The estimate of the threshold was carried on this equations base. The threshold fo ^{239}Pu body burden correspond 3.8 kBq, for absorbed lung dose - 0.85 Gy. The regres coefficients from equations II and IV corresponds to the excess relative risk owing kBq^2 or 1 Gy^2. Non-linear dose-response curve was divided into three linear inter Excess risk was obtained for them by logit-regression (with the adjusting of smo external gamma-irradiation and mass index): I 0-0.85 Gy, subthreshold effect; II 0.8 Gy - slow increase, excess relative risk 1.7 Gy^{-1}; III 5.21-17 Gy - fast increase, excess rel risk 21.3 Gy^{-1} (Fig. 2).

Interaction of these three factors was estimated. Multiplicativity of body burden [2] and external irradiation is pointed out only high levels of both factors. The interactio plutonium incorporation and smoking, external gamma-irradiation and smoking different at different smoking levels. Additivity were observed in low inte multiplicativity and antagonism in middle and high interval of smoking scale. T effects were considered the base of the two-mutation model of radiation carcinogenesis

SUMMARY

West Bohemian and French uranium miners are characterized by a long duration of exposure to radon and its decay products, in comparison to most of the other groups of miners, studied in the recent international joint analysis by the National Cancer Institute (NCI) in USA. This analysis has confirmed the linearly increasing risk of lung cancer by cumulative radon exposure, describing the different factors that may influence this dose-response relationship. One of the main factors presently discussed is the influence of the exposure-rate effect: in other words, has the same cumulated exposure spread over 10 years the same risk of lung cancer as if it is cumulated in 2 years ? The implication of an inverse exposure-rate effect for low chronic exposures as well as some methodological approaches will be discussed and tested by using the data of the Czech and French cohorts. These two cohorts present annual exposures varying by a factor of 5 to 10, French exposure rates being close or even less than 0.1 Working Level during the last 20 years. The project is integrated in a larger European project on uranium miners, co-ordinated by IPSN.

INTRODUCTION

Cohort studies of uranium miners in the Czech Republic and in France have demonstrated a clear increase of lung cancer risk linked to occupational radon exposure. Both studies contributed substantially to an international joint analysis co-ordinated by the National Cancer Institute (NCI) in Bethesda (USA). The results of this analysis, based on more than 2,700 lung cancer cases observed on 65,000 miners, demonstrated a linearly increasing risk of lung cancer deaths with cumulated exposure to radon decay products for all the cohorts. Factors able to influence this dose-response relationship have been discussed recently in a paper which summarizes the results of this joint analysis (1). An inverse dose-rate effect has been observed in 10 out of the 11 cohorts (2). This inverse dose-rate effect has not yet been demonstrated for low cumulated exposures (< 50 WLM*). Its implication in the extrapolation of the risk coefficient obtained in these miners studies to the risk estimated for domestic radon could be of main importance, because it would lead to higher risk estimation for low chronic daily exposures protracted over the whole duration of life than for the same total exposure cumulated in only a few years. The purpose of our project is to focus on the different factors involved in the study of a low chronic exposure: precision of individual dosimetry, comparability of the cohorts in dosimetric survey, duration of exposure, confounding factors.

EUROPEAN PROJECT ON URANIUM MINERS STUDIES

A European project has been accepted for the next 4 years by the Commission of the European Union (DG XII), in order to study more precisely the different components able to influence the dose-response relationship obtained by the miners studies.

In the large joint analysis, realized by the NCI, not only uranium miners were included but also other miners (iron, tin.....), the criteria of inclusion being the existence of measured information about radon exposure for at least part of the working period. In the European project, only uranium miners will be included, in order to eliminate components which may be present in other types of mines and could influence the dose-response relationship between lung cancer and radon exposure.

The following uranium miners groups will contribute to this European project:

1. Two cohorts of miners from the Czech Republic, defined by the period of entry in the mines and by the region;

2. Two cohorts of uranium miners in France, characterized by the period of entry and, in parallel, by the precision of exposure estimation;

3. A very large group of uranium miners from Germany, having experienced a more or less precise survey of exposure depending on the period of work.

The results concerning the Czech and French uranium miners cohorts have already been partially published and these cohorts are presently undergoing an extension of follow-up with a new estimation of the risk coefficient next year. The German large group needs more time to be followed up in a precise way and the first step decided in the European project is a case-control approach with the aim of identifying other components, like tobacco, able to influence the risk of lung cancer amongst uranium miners.

Consequently the European project is supporting two parallel approaches: the first is estimating the dose-response relationship and its modifying factors, the second is a case-control approach, testing first the feasibility of the collection of different factors directly or indirectly linked to the mining environment. The different steps of the cohort approach are described hereafter.

EXPOSURE ASSESSMENT

The first step of the Czech-French collaboration will be a critical examination of the individual exposure estimation for the different periods of work. This exposure assessment will be discussed not only for radon and its decay products, but also for gamma and long lived uranium dust exposure. A job matrix will be elaborated, mainly to test consistency of the individual exposure for the periods during which direct measurements were rare.

Both the Czech and French cohorts are characterized by a long duration of exposure, giving the opportunity for testing the risk for different durations of exposure and, giving in parallel some guaranty for describing the whole history of an individual mining experience. Indeed, in the joint analysis of NCI, a previous experience of some other mining activity was a modifying factor of the dose-response relationship. Including in this joint analysis mining populations with a very short duration of underground mining (for example less than 2 years) as well as those having passed all their working activity in the same type of mine may also have introduced some bias, these populations being probably different with respect to many other factors.

Distribution of the registered exposures shows a time-dependent variation, linked mainly to the period at which radioprotective measurements were introduced in the mining environment. This period of decline of the annual exposure rate is the same in the Czech and French cohorts, close to the year 1956. Since that time, the individual registration of the exposure is complete and has been realized in time, on a regular basis. Consequently exposure assessment has to focus on different periods of exposure, but mainly on the ten first years, when individual exposure was estimated indirectly. In France, since 1956, the same approach of dosimetric survey has been applied to all the miners and has been registered in time.

For estimating the risk linked to chronic low annual exposure, limiting our cohort analysis to those miners who had begun to work underground since 1956 is probably the best unbiased approach, provided the power of our study is high enough to estimate this risk linked to low annual exposure. Increasing the number of miners by a joint analysis of the Czech and French underground miners makes this analysis more realistic. The opportunity of including or excluding those having worked before 1956 will be tested in this common approach. For those miners entered since 1956, a registration of the gamma exposure and ore dust was done in time on an individual basis in France. Approaching a risk linked to low exposure needs a high precision in the individual exposure and an accurate estimation of confounding factors, mainly of those concomitant to the radon exposure. The analysis will be realized by joining the three following cohorts:

- French miners having worked underground for at least 2 years and having begun underground work before 1972. The French cohort may be extended to a larger group in the future, the follow-up of those having entered since 1972 being not yet complete;

- Czech S cohort, including west Bohemian uranium miners (Jachymov, Horni Slavkov, Chodov), first empoyed between 1948 and 1959;
- Czech N cohort, including uranium miners in central Bohemia (Pribram), first employed between 1968 and 1974.

Considering the present endpoint of follow-up in December 1990, the French cohort is contributing with 1,785 miners for 50,000 person-years, each of the two Czech cohorts respectively for 100,000 person-years, with 4,230 miners in the S cohort and 5,625 miners in the N cohort.

The following table indicates the distribution of mean annual exposure in WLM*, from 1946 to 1990.

Table 1: Mean annual radon exposure ($WLM.y^{-1}$) in the cohorts

Period	French cohort	Czech S cohort	Czech N cohort
1946 - 1950	25.5	50.7	
1951 - 1955	30.5	21.9	
1956 - 1960	2.9	11.8	
1961 - 1965	2.9	9.6	
1966 - 1970	3.5	6.4	1.0
1971 - 1975	2.8	1.8	1.1
1976 - 1980	1.8	0.8	0.8
1981 - 1985	1.0	0.8	0.6
1986 - 1990	0.4	1.2	0.6

** WLM (Working Level Month) is a unit of exposure multiplying a concentration of radon decay products by the duration of exposure. A yearly exposure to 11 WLM corresponds roughly to a monthly exposure to 1 WL, the monthly exposure being defined as 170 working hours. 1 WL is equivalent to any combination of radon decay products in 1 liter of air, that results in the emission of 130,000 MeV of energy of alpha particles.*

METHODOLOGY OF STATISTICAL ANALYSIS

The methodology of statistical analysis is close to the one used for the joint analysis by NCI, but with two modifying points: the time dependent modelling of the dose-response relationship includes also an approach with an external reference group and a different concept of the influence of the rate effect. The usual approach to analyse the exposure rate effect is based on a variable defined as the proportion of cumulative exposure and corresponding cumulative duration of the exposure. However, due to ventilation improvement in the mines, the actual exposure rates were different not only within single studies but also during separate miners' employment periods. Consequently, to take into account the fast decline in time,mainly (between 1955 and 1956), we propose a new approach based on exposure rate windows. The individual cumulative 5 year lagged exposures at each moment of the follow-up are split into four windows according to radon concentrations, the first group being as low as achievable. In other words, if the number of cancers is high enough for the estimation of the risk linked to low doses, then the distribution of annual exposures, as described in table 1, makes it possible to estimate the lung cancer risk for radon concentrations as low as 0.1 to 0.3 WL. These concentrations are lower than those achievable in animal experiments and comparable to annual exposures of 1.1 to 3.3 WLM which correspond to annual radon concentrations indoor comprised between 200 and 700 $Bq.m^{-3}$.

