere was considerably thicker than at present, consisting of up to 10 bars of CO_2 with nitrogen, water vapor, nitrous oxides, and trace gases (11). Due to high CO_2 levels, mean surface temperatures were likely between 20° and 50° C, with a corresponding increase in water content and cloud cover (11). In addition, increased volcanic activity would have increased atmospheric loading of aerosols, including sulfur compounds, many of which absorb strongly in the ultraviolet (12). Because of this we feel that, while UVC levels may have been higher prior to formation of the ozone layer, they would not have added significantly to the radiation levels to which early organisms were exposed. We do not know if life evolved at the surface, in the sediments, in shallow water, or in deep water. We do know, however, that the presence of life today indicates that life evolved in an area in which UV radiation was not lethal to it.

DISCUSSION

It seems likely that life was exposed to much higher radiation levels throughout much of its history than exist at present. We estimate the dose due to internal ^{40}K activity to have ranged from four to eight times that at present throughout the time that only prokaryotic and eukaryotic life existed. At the time that metazoan life arose (0.7-1.0 Ga), internal radiation dose was approximately twice that at present.

The dose from geologic materials has changed in the past, although not as monotonically as has internal dose. As the continents formed, the dose from geologic materials increased to four times what we now experience, decreasing due to radioactive decay and, lately, due to the formation of organic soils.

Mutation rates are proportional to radiation dose and dose rate (13). If radiation levels have changed over time, then mutation rates must also have changed over time. The molecular clock, then, may have run faster in the past. In fact, when we modify Runnegar's (13) plot of amino acid substitution versus time (=molecular clock) to incorporate changing ^{40}K activity levels over time, the predictions match the fossil record and the results of Valentine's (15) cell-type model much better. We are presently exploring the significance of ^{40}K activity levels though time on evolution and molecular clock theory.

Cells have mechanisms to repair damage caused by exposure to ionizing radiation. These mechanisms appear to have evolved to contend with radiation levels that were nearly an order of magnitude higher than today. Has this ability been retained by life through geologic time? Even if in the geologic past there was no threshold for "safe" exposure to radiation, falling radiation exposure levels over geologic time suggest that there should be a threshold at the present, as suggested by the recent work of Kondo (16). Is it not possible, if not probable, that the threshold is equal to the background radiation levels that existed at the time when this repair mechanism evolved?

WORK IN PROGRESS

We are currently working to resolve several issues. Among these are the composition and opacity of the early atmosphere to UVC radiation, the effects of increased radiation levels and dose in the geologic past on current ideas in evolution and the molecular clock, the chemical composition of Archaean seawater, and the concentration of U, Th, and K in the earth's crust during its formation.

ABSTRACT (See instructions overleaf)

Crews working on jet aircraft receive one of the highest average equivalent doses of any occupationally exposed group, but because of the complex nature of the atmospheric cosmic radiation field, there are large uncertainties in aircrew exposures and associated health risks. Neutrons contribute roughly half of the equivalent dose, and the large uncertainty in the neutron spectrum makes the equivalent dose uncertain by a factor of 2.

To reduce these uncertainties and evaluate instruments for monitoring aircraft radiation, we have measured various components of the radiation field aboard a Canadian Forces Boeing 707 aircraft during 3 flights covering 5 altitudes from 10 to 12.5 km (33,000 to 41,000 ft.) and 52°-70° N geomagnetic latitude. Neutron energy spectra were measured using a high-sensitivity multisphere spectrometer. The neutron dose equivalent was measured using a remmeter, a lead-covered remmeter, and superheated-drop/bubble detectors. Gamma-ray and charged-particle energy spectra were measured using BGO, NaI(Tl), and plastic scintillators with anticoincidence shells. The dose rate from a pressurized argon ionization chamber was recorded every minute, and the dose for each flight was measured using three types of TLDs. The TLDs and bubble detectors were located within and on an anthropomorphic phantom and throughout the aircraft.

We will present results for the ionization dose rate, neutron dose equivalent and gamma-ray spectrum as a function of altitude and geomagnetic latitude, and doses in the phantom for each flight. Methods for determining the high-energy response of the neutron detectors will be discussed.

COSMIC RADIATION DOSES IN COMMERCIAL AIR TRAVEL

Chien Chung and Chien-Yi Chen

Department of Nuclear Science
National Tsing Hua University
Hsinchu 30043,Taiwan ROC

INTRODUCTION

Cosmic radiation doses received in commercial air travel are considered important because of the large number of passengers carried, the long distance traveled, and the high geomagnetic latitude at some flights occurred.[1] In particular, the crew members of pilot and flight attendant serve more than 720 flight-hours each year , exposing to the cosmic radiation much more than those received by average passengers. The in-flight cosmic radiations are measured using pocket-sized solid state detector for electromagnetic radiation and the bubble detector for fast neutrons. Both domestic and international flight routes of airlines homebased in Taiwan are chosen for in-flight measurements, as illustrated in Fig.1

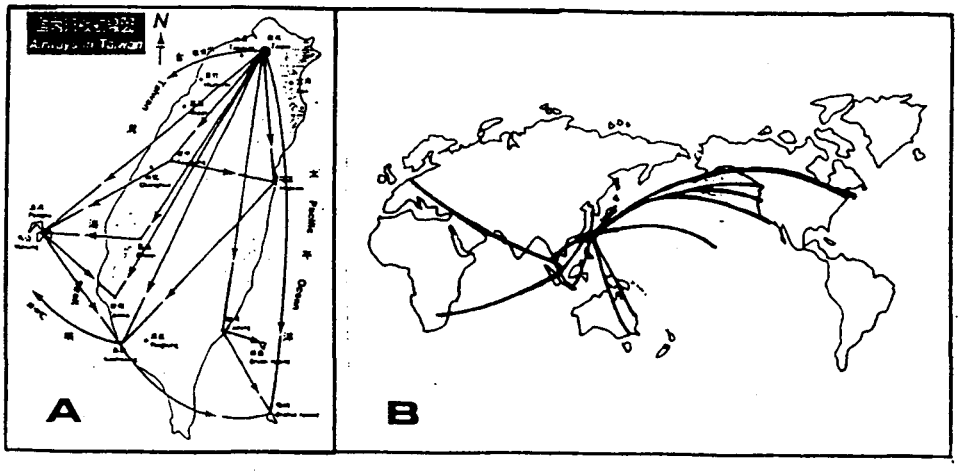

Fig. 1. Domestic and international flight routes of Taiwanese air-liners.

RESULTS

Sensitivity of both detectors are 0.01 μSv/h for gamma rays and 3 bubbles /μSv for neutrons, satisfactory for the in-flight measurements. Calibration of both detectors are conducted on ground using reference sources of high-energy gamma and neutrons. The measurements are carried out in all commercial flights served by the Eva Air and China Airline; the flight patern of initial and final ascending/descending, crusing, and landing approach are logged on-line, while the in-flight doses are recorded in cumulative modes. Typical result is 42 ± 3 μSv for Taipei-NYC flight route, to which the neutrons contribute more than 50% of the total cosmic doses. Annual dose for crew members can be assessed by the measured data and the information of their flight-hours, aircraft types, flight routes, and flight patern. The annual doses for crewmembers are 108 μSv for domestic service and up to 7200 μSv for international service, as summarized in Table 1.

Table 1. Air travel statistics and in-flight dose assessment for civil aviation in Taiwan

Statistics	Flight routes Domestic	International	Evaluation	Flight routes Domestic	International
Average crusing altitude (ft)	14,000	37,000	In-flight dose rate (μSv/hr)	0.15-0.80	3-10
Average distance per flight (km)	135	2,613	Dose per flight (μSv)	0.06-0.34	9.8-32.5
Average air borne time per flight (hr)	0.42	3.25	Annual collective dose(man-Sv)	0.82-4.41	82.2-274
Flights per day[1]	811	81	Annual dose (μSv)	0.12- 0.68	19.6-65
Flights per year	296,056	29,429	Contribution to population (μSv/yr)[3]	0.04-0.23	4.13-13.76
Seats per flight[2]	81	287			
Seats per year (millions)	13.12	8.43			
Seat-kilometers per year(giga person-km)	1.77	22.03			

Note 1. Only commercial flights landing to and taking-off from airports in Taiwan are accounted for.
2. Only citizens of Taiwan who travel on board are accounted for, foreign travelers are excluded.
3. The population in Taiwan is 20,752,000 in 1992; the in-flight portion (4.14-13.99 μSv/yr) is far less than the ground radiation background caused by cosmic origin (around 280 μSv/yr).

International Commission on Radiation Protection ICRP60 recommend that the cosmic radiation exposure in civil aviation should be taken into account as occupational exposure. Recent measurements at civil airlines show a radiation exposure in the range of 3 - 10 mSv / year. An economic and simple active method to assess the radiation exposure in aviation altitudes is described in this paper. This method takes account of the contribution of solar particle events, changing flight pattern and altitude. First experimental data by in-flight measurement are presented.

INTRODUCTION

In 1990 ICRP published its report ICRP 60 with updated excess cancer risk estimates, which led to significantly higher risk coefficients for some radiation qualities. An increase of the radiation weighting factors for mean energy neutron radiation increases the contribution for the neutron component to the equivalent dose by about 60%, as compared to the earlier values of ICRP26. This higher risk coefficients lead to the recommendation of the ICRP, that cosmic radiation exposure in civil aviation should be taken into account as occupational exposure. Numerous recent exposure measurements at civil airliners in Germany, Sweden, USA, and Russia show exposure levels in the range of 3 - 10 mSv / year. This is significantly more than the average annual dose of radiation workers (in Austria about 1.5 mSv / year). Up to now no practicable and economic radiation monitoring system for routine application on board exits. During the last year the Seibersdorf group for radiation protection studied an active dose assessment method for aircrew [1].

ACREM CONCEPT

The exposure of air crew can be assessed by different methods [1], basically by using active or passive dosimeters. Detailed in-flight dose investigations on different positions at aircraft has shown that individual dosimetry for each crew member is unnecessary, since the personal and area dose equivalent are essentially independent of the location at aircraft.

Several cosmic ray transport codes exist which are able to calculate the radiation exposure at aviation altitudes. The well-known CARI code has been used for some years to calculate the equivalent dose between two flight destinations and was up-dated last year by CARI 3. Basis for the CARI 3 calculation is the more detailed transport code called LUIN94 [2]. Even though the calculations are in agreement with measurement results, for dose assessment they require knowledge of the actual flight pattern and can not account for unexpected solar particle events. To solve this problem active dosimetry is necessary.

An economical and simple active method to assess the radiation exposure, presently being studied in our laboratory, is realised with ACREM (Air Crew Radiation Exposure Measuring) system. ACREM is based on a combination of measurement of the ionising component and calculation of the neutron component. Up to know we use a GM-counter with an energy range of 50 keV to 1.3 MeV for dose measurements. The instrument is based on the Seibersdorf Radiation Protection Survey Meter SSM-1, designed for Austrian military and civil protection. Two GM-detectors and microprocessor controlled electronic, are used for real-time, continuous measurement of the equivalent dose (rate) at aircraft.

For calculations the transport code LUIN94 is used. LUIN94 provides the neutron component, as well as the ionising component of equivalent dose caused by cosmic ray for different flight patterns and altitudes. The sum of both components gives the total equivalent dose. The relation of the total calculated equivalent dose to the calculated ionising component gives a conversion factor for a certain aircraft position. This factor is tabulated for suitable values in altitudes and grid distances and is stored in a database of a micro computer system. This provides fast data acquisition. The ionising component measured by a GM-counter, is weighted with the

1 Developed under Research Contract by Allgemeine Unfallversicherungsanstalt, Vienna; Patents pending

calculated conversion factor. The result gives an estimation of the equivalent dose (rate) in typical time intervals of some 10 seconds, for a momentary flight position. The dose value is stored in real-time mode and direct readable on a display. A warning system tells about unusual high dose rates. Dose assessment to crew members is achieved by personal chip card. The concept of the Air Crew Radiation Monitor is shown in fig.1.

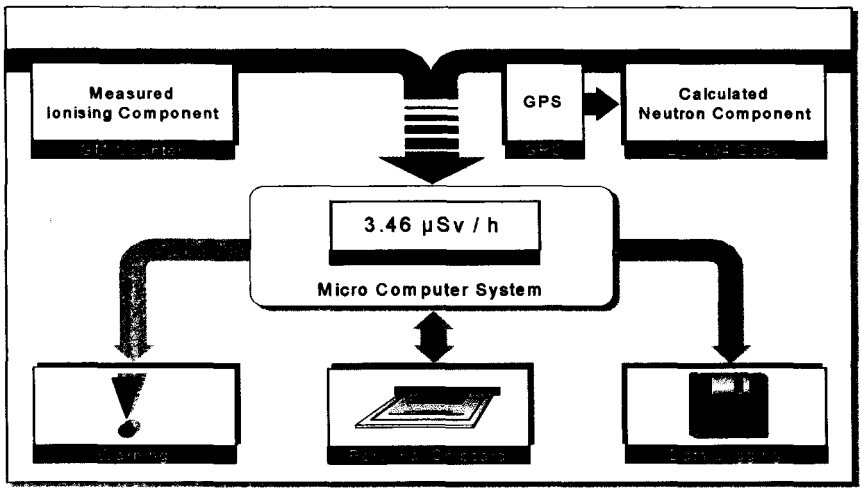

Fig. 1: The concept of the active aircrew dose assessment system - ACREM

PRELIMINARY RESULTS

Recently first in-flight measurements have been performed in co-operation with Universität der Bundeswehr, Munich, Germany. The experiments were performed on a Boeing 707 of the German Airforce during a flight from Cologne to El Paso with an intermediate landing in Washington. A low pressure tissue-equivalent proportional counter (TEPC) serves as reference instrument. The used TEPC system with an internal ^{244}Cm calibration source, has been described in greater detail in [3]. Additionally a Reuter-Stokes, high pressure ionisation chamber was on-board to compare results with the low-LET component of TEPC measurements. All detectors were calibrated for ^{137}Cs at the radiation calibration facility of Seibersdorf. The overall uncertainty for measurements by the GM-counter as well as by the ionisation chamber is about 20 %. The uncertainty for TEPC measurements is nearly the same.

For first data analysis the ionising component of cosmic rays and the low-LET measurements by TEPC will be discussed. Fig.2 shows the dose equivalent rate in µSv/h provided by measurements with the GM-counter (SSM-1), the ionisation chamber (Reuter Stokes RS 111) and the TEPC (low-LET) at the flight route Washington - El Paso. Additionally the dose equivalent rate for the ionising component, calculated by LUIN94, is included for several flight-positions. The integration time for GM-counter and ionisation chamber data points was about 30 seconds. The bar of TEPC data points indicates a measurement time of 1000 seconds. Fig.3 shows the same measurement situation like Fig.2 but for the flight route Washington - Cologne.

During the Washington- El Paso flight mostly the same altitude was used: 39.000 feet. The latitude decrease from 39° north to less than 32° north rather directly. All measurements and the calculations describe this well known fact by reduction of the dose equivalent value, caused by interference of cosmic rays and earth magnetic field. The largest dose value of 4.5 µSv/h was measured by the GM-counter at the most northern position of this flight, for measurements by the Reuter Stokes chamber 3.7 µSv/h at the same position. The TEPC low-LET data and the LUIN94 data fit the Reuter Stokes data very well.

At the flight from Washington to Cologne several different altitudes have been used. All instruments describe the change of altitudes very precisely. The latitude increase from 39° north to 55° north (about 3:00 UTC) and decrease at Cologne to 50° north. Since the changing of altitude and latitude goes in parallel a significantly observations of the "latitude-effect" like at the Washington - El Paso flight can not be expected. More detailed analysis would be necessary. Dose equivalent values range from 2.1 µSv/h at 29.000 feet, 3 µSv/h at 33.000 feet to about 3.5 µSv/h at 35.000 feet.