CONCLUSION

We consider that the follow-up of low exposed miners will be, in the next years, the best way for testing the linear dose-response relationship and its possible modification by the exposure-rate effect in the field of low chronic alpha radiation exposure, provided that a precise information on individual exposure to radon and to other confounding factors is available.

INTRODUCTION

In the centre of a region of granitoids, carrying geological term the Central Bohemian Pluton, is a smaller area with considerable geological disturbances comprising 80 villages with 2501 houses. The houses situated on the lines of such breaks exhibit very high levels of radon-222 and products of its transformation. In the adjacent houses outside the lines of disturbances the levels are manifold lower, being still higher than the average value in the country (40 Bq/m^3 of the equivalent equilibrium concentration of radon -EEC). Other conditions being also favourable for assessing possible effects of cumulated radon exposure, e.g.. prevailing agricultural character of the area with only small migration of inhabitants, a prospective (non-parallel) cohort epidemiological study was started in 1991 by the late Josef Ševc.

METHODS

The study population includes inhabitants of the area, who had resided there for at least three years and at least one of these between 1.1.1960 and 31.12.1990. Persons with mining experience were not included in the cohort.

Data on vital status of each cohort member, residences in the past, smoking habits, occupational and other exposures have been collected through interviews of residents or relatives at home during which also data on constructional changes of buildings have been gained. Information on vital status and causes of death was collected from and/or verified at the local authorities, in the national population registry and in the health documentation of the corresponding district hospital or oncological facilities and their pathologico- anatomical departments (with regard to histological characteristics of the tumour).

Cohort members were entered in person-years accumulation either at 3 years after their birth for those born after 1960 or at 1961 for those born before 1960 and removed at the earliest date of death, emigration, or termination of follow-up. Expected numbers for mortality analyses were taken from the country statistics.

One year lasting measurements of radon daughter products by integral dosimeters (Kodak film LR 115) were performed in almost all the dwellings of the specified area (mostly 2 detectors in a house).

Individually estimated exposures were calculated by combining residence information (number of years spent in the study area) with exposure measurements in the resident dwellings). At this stage of the study the concentrations measured in a particular year (1991 or 1992) were taken as representative for all the time an individual lived in the dwelling and no specific methods were used for the assessment of previous exposures, as will be done further (measurement of Pb^{210} in surfaces, evaluation of possible influence from construction changes in the building, chromosomal analysis etc.). Fot the time spent outside the study area the country mean values were applied. Missing measurements within the study area were replaced by the corresponding site means. Individual exposures in the last 5 years were ignored (lagging) for the analysis of relation of cancer incidence to the cumulated exposure.

RESULTS AND DISCUSSION

Table 1. displays the distribution of 3727 measurements performed in the greater part of area houses , especially in permanent dwellings (1869 out of 2501), the measurements in the other part (mostly consisting of houses used for recreational purposes) are being actually revised.

Table 1: Distribution of the equivalent equilibrium concentration of radon (EEC) in 1869 houses.

EEC Rn $Bq.m^{-3}$	N(3727)	%
20-99	170	9
100-199	514	28
200-499	895	48
500- 999	246	13
1000-	44	2

The overall mean was 327 $Bq.m^{-3}$ and the maximum value found was 11 000 $Bq.m^{-3}$. The existence of two groups of dwellings with different radon levels both substantially higher than the indicated average country value was confirmed.
Maximum individual cumulated exposure found was 386 $Yr.kBq.m^{-3}$, the mean value among the cohort members was 13 $Yr.kBq.m^{-3}$.
A total of 11865 inhabitants satisfied the above mentioned criteria, however, 485 people had to be excluded for the given analysis because of incomplete data. By the end of 1994 in the cohort of 11379 persons, 2769 death were registered and their cause of death identified. The distribution of the death causes by calendar period is given in table 2.

Tab 2: Cause and calendar period specific mortality.

		lung ca		non lung ca		violence		other		unknown	all causes	
Period	PY	O	O/E	O	O/E	O	O/E	O	O/E	O	O	O/E
1961-65	27 468	12	0.83	52	0.90	8	0.36	197	0.94	6	275	0.90
1966-70	31 507	16	0.81	62	0.85	24	0.80	282	1.01	10	394	0.98
1971-75	32 720	27	1.25	72	0.91	20	0.64	269	0.84	17	405	0.90
1976-80	34 537	25	1.08	68	0.81	21	0.64	312	0.87	11	437	0.88
1981-85	36 450	34	1.45*	68	0.80	23	0.71	358	0.95	13	496	0.96
1986-90	38 476	20	0.83	73	0.83	26	0.79	329	0.94	9	457	0.92
1991-94	31 901	11	0.56	43	0.61	17	0.60	184	0.67	50	305	0.78
total	233 060	145	0.99	438	0.81	139	0.66	1 931	0.89	116	2 769	0.91

Table 3. relates the ratio of observed to expected fatal lung cancer cases to individual cumulative exposure by 1990.

Table 3: Lung cancer mortality by cumulative exposure categories by 1990.

Exposure category (Yr. kBq. m^{-3})	Person- years	O	O/ E
0- 4	79 556	7	0.78
5- 9	51 294	22	0.81
10- 19	50 591	69	1.26*
20-29	15 279	25	1.02
30-	6 480	11	0.99
total	203 201	134	1.06

The coefficient of the excess relative risk per unit exposure (Yr.kBq. m^{-3}) calculated from these data is 0.019 with 95 % confidence interval 0.006- 0.032, which using conversion factors recommended in ICRP publication No. 65 (1) on assumption of 7000 hours per year of exposure and equilibrium factor 0. 4 corresponds to 0.01 and 0.004- 0.02 per WLM. This value falls within the range of risk coefficients found in eleven epidemiological studies on miners (2) and is near to the most recent finding in the Czech uranium miners (3).

These results must be considered as preliminary only, the collection of the data on mortality and improvement of exposure estimates, resulting e.g. from methods, indicating the possible value of previous exposure, still proceeds and possible significance of important factors, which can contribute to the lung cancer mortality, such as smoking, were not yet evaluated. Although the majority of deaths in the cohort has already been registered, further cases might be identified a.o in those respondents who moved out from the area.

Data on individual cumulative exposure and lung cancer incidence will then be analysed by appropriate statistical methods, taking account of the factors which can influence the lung cancer incidence such as age, gender, smoking habits, exposure to another noxae in occupation etc. For the analysis, regional and national data on age and gender specific lung cancer mortality as well as an internal control group approach will be used. An evaluation of the collected information by the nested-in case control approach, which would enable better comparison with the data from other epidemiological indoor radon studies, prevailingly of the case- control type, will be applied too.

INTRODUCTION

Long term exposure to radon and its progeny is one of the most important health problems. Epidemiological studies have demonstrated that exposure of miners to radon in a mine atmosphere can cause lung cancer. It has been recognized that lung cancer risk in uranium miners is associated with increased incidence of certain histological types, especially epidermoid and small cell type (1, 2). Previous results showed that the basic dependence of the relative risk for the two main histological types is linear with cumulative exposure (3). However, there is a suggestion that time and age modifiers of the dependence may be different for the two types. The aim of the study was firstly to verify the assumed differences in incidence of histological types of lung cancer for the studied cohort and general population and secondly to characterize the relation of histological types specific incidence to different exposure patterns.

The study is based on data of the oldest Czechoslovak cohort, which belongs among the largest ones with the longest follow-up. The cohort includes 4320 former uranium miners who started working in uranium mines in West Bohemia in the period 1948-59, the work lasted more than 4 years (4, 5). The study method is long-term prospective follow-up. The cohort was divided in two groups according to exposure rate pattern in order analyze the impact of exposure conditions on main histological types incidence. The exposure rate never exceeded the level of 5 WL since the third year of exposure in the group 1 while the exposure rate exceeded at least once the level of 5 WL in group 2. The first two years of exposure had not been taken into consideration in order to confirm the hypothesis about the inhibitory effect of high exposure rate levels. Consequently, it could influence lung cancer risk level caused by previous exposures.

The basic method of the study is an analysis of observed frequencies of lung cancer and their histological type specification in relation to expected standardized frequencies (age and time period). In accordance to WHO classification and from previous data analysis (6), lung cancer cases were divided into four groups:

1 - epidermoid
2 - small cell
3 - adenocarcinoma
4 - other histological types

RESULTS

A total of 705 lung cancer cases were recorded by 31 December 1990. The ratio of observed and expected numbers was 5.11. Morphological diagnoses were available in 458 cases. This represents histological type specification in 65% of lung cancer cases in the cohort as shown in Table 1.

Tab. 1: Distribution by histological types

Histological type	Code	Cases	%
no information	0	201	28.5
epidermoid	1	173	24.5
small cell	2	185	26.2
adenocarcinoma	3	31	4.4
other types	4	29	4.1
unspecified	5	40	5.7
no material	9	46	6.5
Total	-	705	100.0

Tab. 2: Age and histological type specific mortality

Age	Small cell		Epidermoid	
	O	O/E	O	O/E
- 44	24	35.02	7	10.64
45 - 54	71	11.97	39	7.20
55 - 64	65	4.27	81	5.39
65 - 84	25	2.65	46	3.79
Total	185	5.91	173	5.20

Histological types could not been specified in 41% of cases. In 40 cases the morphological findings are available (code 5), but it is impossible to specify any reliably histological type from these. In 46 cases, no material is available to specify the histological type (code 9),althought the diagnosis of lung cancer is correct.

Table 2 summarizes observed (O) and expected (E) death frequencies in dependence on attained age for both main histological types. The decrease of relative risk with age is apparent in both histological types. A more detailed analysis shows that decrease of relative risk in epidermoid type is less rapid than in small cell type. From this fact follows that risk of lung cancer death will be significantly lower in small cell carcinoma than in epidermoid one in higher age of former miners. This is the contrary of situation in younger age groups of miners.

Table 3 demonstrates dependence of relative risk on cumulated exposure (lagged by 5 years) for the two types. The relative risks show similar values in corresponding exposure categories.

Tab. 3: Exposure and histological type specific relative risk

Exposure WLM	Small cell		Epidermoid	
	O	O/E	O	O/E
0 - 99	18	2.72	17	2.42
100 - 199	69	5.03	62	4.26
200 - 299	48	8.36	42	6.98
300 - 399	21	7.72	21	7.07
400 -	29	11.68	31	11.52

RISK MODELS

Epidemiological studies have demonstrated that time since exposure and attained age considerably influence excess relative risk of lung cancer (7). In this study, the modifying effect of three factors on exposure - risk relationship was examined (Table 4):

(1) time since exposure (TSE),
(2) age at exposure (AM),
(3) time pattern (TP).

Tab. 4: Relative risk models for histological types

ERR/WLM	Epidermoid	Small cell
	0.066	0.329
TSE		
5 - 14	1	1
15 - 21	0.926	0.110
25 - 34	0.150	0.014
35 -	-0.016	0.008
AM	-0.0338	-0.0878
TP	0.708	0.534

The estimated values of model parameters for the two histological types show important differences (Tab.4). The ERR/WLM was 6.6% in epidermoid and 32.9% in small cell type (5 times higher). The effect of time pattern was found significant in small cell type and not in epidermoid type, which confirm hypothesis about parallel inhibitory effect of alpha radiation on small cell type of lung cancer. Significant negative values of the AM parameter confirm the assumed decrease of lung cancer risk with age at exposure. This trend is more pronounced in small cell type.

SUMMARY

The recent results of the study confirme the linear dependence of exposure and relative risk, decrease of alpha radiation effect with time since exposure and decrease of effect in older age categories.

More detailed analysis of exposure - effect relationship in main histological types of lung cancer confirmes hypothesis formulated by J. Ševc about parallel inhibitory effect of alpha radiation in higher exposure rates which followed after period of initiation of malignant process of bronchial epithelium cells. This phenomenon is observed in small cell type of lung cancer. These conclusions are based on application of proportional risk model.

ABSTRACT

The deceases by respiratory cancer(bronchopulmonary and laryngeal) arised among miners from two uranium mines for the period 1960-1993 were studied.The control groups were formed by the male population deceased by the same cause in the native localities of the miners.

It resulted an enhanced occurrence risk of lung cancer among miners in comparison to the unexpected controls.

INTRODUCTION

Bronchopulmonary cancer is a specific occupational desease for uranium miners,the cause being the protracted exposure to high levels of alpha active radon daughters; depending on the magnitude of the pulmonary doses the desease occuring after 10-15-20 years from the beginning of exposure.(1-3)

For the knowledge of sicken risk by cancer of respiratory tract(bronchopulmonary and laryngeal) among uranium miners it was conducted an epidemiological study for two uranium mines from Romania for a 34 years period(1960-1993).

METHODOLOGY

The studied period(1960-1993) was established on the basis that a longer study period offers a higher certainty to find respiratory cancer among uranium miners.Were chosen out the localities that have provided the working force for the two mines,after that,from official records, were extracted the deaths by respiratory cancer among the adult male population.

Then fallowed the identification of retired miners from personnel records.So,it could be established the occupational route, the level of cumulative exposure to radon(WLM) and the smoking habit for each miner deceased due to respiratory cancer.

The controls were made up by unexposed adult male population from the native localities of the miners.

The statistical computations had in view the incidence of deaths/10.000 person-year, the expectancy, the observed/expected cases ratio and the relative risk coefficient.

The interpretation of data was made depending on age, years of underground service, cumulative exposure to radon and smoking habit for the miners, but on age for controls.

RESULTS AND DISCUSSION

The study group for Mine I was of 28,796 persons from 22 localities and for Mine II was of 8,164 persons from 2 localities.

In the period 1960-1993, in the areas of Mine I and Mine II were observed 103 deaths by respiratory cancer among miners and 480 among controls, respectively 34 among miners and 130 among controls.

As regarding the anatomical position in the respiratory tract, as for miner as for controls, obviously prevailed the bronchopulmonary cancer (over 80%).

The incidence of deaths by respiratory cancer is significantly increased among miners in comparison to controls ($p<0,001$) : almost 6 times higher for Mine I and almost 3 time higher for Mine II (Figure 1)

Incidence/10,000 person-year

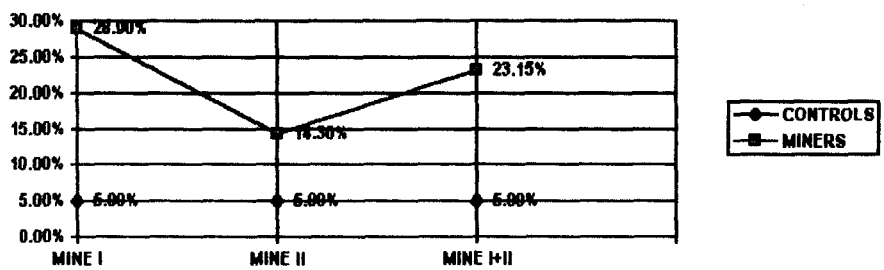

Figure 1. The incidence of deaths by respiratory cancer for the miners from Mine I and Mine II in comparison to the controls(1960-1993)

The risk of being taking ill by respiratory cancer, as expressed by the observed/expected cases ratio, as well as by the relative risk coefficient, it is significantly higher for miners in comparison to controls (Mine I:5,78>1.00 and Mine II : 2.80>1.00).

The average age at death for the miners from Mine I and Mine II(57.5 and 53.8years,respectively) is significantly lower($p<0,001$) in comparison to the controls(61.7 years and 61.3 years,respectively).(Figure 2)

Figure 2. Mean age at the date of death by respiratory cancer for the miners from Mine I and Mine II in comparison to controls(1960-1993)

The average years of underground service for the deceased miners from the two mines are 15 years for Mine I and 12 years for Mine II, predominanting the service in uranium mines: 11.3 years for Mine I and 11.1 for mine II.

As for the cumulative exposure to radon, deceases by respiratory cancer show enhanced ratios among miners having a cumulative exposure over 120WLM(Figure 3).The average exposure of the 103 deceased miners form Mine I was 401.1WLM and that for the 34 deceased miners from Mine II was 119WLM.

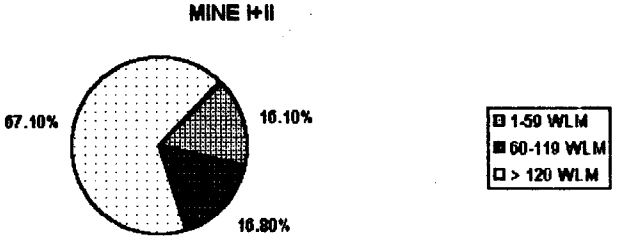

Figure 3.Distribution of deaths for the miners from Mine I and II versus cumulated exposure to radon(1960-1993)

The information regarding smoking habits of Mine I miners allowed to correlate the frequency of deaths and smoking habits, being proved the sinergetic effect of exposure to radon and smoking. The risk coefficient due to smoking is more obvious if the deaths are discussed in comparison to the smoking index(4)(no. of daily smoked cigarettes multiplied by no. of years of smoking):the proportion of respiratory cancer cases is 62.4% for smokers, with an index higher than 500, in comparison to only 4.3% for those having an index under 150.

The latency period calculated for miners deceased by respiratory cancer averaged to 26.7 and 21.0 years for Mine I and Mine II, respectively. The significantly increased incidence of deaths among miners, the obsviously lower age at death in comparison to controls, taking into account, also, the level of occupational exposure prove the occupationl character of respiratory cancer among uranium miners.

CONCLUSIONS

The epidemiological study of deaths by respiratory cancer among uranium miners proved that the increased incidence of deaths, much higher in comparison to controls(5.7 times for Mine I and 2.8 times for Mine II), is due to cumulative exposure to radon and its daughters, and it confirmed the occupational

character of deceases. Also, it can not be neglected the sinergetic effect of smoking, over 90% from the deceased miners being smokers.