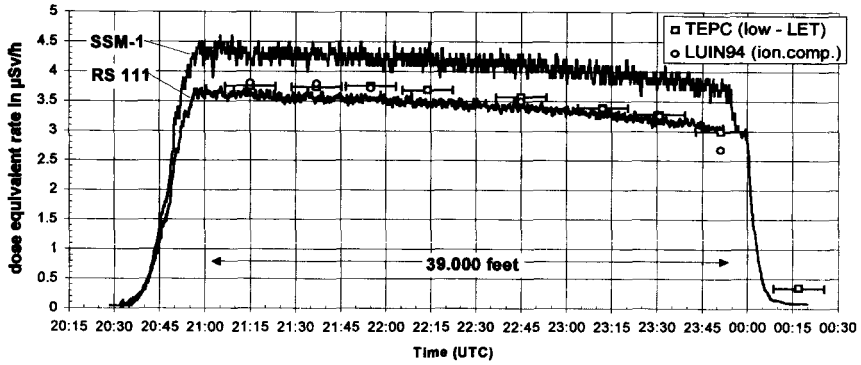

Fig. 2 : Dose equivalent rate determined by GM-counter (SSM-1), Ionisation Chamber (RS 111), TEPC (low LET component) and LUIN94 (ionising component) at the flight route: Washington - El Paso.

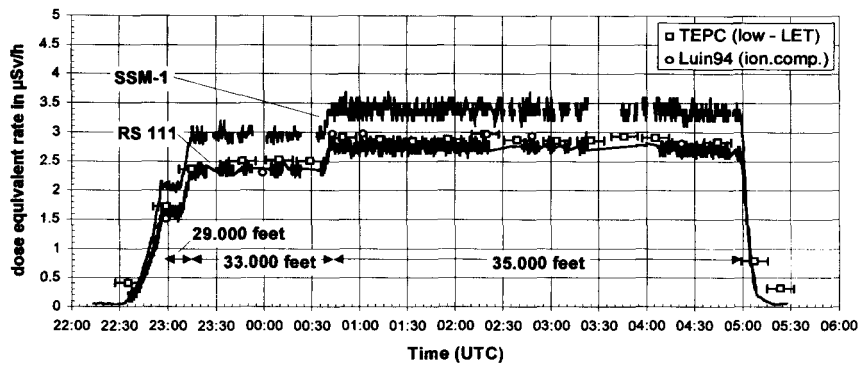

Fig. 3: Dose equivalent rate determined by GM-counter (SSM-1), Ionisation Chamber (RS 111), TEPC (low LET component) and LUIN94 (ionising component) at the flight route: Washington - Cologne.

CONCLUSION

Taking measurement uncertainties into consideration no significant difference between used instruments and calculations could be observed.

ACREM, if eventually verified under routine flight conditions, can be a simple and economical solution for active airborne dosimetry. This method can also account for the contribution of solar particle events, changing flight pattern and altitude.

ABSTRACT

Measurements of the average LET and the equvialent doserate in high altitude aircrafts were performed with TLDs using absorber material of varying thickness. Besides these TLD-packets Bonner spheres were used.
The determination of the equivalent doserate was carried out with two methods. With the Bonner spheres calibrated for their neutron energy dependent response the equivalent doserate induced by neutrons and gammas is measured with TLD-600 and TLD-700 in pair use.
In addition the high temperature region of the TLD-700 is analysed. Using a LET calibration of the HTR (high temperature ratio) the quality factor and the average equivalent dose can be determined in dependence on the absorber thickness. The deviation in the equivalent doserate of the two methods is discussed. Furthermore the results of two different flight periods are shown.

INTRODUCTION

Interest in radiation protection measurements in mixed (n,γ)-fields as they occure in high altitude aircrafts has increased with improved knowledge of the biological effectiveness of some of the components. The mixed radiation field induced by solar and galactic cosmic radiation consists of a broad spectrum of different particles (protons, neutrons, electrons, gamma-quants,..) with varying energy and LET. Beside absorbed dose measurements particular investigations for the evaluation of the LET-spectrum of the mixed radiation field have been made using LET-spectrometers (1). Furthermore increased efforts are made concerning neutron dosimetry in aircrafts (2) because about half of the equivalent dose is caused by neutrons of various energies. Since most of the applied systems are very complex, unwieldy and heavy, especially for radiation protection purpose investigations based on TLDs are of particular interest.
TLDs are mainly used to obtain the absorbed dose of the ionising component of the mixed radiation field (3, 4). Analysing the high temperature region (5) the average LET can be evaluated in addition. Beside determination of the equivalent dose using the high temperature ratio (HTR), the neutron induced equivalent dose was measured with a calibrated neutron detector.

MEASUREMENTS IN AIRCRAFTS

Measurements in aircrafts were performed during two different flight periods. Flight period 1 covers three flights Köln - Washington - Köln (exposure time: 60.25 h), during flight period 2 the dosemeters were exposed on four flights the same distances (exposure time: 108 h). For both periods the latitude was between 32 - 52°N in 10 - 11 km altitude.
For flight 1 a standard packet (3mm poystyrol), a standard packet with 20 mm polystyrol in addition and a Bonner sphere with 25 cm diameter was used. Since a dependence of the equivalent dose on the absorbing layer was measured, for flight 2 a second Bonner sphere with 12 cm diameter was used to evaluate the depth dependence in more detail. Each packet included TLD-600, TLD-700 and TLD-200, the two spheres only TLD-600 and TLD-700. During flight 2 labor-made single crystals with different magnesium content were exposed in one of the standard packets.

DETERMINATION OF THE EQUIVALENT DOSERATE CAUSED BY NEUTRONS

For tissue equivalent dose measurements of the neutron dose a neutron detector consisting of TLDs embeded in the centre of a Bonner sphere with 25 cm diameter was used. This sphere enables nearly neutron energy independent measurements in the energy region between approximately 0.025 eV and 10 MeV. In the centre of the moderator sphere a special inset containing the TLDs was developed to improve neutron shielding of the TLD-700 particular against thermal neutrons: TLD-700 situated in the centre of the compartment are surrounded by TLD-600.
To determine the equivalent dose caused by neutrons in mixed (n,γ)-fields the pair method is applied to discriminate between the neutron- and the γ-component (6). TLD-700 were used to measure the γ-dose. The TLD-600 glowcurve is caused by composition of the γ- and the thermal neutron component. Therefore the glowcurve caused by neutrons can be obtained by subtraction of the γ-fraction of the total glowcurve. The calibration of the neutron detector is described in more detail elsewhere (7). Analysing the peak 5 maximum of this neutron glowcurve and using the energy dependent calibration the neutron induced equivalent dose can be determined.

The neutron equivalent doserate measured in the aircraft with the calibrated neutron detector was 3.7 ± 0.5 μSv/h for flight 1 and 2.6 ± 0.4 μSv/h for flight 2. For the calculation a mean calibration factor of 1473 ± 221 cts/mSv was used. The total equivalent doserate is obtained by addition of the absorbed doserate measured with TLD-700. This gives a total equvialent doserate of 5.7 ± 0.5 μSv/h (flight 1) and 3.9 ± 0.4 μSv/h (flight 2).

DETERMINATION OF THE TOTAL EQUIVALENT DOSERATE

The absorbed dose in the aircraft was measured with TLD-700 and TLD-200. Table 1 shows the dependence of the absorbed doserate on the layer thickness. Measuerments of period 1 indicated that the dose increases with absorber thickness. The more detailed measuements of period 2 however shows a maximum at 6 cm depth. This function of the dose is the result of the production of secondary protons by neutrons penetrating the absorbing material. This is also indicated by the dependence of the neutron flux on the absorbing layer (table 1). For flight 2 two identical standard packets were used which show a discrepance in the absorbed doserate. This can be due to a different positions of the packets with different shielding thickness or material in the aircraft.
Furthermore the absorbed doserate was measured with labor made single crystal exposed in packet 1 during flight 2. Crystal E (280 ppm Mg, 11.5 ppm Ti) gives a doserate of 1.83 ± 0.07 μGy/h, crystal F (150 ppm Mg, 11.5 ppm Ti) 1.73 ± 0.11 μGy/h and crystal I (410 ppm Mg, 28.8 ppm Ti) 2.06 ± 0.05 μGy/h. These values are in good agreement with the doserate obtained with TLD-700.

	absorbed doserate [μGy/h]		thermal n-fluence [n/cm²s]	
	flight 1	flight 2	flight 1	flight 2
packet 1	1.50 ± 0.09	1.32 ± 0.07 2.20 ± 0.06	0.61 ± 0.20	0.35 ± 0.08 0.23 ± 0.05
packet 2	1.69 ± 0.04	-	0.56 ± 0.05	-
sphere 1	-	1.50 ± 0.10	-	0.71 ± 0.02
sphere 2	2.00 ± 0.03	1.09 ± 0.05	0.44 ± 0.05 0.49 ± 0.03	0.35 ± 0.06

table 1: Dependence of the γ-doserate (measured with TLD-700) and the thermal neutron flux on the absorbing layer. For calculation of the neutron flux the peak 5 maximum was analysed after subtraction of the γ-component, the calibration factor is $3.03 \cdot 10^{-3}$ cts/ncm².

In addition the total equivalent doserate was evaluated applying the HTR-method. This method compares the high temperature region of the glowcurves with a Co-60 irradiation, normalized on the peak 5 maximum. Since this ratio correlates with the distributaion of the energy deposition, a LET-calibration allows the determination of the average LET of unknown mixed radiation fields (5). The method was used to evaluate the average LET of the measurements in the aircraft.
The increase of the high temperature region of TLD-700 is shown in figure 1. According to the measurements of the neutron flux, an increase of the LET respectively the equivalent dose with absorber thickness was obtained for both periods (table 2).

	HTR		$LET_{average}$ ICRP 26 [keV/μm]		$Q_{average}$		H [μSv/h]	
	flight 1	flight 2	flight 1	flight 2	flight 1	flight 2	flight 1	flight 2
packet 1	4.4 ± 0.8	1.57 ± 0.1	18.0 ± 3.6	8.7 ± 0.3	4.1 ± 0.4	2.4 ± 0.2	8.3 ± 1.6	3.1 ± 0.3
packet 2	3.2 ± 0.6	-	15.0 ± 2.3	-	3.5 ± 0.8	-	7.4 ± 1.5	-
sphere 1	-	2.81 ± 0.3	-	16.3 ± 1.7	-	3.7 ± 0.6	-	5.6 ± 0.9
sphere 2	6.6 ± 1.8	1.71 ± 0.1	25.4 ± 7.1	9.5 ± 0.6	5.4 ± 1.3	2.5 ± 0.3	15.4 ± 4.6	2.7 ± 0.3

table 2: Evaluation of the average LET and the equivalent doserate using the HTR-method. If measurements were made using two equal packets for one flight the mean value is given. The increase of the high temperature region of the TLD-700 glowcurves is shown for both flights in figure 1. $LET_{average}$ is only meaningfull using ICRP 26 because ICRP 60 demands the assessment of the various components of the mixed radiation field.

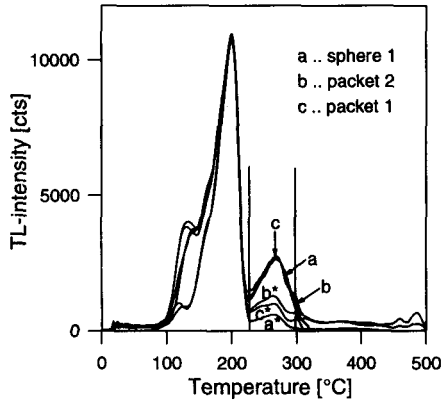

figure 2: Comparision of the TLD-700 glowcurves obtained during flight 1 (a, b, c) with the corresponding Co-60 calibration (a*, b*, c*). Glowcurves are normalized on peak 5 maximum.

DISCUSSION

Comparision of the neutron equivalent doserate of the two flights shows that flight 2 gives only about 70% of the doserate obtained on flight 1. This situation can also be seen by comparing the results of the HTR-method. The values differ between flight 1 and 2 about a factor of 2 to 5 depending on the absorber thickness. Part of this discrepance can be explained by the lower neutron flux during flight 2 (table 1). This indicates that the particle spectrum must have changed quite significantly in this short period between flight 1 and 2. A further indication of this variance of the particle specturm is given by analysis of the dependence of the equivalent dose on the absorbing layer. Flight 1 shows an increase of the equivalent doserate with absorber thickness whereas on flight 2 packet 1 with 1.5 mm absorber and sphere 2 with 12 cm absorber give the same equivalent doserate, only at 6 cm depth a maximum occurs. This discrepancy can be caused by a differing neutron and proton spectrum during each flight. A direct correlation of the results obtained with the HTR-method and the variation of the solar activity was found comparing measurements performed in 1989 and the flights in 1995. In 1989 (route: Köln - Aschchabad, altitude: 10 - 11 km, latitude: 40 - 55 °N) an absorbed doserate of 2.3 ± 0.2 µGy/h, a neutron flux of 0.17 ± 0.05 n/cm²s and an equivalent doserate of 5.2 ± 0.22 µSv/h were measured. If these values are compared with the results of the two flights in 1995 a decreased absorbed doserate and an increased neutron flux is determined. In correlation to these results in 1989 a solar maximum reduced the primary proton and neutron component compared with the situation of 1995 (minimum solar acitivity).

CONCLUSION

The deviation of all the investigated parameters compared with former measurements correlates with the variation of the solar activity. Furthermore the differences of the parameters between flight 1 and 2 explained by a variing particle spectrum shows the sensitivity of the HTR-method. It can be seen that the composition of the mixed radiation field in aircrafts changes significantly with the solar acitivity. Since these variations cannot be predicted continous measurements of the absorbed dose and the LET are proposed.

Using TLD-700 not only the absorbed doserate can be determined but also the evaluation of the average LET is possible. The differences in the equivalent doserate dependence on the absorber thickness for the two flights show that further efforts have to be made to obtain the depth dose in more detail. Measuerments with more Bonner spheres of different diameters are planned.

CONTRIBUTION OF SECONDARY HIGH LET PARTICLES TO THE ENERGY TRANSFER FROM HIGH ENERGY PROTONS

V.E. Dudkin[1], F. Spurný[2]

[1] Research Center of Spacecraft Radiation Safety, 123182 Moscow, Russia
[2] Nuclear Physics Institute, Czech Academy of Sciences, CZ-180 86, Prague, Czech Republic

INTRODUCTION

The most of dose absorbed in the human tissue from cosmic radiation outside of the Earths' atmosphere is delivered through high energy proton energy transfer (1). There are principally two basic processes contributing to this transfer:

- ionization losses, and
- the energy transfer due to high energy protons interactions with tissue constituting nuclei.

This paper presents the results of both theoretical and experimental studies of the energy transfer from high energy protons to tissue through the second process mentioned above, i.e. via secondary, mostly high LET (LET - linear energy transfer), charged particles. Available cross sections data were used to characterize the doses due to these secondary particles theoretically. Theoretical results are compared with experimental data obtained through the response of track etch detectors to high energy protons.

THEORETICAL CALCULATIONS

Let a broad beam of protons of the energy E_p^0 impinge on a slab of the thickness x_0. The number of secondary particles leaving such slab can be calculated through the procedure described in more detail preciously (2). The calculations have been performed for the slab thickness x_0 equal to 0.1; 0.3; 0.5, and 1 g.cm^{-2} of the tissue, and for the initial proton energies equal to 100; 200; 350 and 660 MeV. Following types of secondary charged particles have been taken into account:

- protons created through the cascade processes, i.e. with LET up to 30 MeV.cm^{-1};
- particles created through evaporation processes, i.e.:
  - protons with LET between 30 and 145 MeV.cm^{-1};
  - α-particles with LET between 150 and 1900 MeV.cm^{-1}; and
  - heavier fragments (z~4) with LET between 1200 and 5200 MeV.cm^{-1};and
  - recoil particles (z~7) with LET between 6000 and 10000 MeV.cm^{-1}.

Some simplifications and additional hypothesis have been admitted:

- the independence of the inelastic processes cross section within the slab thickness;
- the independence of the differential evaporation cross section on the proton energy between 100 and 660 MeV;
- only first generation of nuclear processes has been considered
- the ratio of forward and backward evaporation cross sections is equal to about 2;
- the form of spectra of any secondary particle in a group mentioned above is the same.

The results of calculations showed that:

- the integral LET spectra of secondary charged particles do not depend on the proton energy between 100 and 660 MeV;
- absolute contribution of particles is the same, relatively it increases with decreasing ionization losses, i.e. with increasing proton energy;
- the thickness x_0 starts to be important only at the lowest LET values.

The integral LET spectra of secondary charged particles obtained are presented in Fig. 1.

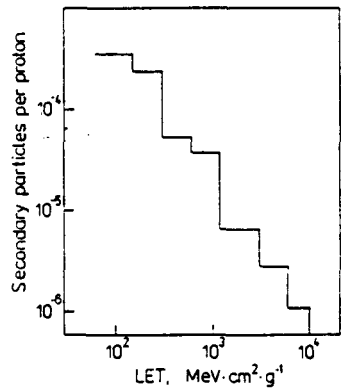

Figure 1. Calculated integral LET spectra of secondary charged particles (x_0 = 0.3÷1g.cm^{-2}).

EXPERIMENTAL RESULTS

Experimental data on LET spectra of secondary charged particles have been obtained by means of track etch detectors (TED), devices, response of which is directly related to the LET (3). There are principally two possibilities how to determine LET spectra of charged particles in a TED:

- to use several TED with different LET thresholds; or
- to determine LET spectra through the analysis of parameters of an individual chrged particle track (5).

Both approaches have been used in our studies. Responses of several different TED to high energy protons have been recieved in our recent publication (4). It was found out that numbers of registered tracks do not depend on the proton energy above about 100 MeV. Their numbers are equal to about $4x10^{-5}$ per perpendiculary incident proton in the use of electrochemically etched CR 39 (LET threshold about 300 MeV.cm^{-1}), about $1.5x10^{-5}$ for cellulose nitrate LR 115 (threshold about 800 MeV.cm^{-1}), respectively about $1x10^{-5}$ in the case of electrochemically etched MELINEX 0 (threshold about 7000 MeV.cm^{-1}). All these figures are close to the theoretically calculated values (see Fig.1).

Much more straightforward comparison can be obtained through the determination of full LET spectra of secondary particles registered in detectors irradiated with high energy protons. Typical LET spectra in CR 39 TED after the irradiation with high energy protons are presented in Figure 2. One can see there that the general shapes of curves in Figures 1 and 2 are very similar.

Both theoretically calculated and experimentally measured LET spectra of secondary particles permit to estimate the dose absorbed in a thin layer of a material due to these particles. The dose is calculated through the equation:

$$D = \int(dN/dL) \times L \times dL, \quad \text{where}$$

dN/dL is the number of tracks in a LET interval; and
L is the value of LET.

When only particles with LET higher than 100 MeV.cm^2.g^{-1} (threshold of registration by CR 39 TED) are taken into account, the doses absorbed in a layer of the thickness of 0.1 g.cm^{-2} can be obtained from both theoretical and experimental data. The results obtained are presented in Table 1.

One can see there that both, quite different ways of the estimation of the secondary high LET particles contribution to the dose from high energy protons give quite comparable results, some

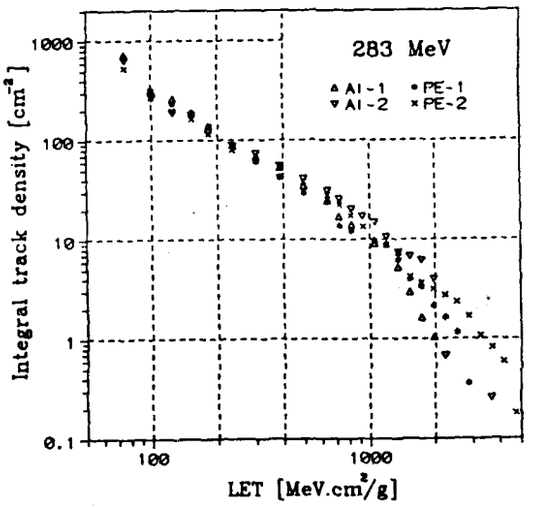

Figure 2. LET spectra of secondary charged particles as measured in CR 39 TED irradiated with high energy protons (Al, PE - covered with aluminium or polyethylene).

Table 1: Dose conversion factors in small layer of tissue-like material.

Initial proton energy [MeV]	Dose conversion factor, Gy.m²; due to					
	Secondary particles with LET higher than 100 MeV.cm².g⁻¹				Ionization losses [5]	
	Theory		Experiment			
100	1.71	-11	1.80	-11	1.15	-9
200	1.68	-11	1.88	-11[1]	7.08	-10
350	1.63	-11	1.16	-11[2]	5.11	-10
660	1.56	-11	-		3.89	-10

[1] For 160 MeV; [2] For 238 MeV

differences observed will be further studied. The data obtained show that the relative contribution of such particles is relatively low at energies about 100 MeV (and less). At 660 MeV, however, this contribution increases substantially, when higher quality factor for these secondary particles is taken into account the relative contribution to dose equivalent values exceed 10%. Further studies of this topic are in progress.

ABSTRACT

For determination of the absorbed dose and the equivalent dose in complex mixed radiation fields, a new method was developed. The method utilizes the changes of peak height ratios in thermoluminescence glowcurves. Peak height ratios depend on the linear energy transfer (LET) of absorbed radiation. This effect was calibrated in different radiation fields (alpha-, beta-, gamma-, neutron fields and heavy charged particle beams). The method was approached for dose measurements in space. Measurements were carried out on space station MIR during the mission AUSTROMIR and during the Russian Long Term Flight RLF experiment ADLET. During this experiment dosemeter packets were exposed under different shielding conditions in order to measure the variation of absorbed dose as well as the variation of average LET of absorbed radiation within the habitable part of space station MIR. The results are compared with calculations based on models for trapped belt radiation (AP8). Additional measurements were carried out within space shuttles during the missions STS-60 and STS-63. Our results are compared with results obtained by Russian specialists (IMBP) and by the Space Radiation Analyses Group (NASA).

INTRODUCTION

In space respectively in a space station humans and matter are exposed to charged particles as well as to electromagnetic ionizing radiation (X-rays and gamma radiation) with various energies. The radiation environment in space results from three main components: galactic cosmic radiation, solar particle-event radiation and geomagnetically trapped radiation. Interaction processes with matter transform this primary space radiation into secondary radiation consisting of charged particles, neutrons, gamma - and X-rays. A considerable part of the resulting radiation is characterized by a high linear energy transfer (LET). For determination of the biologically relevant equivalent dose, beside the knowledge of the absorbed dose, information about the LET-spectrum is required. The doserate and the LET-spectrum within a spacecraft depend on the orbit parameters, the time (solar flares) and the shielding conditions.

SCIENTIFIC METHODS

In standard TL-dosimetry with LiF dosemeters light emission at temperatures below about 240 °C is analysed. The intensity of the dominant peak (peak 5) in the glowcurve appearing at about 200 °C is linear over a wide range of absorbed dose. For evaluation of absorbed dose either peak amplitude or peak integral is used. Peak ratios are more or less constant at low doses after beta or gamma iradiation. After absorption of radiation with higher LET, peak ratios change significantly. In general high temperature peaks arising from recombination of thermally more stable thermoluminescence centers are enhanced after absorption of high LET radiation. These peaks appear in the temperature range from 240 to 350 °C. In our former investigations we calibrated this effect with test irradiations of different LET (1.2.3.and 9). As parameter for the average LET of absorbed radiation we used the ratio of the intensity of TL-light in the high temperature region (HTR) to the intensity of emission in the same temperature range after Co-60 (gamma) irradiation. Intensity of the dominant peak 5 was normalized before calculation of the HTR-ratio.

EXPERIMENTAL

The experiment ADLET was carried out on space station MIR during the Russian-Austrian joint project RLF (Russian Long Duration Flight). Six dosemeter packets designed for a former experiment (2) were used for measurements. Absorbed dose and average LET was recorded over three periods (RLF-1: 8.1.1994 - 9.7.1994, duration 183 d; RLF-2: 8.1.1994 - 4.11.1994, duration 300 d and RLF-3: 8.1.1994 - 22.3.1995, duration 437 d). During each period packets were exposed in the cabin of the board engineer, position 1 (minimum shielding, packets no.9,11,12); and in the central working area, position 2 (maximum shielding, packets no.10,13,14), in order to measure the variations of doserate and average LET respectively quality factor within the habitable area of the space station MIR. The positions of the dosemeter packets are indicated in the scheme of space station MIR (fig.1).
During the shuttle missions STS-60 and STS-63 we could take part in an US-Russian dose measurement intercomparison experiment. So our data can be compared with Russian and NASA dosimetry results, and with data gathered with a TEPC by NASA. All our TL-dosemeters were read out with the labor-made read-out system TL-DAT-II using a Thorn Emi 9635QB photomultiplier and evaluated by a specifically developed software (4).

RESULTS

For the measurement of the absorbed dose the amplitude of peak 5 in LiF-dosemeters was used. All dosemeters were calibrated with Co-60 gamma radiation. Gathered data show that the measured average doserate depends very strongly from position. During period RLF-1 the ratio of measured absorbed dose in the two positions was 1.48. This difference depends on exposure period in space. During period RLF-2 the ratio was only 1.27. The absorbed doserate varied from 0.205±0.01 mGy/d (RLF-1 pos.2) to 0.302±0.01 mGy/d (RLF-1 pos.1). Austrian and Russian results of absorbed dose are in good agreement (see table 1: Dose-ATI: Austrian results, Dose-IMBP: Russian results). During STS-60 mission we measured an absorbed dose of 1.37±0.09 mGy with TLD-600 and 1.24±0.08 mGy with TLD-700. These results are in excellent agreement with NASA results from TLD-700 in compareable position: 1.24 ± 0.03 mGy.

For evaluation of average LET of absorbed radiation the method of HTR was approached (1,2,3,9). Glowcurves from LiF-TLDs exposed in space show a significantly enhanced high temperature TL-emission compared to glowcurves after Co-60 irradiation (fig.2). According to LET-calibration a maximum variation of average LET from 5.8±0.2 keV/µm (RLF-2 pos.1) to 7.1±0.1 keV/µm in tissue (RLF-1 pos.2) was measured. A summary of results from space station MIR is shown in table 1.

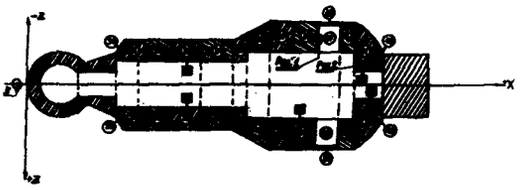

Fig.1: Scheme of space station MIR used for calculation of mass distribution. The positions of dosemeters are indicated.

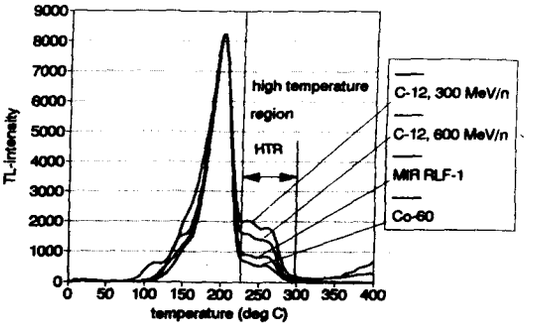

Fig.2: Glow curve from TLD-600 exposed on space station MIR compared to glow curves after irradiation with C-12 ions and Co-60 gamma radiation

Equiv. Doserate(mSv/d)	0.5 ± 0.02	0.45 ± 0.03	0.52 ± 0.02	0.42 ± 0.02

The values measured on MIR-station were obtained from TLD-100. In general average LET is lower at the position with weaker shielding and higher behind stronger shielding. The values obtained by TLD-600 are higher because of the

evidence of thermal neutrons. This difference is more significant in the results from space shuttles. Due to the havier shielding of the space shuttle compared to space station MIR the contribution of secondary neutrons is higher. The value of average LET obtained during STS-60 mission was 10.6±0.6 keV/µm in tissue (TLD-600) and 6.5 ± 0.4 (TLD-700). The quality factor was 2.8 (TLD-600, overestimating thermal neutrons) and 1.8 (TLD-700, neglecting thermal neutrons). The quality factor obtained from NASA TEPC was 2.55. During STS-63 mission the contribution of secondary neutrons was less. The results from space shuttle missions STS-60 and STS-63 are resumed in table 2.
The errors given with the results are only statistical. The total error for dose measurements is assumed to be less than 5% and the error for LET measurement less than 10%.
For the evaluation of the quality factor the relation between LET and Q proposed in ICRP-26 was used because „average LET" is only meaningful using ICRP 26. Contrarely ICRP 60 demands assessment of the various components of the radiation field.

ANALYSES OF MEASURED DATA IN COMPARISON WITH DOSE CALCULATIONS

Measurements of absorbed dose have been routinely made on all space missions. A comparison of measured dose rates with results obtained by trapped radiation belt models (AP8) (5) have shown that dose is underestimated using AP8 min (calculation for solar minimum) and overestimated using AP8 max (solar maximum) by about 30%. The anisotropy of proton fluxes is a well understood phenomenon but is not included in the models up to now (6). Studies have also indicated that the most propable energy of protons predicted by the model differs from the measured energy by about 30 MeV (7).
For the STS-60 mission dose calculations for the positions of the dosemeters were carried out using the AP8min-model from IMBP and the NASA. Although the predicted doses on the one hand and the measured dosea on the other hand are in excellent agreement, there is an average ratio of the calculated doses to the measured doses of 1.8. Therfore there is a great international interest to improve the models of trapped belt radiation. Data gathered during these experiments may contribute to the improvement of calculation models. More detailed analyses of our data are in progress.

DISCUSSION

The method of LET-determination with TLDs on space station MIR was very successful. Absorbed dose rate and average LET respectively quality factor within the space station depend strongly from the mass distribution around the position. The small detectors allow the measurement of dose rate distribution as well as the position sensitve determination of average LET. This opens a wide field of applications. The results regarding average LET respectively quality factor are in excellent agreement with former measurements with LET spectrometers based on proportional counters (8). Data gathered during this experiment might be important to improve radiation models in low earth orbits.

INTRODUCTION

Cosmic-ray neutrons are produced by the interaction of galactic cosmic radiation with magnetic-field-bearing plasma cloud emitted from the sun (solar wind) and with the atmosphere. This neutron radiation varies with altitude, geomagnetic latitude and in different solar events. Commercial aircraft's have optimum cruising speed of 800 -900 km/h and the cruising altitude near 13 km. The flight paths are assigned according to airway corridors and safety requirements. The relatively high dose-equivalent rates at cruising altitudes near 13 km (about 1-2 μSv/h) cause exposures greater than 5 mSv/y (the maximum permissible dose for the general population) for a crew with full-time flight (500 - 600 h/y). The radiation exposure of the crew in commercial air traffic has been studied for the associations of the air crews and airline management and published, [1-5], and regulatory authorities are slowly accepting the fact that there indeed is a problem which needs investigations and protective regulation, [6-8].

The radiation exposure assessments of the crews in Yugoslav Airlines (JAT), are presented in this paper. Yugoslav Airlines (JAT) has the fleet of 30 aircraft's and 65 years of experience in commercial traffic (3.500.000 passengers per year and 35th on the IATA list before the war in Yugoslavia).

ANNUAL DOSE ASSESSMENT FOR YUGOSLAV AIRLINES CREWS

The flights of selected groups of crews (from each work category group of pilots and cabin crew members) have been studied during one year. All flights (about 17000) of selected 34 pilots and co-pilots and 41 cabin crew members have been analyzed. Each work category group of pilots and cabin crew members has mostly full-time block hours during 1989 (the last year of normal traffic for JAT). Selected pilots make four groups, for four aircraft types in use by JAT (DC-9, DC-10, B-727, B-737), and two groups of the co-pilots ("flight engineers" for B-727 and DC-10). Cabin crew members make three groups of pursers and two groups of STW/STD (they include both male and female workers).

Pilot (aircraft)	Total time of flights [h:min]	Annual effective dose [mSv]

Table 1. Aircraft types, total times of flight during one year and assessed annual effective dose for four selected groups of pilots and two groups of co-pilots ("flight engineers")

Model for calculations of the annual absorbed doses and effective doses uses data for annual cosmic-ray dosimetric profile in the lower atmosphere for solar minimum, taken from literature, [2]. The flight paths of aircraft's during various phases of the flight are approximated by different vertical profiles according to the

operational flight plans, with constant climbing and descending speed and the flights at constant altitude. The average times spent during climbs and descents were assumed using a set of the data for the flights.

Cabin crew (Pursers 35-57) (STW-STD 58-75)	Total time of flights [h:min]	Aircraft (in % of the total time of flight)					Annual effective dose [mSv]

Table 2. Aircraft types, total times of flight during one year and assessed annual effective doses for three selected groups of pursers ("cabin chiefs" 35-41, "check pursers" 42-49, "pursers" 50-57) and two selected groups of STW/STD ("seniors" 58-66, "STW/STD" 67-75)

About 17000 flights have been simulated and annual effective doses for each of analyzed pilots and cabin crew members have been assessed. The calculated annual effective doses for each selected pilot and co-pilot are presented in Table 1. and for each selected cabin crew member in Table 2.