DOSE AND RISK ASSESSMENT FROM RADON IN THE URAL

Mikhail Zhukovsky, Ilya Yarmoshenko
Institute of Industrial Ecology Ural Branch of RAS,
Ekaterinburg, Russia

INTRODUCTION

The radiation situation in the South and Middle Urals is quite complicated due to two main reasons:

- High radon exposure levels derived from the geological structure of Ural region (relatively high concentrations of U and Th in lithosphere, ground waters with high Rn concentration, increased permeability areas etc.).
- Consequences of radiation accident at "Mayak" nuclear plant in 1957. As a result of this accident a considerable territory of Chelyabinsk and Sverdlovsk regions was polluted by mixture of nuclear fission products $^{90}Sr+^{90}Y$ - 5.4%, $^{95}Zr+^{95}Nb$ - 24.9%, $^{144}Ce+^{144}Pr$- 66%, $^{106}Ru+^{106}Rh$ - 3.7%, ^{137}Cs - 0.036% (the so called East Ural Radioactive Trace - EURT).

The main purpose of this paper is to compare the radiation risks due to equivalent doses in different organs and effective doses resulting from radiation pollution and radon and thoron daughters exposure.

METHODS OF MEASURING Rn AND Tn CONCENTRATIONS

The survey was made by the following two methods: aspiration technique of measuring of equivalent equilibrium concentration of radon and thoron and determination of season mean concentrations of Rn by applying the nuclear track nitrocellulose detectors. The cellulose nitrate films were used as sensitive materials. The cellulose nitrate detector was placed in special plastic chamber, provided with silicon rubber filter preventing the penetration of ^{220}Rn and radon daughters into chamber space. The measuring chambers with detectors were exposed for 1-3 months. Detectors were etched in 6N NaOH solution after exposition and track density was determined by spark counter.

The equilibrium equivalent concentration EEC of radon and thoron was determined by Markov modified method [1].of measuring filter α-activity after deposition of radioactive aerosols on it. For measuring of equivalent equilibrium concentration of radon and thoron we used both serial alpha-radiometers and devises developed at our Institute together with the Urals State Technical University. The results obtained by both methods correlate well.

DOSE ASSESSMENT

The intake of radionuclides for EURT zone due to inhalation and food chains was estimated by the official Methodical Recommendations [2]. Equivalent doses for different organs and effective doses were calculated using ICRP Publication 56 data [3].

The data on average annual gaseous radon activity (C_{Rn}), equilibrium equivalent concentration of thoron (EEC_{Tn}) and annual exposure effective doses (E_{Rn}, E_{Tn}) in various districts for village types of buildings are shown in table 1. Doses due to radon and thoron daughters exposure were calculated using ICRP Publications 50 and 65 [4,5].

During our investigation we obtained that the very high concentrations of thoron daughters are characteristic for the Urals region. Average world value of annual effective exposure dose due to thoron is listed in Report of UNSCEAR, 1993 [6] and is equal to 0.067 mSv/a. So, we can see that the thoron exposure in the Urals is an order of magnitude higher than the average world values.

Table 1

Average annual gaseous radon activity, equilibrium equivalent concentration of thoron and annual exposure effective doses in Sverdlovsk region

District	C_{Rn}, Bq/m^3	E_{Rn}, mSv/a	EEC_{Tn} Bq/m^3	E_{Tn}, mSv/a
Bogdanovich	117.1	2.1	3.7	1.3
Kamensk	110.7	2.0	2.6	0.91
Rezh	231.6	4.1	3.8	1.3

RISKS ASSESSMENT

During our work we used some assumptions and risk projection models :

1. Absolute risk model for risk assessment of leukemia [7].
2. Constant relative risk model for assessment of total cancer risk excluding leukemia and some internal organs [7].
3. Modified relative risk model (Jakobi model) for risk assessment of lung cancer due to radon and thoron daughters exposure [5].
4. For all risk projection models we assumed linear no-threshold dose response.

Risk comparing was made for rural districts of Sverdlovsk region: Kamensk and Bogdanovich which were polluted during the radiation accident on "Mayak" nuclear plant in 1957. For considered in this paper territories the average surface contamination by ^{90}Sr was ~3 Ci/km^2. The Rezh district was chosen because it's the district with maximum radon exposure rate in Sverdlovsk region. Statistical data on survival probability, mean life expectancy (L_m=59.7, L_f=71.4 years) and baseline cancer risks typical for Sverdlovsk region were used for risks assessment. Relatively low regional survival probability and mean life expectancy decreases radiation cancer risks in comparison with thatin the developed countries.

The results of radiation risk assessment and the attributable excess cancer death frequency F_r are listed in table 2. For individual organs the equivalent doses are shown, for total cancer risk assessment - the effective doses without contribution of red bone marrow. For radon and thoron exposure the average annual effective doses are shown.

As one can see from the table 2 the lifetime radiation risks due to radon exposure in the village houses in Sverdlovsk region are comparable to or exceed the radiation risks due to serious radiation accident.

ESTIMATION OF INFLUENCE OF RADIOACTIVE FACTOR ON CANCER RISK AMONG INDUSTRIAL CITY DWELLERS

Eugene V.Polzik, S.V.Kuzmin, B.A.Katsnelson,V.S.Kazantsev

Institute of Industrial Ecology, Ekaterinburg, Russia

The estimation of the role of chronic radioactive exposure (ChRE) in development of malignant neoplasms under the conditions of constatnt exposure of population along with radiation to other carcinogenic factors is a complex epidemiological problem. Such situiation is typical for city Kamensk-Uralsky (Middle Urals, Russia), where some enterprises intensively polluting the environment with carcinogenic substances are located (i.e. the aluminium-smelting plant). In 1957 the city was subjected to the influence of radioactive fallout as a result of an accident at PA "Mayak" and forming the East Urals Radioactive Trace (EURT). The most contaminated was the north-western part of the city, where the contamination density was about 4 Ci/Sq.km by Sr-90, at the rest of the territory it was about 1 Ci per Sq.km. Cancer incidence in Kamensk-Uralsky during 1960-1994 has increased 1,8 fold, but it can hardly be connected only with the influence of radiation.

The city has a population of 210 000, which is served by oncological centre. The materials of this centre made it possible to form sufficient groups of cases for our study and to obtain all the necessary information about each of them. The base cohort for the information of control groups was the part of the population that had never had any neoplasms diagnosed.

Many cancer risk factors are well known. That's why the influence of one of them (in this particular study - radioactive exposure) may be estimated only in the result of multifactorial analysis. For this analysis we used the pattern recognition methods, that have proved their effectiveness in many other medico-ecological studies(1,2,etc.).

Some investigations were held aiming at estimation the role of radioactive factor in development of cancers of three most widespread sites: lung,stomach and breast. Information about all known cancer risk factors for both "case" and "control" groups was collected. The information included data concerning age, sex, nationality, smoking habit, alcohol abuse, diet, residing in one of the 4 areas differing in intensity of non-radiational ecological contamination, residing close to a major industrial atmospheric polluter, occupation, duration of occupational exposure to carcinogens, characteristic of housing conditions (building materials, plastic flooring in the house, gas stove), chronic diseases, family cancer history, predisposition phenotype evaluated by the peculiarities of dermatoglyphic pattern (palm and finger prints) on the basis of previously elaborated criteria, length and strength of radioactive exposure.

Diversity and lack of reliable information on radiological situation in EURT zone in Sverdlovsk region after the accident gave no opportunity to obtain the reliable retrospective data concerning the individual radiation doses for the dwellers of this zone. ChRE is estimated by two indirect parameters: (a)the fact of residing in the north-western (most contaminated) part of the city during the years of maximal radioactivity of the territory (1957-62) and (b) total length of residing in the EURT zone.

In our breast cancer studies the information of risk factors was completed by the data about gynecological status of women. In lung cancer studies the analysis embraced in total 18 factors. Basing on this results it was shown that this information

is sufficient enough to reliable discrimination between the "case" and "control" patterns. Along with this the quantitative estimation of each factor influence was given (Table 1). The results of similar analysis of complex of 22 risk factors for breast cancer and 20 risk factors for gastric cancer are shown in Tables 2 and 3.

At analysis of studied cancer risk factors we noted first of all the expected character of their interrelation with the disease. For example , risk of cancer development was higher in smokers, in workers of aluminium smelting plant, it has increased with age ,etc. This particular coincidence of obtained results with the already proved influence of some biological and environmental factors on malignant neoplasms development made it possible to estimate adequately the role of ChRE, that proved to be quite sufficient. Moreover, it was noted, that risk of development of cancer of all three studied sites increases with both duration of residing at the EURT territory and, particularly, with residing in the most radioactively contaminated zone during the years of maximal intensity of radioactive contamination (1957-62).Thus,applying the special methods of analytical epidemiology and multifactorial analysis gave us an opportunity to receive the proofs of the chronic radioactive exposure influence on cancer incidence among the dwellers of EURT zone.

Table I

COMPARATIVE DEGREE OF INFLUENCE OF THE MOST SIGNIFICANT LUNG CANCER RISK FACTORS (for population of Kamensk-Uralsky)

Rank	Name of the feature	Comparative informativity (relative units)
1	Sex	1.000
2	Smoking	0.749
3	Occupation	0.360
4	Building material	0.319
5	Residing in the zone of maximal radioactive contamination in 1957-1962	0.247
6	Age	0.245
7	Alcohole abuse	0.207
8	Genetic predisposition	0.152
9	Chronic obstructive lung disease	0.152
10	Residing close to a major industrial atmospheric polluter	0.136
11	Plastic flooring in the house	0.098
12	Total length of residence in EURT zone	0.087

Table 2.

COMPARATIVE DEGREE OF INFLUENCE OF THE MOST SIGNIFICANT BREAST CANCER RISK FACTORS (for population of Kamensk-Uralsky)

Rank	Name of the feature	Comparative informativity (relative units)
1	Menopause	1.000
2	Alcohol abuse	0.844
3	Residing in the of zone of maximal radioactive contamination in 1957-62	0.676
4	Building material	0.581
5	Residing in the zones of various degrees of non-radioactive technogenous pollution	0.516
6	Total length of living inthe EURT zone	0.491
7	Genetic predisposition	0.339
8	Gas-stove	0.339
9	Occupation	0.248
10	Age	0.245
11	Family cancer history	0.216
12	Plastic flooring in house	0.175

Table 3

COMPARATIVE DEGREE OF INFLUENCE OF THE MOST SIGNIFICANT GASTRIC CANCER RISK FACTORS (for population of Kamensk-Uralsky)

Rank	Name of the feature	Comparative informativity (relative units)
1	Sex	1.000
2	Occupation	0.498
3	Gastric diseases (gastritis,ulcer)	0.460
4	Smoking	0.451
5	Genetic predisposition	0.364
6	Alcohol abuse	0.326
7	Age	0.249
8	Residing close to a major industrial atmospheric polluter	0.231
9	Residing in the zones with various degrees of non-radioactive technogenic pollution	0.211
10	Gas-stove	0.195
11	Total length of living in the EURT zone	0.185
12	Residing in the of zone of maximal radioactive contamination in 1957-1962	0.139

DOCUMENTATION OF OCCUPATIONAL ACCIDENTS AND DISEASES BY IONISING RADIATION IN GERMANY

G. Seitz[1]; F. Fehringer[1]; G. Laude[2]; U.Wolf[2]

[1]Berufsgenossenschaft der Feinmechanik und Elektrotechnik, Köln; Deutschland
Industrial Injuries Insurance Institute for the Electrical Industry
including Precision Mechanics, Cologne; Germany
[2]Robert-Koch-Institut; Berlin

The investigation of accidents and diseases, caused by ionising radiation, is important not only from the more technical point of „accident prevention" but even more from medical and biological aspects in investigating human response to exposure of ionising radiation.
As industrial use of radiation sources grew rapidly from the 70th on, and so did the workforce handling the sources, it is evident, that the amount of occupational exposed persons who will now come to an age where (spontaneous) cancer diseases become manifest is also growing. There will be a certain number of people who will declare this disease being caused by the occupational exposure. Investigation and decision in such cases have to be performed in short time and will be enhanced by a good experience from former cases.
In Germany the workman's compensation institutions (Industrial Injury Insurance Institutes [IIII] - Berufsgenossenschaften) are responsible for all questions of medical care, rehabilitation and compensation of occupational accidents and diseases. They decided to provide a registry for all cases which came to investigation. Since 1980 the institute of radiation protection which was founded in the late 70th by two of this IIII (Berufsgenossenschaft der Feinmechanik und Elektrotechnik and Berufsgenossenschaft der Chemischen Industrie) is performing the data-collection. The quality of the data depends of course on the details which are reported to the Institute in each case and on the criteria, when at all a case should be reported to the registry. Unfortunately it was not possible to edit general reporting criteria. Each Industrial Injury Insurance Institute in Germany (there are 36 of them) decides by itself about the reporting criteria Of course this leads to a loss of information as is shown later.
For statistical purposes the numbers of occupational accidents and diseases, categorised to the causing influence, which have been announced for compensating at the IIII, are reported to the ministry of health and are edited in the annual „Accident Prevention report" of the federal government.
A more detailed view to this numbers can be derived from the annual report of the IIII´s association.
Figure 1 gives a annual distribution for the last ten years of all cases where overexposure was announced as reason of injury or disease and also shows how many cases left, where the investigation gave reason to certify this relation and where the injury or disease was acknowledged as occupational.

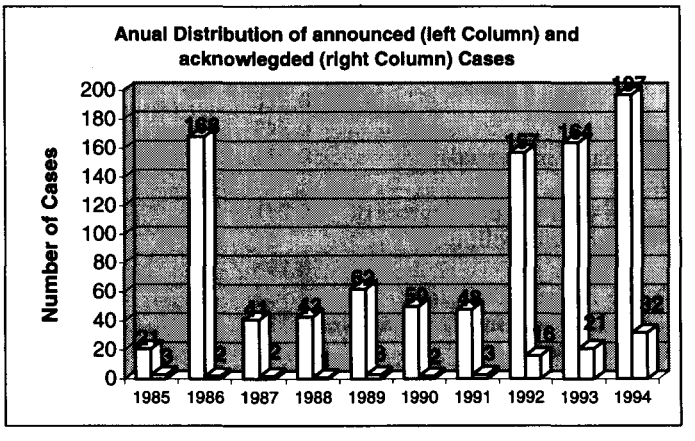

Fig.1 Annual distribution (1985-1994) of injuries and diseases which have been announced as occupational disease due to ionising radiation and which have been acknowledged as those.
(Without the numbers of the IIII of the mining industry - see text)

It becomes obvious, that the number of diseases which proofed to bee radiation induced is much smaller than the announced number. The peak at 1986 results from German workers in the former SU near Tschernobyl whose registration was done in precaution and without having been really exposed. Although the numbers of the IIII of the mining industry are taken off, the increase from 1992 on results from miners of the uranium mining in the former DDR. According to special regulations in Germany a certain number of those compensations have to be done by other IIII.

As can be seen from Fig.1. a total amount of 951 cases of announced diseases (and injuries) have been reported in Germany from 1985 to 1994. Not included in this number are the cases announced to the IIII of the mining industry. Further not included are the incidents which had happened in the former DDR.
Using the same criteria, we will find only documents of 361 cases in our registry. Only 37% of all cases are reported by the IIII to our institute.
An enhancement was brought in by updating the registry with the cases from the former DDR. The much more centralised system of occupational health and safety including radiation protection of the workers promoted the centralised collecting of the documents.
Including this cases and extending time to 1995 makes it possible to look to total of 517 cases.
As the health situation of the east German uranium miners is subject of special investigation programs, all of this cases will be omitted in the further analysis of this paper.
If doing so, 371 documents are remaining. 102 of them are connected to Tschernobyl as described previous. So there are left 269 files in the registry which indicate the situation in industry and health service. A view to the annual distribution of the year of announcement is done in fig. 2.

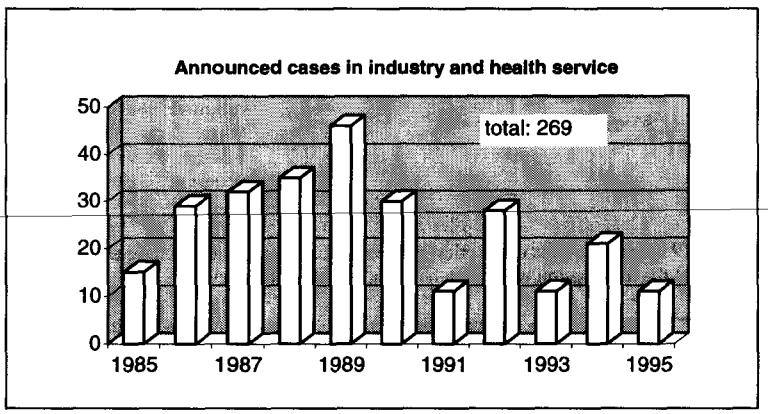

Fig.2 Annual distribution (1985-1995) of injuries and diseases which have been announced as occupational caused by ionising radiation. All cases connected to mining and the registered cases in connection with Tschernobyl (see text) have been omitted.

After a continuos increase until 1989, which corresponds to the increasing number of radiation workers, the numbers seem to decrease until today much faster than the number of radiation workers decreases (today about 340,000 persons). We presume, that this decrease is caused simply by rearranging the administration structures of the IIII after the German unification in October 1990 which led to a certain neglecting of reporting. It will be one of the next investigations of the registry to check this phenomenon.
The next step of analysis is to get a survey of the branches where the cases are coming from. This is indicated in fig. 3.