The results show that the doses for the long-distance flights (DC-10 aircraft) are higher than the doses for domestic and continental flights. This demonstrate an assessment of the effective dose during the flight Belgrade - Beijing - Belgrade (1,22 mSv, [10]). Exposure of air crews can be up to 5 times higher than the average exposure of the ground based occupational workers. The assessed annual effective doses (1-2 mSv) are smaller than the maximum permissible dose for the general population (5 mSv), but they are comparable with the values for some radiation workers. The model for the calculations includes minimized influence of the cosmic neutrons. The newly reevaluation of health effects of the radiation (ICRP 1990.) changes proposed limits for the general public and professional radiation workers. Inflight radiation exposures of air crews can be higher then the newly proposed limits for the general public, [7]. The exposure rates during solar flares can rise up 3-4 times (many times in extremely rare cases), lasting for several hours up to several days, [7].

The calculated values for Yugoslav Airlines (JAT) are generally less than doses from similar studies, [7-9], because of the structure of the intercontinental flight (only two aircrafts DC-10 in use in 1989.), but the problem is interest for future studies according to the newly proposed limits of ICRP.

Assessed doses for cabin crew members have the variations for similar block hours. The reason for this is that cabin crew members function in various aircraft types.

Some discussions and comparisons with experimental results and the results from literature are also realized. The validity of the flight path approximation in calculations is analyzed, [10]. The comparison shows the small difference (1%-5%). An example for the flights Belgrade - Athens and Athens - Belgrade-Belgrade (two types of the aircraft) shows the difference less than 1% (the calculated effective dose according to the operational flight plan is 2, 157 μSv, and these value by using the approximation of the flight path is 2.039 μSv), [10]. Similar results gives the calculation for the flight Frankfurt - Belgrade (2, 645 and 2.624 μSv, [10]).

A dosimetric experiment has been realized during a routine flight (the flight Belgrade - Podgorica - Belgrade, February 24, 1994). Dosimeter 6150 AD 2 - Automess GmbH (D-6802 Ladenburg), S/N 57787 has been used. Dosimeter has measuring range 0,1 μSv/h -10 mSv/h, energy range of gamma radiation 60 keV - 3 MeV. The measured dosimetric profile (altitude vs. effective dose rate) is compared with the theoretical values, [2]. The results confirm the validity of the used model for calculations, [11].

The calculated values can have an uncertainty of about 20%: the cosmic rays vary with solar cycle (more than 10%) and geomagnetic latitude (about 2%) and the approximation of the real flight paths includes an additional uncertainty (1-5%).

CONCLUSIONS

The presented study shows that the crews of the intercontinental flights can receive significant annual effective doses (1,5 -2,0 mSv). The exposure of the crews is comparable with natural radiation level on the ground level (it can be up to 5 times higher for some air crew members in the intercontinental flights), but smaller than maximum permissible dose for general population. The annual exposures of the passengers are generally smaller than the exposures of the air crews, because the passengers have a limited number of flights per year compared with the members of the air crews.

COMMERCIAL AIRLINE CREWS - A NEW GROUP OF OCCUPATIONAL RADIATION WORKERS

L. Denis Brown Ph.D.
BB Health Physics Services, 55 Leopold Crescent, Regina SK, S4T 6N5, Canada

Introduction

It has been recognised for a long time that aircrews who spend significant periods flying at high altitudes experience background radiation exposures considerably larger than those arising at ground level. The problem is most extreme in the case of astronauts, and in the U.S.A. the NASA has conducted or sponsored a number of well document studies of this problem. In the case of commercial airline operations, the exposures are most significant for the crews of supersonic aircraft which generally travel at much higher altitudes than regular flights, and such aircraft are provided with radiation alarm systems designed to indicate when background radiation levels temporarily become much higher than normal due to solar flares or other sources of abnormally high cosmic radiation. The pilots can then reduce altitude to regain additional protection from greater atmospheric shielding.

Aircrews on regular commercial flights are not generally regarded as occupationally exposed radiation workers. Although several studies have indicated that they may receive radiation doses in excess of the ICRP recommended limit for members of the public, the same is true of individuals living at ground level in one of the areas of abnormally high background gamma radiation; and in the past it has been general practice to avoid regarding either of these situations as coming within the radiation dose control practices of the various regulatory agencies. Furthermore it must be recognised that in areas prone to high background radon levels, even greater unregulated radiation exposures of many individuals take place. ICRP 65 recommends an action level for correcting high radon concentrations in dwellings which comes in the range corresponding to effective doses of between 3 and 10 mSv/y but experience has shown that few homeowners voluntarily carry out remedial work even at these levels. An aircrew member living in a home with abnormally high radon levels may well experience lower effective dose rates whilst in flight than whilst relaxing at home.

Dose Rates

The outdoor gamma dose rate at ground level in many areas is below 0.1 μSv/h, and of this only about half results from cosmic radiation passing through the atmosphere, the remainder results from gamma emitters in rocks and soil. In middle latitudes, at an altitude of about 4 km the dose rate from cosmic radiation increases to about 0.2 μSv/h, and above this height it increases steadily to an average value of about 12 μSv/h at the altitude at which a supersonic airliner would be likely to fly (16km). For most commercial jet aircraft the typical flight altitudes are about 12 km where dose rates of about 7 μSv/h are likely to be experienced. Transpolar routes involve significantly greater dose rates than those which take place at lower latitudes. It follows from this that a working year of 2,000 hours, mainly spent in flight, could be expected to lead to the typical crew member receiving a radiation dose of about 10 mSv. These estimates, based on measurements of cosmic ray intensities carried out at many centres, over many years, have been supported by several direct radiation dose measurements carried out in co-operation with airline operators, mainly in the last 5 years. For example in 1992 a study made at Tokyo University concluded that the annual doses received by typical flight crew personnel flying for about 900 hours per year were about 4 mSv; and a similar study made at Giessen University based on North Atlantic routes concluded that aircrew doses were higher then those actually received by nuclear plant operators in Germany. In 1990, at Oak Ridge, Fry carried out a theoretical study based on NASA satellite data and concluded that aircrew doses come somewhere between the recommended limits for occupationally exposed workers and those for members of the public. His data suggested that dose rates on trans-polar routes are about 2.5 times greater than those on low latitude flights.

Epidemiological studies have also been carried out. In 1989 the British Columbia Cancer Control Agency published a study of cancer incidence among 900 Canadian Airlines pilots. This showed statistically elevated incidences of lymphoma, Hodgkins disease and non-fatal skin cancers, but the numbers studied were not high enough for these results to be of high statistical significance and the study group were of course exposed to other

potential carcinogens in addition to cosmic radiation. Further studies are in progress and additional data is expected to gradually become available.

The nature of air transport is such that no abnormally high annual doses are likely to occur, as regulatory requirements designed to minimising the fatigue of aircrew members will also serve to limit their maximum radiation dose. Equally little can be done to further reduce such doses, except by planning flight schedules so that a reasonable proportion of the flight time of all aircrew personnel is spent operating short range services which generally take place at lower altitudes and therefore with lower dose rates. The questions that must be addressed are whether existing doses should be regarded as excessive and whether future developments in air transportation may introduce any factors which would cause them to increase. In the latter context it can be recognised that there has been an ongoing tendency for the average cruising altitudes of new aircraft to increase, partly in the interests of fuel efficiency. It may also be significant that, whilst high altitude ionizing radiation levels appear to be fairly consistent, UV levels are rising rapidly as a result of depletion of the ozone layer. It is important to ensure that the acrylic windscreens on commercial aircraft do not permit significant UV exposures of cockpit crews.

ICRP Recommendations

Since ICRP 60 recommended lowering the radiation dose limit for non-occupationally exposed members of the public to 1 mSv/y, the radiation exposure of aircrews has received a great deal more attention than in the past. It is clear that aircrew personnel may in the past have exceeded the old ICRP recommended dose limit of 5 mSv/y for members of the public, but when the recommended dose limits were higher it was easier to justify regarding aircrew doses as an example of high background doses which are not amenable to ready control. Recently this has become one of a number of areas in which attention is currently being directed towards more effective control of doses arising from various forms of what is commonly referred to as "technologically enhanced background radiation", and in the USA the FAA now recommends the classification of aircrews as occupationally exposed radiation workers. The increasing tendency for pregnant radiation workers to continue in employment until very close to their date of delivery is another important factor which has led to greater recognition of the need to reduce doses to all pregnant workers. A significant proportion of airline flightcrew personnel are women of childbearing age, and pregnancies among them arise frequently. The high altitude background cosmic ray dose to which these workers are exposed is not directly comparable with the corresponding background doses received at sea level as it will not consist exclusively of soft gamma radiation but will also include more penetrating meson and neutron components. The ratio of foetal dose to skin dose will therefore be greater than at ground level.

All these factors have led to a situation where aircrew personnel have themselves begun to recognise radiation exposures as a potential hazard of flight, and to demand that it receives appropriate attention from airline operators. The international aspect of the air transportation industry means that there would be likely to be intense pressure from all workers in the industry to see that any dose control procedures which might be introduced by one airline operating in one country, were quickly and generally adopted throughout the world. Nevertheless the complexity of establishing common standards in countries with very different legal codes and approaches to ionizing radiation control is very great. In the case of sea transport, much of the world's merchant shipping operates under "flags of convenience" which often simplify the regulatory requirements that individual operators would have to meet if their fleet was registered under the flag of countries with a more highly developed regulatory approach. It would be unfortunate if a similar situation was to develop among major airlines, and it is therefore very desirable that a uniform and carefully considered dose control policy should be introduced by international consensus and adopted by airline operators registered in all countries.

The Legislative Approach

It must also be recognised that regulatory control of the radiation doses received by aircrews may not be easily implemented under the legislative systems developed by some jurisdictions. These doses do not arise from either machine generated radiation or artificial or natural radioactive sources. They cannot even be classified as arising from technologically enhanced background radiation, they simply represent normal background radiation doses that have been received as a direct consequence of technological activities which have led to an increased potential for exposure to abnormally high background radiation levels. In both the U.S.A. and Canada the control

of sources of machine generated radiation is the responsibility of provincial or state authorities, control of doses received from artificially produced radionuclides is a national responsibility. The radiation doses received by aircrews do not readily fit into either of these categories. Occupational health regulations applicable to most Canadian workers are generated provincially and differ from one province to the next - a similar situation applies in the U.S.A. Nevertheless certain categories of workers are deemed to be employed nationally and for such workers national health and safety legislative standards apply. In Canada these categories include workers employed in national or international transportation activities (i.e. intra-provincial travel but not inter-provincial travel.) Such workers, which will include most of the staff attached to registered Canadian airlines, are subject to occupational health regulations developed by Labour Canada rather than to the corresponding provincial regulations. Until recently Labour Canada has had no regulations relating to radiation dose limits for workers, but last year proposed new regulations were introduced and these were published in Canada Gazette Part I on June 24th 1995. This is an intermediate stage in the introduction of legally binding regulations. New regulations generally become legally enforceable shortly after publication in Canada Gazette Part 1, unless they have aroused concerns which necessitate a further review. In this case it appears possible that some concerns about these proposed new Labour Canada regulations may lead to certain revisions taking place before they become legally enforceable. Should they be implemented as published, they would have a considerable impact on the operation of commercial airlines in Canada. Although the proposed new dose limits will not apply to the doses received by employees of organizations licenced by the federal Atomic Energy Control Board, they will be applicable to all federal workers whose employers do not require licencing for the use of radioactive sources. Employees of commercial airlines come into this category, and if these proposed new regulations are eventually introduced in their present form, they will require that the doses received by such workers are kept below both the current ICRP recommended dose limits and the dose limits currently enforced by the Atomic Energy Control Board for the employees of organizations licenced to use radioactive controlled substances. Since the proposed new regulations make no provision for registering certain employees as occupationally exposed workers, it appears implicit that the appropriate limits will be those applicable to members of the public rather than those applicable to registered atomic radiation workers; and it is clear from much of the data above that this could lead to considerable difficulties in the case of airline operators.

A Possible Role for IATA

Similar legal initiatives are likely to arise in other jurisdictions, and in some extreme cases there might appear to be advantages to be gained by commercial airline operators if they restructure their companies so that these are registered in countries where less restrictive legal requirements are in force. Ultimately there would be no advantage to be gained by either operators or crew members in developing a network of partially incompatible standards based on different jurisdictions and it appears desirable to develop an international approach to this problem which would avoid such problems arising. One way in which this could be done would be through an organization such as IATA which could establish a working group, incorporating representatives of both airline operators and crew members, that was charged with the responsibility for developing an agreed Code of Practice relating to dose monitoring procedures and, in circumstances where this might be necessary, procedures for modifying flight schedules to avoid occasional excessive doses to any crew members from arising. It would also be important for this Code of Practice to provide definitive guidance, based on authoritative medical opinion, on procedures for dose limitation in the case of pregnant employees. Once such a Code of Practice had been generally accepted by most major airlines and their employees, it could be enforced through IATA as a formal requirement for all IATA member organizations. In this way there would be a uniform standard of radiation protection for aircrews which would be enforced by airlines in all countries regardless of the legislative requirements of the country in which the company was registered. Once such a scheme was introduced there would be little point in individual countries introducing any legislation other than a regulation requiring all national carriers to adhere to the IATA standards.

It would also be easy for such a Code of Practice to be updated on an ongoing basis as additional scientific data became available. This is contrary to the situation which often occurs when updating formal legislative requirements in cases where the reasons for the proposed changes are highly technical and are not readily understood by members of the legislative body responsible for making the changes.

MEASUREMENTS OF COSMIC-RAY DOSES IN COMMERCIAL AIRLINE CABINS

INTRODUCTION

Cosmic radiation doses which aircrew and air passengers receive in airplanes have been calling attention in many countries especially in the last decade. In this relation, various types of information had been reported on cosmic radiation intensity. In Japan, the cosmic radiation intensity had been measured in commercial airline cabins as well as chartered flights(1-3). While the intensity depends on altitude, geomagnetic latitude(or cutoff rigidity), and temporal variation of the solar activity, their doses are often speculated based on paper records on airflights combined with the intensty-altitude relationship(4). In this study, however, efforts were made to estimate more realistic integrated doses in airline cabins based on actual on-board measurements which had been conducted several dozens of times in each year(e.g., 45 times in 1994 and 27times in 1995).

MEASUREMENTS AND EMPIRICAL FORMULA

The measurements were done by the uses of several kinds of spherical scintillation spectrometers, an ionization chamber, neutron detectors and personal dosimeters. The main device was a scintillation spectrometer which accomodated a 3" ϕ NaI(Tl) spherical detector, and signal components above 3MeV were regarded as cosmic contribution. The neutron contribution was estimated based on intercomparison tests between an ionization chamber and Bonner sphere neutron detectors on board a DC-8 chartered flight(2-3). The results showed that the neutron dose is about 40% of observed charged particle doses with small deviations. The results also suggested that the integrated cosmic radiation dose(D) can be practically expressed in terms of flight time at the main flight altitude(T) plus 10 minutes, dose rate factor(R) and correction factors as follows:

$$D = [R(T + 10)/60] \times F_g \times V_t$$

where F_g is a correction factor due to geomagnetic latitude(F_g =1.1 - 0.95), and V_t is another correction factor due to solar activity(V_t =1.15 - 0.85). R is the dose rate as a function of altitude as presented in Table 1. The uncertainty of obtained results was estimated to be less than 5%.

Table 1. Cosmic radiation dose rates at various altitude.

Altitude(kilo feet)	19	22	25	28	31	33	35	37	39
Dose rate R(μ Sv/h)	0.38	0.57	0.83	1.12	1.42	1.62	1.83	2.03	2.23

ESTIMATED DOSE RATES

In case realistic integrated doses should be evaluated, attention must be paid to flight direction, too. That is because airflight time is considerably influenced by wind such as the westerly. Such was studied in east-west flights(Tokyo-Matsuyama), north-south flights (Tokyo-Hokkaido as well as Tokyo-Okinawa) along with other short distance flights. The mean doses and their ranges were 1 μ Sv(0.7-1.5 μ Sv), 1.5 μ Sv(1.0-1.8 μ Sv) , 2.5 μ Sv(2-3 μ Sv), and negligible(less than 0.5 μ Sv), respectively. Figure 1 compares the integrated doses between eastward(from Tokyo to Matsuyama: against the westerly) and westward(from Matsuyama to Tokyo: with the westerly) flights. It is clearly demonstrated that the integrated dose depend on both flight altitude and flight direction.