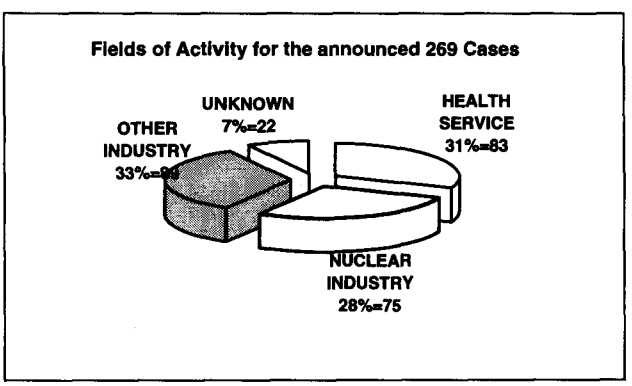

Fig. 3 Distribution of the left 269 announced cases to the reporting branches

According to missing reporting criteria, only in 165 of the 269 files we find a clear indication of the state of the case. That means, that 104 cases have been reported at a certain state of investigation, but the reported information was never updated. So we are not able to classify them, we even do not know, whether they are still in work, whether they are acknowledged or refused.

Finally we can work through the 165 remaining cases. Figure 4 shows that in 110 of this a decision was made: 19 have been acknowledged and 91 have been refused. In 55 cases work is still in progress.

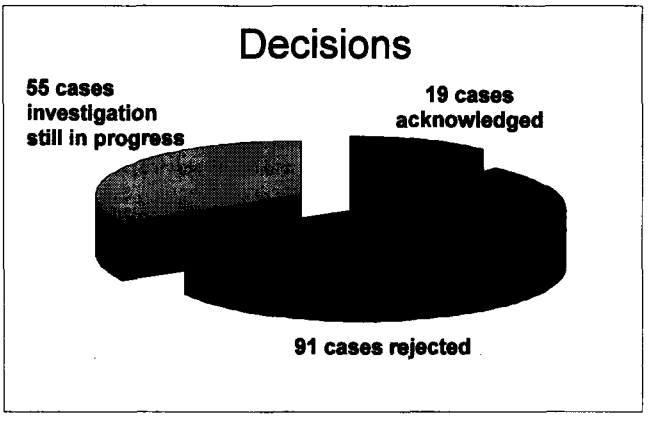

Fig.4 Only in 165 of the reported files is indicated which decision was made or whether the work is still in progress.

Interest is focused now to those 19 cases where the connection between radiation exposure and disease was accepted. The following tables list the information which can be taken out of the registry.

# of cases	Exposure
3	acute
15	chronicle
1	unknown

As can be noticed from this table, the by far most accepted diseases are caused by chronic exposure. 13 of these belong to the health service and concerns to physicians or medical personnel who used to apply X-rays - often in the 50th and 60th without adequate radiation protection measures. Two of the acute cases come from the non-destructive material testing and one is registered in health service again.

Information about diagnoses is sometimes poor and is given in the next table. Unfortunately, the dose information in the registry is quite insufficient. Even in cases of acute radiation injuries sometimes effective dose is reported but organ dose or skin dose is omitted. Sometimes a dose value is given but is obviously wrong. In other cases the reported unit of a dose-value does not fit the rest of the information.

# of cases	group of diagnoses/reported doses
2 acute	X-ray-burn; ulcers
4 chronic	cancer of homeopathic system/515 mSv/-/1500mSv/1000mSv all eff.
1 chronic	cancer of thyroid/1019mSv eff.
1 chronic	cancer of the skin/150 Gy org. (thumb)
9 chronic	unknown
1 acute	unknown

Although a lot of information can be derived from the registry, it is shown in this paper, that a reanalyses of the original data documents is necessary for enhancing the quality of the medical and dosimetric data.

Epidemiological Studies Using the National Dose Registry of Canada

Patrick Ashmore Radiation Protection Bureau, 775 Brookfield Road, Ottawa, Canada, K1A 1C1

Introduction

The National Dose Registry(NDR) is a centralised record keeping system for occupational doses of all monitored workers in Canada(1,2). Its foundation is Canada's National Dosimetry Service which was started by Health Canada in 1951. Since that time the Registry has expanded to receive and include records from nuclear power stations which perform their own dosimetry, uranium mines, and other dosimetry processors. It currently includes records for 520,000 workers some of which date back to the early 1950's. The workers are classified into 80 different occupational categories(e.g. radiologist, reactor mechanical maintenance)and the employing organizations into 14 different categories(e.g. hospital, reactor). The Registry resides on an HP3000 Model iX computer. It contains approximately 3.4 million annual summary dose records and an estimated 16 million discrete transaction or dosimeter records.

In addition to its use in epidemiological studies the Registry is also used to: i)assist the regulatory authorities in their control of occupational radiation exposures; ii)monitor long term dose trends and; iii) provide dose histories for use in radiation exposure planning and for use in compensation claims. The NDR is involved in a number of epidemiological studies on the long term effects of radiation. These will be described separately below.

Paternal Radiation Exposure and Childhood Leukaemia

This case control study(4) was undertaken in collaboration with the Ontario Cancer Treatment and Research Foundation who were the initiators and lead agency in the study. The study was prompted by findings which suggested a link between paternal radiation exposure and childhood leukaemia(3). Funding was provided by the Atomic Energy Control Board of Canada and Health Canada.

Cases were children ages 0-14 , living within the proximity of a nuclear facility in the province of Ontario who died from leukaemia or were diagnosed between 1950 and 1988. The facilities covered in the study are listed below.

Type of Facility	Location	Dates of Operation
Research and development	Chalk River	1944 - Present
Uranium Mining/Milling	Elliot Lake	1954 - Present
Uranium Refining	Port Hope	1934 - Present
Nuclear Generating Station	Rolphton	1962 - 1971
Nuclear Generating Station	Bruce	1967 - Present
Nuclear Generating Station	Pickering	1971 - Present

Out of a total of 3,366 childhood leukaemia cases in the province 112 were from within the proximity of one of the nuclear facilities. 8 controls per case were selected, matching on date of birth(within 3 months of case) and the region where the mother lived at time of birth.

Parents' names were taken from the children's birth certificates and a computer file of parents names was created. The names in this file were then linked to the records of the National Dose Registry in order to obtain any dose record information. Linkage was by computer and involved weighted linkage based on agreement of identifiers.Out of the 1002 fathers of the children(cases and controls), 95 linked to dose records in the Registry(84 controls and 11 cases) .

Dose records included dose from external gamma and neutron doses as well as internal dose from tritium and Radon daughters.Gamma doseś for Uranium miners were available back to 1981. Prior to that date dose estimates were used based on occupancy factors and mine characteristics.

The overall odds ratio was 1.07 with the 95 % confidence interval (95%CI)from 0.22 to 2.29. The findings thus do not support the hypothesis that paternal radiation exposure prior to conception is related to childhood leukaemia. Further details are shown in the table below.

Category	# Cases	# Controls	Odds Ratio(95%CI)
Never Exposed	101	806	1.00
Reactor Worker	4	48	0.64(0.22-1.86)
Uranium Miner	5	26	7.27(0.59-88.7)
Other/Unknown	2	10	1.59(0.34-7.44)
All Linked	112	890	1.07(0.50-2.29)

Cohort Mortality Study(1987)

This large scale cohort study(5) was initiated by Health Canada in the mid 1980's. Funding was by Health Canada, the Atomic Energy Control Board, and Statistics Canada. The cohort consisted of 206,426 workers(105,346 males, 101,168 females) in Canada who were monitored for external radiation between 1951 and 1983, and who had at least a surname, first given name, sex, and year of birth in their records. (This was necessary to ensure the successful linkage of the records). The total collective dose for the cohort was 12.9 person-Sv. The median attained age(as of 31, December 1987) was 41 years for males and 36 for females indicating that this is a relatively young cohort.

This cohort was linked to the mortality data base maintained by Statistics Canada using probabilistic record linkage techniques(6). Records in both files were grouped into phonetically equivalent "pockets". The identifiers of records in corresponding pockets of each file were then compared and assigned a weight based on the agreement between the identifiers. Records above a certain threshold weight were then deemed to be linked and belong to the same individual. This threshold weight was set at the point where the false positive link rate was equal to the false negative rate. The false links were identified by reviewing a sample of linked records and comparing with subsidiary information such as occupation and place of last employment.

Through this process a total of 5,430 deaths were identified. Cause of death was taken from the mortality data base and coded to correspond to the 9th revision of the ICD codes(7). Standardised Mortality Ratios(SMR's) relative to the Canadian population were calculated. Trend tests for mortality were undertaken in which the dose was lagged by 2 years for leukaemia and 10 years for solid tumours. A relative risk regression model was used to determine the excess relative risk(ERR).

A selection of the results is summarized in the table below. The overall SMR was 0.59 for males and 0.62 for females indicating a strong "healthy worker effect". While for males and females there were no specific sites which showed a significant trend($p<0.05$) or excess relative risk, the p-value for all cancers(males) was significant(0.041) as was the ERR(3.0). However this appears to be a weak association which disappears at the 95% confidence level.