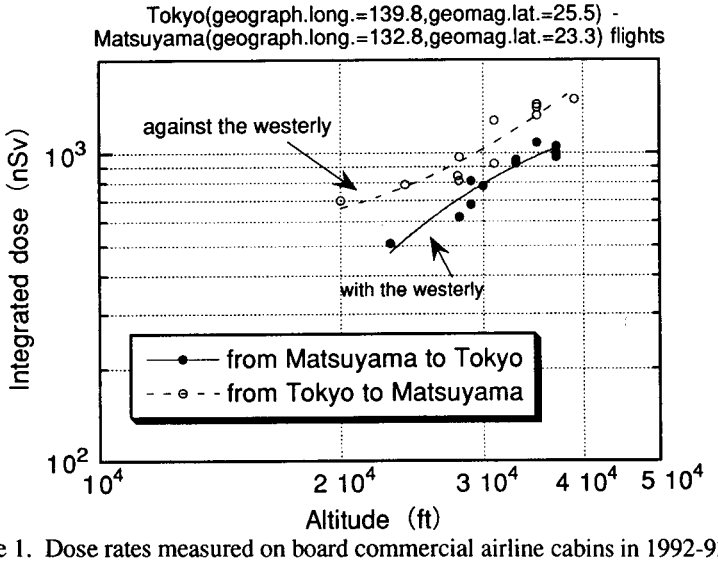

Figure 1. Dose rates measured on board commercial airline cabins in 1992-93.

As for domestic flights in Japan, it was obtained that a typical integrated dose in short flights (Tokyo-Osaka, Osaka-Kyusyu, etc.), middle flights(Tokyo-Hokkaido, Tokyo-Kyusyu, etc) and long flights(Tokyo-Okinawa, Hokkaido-Okinawa) were $\sim$0.5 μ Sv, $\sim$1.5 μ Sv and $\sim$ 3 μ Sv, respectively. International flights were also studied, and comparison between Japan-Europe routes, one via Anchorage and another via Singapore, was possible. Generally, the dose level estimated here are lower than other reported ones. Figure 2 compares altitude dependence of the dose equivalent rates in NCRP report and that of actually measured ones.

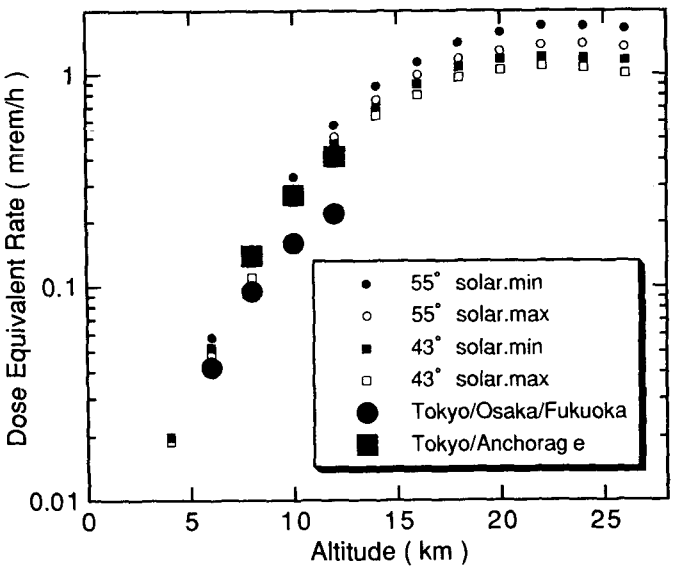

Figure 2. Dose equivalent rate in old unit at 5 cm depth in a 30 cm slab of tissue. NCRP values for Solar maximum and solar minimum are compared to 1000 km flights within Japan along with polar flight which passed Anchorage in Alaska.

CONCLUSION

To discuss the dose limit for aircrew and passengers, care must be paid not only to boarding hours but also to flight routes which reflect many other factors. As present data are based on numbers of actual commercial flights, it will contribute to find proper countermeasures to avoid over exposure.

INVESTIGATION OF COSMIC RAY INTENSITY AT SEA LEVEL BETWEEN TOKYO BAY AND INDIAN OCEAN

Masahide Furukawa, Kazunobu Fujitaka
and Masaharu Okano

National Institute of Radiological Sciences, Chiba, Japan

INTRODUCTION

In the Earth's atmosphere, the distribution of cosmic ray intensity changes as a function of both altitude and geomagnetic latitude. To estimate the human dose from cosmic rays, it is necessary to take into consideration these geographic factors. The purpose of this study is to investigate the actual distribution of cosmic ray intensity by *in situ* measurements on a global scale.

MEASUREMENTS

A wide area survey, which aimed at the estimation of cosmic ray intensity at sea level in Asia, was conducted during the KH93-3 Indian Ocean Research Cruise of R/V Hakuho-maru of the Ocean Research Institute, the University of Tokyo[1]. Cosmic rays were measured with a multi-channel spectrometer with a 3" ϕ spherical NaI(Tl) scintillation detector[2]. Geomagnetic field was also measured by a shipboard three component magnetometer (STCM)[3] simultaneously to examine the change of cosmic ray intensity. The measurements were carried out on the upper deck of the vessel from July 8, 1993 in Tokyo Bay to August 10, 1993 in Mauritius, southwestern part of Indian Ocean, by way of Singapore and Sunda Strait (Fig. 1).

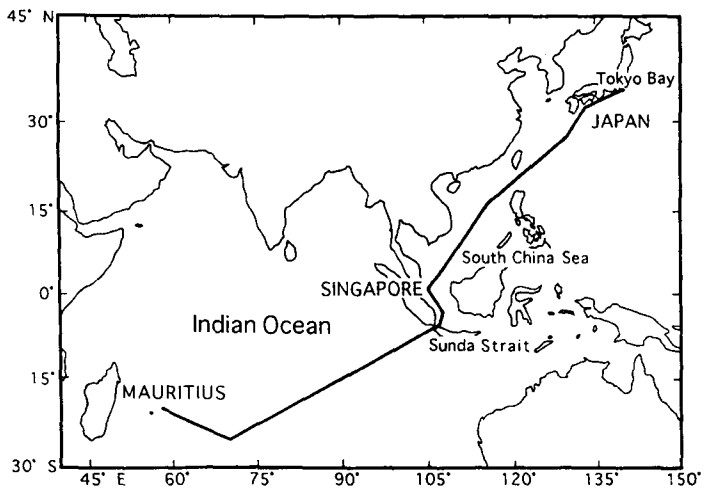

Figure 1. Index map of the survey area. Solid line shows the ship's track.

RESULTS

Analysis was made for the energy spectral region above 3 MeV by the peeling-off method, and the cosmic ray intensity was calculated as the absorbed dose rate in air from the ionizing component of cosmic rays. Then the atmospheric pressure effect was subtracted from the calculated intensity. Figure 2 shows a variation of the cosmic ray intensity with the geomagnetic latitude derived from the International Geomagnetic Reference Field (IGRF)[4]. Figure 3 also shows a relationship between the cosmic ray intensity and the horizontal component of geomagnetic field measured by the STCM.

The cosmic ray intensity decreased from about 30 to 24 nGy/h with the decrease of the geomagnetic latitude (Fig. 2), and also decreased with the increase of the horizontal component of geomagnetic field (Fig. 3). The minimum value of the cosmic ray intensity was observed at a geographic latitude of 8.5° N in South China Sea (Fig. 1) where the horizontal component of geomagnetic field was the largest, about 40,900 nT. This geographic latitude almost agrees with the geomagnetic equator derived from the IGRF. Based on Figure 2, the latitude effect in this study area, a rate of change of the cosmic ray intensity with the geomagnetic latitude, was estimated to be about 0.15 nGy/h/degree on the average.

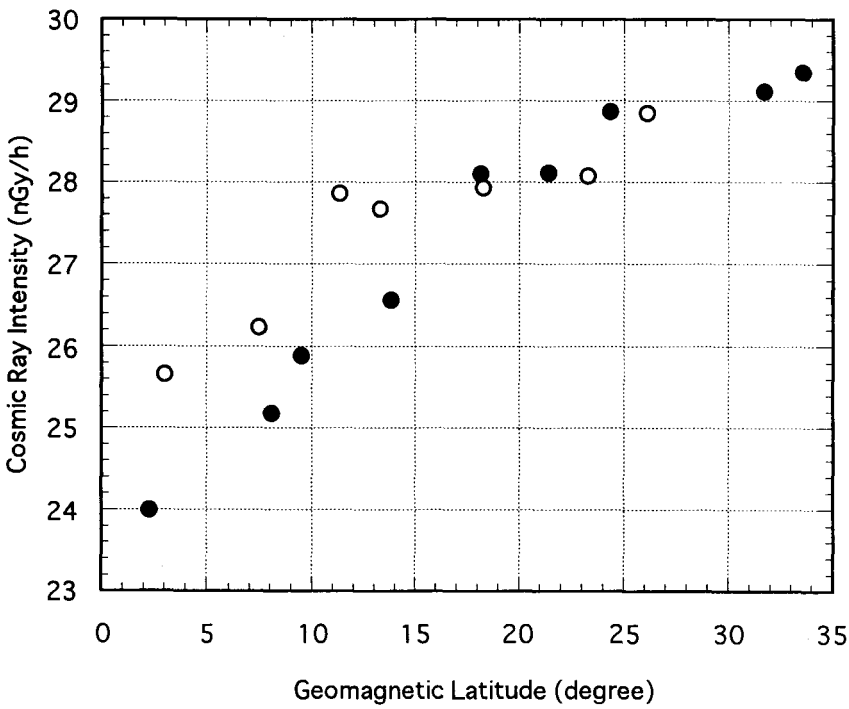

Figure 2. Variation of the cosmic ray intensity at sea level between Tokyo Bay and Indian Ocean with the geomagnetic latitude. Open and black circles show the data measured in the north and the south geomagnetic latitude, respectively.

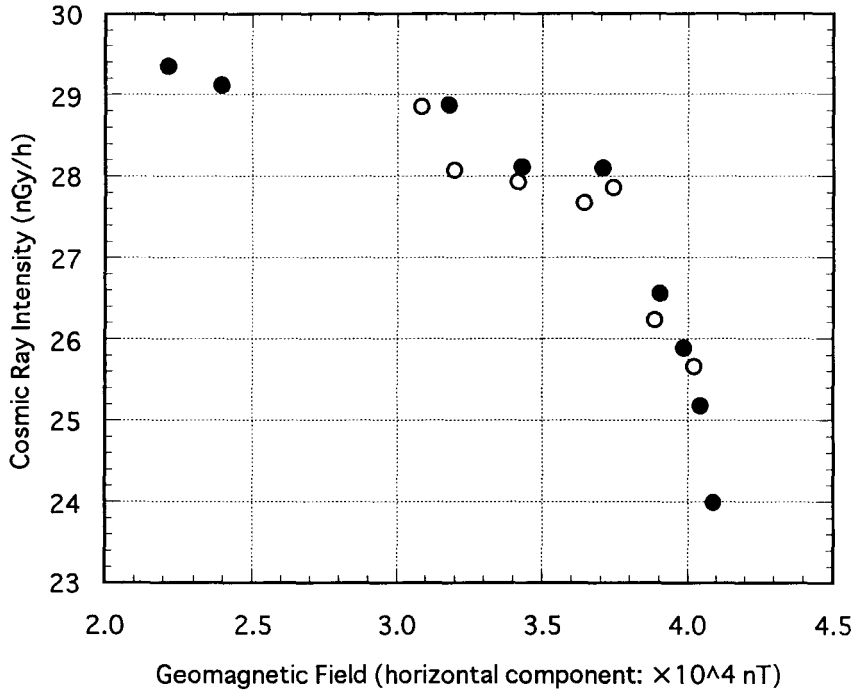

Figure 3. Relationship between the cosmic ray intensity and the horizontal component of geomagnetic field at sea level. Open and black circles show the data measured in the north and the south geomagnetic latitude, respectively.

SUMMARY AND CONCLUSIONS

This study provides the first direct measurement of the relationship between cosmic ray intensity and geomagnetic field at sea level by means of vessel. From the results (Figs. 2 and 3), the geomagnetic field is considered to be a good indicator of the cosmic ray intensity. Using the relationship, we can estimate the cosmic ray intensity at sea level on a global scale. In the same manner, the above observations are useful when we examine the human dose from cosmic rays and its effect especially in the populous subtropical and tropical regions around the studied area.

INTRODUCTION

In the natural radiation background, neutron dose is far much lower than gamma-ray dose generally. When one talks about external dose of natural background, only gamma-ray dose is considered or monitored and neutron dose is normally neglected. According to UNSCEAR 1993 Report (1), the average effective dose rate from cosmic-ray neutrons at sea level is estimated to be 3.6 nSv h^{-1} which is equivalent to 30 μSv per year. This value is comparable with the 50 μSv per year dose limit imposed to the site boundary of individual nuclear facility by the regulatory authority in Taiwan. For nuclear power plants, spent fuel interim storage facilities, and high energy accelerator facilities from which both gamma rays and neutrons emanate, the radiation dose at site boundary comes, therefore, not only from skyshine gamma rays but also from stray neutrons scattered from the facility buildings and from the air. The detection of cosmic-ray neutrons has become important and necessary in order to inspect the compliance of nuclear facilities with the dose limit imposed to the site boundary. The composition and intensity of the cosmic radiation change with time and location due to, among others, mainly the following factors (2) : solar-cycle modulation effect, solar flare effect, latitude effect, altitude effect, and temperature effect. Because this change with time and location is more prominent for the neutron component than for the ionized component, the need for long-term monitoring of cosmic-ray neutrons is clear. In this paper a measurement system consisting of large-size BF3 counters with polyethylene enclosure of different radii was set up. The response functions of the BF3 counters were calculated by using the one-dimensional transport code ANISN (3) performed in adjoin mode. A preliminary survey measurement of the cosmic-ray neutron intensity on the plain and on the mountains in Taiwan area was performed.

EXPERIMENTAL SET UP

In this study high sensitivity large-size cylindrical BF3 counters with polyethylene (PE) enclosure of different radii , namely , 5, 8.5, 10 cm and bare BF3 counters were used to measurement of cosmic-ray neutrons. The BF3 counter has a dimensions of 1.5" in diameter and 34" in active length and is filled with BF3 gas in pressure of 45-cm Hg. The enrichment of ^{10}B is 95%. Figure 1 shows the block diagram of the experimental set up. The 4-way fan out was used

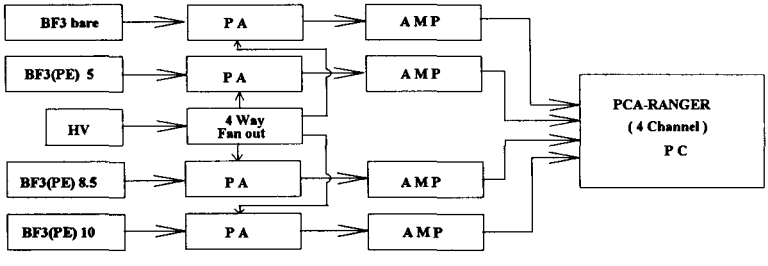

Figure 1. The block diagram of the experimental set up.

to distribute the high voltage to each of the four detectors. The amplifier signals from each detectors were fed into a PCA-Ranger card plugged in a personal computer (PC). The data were

acquired every 10 minutes and showed on the hard disk of the PC.

The response functions of the cylindrical BF3 counters with PE enclosures of different radii and bare BF3 counter were calculated by using ANISN code performed in adjoin mode with BUGLE cross section library (4) for energies below 17 MeV and HILO cross section library (5) for energies above 17 MeV. The detector calibration was made in a neutron calibration room with a normal 100 μg californium-252 source.