Summary of Results - Males

Cause of Death	# Obs. Deaths	SMR	Dose Trend p value	ERR(% per 10mSv) (90% Conf. Int.)
Prostate	71	0.88	0.708	2.6(-5.0,10.1)
Multiple myeloma	17	0.73	0.802	6.5(-17.0,29.9)
Leukaemia	56	0.77	0.855	0.1(-4.7,5.0)
Leukaemia(Ex CLL)	46	0.83	0.733	0.4(-4.9,5.7)
Myeloid Leukaemia	27	0.88	0.379	1.9(-6.2,10.1)
All Cancers	1136	0.68	0.041	3.0(1.1,4.9)

Summary of Results(Cont'd) - Females

Cause of Death	# Obs. Deaths	SMR	Dose Trend p value	ERR(% per 10mSv) (90% Conf. Int.)
Multiple myeloma	5	0.69	0.875	0.2(-70.6,71.0)
Leukaemia	26	0.85	0.835	-0.2(-19.4,19.1)
Leukaemia(Ex CLL)	23	0.87	0.837	-0.2(-20.3,20.0)
Myeloid Leukaemia	11	0.71	0.858	-0.2(-20.5,20.2)
All Cancers	495	0.71	0.756	1.5(-3.3,6.3)

Cohort Cancer Incidence Study(1987)

A cancer incidence study using the cohort(1987) from the mortality study is currently in progress. This study is being funded by Health Canada. The cohort has been linked, using the same techniques outlined above, to a Cancer Incidence Reporting System maintained by Statistics Canada. A file of linked records for an estimated 5,252 workers from the cohort reported as having cancer has been created and is currently being analyzed. First analysis is expected to be completed in 1996.

Cohort Mortality Study(1994)

An updated NDR cohort has been created in preparation for updating the cohort(1987) study. The study is being funded by Health Canada. This study will include workers monitored between 1984 and 1994 and will also include uranium miners who were not included in the original study. In addition, a number of individuals who were left out of the original study because of lack of adequate identifiers have been fully identified and included in the updated cohort. The new cohort is estimated to contain 380,877 workers with a collective dose of 18,100 person-Sv.

Contribution to the IARC study on Nuclear Industry Workers.

Canada is also participating in the International Agency for Research On Cancer study of nuclear workers(8). A subcohort of the 1994 mortality study will be created for separate analysis and as Canada's contribution to the international study. It is estimated that the cohort of nuclear industry workers will consist of 58,000 workers.

Conclusions

As is shown above it is possible to use a centralised data base of occupational radiation exposures for epidemiological studies as well as for regulatory control and other purposes. While the requirements may be different for different purposes these can be accommodated by the careful design of the dose registries.(9)

GERMAN CONTRIBUTION TO THE INTERNATIONAL EPIDEMIOLOGICAL STUDY TO THE RISK OF WORKERS IN THE NUCLEAR INDUSTRY

M. Blettner,[1] F. Fehringer,[2] G. Seitz[2]

[1]Deutsches Krebsforschungszentrum, Abteilung Epidemiologie, Heidelberg
[2]Berufsgenossenschaft der Feinmechanik und Elektrotechnik, Köln

INTRODUCTION

The International Agency for Research on Cancer has initiated and coordinated epidemiological cohort studies among employees in nuclear industry in several countries with the aim to carry out a common analysis. The magnitude of the number of persons who are included in this study and the derived number of person-years is assessed in such a range that it should be possible to get information to the risk of carcinogenic effects after a chronic low-dose radiation exposure. The results of that analysis will be compared with the risk factors derived from persons who are exposed by high-dose radiation: e.g. the A-bomb survivors of Hiroshima and Nagasaki.

MATERIAL AND METHODS

A group of experts has worked out guidelines for the collection and analysis of the data (1). The study will only include persons who work in the nuclear industry. The German study population is restricted to workers of the nuclear power plants and larger contractors who are working as occupational radiation exposed persons of the category A as defined in the German radiation protection regulatons. The basis for the German data is a data collection of the Industrial Injuries Insurance Institute for the Electrical Industry including Precision Mechanics.

For reason of prevention of industrial accidents and occupational diseases the Industrial Injuries Insurance Institutes (IIII) are committed to ensuring a safe and healthy working environment. Beside laws and statutory ordinances of the government the IIIIs have issued Accident Prevention Regulations (Unfallverhütungsvorschriften). One of these regulations is the „Preventive Occupational Medical Care" (VBG 100) (2). That VBG 100 describes the required occupational medical examinations: a first examination before employment starts, examinations during employment in regular intervals and regular examinations after the end of the employment. The latter examinations are also required for occupational radiation exposed persons of the category A.

For the organization of these medical examinations since 1989 the companies have to report all employees to the IIII. Personal and occupational data are reported. Among the latter annual dose is additionally necessary for appropriate risk assessment. This can be explained by evaluating the probability of causation (PC). The PC of a radiation-caused late effect like cancer is different for different dose distribution. That effect is shown in the following example.

Suppose, leukaemia is diagnosed for a person of age 60. The following table shows the calculated PC (3) for exposure at different ages.

Dose [mSv]	Age at exposure [years]	Latency Period [years]	Probability of Causation [%]
50	40	20	2.7
50	45	15	4.0
50	50	10	6.3
50	55	5	9.2
5 x 10/year	41 - 45	19 - 15	4.7

Table 1. Calculated PC for an exposure to different ages

It can be seen that the age at exposure and the latency period have an important influence on the risk estimates. Both quantities are derived from the annual dose distribution.

PRELIMINARY RESULTS

Until today about 6,800 persons who are or had been working in the nuclear industry have been reported from the companies. 774 of them have already stopped working as occupational radiation exposed person. The lifetime-dose distribution of these 774 persons is shown in Table 2.

Dose Range [mSv]	0	>0 - <=50	>50 - <=100	>100 - <=150	>150 - <=200	>200 - <=250	>250 - <=300	>300 - <=350	>350 - <=400	>400 - 575
Number of Workers	138	489	56	26	22	8	10	5	7	13

Table 2. Distribution of the lifetime-dose of the 774 persons who have stopped working as occupational radiation exposed person of category A.

It will be possible to consider the effect of risk dependency of dose distribution over time because the annual dose distribution belongs to the reported data. Figure 1 shows examples of the dose distributions for 4 persons.

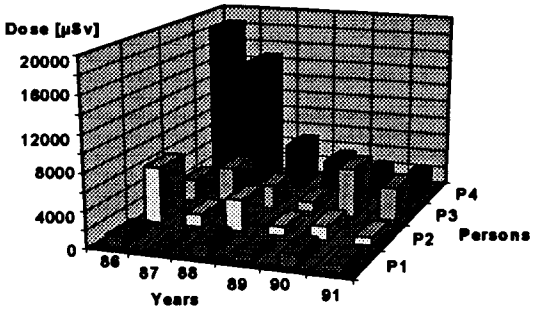

Figure 1. Example for different annual dose distributions among 4 workers

It can be seen that similar lifetime-dose can be a result of very different dose distributions.

An important factor for a precise risk calculation is not only the number of persons included in the study but also the number of person-years. That number depends on the lenght of the follow-up period for the workers in each company. The earliest possible starting point of the observation period is the date of commissioning of the installations. It will be important to obtain this data as complete as possible therefore it might be necessary to fix starting points for the companies different from the date of commissioning.

In a first step the statistical power of the German data alone was calculated based on the assumptions that 96,000 person-years were accumulated until the year 1995 and that the average age of the workers at time of entrance into the study was 30 years. Then the German part of the cohort study has enough power to exclude a 3fold or higher relativ risk (with 95% probability) for lung cancer (power about 100%) and leukaemia (power about 97%) by following up the cohort until the year 2000 (4).

A first joint analysis of the international study is planned in 1996/97.

INTRODUCTION

An international study, initiated by the International Agency for Research on Cancer, is being carried out concerning the effects of protracted low doses of ionising radiation. The following organisms: Commissariat à l'Energie Atomique (CEA), COGEMA and their subsidiaries are involved in this study, which concerns a retrospective cohort of workers. The main objectives are to assess health effects through a mortality analysis and to compare results with currently admitted dose-effect relationship.
The doses registered for the monitored workers of the cohort refer to the notion of « whole-body dose equivalent », which results from the necessity to comply with radiation protection standards and not from epidemiological purposes. It is thus important to reconstruct the historical practices of dosimetry and radiation protection for two purposes: i) to be able to define rules for assessing cumulated doses in a consistent way over time and facilities included, and ii) to assess the biases resulting in the differences noted down.
This paper discusses the role of two main factors: the technical evolution of dosimetry and variation in dose thresholds used in registration.