RESULTS AND DISCUSSION

In order to perform field measurement of cosmic-ray neutrons, a portable diesel generator for power supply and a tent for rain protection were carried with the neutron detection system. First of all, the measurement was made on the plain in National Tsing Hua University and in Synchrotron Radiation Center. Trips were then made to the Ali Mountain and the Hohuan Mountain in summer 1995. Measurements were made on the way at some representative locations with different altitudes. Table 1 shows the altitudes and the measured counting rates for the four BF3 counters at each measurement locations. The measurements at each locations look about one hour in order to make sure the stable operation of the counting system and the counting rates at each locations were the average values over the whole measurement period. Figure 2 shows the plot of measured counting rates of four BF3 counters as a function of altitude. It can be seen from Fig. 2 that the counting rate increases steadily with the altitude and the ratios of counting rates among the four BF3 counters keep more or less constant at each measurement locations, irrespective of the altitude and the BF3 counter with 5-cm polyethylene enclosure has the highest counting rates. Therefore, it seems reasonable to assume that the cosmic-ray neutron spectrum remains the same independent of the altitude. In our previous study (6) , the annual effective dose of cosmic-ray neutrons on the plain was estimated to be 14 μSv by using the BF3 counter with 8.5-cm polyethylene enclosure. When changes to radiation weighting factor for neutrons recommended by the ICRP in 1991 (7) were taken into account, it will lead to an increase of 50 %. of the effective dose rate of cosmic-ray neutrons. therefore, the effective dose rates of cosmic-ray neutrons on the plain was corrected to be 21 μSv /year. If the cosmic-ray neutron spectrum remains the same, as being a reasonable assumption, the effective dose rate will be proportional to the counting rate of the BF3 counter with 8.5-cm polyethylene enclosure. The effective dose rates at other measurement locations could then be estimated accordingly as include in Table 1.

Table 1 . Measured counting rates (counts / 10 min.) of BF3 counters and effective dose rates (μSv/ year) as a function of altitude.

Altitude (meter)	BF_3 bare	BF_3(PE) 8.5 cm	BF_3(PE) 5 cm	BF_3(PE) 10 cm	Effective dose rate
3275 (Mount Wulin)	120.2 (5.9)*	304.0 (12.9)	395.4 (10.7)	268.6 (9.2)	152
2500 (Mount Ali)	84.5 (5.2)	200.3 (9.0)	268.0 (21.5)	159.8 (7.9)	100
1800	58.0 (5.2)	124.3 (3.5)	157.0 (8.9)	99.0 (11.5)	62
1300	47.3 (8.2)	104.5 (14.2)	133.3 (2.2)	80.8 (9.0)	52
1148	40.7 (5.1)	87.8 (8.7)	123.7 (8.2)	75.3 (7.6)	44
500	29.8 (4.9)	61.3 (7.7)	71.5 (8.6)	45.8 (7.6)	33

* standard deviation

Figure 3 shows the plot of the effective dose rate of cosmic-ray neutrons as a function of altitude. The diamond marks show the data of this work. The smooth curve comes from analytical expressions developed in reference (8) and cited in UNSCEAR 1993 Report (1). It can be seen from Fig. 3 that the increase of cosmic-ray intensity with altitude indicated in our measured data agrees very well that cited in UNSCEAR 1993 Report although our measured effective dose rates are about 50% lower, which is clearly due to the lower latitude of the measurement locations (23.5°N). It is also interested to note from Table 1 and Fig. 3 that the effective dose rates of cosmic-ray neutrons at Mount Ali (2500 m above sea level) and at Mount Wulin (3275 m above sea level)were about five times and 7.2 times higher than that on the plain, respectively.

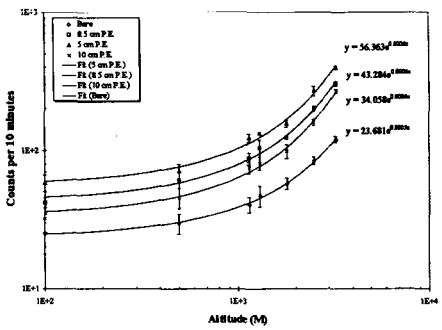

Fig.2 Measured counting rates of BF_3 counters as a function of altitude

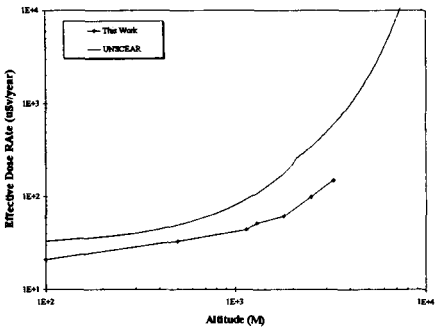

Fig.3 Effective dose rate of cosmic-ray neutrons as a function of altitude

CONCLUSIONS

In this paper a high sensitive neutron detection system has been successfully established. By using this detection system it is the first time the effective dose rates of cosmic-ray neutrons as a function of the altitude in Taiwan area has been measured. On the plain the effective dose rate was estimated to be about 21 μSv /year. On Mount Ali (2500 m above sea level) and Mount Wulin (3275 m above sea level) the effective dose rates were found to be about five times and 7.2 times higher than that on the plain. The measured variation of the effective dose rate as a function of altitude agreed very well with that cited in UNSCEAR 1993 Report. Since cosmic-ray neutron intensity changes with time and space, it is strongly suggested that the extensive survey and long-term monitoring should be taken as soon as possible.

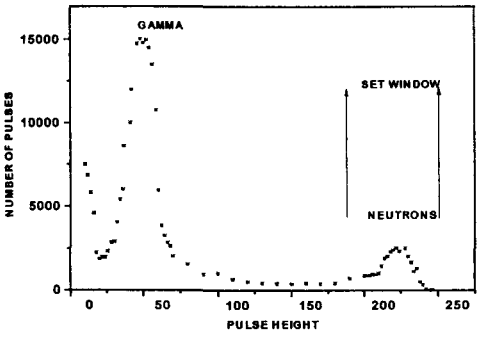
INTRODUCTION. Determination of the neutron fluence rate dependence on the elevation at small distances above the earth's surface is important both for estimation of the neutron radiation contribution to the whole population dose and from point of view of the influence of neutron radiation on detector back-ground as well. We carried out such the measurements at localities with various elevation from 113 m to 2632 m, placed between geodetic latitudes 48° -52° N and longitudes 16° - 20° E (Czech and Slovak Republic).

The spectrum of the ambient neutrons were determined using a calibrated Bonner spectrometer placed on the site with the highest elevation (Lopmnitsky Peak in The High Tatras, 2632 m). A ^{3}He-proportional counter with a sensitive volume of $1*10^4$ cm^3 was the second used detector [1]. The amplitude spectrum of the ambient neutrons registered by ^{3}He-detector is shown on Fig.1.The significant peak generated by thermal part of ambient neutrons (reaction He[n,p]T) was observed. We set the window of a single channel analyzer on this peak The back-ground counting rate (in the set window from interior surface alpha activity was N=(0.061±0.0002) s^{-1} The effective detection area (or sensitivity) C of the counter, determined according

Fig.1



$$N[s^{-1}] = C[m^2].\Phi\ [m^{-2}\ s^{-1}] \quad /1/$$

depends on the shape of the neutron spectra. For thermal neutrons it amounted to C_{th} =(0.015±0.0013) m^2. This value exceeds by approximately 600 times the sensitivity of a LiJ(Eu) crystal with dimensions of 4 * 8 mm.

The thermal part of natural neutrons spectrum Φ_{th} was detected directly by the proportional counter. In order to detect possible changes in the intermediate Φ_{in} and fast Φ_f components ambient neutrons at different sites we also used the ^{3}He-counter which was wrapped in layers of polyethylene (PE) moderators, 23 mm or 64 mm thick, lined (on the outside) by a thermal neutron absorber of Cd 0.8mm thick, for to shift the maximum of a response function into the intermediate or the fast region neutron energy.

Measurements on the other sites were carried out with only a ^{3}He-counter. We supposed that the shape of neutron spectrum, is elevation independent at law altitudes. This assumption is based on theoretical models of Lal [2], O'BRIEN [3] and MASARIK and REEDY [4] calculation.. Physical foundations for it is the existence of an equilibrium distribution of low energy nucleons (E < 500 MeV) through out the low altitudes region in the atmosphere.

RESULTS AND EVOLUTION OF MEASUREMENTS

The results of measurements are presented on Fig.2 (thermal part of natural neutrons) and Fig.3. (when were registered mainly intermediate or fast neutrons).The measured counting rates were corrected for the intrinsic background of the counter and they exhibit an exponential dependence on the elevation of the site **z**. Consequently the neutron fluence rate and dose equivalent rate can be approximated by the exponential function in the form ~ $\exp(\alpha * z)$. From our experimental data $\alpha = (0.85 \pm 0.05)\ 10^{-3}\ m^{-1}$.

For the neutron spectrum evaluation the SAND II. code has been applied. For the response functions of Bonner-Spheres the published data calculated by Hertel were used [5]. The neutron fluence rate were calculated from neutron spectra.

Fig.2

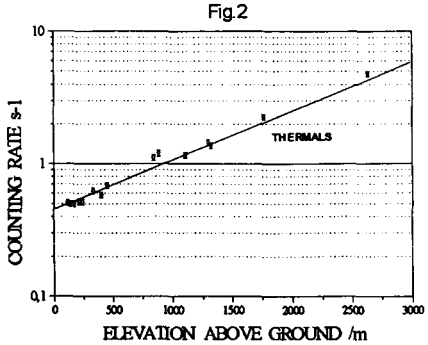


Fig.3

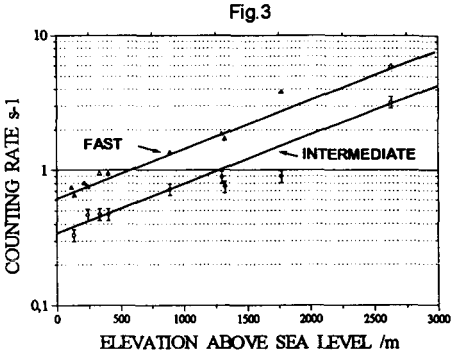


The dose equivalent rate were calculated from the neutron spectra. All data given in the publication have calculated before the ICRP 60 Recommendation has been published. In this way we got the value 40 nSv/h for elevation 2632 m . Partial and total fluence rate ϕ on this site determinated by Bonner spectrometer are on theTab.1 The extrapolation of the height dependence counting rate to zero altitude gives the values: $\Phi_{th}(0)=(30\pm6)m^{-2}*s^{-1}$; $\Phi_t(0) = (100\pm20)\ m^{-2}*s^{-1}$ .and H(0) = (4.1 ± 1.2) nSv/h.

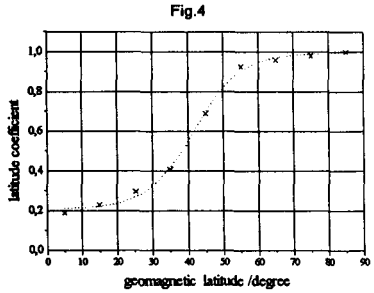
Energy group	$\phi[m^{-2}*s^{-1}]$
Φ_{th} ($E_n < 0.5$ eV)	280
Φ_{in} (0.5 eV ≥ E_n > 0.1 MeV)	330
Φ_f ($E_n \geq 0.1$ MeV)	340
Φ_t	950

DISCUSSION

Our measurement were carried out at varies localities with different relative concentrations of clay, sand and stone in the composition of ground. The statistical errors of our measurement were less then 5 %. As can be seen in Fig.2-3, the results confirm that the elevation dependence of neutron fluence rate and also dose equivalent can be with reasonable accuracy approximated with the functions ~ exp(α*z) , where α = 0.85 km^{-1}. Deformation of the neutron spectrum occurs with the increase of ground moisture content. Such deformation of the neutron spectrum lowers the annual dose equivalent. Because our measurements were done in the summer season during a long-lasting period without precipitation, the value of H(z) obtained should be considered as a maximum one.

In order to find the dependence of the mean value of the annual dose equivalent <H(z)> on relevant elevation, both <H(0)> and parameter α have to be decreased, because precipitation increases with increasing elevation.This fact is reflected in analytical expressions have been developed for the general relationship between annual dose and elevation for the neutron component of cosmic ray, which are given by BOUVILLE and LOWDER [6] and recommended by Forty-first session of UNSCEAR (1992) for estimate the distribution of collective effective dose with elevation. There are two expressions [6]: one for elevation z< 2 km, in the form H(z)=H(0)*exp(1.04*z), and second in the form H(z)=H(0)* [1.98*exp(0.7*z)] for elevation z > 2 km, where H(0)=20 μSv/a = 2.4 nSv/h. These equations may by applied to estimate doses from natural neutrons at habitable elevations around the world. Because there is strong dependence of neutron fluence rate on latitude, our experimental data valid for latitude ~50° N distinguish (Fig..4) from latitude-averaged value[6]. Comparing our value α = 0.85 km^{-1} with value 0.7 km^{-1} [6] we made conclusion, that seasonal variations should be lead to decreasing α maximum 20%. Unfortunately, the accuracy of experimental data is not satisfactory for making the unambiguously conclusion.

Fig.4



LCS was used also for estimation of latitude dependence of neutron fluence rate that is expressed through coefficient k_φ. Its values for sea level altitude are presented in Fig.4. Our measurements were carried out at near geomagnetic latitudes ~50°, that are characterized with k_φ =0.84 (values are normalized to unit for high latitudes) and we estimate latitude-

averaged value assign weights to Earth'area for different latitudes with step of 10°. We get the same value 2.4 nSv/h, that was used by BOUVILLE and LOWDER [6].

We can normalized the values in the front of the exponential factor (in accordance with the value for geomagnetic latitude φ=90°) as latitude-independent parts, that is multiply by factor k_φ . Then dependence of total, thermal neutron fluence rate and dose equivalent rate on elevation z and latitude φ can be parametrized

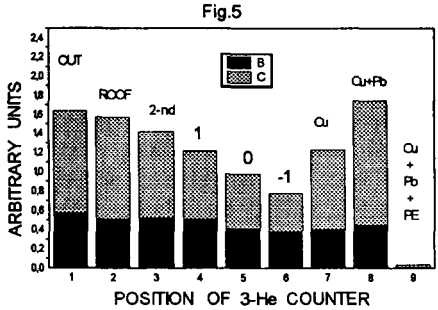
$$\phi_t (z,\varphi) = 119*k_\varphi*\exp(\alpha*z) \qquad /2/$$

$$\phi_{th} (z,\varphi) = 35* k_\varphi*\exp(\alpha*z) \qquad /3/$$

$$H (z,\varphi) = 4.8*k_\varphi*\exp(\alpha*z) \qquad /4/$$

Knowledge of elevation and latitude dependence thermal component of natural neutron fluence is important for determination of high-sensitive neutron detector backgrounds, because it is determined mainly by this energy group. Effective area of neutron detector C_{th} can be easily calculated or experimental determination using /1/, where ϕ_{th} is calculated from /3/ for a given locality. In the case of experimental determination, detector have to be located in the open space, far enough from massive constructions, buildings.etc. As an illustration Fig.5 shows the influence of the construction materials on the natural fluence rate (B - ϕ_{th} , C - ϕ_f + ϕ_{in}) on the locality outside the building of the Department of Nuclear Physics (position 1), on the roof (2) and the different floors (3,4). Into the basement there is a low background massive shielding , position (5) - the counter placed into the shielding, when it was made of copper only, next position - the shielding was made of copper and lead and last - the shielding was made of copper, lead and polyethylene (PE) with boron.

Fig.5



CONCLUSION

Results of our measurements show, that change in dose equivalent rate [nSv/h] from natural neutrons for the Middle Europe region can be described with reasonable accuracy exponential dependence H(z)=4.1* exp(0.85*z) valid for elevation z = 0 - 2.6 km, having an error about 30 %, where the errors of calibration (20 %), the statistical errors (5 %) and the error (20 %) caused the variation of moisture in ground in during year are included. The calculated by us the values k_φ quote to the good agreement with the latitude-averaged annual value <H(0) > , but they need experimental tests for localities with different latitudes.

BE-7 CONCENTRATIONS IN GARDEN AND WILD VEGETABLES IN JAPAN

Nobuhiko Ito, Iwao Kunugiyama, and Yoshinori Furukawa

School of Veterinary Medicine and Animal Sciences, Kitasato University, Towada, Japan

INTRODUCTION

Beryllium-7 is a natural radionuclide produced by cosmic rays(1). Be-7 is found vividly in the atmosphere, so the concentrations in airborne particles were analyzed by many investigators(2-3). It is known that airborne particles with Be-7 in the atmosphere fall slowly to the ground and adhere to plant surface. However, Be-7 concentrations of foods were not measured too much. So we measured Be-7 concentrations of garden vegetables, wild vegetables, grasses, beef and milk, and calculated internal exposure dose from Be-7.

EXPERIMENTAL

Eleven species of garden vegetables (carrot, Japanese radish, cabbage, Chinese cabbage, spinach, cucumber, broccoli, etc.) and three species of grasses were collected from a farm in Towada city of Aomori Prefecture, and ten species of wild vegetables (*Anemone flaccida, Aralia cordata, Aralia elata, Cacalia hastata, Cardiocrinum cordatum var glehnii, Laportea macrostachya, Matteuccia Struthiopteris, Petasites japonicus, Pilea hamaoi, Pteridium aquilinum*) were gathered in a forest area of Mt. Hakkoda of Aomori. Beef and milk samples produced in Aomori were purchased at a store. As beryllium is scarcely scattered by heating, these samples were burned out to dry ash at 400 ℃ for 30hours using an electric furnace. The preprocessed samples were packed compactly into plastic vials, and counted for 24 hours using a Canberra 30% HPGe detector coupled a Canberra Series 35plus MCA. The surface areas of leaf were calculated by counting pixel numbers of picture using computer. Internal exposure doses from Be-7 in foods were obtained by S-value of MIRD Pamphlet(5) and the metabolic data of ICRP(6).

RESULTS AND DISCUSSION

Beryllium-7 concentrations of plant samples are shown in Table 1. Beryllium-7 concentrations of garden vegetables were from 0.2 to 25.3 Bq/kg, and concentrations of wild vegetables were from 0.8 to 23.5 Bq/kg. There is no difference in Be-7 concentrations between garden vegetables and wild vegetables. Leaf vegetables have almost higher concentration of Be-7. Though *Matteuccia Struthiopteris* and *Pteridium aquilinum* are ferns, their eatable stages are sprouts.

Figure 1 shows relationship between surface area and Be-7 concentration in some vegetable leaves gathered simultaneously at the same farm. Beryllium-7 concentrations of leaves correlate significantly with the surface area/weight ratios. What high concentration vegetables have proportionately broad leaves suggests that atmospheric Be-7 particles adhere to surface of leaves.

As grasses have the higher surface area/weight ratios, their Be-7 concentrations (especially timothy) were very high. Figure 2 shows relation between ablution

frequency and Be-7 concentrations of leaves when these grasses were washed by a synthetic detergent. Beryllium-7 concentrations of grasses fell markedly after first washing. However, these concentrations were not decreased after second, third and fourth washing respectively. This fact was found similarly in other vegetables. A binding portion of Be-7 should be on the leaf or in the leaf. Beryllium-7 concentrations of root vegetables and cucumber were very low level, and concentrations Be-7 in peeled vegetables were still lower. Consequently, it is supposed that the plants have little ability to absorb beryllium from roots.

There are probably two components of Be-7 that loosely adhere to the outside of vegetables and firmly cling to that.

Concentrations of Be-7 in beef and milk were all under limit of detection. As the concentrations of Be-7 in grasses were high, it was guessed that transfer coefficient of Be-7 to beef and milk from feed is very low. Therefore it is thought that contribution to internal exposure from Be-7 in beef and milk is negligible.

Table 1. Be-7 concentrations in vegetables.

Garden vegetables	
Broccoli	1.1
Cabbage	8.7
Carrot (leaf)	25.3
Carrot (root)	0.4
Chinese cabbage	11.2
Cucumber	0.2
Japanese radish (leaf)	10.4
Japanese radish (root)	0.2
Spinach	5.0
Wild vegetables	
Anemone flaccida	20.9
Aralia cordata	1.0
Aralia elata	4.1
Cacalia hastata	13.4
Cardiocrinum cordatum var glehnii	2.2
Laportea macrostachya	7.8
Matteuccia Struthiopteris	1.7
Petasites japonicus	23.5
Pilea hamaoi	9.2
Pteridium aquilinum	0.8

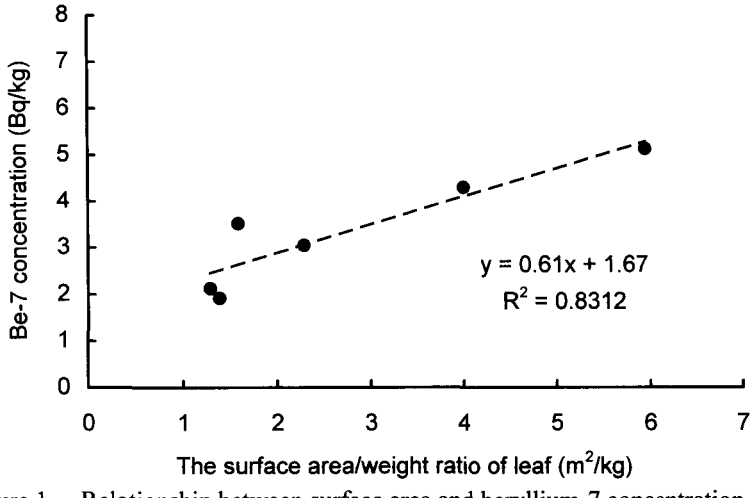

Figure 1. Relationship between surface area and beryllium-7 concentration in some vegetable leaves.

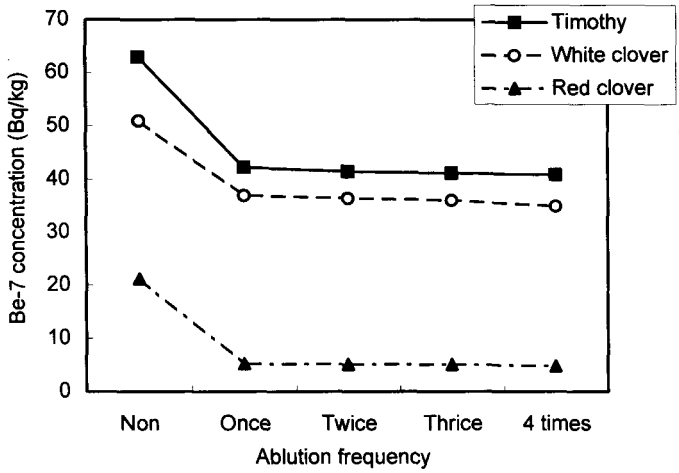

Figure 2. Deciduation of beryllium-7 from leaves by washing.

Beryllium-7 is taken in the body via the respiratory organ and gastrointestinal system, and contributes to internal exposure. Though there are very little reports on internal exposure from Be-7 in food, NCRP reported on the exposure dose from Be-7 in leaf vegetables as 8μrad/yr(80nGy/yr) and on the dose conversion factor to exposure as 2.7×10^{-9} mrad/pCi intake (0.73pGy/Bq).

We tried to evaluate the internal exposure from Be-7 in vegetables above-mentioned. Hypothetical Japanese annual intake amounts of leaf vegetables and wild vegetables are 35 kg/yr and 3 kg/yr respectively. The absorption coefficient of GI tract f_1 is 0.006, and absorbed Be-7 deposit in bone (6). The retention periods of stomach, small intestine, upper large intestine and lower large intestine were used for calculation as 1, 4, 13 and 24 hours respectively. Finally we obtained the dose conversion factor from the S value (5) as 7.8 pSv/Bq. We used the higher concentration values (leaves of carrot and *Petasites japonicus*) for calculation, then we obtained the internal exposure dose 7.5 nSv/yr.

Though the dose conversion factor in this study was ten times higher than NCRP report, the evaluated internal exposure dose was ten times lower than NCRP. If the dose conversion factor of NCRP, our concentration values and the annual intake amounts are used, calculated internal exposure dose is a hundred times lower than NCRP.

Long-Term Variation of Atmospheric Beryllium-7 in Taiwan

Yu-Ming Lin, Chi-Chang Liu and Ching-Jiang Chen
Taiwan Radiation Monitoring Center, Atomic Energy Council
Kaohsiung 833, Taiwan, ROC

ABSTRACT

Taiwan Radiation Monitoring Center (TRMC) has measured the concentration of atmospheric ^{7}Be at the four stations on Taiwan for almost twenty years. Gamma emitting nuclides have been collected by air samplers and measured by gamma spectrometry. Cosmogenic ^{7}Be and other man-made radionuclides produced by Chinese nuclear weapon testings have been detected. Compared with ^{7}Be, man-made nuclides vanished quickly because of their short half life. The behavior of ^{7}Be in long-term concentration variation is different between northern and southern Taiwan because of local meteorological conditions. The results of Fourier analysis show that washout effect of rainfalls and transportation from stratosphere to troposphere are closely related to the variation of ^{7}Be concentration in near surface air. All the measured data of ^{7}Be show that the characteristic of yearly data coincides with the 11-year solar cycle.

INTRODUCTION

From the viewpoint of environmental preservation, it is very important to understand the short-term and long-term variation behaviors of radioactive or nonradioactive substances in the atmosphere. The understanding can provide valuable information of atmospheric changes from past to present, which may be used as baseline data for environmental monitoring. TRMC has monitored radionuclide concentrations in the atmosphere for the last twenty years. The measured data could help understanding the radionuclide distribution and determining the most important factors that affect atmospheric radionuclide transportation in the air. Fourier analysis can be used to check if the substance concentration varies periodically. In this paper we have analyzed the long-term data of radioactive substance concentration in the air by the Fourier method.

EXPERIMENT

Aerosol samples have been collected on the 0.8 μ m glass-fiber filters using constant flow-rate air samplers (Radeco HD-28) with pumping rate of 40 ℓ /min at four different sites in Taiwan. Filters were changed once a week. The sampling instrument on each site was setup in a weather house about 1 meter above ground. These filters were sent to laboratory and analyzed for gamma emitting nuclides by HPGe detectors.

In order to identify the reason for variation, a stainless water tray of 1 m^2 and gummed papers with 50×25 cm^2 were used to calculate deposition velocity in each station. A 1-m diameter pan for collecting rain water was set at station No.3 for calculating washout ratio.

RESULTS AND DISCUSSIONS

Results of measured gamma emitting nuclides show that cosmogenic ^{7}Be is the only nuclide found in the air of Taiwan. Some man-made nuclides such as ^{103}Ru, ^{106}Ru, ^{131}I, ^{134}Cs, ^{137}Cs, ^{140}Ba, ^{140}La, ^{141}Ce and ^{144}Ce produced by nuclear testings in China were detected. The consideration of variation behavior of these nuclides should be based on their production and removal processes. Man-made nuclides vanished within two months because of their short half life. Cosmogenic nuclides existing in the air are continuously generated.

The monthly average ^{7}Be concentrations measured in a 20-year period at four monitoring stations are shown in Figure 1. Spring peak and minima in fall and winter is a well known phenomenon.(1,2) However, in some areas of the world, two peaks may appear in spring and fall.(3,4) The northern part of Taiwan shows two peak during winter and spring while in the southern part two peaks appear in spring and fall. Both

demonstrates that these phenomena reveal two effects: one effect is with an obvious one-year cycle,and the other with a half-year cycle. In northern Taiwan, the one-year cycle is more notably than the half-year cycle.

The galaxy cosmic-ray dose is calculated by the CARI-2 computer program.(5) Input parameters include longitude and latitude of Taiwan, depth of atmosphere and heliocentric potential in each year.(6) The program calculates cosmic ray flux intensity and converts it into effective dose by conversion factors Based on ICRP No.60 table A-2. Correlation coefficients between ^{7}Be concentration and cosmic ray dose are listed in Table 1. Yearly average data have better, although weak, correlation with cosmic ray, but monthly data seem to have no correlation. This result indicates that the 11-year solar cycle of cosmic ray plays an important role of long-term variation of ^{7}Be concentration because of the change in production rate. However, for seasonal variation cosmic ray makes no obvious influence.

Transportation from stratosphere to troposphere has been shown to occur in spring and fall because of the direction change of the jet flow in stratosphere. This is the reason that half-year cycle variation exists. Deposition and washout by rainfall can be collected by water trays, gummed papers and a pan. Dry deposition is related with aerosol size that varies negligibly in natural environment. This can be proved by the result obtained from ^{7}Be on gummed paper. We could divide the lid height by residual time of ^{7}Be to estimate dry deposition velocity, which is 0.4 cm/s in Taiwan. That is quite close to the calculated value 0.45 cm/s obtained from monitored result of gummed paper. However, total deposition velocity is different as shown in Table 2. The 10-year's average washout ratio is 390. It means that after raining ^{7}Be in rain water is 390 times higher than in air. Washout effect by rainfall is the only reason for different deposition velocities and seasonal variations.

CONCLUSION

From the results of analysis mentioned above, we conclude that:

1. Concentration of ^{7}Be in air has minor difference between northern and southern Taiwan, with respective value of about 4 mBq/m^3 in the north and 3 mBq/m^3 in the south.
2. Seasonal variation of ^{7}Be concentration behavior is different between northern and southern Taiwan. One year cycle in Northern Taiwan is apparent.
3. Seasonal variation is due to different deposition velocities caused by washout effect of rainfalls.
4. Half-year cycle may be due to air transportation from stratosphere to troposphere.
5. Variations of yearly average data are almost consistent with the 11 years' solar cycle.

ABSTRACT (See instructions overleaf)

Natural radiation environment is characterised by existence of terrestial gamma component and cosmic mixed radiation component. The cosmic component is in fact the mixture of different types of particles whose contribution to the total absorbed dose depend on the latitude and altitude. At the sea level and at the altitudes of the passenger aircrafts, fotons, muons and neutrons have to be considered.
A new method for determination of ambient dose equivalent in natral radiation environment with the sensitivity down to single nSv is based on the use of high pressure 3He proportional counter in a polythene moderator. The very high sensitivity, especially for monitoring of neutron component , is achieved by applying of an active spectrometry system which register the pulse height apectra from 40 mm diameter spherical 3He proportional counter. The inherent background of this counter was determined in Low Level Laboratory at Asse salt mine. It is shown that spectral analysis of the signals from 3He detector give not only high sensitivity with regard to ambient dose equivalent but also improves the quality of the measurements. A special instrumentation for low-level neutron monitoring is described in which a quality control method has been implemented.

Cross Sections for Production of ^{7}Be, ^{22}Na, and ^{24}Na in Thin Targets of Carbon, Magnesium, Aluminum, Silicon, and Silicon Dioxide by Bombardment with Monoenergetic Protons at 30 to 67.5 MeV

Clinton D. Gans

San Jose State University, San Jose, CA 95192, internet[cdg2@pge.com]

ABSTRACT

Measurements of cross sections were made for the proton-induced production of ^{7}Be, ^{22}Na, and ^{24}Na from carbon, magnesium, aluminum, silicon, and silicon dioxide. The cyclotron of the Crocker Nuclear Laboratory at the University of California at Davis was used to bombard small stacks of thin, high purity target foils with protons at discrete energies between 30 and 67.5 MeV. Following bombardments, pulse-height spectroscopy was used to count easily-detectable radionuclides in the target foils. The cross sections measured agreed with prior studies where thin targets were used. Applications for the results of this work may include: dose-component calculations for radiation buldup due to cosmic-ray bombardment in the hulls of air- and spacecraft; shielding and dosimetry calculations to support the application of proton accelerators in medical radiation therapy; or interpretation of the history of meteorites and the processes that shape planetary surfaces.

ACKNOWLEDGEMENTS

This project was directed and funded by Dr. Peter Englert of San Jose State University and sponsored by Dr. Carlos Castaneda of the University of California at Davis Crocker Nuclear Laboratory. Mr. Anthony Beverding and Miss Kyeong Kim worked with me during collection of the data.

INTRODUCTION

The probability for the occurrence of a nuclear reaction between an accelerated particle and a stationary target nucleus is expressed as a quantity called the reaction cross section. A cross section is the effective target area presented by the stationary nucleus from the perspective of the incident particle. The purpose of this study was to measure the cross sections for production of readily detectable radionuclides in high purity foils of common materials. Energetic protons are present at very high altitudes, in space, and are used in special types of medical radiation therapy. Accurate cross sections for proton-induced reactions in materials found on planetary surfaces and in medical radiation therapy settings, or used to construct air- and spacecraft, may be valuable as humanity's knowledge and reach expand.

EXPERIMENTAL AND MATHEMATICAL METHODS

Stacks of five, thin, high-purity (at least 99.999%) targets were bombarded with protons accelerated in a vacuum by the Crocker Nuclear Laboratory (CNL) cyclotron at the University of California at Davis on nine days during 1993. Target stacks were composed of three, 15-mm-diameter disks of carbon, magnesium (both 0.125-mm thick), silicon, or silicon dioxide (both 0.500-mm thick) with 0.055-mm aluminum foils upbeam and downbeam. Proton energies within the stacks were calculated using the modified Bethe-Bloch formula as described by Attix (1). Proton current was measured using a Faraday cup at the end of the beam line. After bombardment, short-lived ^{24}Na activity in the aluminum, magnesium, silicon, and silicon dioxide targets was promptly measured at CNL and San Jose State University, where longer counts for ^{22}Na were also made. Carbon and silicon dioxide targets were also counted for ^{7}Be. Production cross sections were calculated using the relation described by Fink, Sisterson, Vogt, *et al.* (2). The percent uncertainty associated with each measured cross section was calculated by the root-sum-of-squares method.

RESULTS

The results of the measurements described are shown below. Table 1 contains cross sections with associated percent uncertainties for proton-induced production of ^{7}Be from carbon and ^{22}Na-^{24}Na from magnesium and aluminum. Table 2 contains cross sections with uncertainties for proton-induced production of ^{7}Be, ^{22}Na, and ^{24}Na from silicon and silicon dioxide.

DISCUSSION

Cross sections measured for the $^{27}Al(p,3pn)^{24}Na$ reaction (Table 1) agreed up to 50 MeV proton energy with those reported in a recent compilation (2). Above 50 MeV, the cross sections for production of ^{24}Na from aluminum described in this work agreed with those reported by researchers who used a similar thin-foil bombardment geometry at the Harvard Cyclotron Laboratory (3). Cross sections for proton-induced ^{22}Na production in aluminum (Table 1) also agreed with those reported in Reference 2. Cross sections for ^{7}Be production in carbon (Table 1) were 5 to 10 mb higher than those reported in a prior study (4). The cross sections measured for the $^{25}Mg(p,2p)^{24}Na$ and $^{26}Mg(p,2pn)^{24}Na$ reactions (Table 1) did not clearly define the proton energy at which the production maximum occurs. Cross sections for the ^{22}Na production from magnesium showed a gradual decline from 83 to 62 mb between 42 and 67 MeV proton energy. The cross sections measured for ^{22}Na and ^{24}Na production from silicon (Table 2) showed maxima near 60 MeV proton energy. The results in Table 2 defined the thresholds for production of ^{7}Be, ^{22}Na, and ^{24}Na from silicon dioxide, but did not clearly define the maximum cross sections.

CONCLUSION

High purity, thin target foils of carbon, magnesium, aluminum, silicon, and silicon dioxide were bombarded with protons at discrete energies from 30 to 67.5 MeV. The ^{7}Be, ^{22}Na, and ^{24}Na produced were measured by pulse-height spectroscopy. Experimental cross sections for production of these radionuclides were calculated using the results of the spectroscopic analyses and the target and bombardment parameters. Where existant, agreement with previously-reported values was observed except where Coulombic interactions in the target stacks may have caused proton energy losses.

LUNG CANCER RISK FROM RADON
MODIFIERS OF EXPOSURE - EFFECT RELATIONSHIP

Ladislav Tomášek [1] and Václav Plaček [2]

INTRODUCTION

Studies of underground miners of uranium and other substances are at present the principal source of information on the long term effects of exposure to radon and its progeny. One of the largest such studies is that of uranium miners in West Bohemia (Jáchymov). This study, sometimes referred to as the S cohort, was set up in 1970 by the late Josef Ševc (2). The purpose of this paper is to show, how the exposure - effect relationship is modified by time since exposure, age at exposure, and exposure rate.

METHODS

The study population of the S cohort involve uranium miners, that started underground work at the Jáchymov and Horní Slavkov mines in the period 1948-59, and had worked for at least four years. A total of 4320 men satisfied these criteria.

During the decade up to 1990, follow-up of the cohort mainly relied on the national population registry. In order to improve the follow-up, a series of additional checks were conducted: in the files of the Czech and Slovak Pensions Offices, by local enquiries, and by direct correspondence (4). These additional efforts resulted in an increase of more than 10% in the numbers of men known to have died or emigrated.

An exceptional feature of the S study is the large number of measurements of radon concentrations made in each mine-shaft (mean number per year and shaft was 223 in the period 1949-60). Each man's annual exposures to radon progeny in terms of working levels were estimated combining measurement data with the men's employment details. Recent data revisions revealed that for some of the men (about 10%), exposures at other Czech mines had not previously been taken into account (3). In the most recent revision of exposures, appropriate adjustments were made for individual job categories (miners, other manual professions, supervisors, and exploratory workers) using information on exposure levels in different work places (stope, drift, cross-cut, and raise).

Generally, person-years at risk were calculated for each man, starting at four years after entering underground employment and ending at the earliest of date of death, emigration, 85th birthday, loss to follow-up, or 1.1.1991. The person-years were cross-classified by attained age, cumulated exposure in windows formed by time-since-exposure, exposure rate, and age-at-exposure. Poisson regression models for excess relative risk (ERR) were

fitted by maximum likelihood method. It was assumed that the number O of deaths observed in each cell had mean in the form

$$O = c\,E\,(1 + ERR(w,x)),$$

where E is the number expected from national rates, ERR is excess relative risk, w and x denote exposure history and modifying variable, respectively, and c is an intercept term that allows the mortality rate for 'unexposed' cohort to differ from that in the general population.

RESULTS AND DISCUSSION

The increased mortality (O/E=1.58) in the cohort is largely affected by mortality from lung cancer. Nevertheless the mortality from violence and accidents is also increased, namely in the first part of follow-up, whereas the mortality from other causes increases after 20 years since first exposure (Tab.1).

Tab.1: Time and cause specific mortality

Time since 1st exp	Lung cancer	Violent deaths	Other causes	Respiratory diseases	Circulatory diseases	Cancers excl lung
4- 9	5.22 *	1.80 *	0.79	0.48	0.86	0.83
10-19	8.62 *	1.75 *	1.10	1.23	1.22 *	1.08
20-29	5.14 *	1.30 *	1.27 *	1.38 *	1.27 *	1.13
30-	3.12 *	1.37 *	1.22 *	1.35 *	1.14 *	1.30 *

(the asterisk denotes significant increase at 5% significance)

A similar time pattern is observed in some groups of diseases generally associated with tobacco consumption. When the cohort was identified in 1970, information on the smoking habits in the cohorts could not be recorded. As the increase in mortality from cancers other than lung cancer is not likely to be associated with radon exposure (6), the data indicate that smoking in the S cohort might be different from the general population. This conclusion is supported by a survey in other uranium mines (study N) estimating about 75% smokers in the miners, somewhat more than 66% corresponding the male average in the country (5) .

Most of the miners' studies demonstrated the linear relationship between relative risk and cumulative exposure (5). In a simple model in which the excess relative risk increases linearly with total 5 year lagged cumulative exposure, two parameters are estimated: the coefficient of ERR/WLM and intercept. The overall ERR/WLM estimate 0.013 for the most recent data is higher than the comparable estimates previously reported for the study: 0.0034 (5) and 0.0064 (4). The corresponding intercept is 2.43 (CI:1.73-3.41).

Factors known to influence the excess relative risk per unit exposure were analyzed. The strong influence of time since exposure (TSE) was found. In addition, the effect of exposure rate was investigated. The cumulative lagged exposures in the three TSE windows were split into two windows according to their concentrations in term of WL (0-3.9, 4+). It was found that the ERR/WLM estimate corresponding to higher exposure rates was significantly lower. The effect of age, that was found in almost all miner studies (5), was investigated in the same way as the other exposure modifiers, i.e. by the method of windows. The analyses demonstrated a significant influence of the age-at-exposure factor when both time-since-exposure and age-at-exposure factors were included in the model. The estimates in the model with all the exposure modifiers are given in Tab.2 .

Tab.2: Effect of time since exposure, exposure rate, and age

	Estimate	95% CI	Chi-sq	DF
Intercept	1.46	1.00 - 2.14		
ERR/WLM	0.124	0.077 - 0.199		
TSE:			69.53	2
5 - 14	1			
15 - 24	0.26	0.11 - 0.41		
25 - 34	0.07	0.02 - 0.13		
Exp.rate:			8.69	1
0 - 3.9	1			
4 -	0.47	0.21 - 0.72		
Age-at-exp			52.07	2
- 29	1			
30 - 39	0.60	0.36 - 0.85		
40-	0.28	0.18 - 0.38		

The confidence interval for the intercept in the last model is narrower in comparison to other models. Further investigations of the intercept showed that when age factors were present in the model as continuous variables, the age-dependent intercept remained nearly constant (close to 1.5) suggesting that in the absence of exposure to radon, the estimated mortality from lung cancer in the cohort would be about 1.5 times higher than in the general population. If this estimated baseline lung cancer mortality in the study were true, the ERR/WLM coefficient related to simple cumulative exposure would be about 0.015 (95%CI: 0.0135-0.0165).

INTRODUCTION

All possible risk factors must be taken into account for the evaluation of radia risk of human cancer because of the polyetiology of most types of tumors. evaluation of such a "confounding" factor as the smoking, that is a strong carcino agent, is very important for the hygienic reglamentation of irradiation based on lung cancer risk. These circumstances are omitted usually in the epidemiolo investigations of occupational cohorts to be compared, because an exact estimatio smoking factor is very difficult in a large cohort. On the other hand indus hygienists are of the opinion that the persons, working under bad conditions, s more than those in the general population.

Only prospective (cohort) investigations are known for ^{239}Pu incorporation and cancer, where the age are taken into account besides the level of irradiation ef (1,2,3). The use of the "case - control" method broadens the investigation possibi and can give new results.

SUBJECTS AND METHODS

The investigation of lung cancer by "case - control" method was carried for personal of the first Russian atomic plant Mayak. The main factor of the professi effect was the radiation one: the external gamma-irradiation and, in most cases, contact with the airborne ^{239}Pu. External gamma-irradiation doses were accounte dosimeter control service of the enterprise with individual film badges. The amou incorporated ^{239}Pu was estimated by its spontaneous excretion with urine (biophy laboratory of the branch № 1 of Biophysical Institute, the laboratory leader d V.F.Khokhryakov).

The main group consists of all lung cancer cases from 1966 till 1991 among personal of basic shops of the atomic plant, verified by morphological investiga (162 persons, among them 148 men and 14 women). Pair control (persons, that not fallen ill with lung cancer) was matched among the personal of the same plant persons, 296 men, 42 women). Matching was made by sex, year of birth (±5 years), of the working begin at the enterprise (±2 years), profession, working place. The on the smoking was received after direct interviews by unified method, hold by me experts.

STATISTICAL ANALYSIS. The main and the control groups, were compare unvariable and multivariable analysis. The procedure of multiple logistic regres with stepwise selection of independent variates, based on the maximal likeli method, was used for multivariate analysis, was calculated odds ratio (OR). More attributive risk (AR) was calculated. The BMDP package was used for statis estimation of data.

RESULTS

Eleven potential risk factors (professional, condition of life, medico-biological) evaluated using a logistic regression model, 5 insignificant factors, were excl

(preceding professional factors, age of smoking's start, frequent pneum pulmoneum tuberculosis), the rest was arranged (by odds ratio) in decreasing o smoking > plutonium pneumosclerosis > plutonium incorporation in body > chr obstructive pulmonary diseases > decrease of body mass > external gamma-irradia OR for them were accordingly 6.6, 4.6, 3.1, 1.8, 1.8. The portion of the occupati cancers among the workers of the atomic plant, evaluated on the base of attrib risk, is 26%.

Dose-response relation was investigated for the three most important factors of cancer risk (smoking, plutonium incorporation and external gamma-irradiation). gradation were used to describe plutonium incorporation. "Zero" or the lo gradation serves as the basic level to be compared increasing factor gradations "case-control" analysis. A trend to decreased of morbidity risk was noted for t gradations following "zero" 0.149-0.59 kBq, 0.6-2.29 kBq and 2.3-8.99 kB plutonium incorporation, OR-ad was 0.56, 0.59 ($P<0.1$), 0.83; trend of the descen branch of the curve was the significant value ($P<0.05$). The risk to fall ill with cancer became clearly defined at 9-35.6 kBq (OR-ad 2.48) and increased sharpl 35,7-140,6 kBq (OR-ad 59,3) (Fig. 1). Dose-response for absorbed lung dose similar character.

Four gradations were used to describe external gamma-irradiation in the ge cancer group. A certain dose dependence was traced using the crude odds estimates (OR-cr): the highest increase of OR-cr 2.2 was at the gradation >4.0 However, no statistically significant OR were obtained after adjustment. The abs of a clear-cut dose dependence of lung cancer development on the external ga irradiation testifies to a lesser effect for our sample cohort comparing with A-b survivors whose risk of lung cancer occurrence at the dose of over 2 Gy is twice a We can be suggested that, this difference is due to low dose rate in our case, that chronic irradiation.

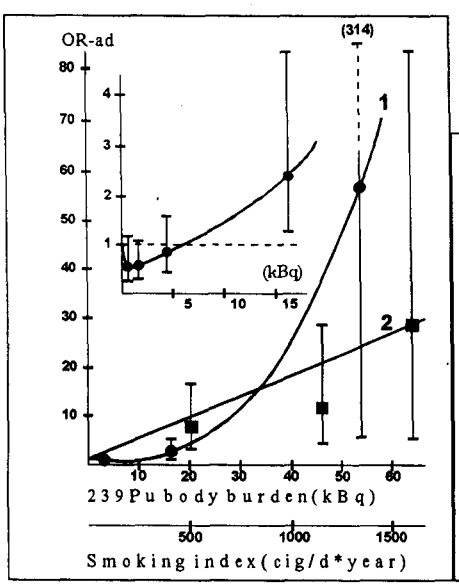

Figure 1. Lung cancer risk, depending on ^{239}Pu body burden and smoking (1 - ^{239}Pu, 2 - smoking, bar - 95% CI)

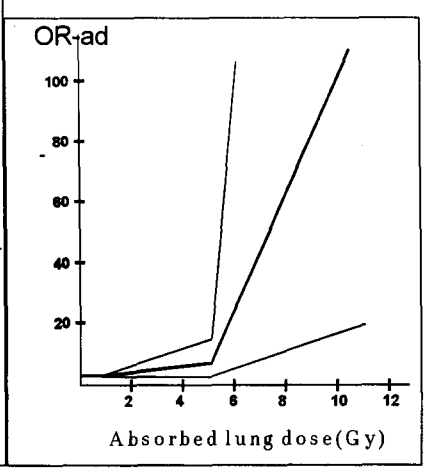

Figure 2. Lung cancer risk (with 95% CI) for separate linear segments of dose-responce curve

Fig. 1 show the dose dependence on smoking for the general carcinoma group progressing increase was observed at all gradations. At the last gradation it was 20. dependence approximated a linear one. Having in view the linear character of response dependence and based on the data presented we can evaluate the risk f smoking. Smoking one pack of papiroses daily for 5,10 and 20 years led to 2-,4-, an fold increases in the risk of lung cancer respectively, as compared non-smokers. increase or decrease in the number of papiroses smoked per day varies the risk respecti Our risk estimates are in good agreement with the values obtained from prospe investigations in which smoking was investigated as an independent factor /BEIR 1980/.

As distinct from a simple relationship for smoking, the dose-response relation plutonium incorporation is more intricate: it has a non-linear threshold character. decrease in lung cancer incidence ratio at low plutonium incorporation is describe American authors at three nuclear enterprises: Los-Alamos Laboratory, in Hanford Rocky-Flats (1). The mechanism of the possible effect may be: the first one is the activa of immune defence, the second one is the intensification of synthesis of DNA-repara ferments. Data on the non-linearity of the effect and on the presence of threshold at radiation levels are accumulating as well. The investigations on indoor radon con point to that fact (4).

Taking into account the non-linear character of the relation between lung cancer and plutonium influence we have used the square and linear-square models to descri Equations of following form were obtained:

$y=(-0.21\pm0,08)x_1+(0.024\pm0.002)x_1^2$ (I), $y=(0.02\pm0,0005)x_1^2$ (II)

$y=(-1.36\pm0,59)x_2+(1.11\pm0.07)x_2^2$ (III), $y=(0.95\pm0,021)x_2^2$ (IV)

were y=ORad, x_1 - ^{239}Pu body burden (kBq), x_2 - absorbed lung dose (Gy)

It should be noted, that the linear-square model contains a the negative linear term. evident, that this negative linear term can represent the defence mechanism of low [2] doses.