TECHNICAL EVOLUTION OF DOSIMETERS

Apart the fact that the introduction of a new type of dosimeter appears from table 1 as for a given year, the dates indicated should not be considered as an absolute reference, since the introduction of a new type of dosimeter is usually progressive. Thus it is often difficult to assert with certainty the metrological origin of a given dose even knowing year and place of registration.
Dosimeters used for compliance with radiation protection standards have always been films, either dental films in the earlier years or dosimetric films, even when thermoluminescent dosimeters became available (in the early 1980s'), the argument being to privilege traceable information.
The quick saturation of dental films implied a reading every week or every fortnight. The other disadvantage was the overestimation of low energy X rays: for instance, for a given dose of 50 keV the blackening resulting from X rays could be 30 times the one resulting from radium (with which the dosimeter calibration was made). To avoid such an overestimation, systematic investigation was made every time the dose was beyond a threshold value and correction was made if necessary. This practice allowed to take into account the highest overestimation component. However, it did not allow to correct for overestimation below this threshold which become non-negligible when cumulated. The only way to correct this bias retrospectively is to use information on the workers' activity during that period. For such a cohort (40,000 workers expected), it is impossible to detail for each individual the exposures of a working life. Another method is to assess exposure indirectly through a matrix associating the probable exposure for each job or, failing that, at the laboratory or the workplace level. It is intended to make such a matrix for CEA workers but the quality of the resulting information will largely depend on the remembrance of older or retired workers for the period considered here: the early 1950s'. This matrix would also take into account other carcinogenic exposures if possible and particularly internal contamination.
In the early 1960s', new film dosimeters appeared. Two types of dosimeters were distributed depending on the workers' activity: the first one was for people working with X generators which produced at that time low energy X rays and the second was for reactor workers exposed to high energy γ rays and thermal neutrons. Several types of films have been in use in CEA facilities (Kodak type 1, 2, 3 films and Du Pont films). These films yielded comparable results.
The dosimeter still in use now integrates filters for all relevant types of external radiation. It appeared around 1967 in Fontenay-aux-Roses and 1965 in Marcoule (with negligible difference).

Table 1: Dosimeters used for routine personal monitoring of external radiation in CEA
(films processed in Fontenay aux-Roses: all facilities, except Marcoule, Pierrelatte and La Hague)

Years	Dosimeter	Filters	Comment
1950-1956	Dental film	Open	Quick saturation and fading
1957-1959	Dental film	Open Pb, Sn	Softening of darkening due to low energy X rays
1960-1966	Kodak type 1 film	Dependent on worker's activity:	
		Low energy X rays exposure: Open 0.2 mm Cu 0.6 mm Cu	X generators → low energy X rays (medical and biological applications, cristallography)
		High γ exposure Open Sn (γ) Cd (thermical neutrons)	Reactors → high energy rays (γ and thermal neutrons)
1967-	Kodak type 1 film	One-body Dosimeter Open 300 mg/cm² plastic 1.5 mm Al 0.2 mm Cu 0.6 mm Cu 0.4 mm Pb + 1 mm Sn	 β, low energy X and γ rays 30 to 100 keV X and γ rays high energy photons and thermal neutrons

DETECTION AND RECORDING THRESHOLDS

The *detection threshold* is the first dose value detectable by a given dosimeter. It depends on the technology used for monitoring and usually decreased over years (see table 2). This value may be different from the *recording threshold* which is defined as the minimal positive value actually recorded.
In CEA group, the recording threshold has often been taken higher than or equal to the detection threshold considering that the recorded dose should take uncertainties into account to err on the side of safety. In North American and British facilities included in a joint analysis performed by the International Agency for Research on Cancer (IARC), the recording threshold was smaller than or equal to the detection threshold in most cases (Cardis, 1995). The idea was to associate to doses below detection threshold an average of actual realistic values, thus smaller than the detection threshold.

Table 2: Monitoring and recording practices for γ exposures in the civilian CEA (except Marcoule and La Hague)

Years	Number of dosimeters issued annually per worker	Detection threshold (mSv)	Recording threshold (mSv)	Convention for doses below level of detection (mSv)	Illustrative example (Annual value in mSv) [2]
1951-1952	52	(1)	0.10	<0.10	0
1953-1954	26	(1)	0.50	<0.50	0
1955-1956	26	(1)	0.50	0.50	13
1957	26	(1)	0.25	0.25	6.5
1958	26	(1)	0.25	/	0
1959	26	0.50	0.50	/	0
1960-1962	12	0.20	0.35	/	0
1963-1994	12	0.20	0.35	0	0
1994 (end of)	12	0.10	0.35	0	4.2
1995	12	0.10	0.20	0	2.4

[1] Unavailable

[2] Worker exposed each fortnight to 0.08 mSv

Values adopted for doses below or at the detection threshold may consistently affect cumulated doses especially when the major part of the population is exposed around the detection threshold, as in most of the cohorts of nuclear workers (Kendall et al., 1984). An arbitrary but illustrative example is described in table 2. A worker exposed to 0.08 mSv every fortnight during his working life would be annually recorded as having cumulated 13 mSv in 1955 and 1956 (26X0.50), 6.5 mSv in 1957, 0 between 1958 and 1993 and 2.4 mSv in 1995, for an actual annual value of 2 mSv. As noted by Kendall et al. (1992), several corrections should be made to avoid the overestimation of the earlier years: threshold doses can be set to zero or the minimum recordable dose (i.e. threshold multiplied by the number of issues in a year) can be subtracted from all annual dose sums. Remeasurements of old films may also be relevant if the recording threshold proved to have been taken much higher than the detection threshold (Smith and Inskip, 1985).
Differences between facilities have to be taken into account as well. The same worker's annual dose would have been recorded 2.4 mSv (12X0.20) in La Hague between 1968 and 1995 (recording threshold being 0.15 mSv and recording increment being 0.05 mSv). With such a protracted exposure for 10 years, this yealds from 0 to 24 mSv for the total cumulated dose.
Those variations due to recording practices should have to be taken into account when defining the classes of doses in the cohort analysis and specially the lowest exposed group. For an illustration [0-10 mSv] is the most common first dose class considered in recent nuclear worker cohort studies (Cardis et al. 1995, Kendall et al., 1992).

CONCLUSION

Technology in dosimetry for external individual exposure evolved from dental films without any filters to one-body dosimeter integrating up to 6 different filters. Main bias for the first period (till approximately 1957) is resulting from the overestimation due to low energy X rays. A method to eliminate or reduce this bias is to use a job exposure matrix. « CEA-EXPO » retrospective job-exposure matrix currently under way should help to do so. Results will largely depend on the remembrance of old workers and on technical information found in the archives.
It has been shown that variations of detection and recording thresholds over time and facilities may have non-negligible consequences on cumulated doses. When all dosimetric data are computerised, different rules will be applied for estimating the cumulated doses. Sensitivity studies will be made when analysing the final cohort to see the influences on conventions adopted and chose the best approximations.

THE THYROID: MEDICAL SURVEILLANCE OF EXPOSED WORKERS

M. VIRGILI*, E. STRAMBI**

* Ospedale Provinciale "Umberto I"
Radioprotezione medica - Frosinone, Italy
** UCSC - Policlinico Gemelli - Rome, Italy

ABSTRACT

In this study the authors: 1) outline a rational approach to diagnosis and management of thyroid diseases; 2) evaluating the prevalence of thyroid diseases on a group of 207 radiation workers observed over a six years period, identify abnormalities which require a careful evaluation and a more restrictive judgement of fitness.

INTRODUCTION

In the system of dose limitation, closely correlated to the hypothesis of a linear relation between dose and occurrence probability of stochastic damage, medical surveillance undoubtely acquires obligations with regard to tumour prevention (secondary prevention). ICRP 90/77 places the thyroid in the group of organs of most oncological competence. The American Cancer Society, in its recommendation on the early diagnosis of cancer in asymptomatic people, extends the diagnostic indication to numerous sites (thyroid included), which also coincide fairly closely with the sites having a high risk coefficient. Based on the above considerations, thyroidology should not be neglected. The only factor that has been shown unequivocally to cause thyroid cancer is radiation exposure.

THYROID CANCER AND THYROID BENIGN ABNORMALITIES AT INCREASED RISK OF CANCER

The thyroid is an uncommon site of cancer accounting for 0,6% of cancers among men and women respectively. In 95% of cases, thyroid cancer presents as a nodule in the thyroid. In contrast to rare thyroid cancer, thyroid nodules are extremely common particularly among women. The prevalence of thyroid nodules is about 5% of the adult population with a female: male ratio of 4:1. Thus most thyroid nodules are benign and the problem is to identify those that are likely to be malignant. Many studies have considered the possibility that thyroid cancer is preceded by other thyroid abnormalities, including endemic goiter, sporadic goiter, benign thyroid nodules, lymphocytic thyroiditis, and Graves' diseases. The findings remain inconclusive; nevertheless, this question is of great interest from the point of view of radiation protection, since these thyroid diseases are common and it is important to know whether such patients should be considered at increased risk of developing thyroid cancer.

CASE CONTRIBUTION

In the period 1889-1995 a total of 207 exposed workers 87 females and 120 males, ranging in age from 19 to 65 years, were tested with clinical examination, FT3, FT4, TT3, TT4, TSH and ultrasound. Selected cases, in the presence of doubtful thyroiditis, were tested with thyroglobulin autoantibodies and thyroid microsomal autoantibodies. Workers known, by palpation or ultrasound, as carriers of alterations of the glandular morphology were tested with scintigraphy, 131 I thyroid uptake and eventualy T3 suppression test in case of doubtful differential diagnosis between hot and cold nodules. Nodules less than 5 mm were not considered. Only in the presence of cold, solid and palpable nodules a fine-needle aspiration biopsy was performed to diagnose malignant nodules, benign nodules or follicular neoplasms. A total of 69 cases of thyroid diseases were found, with a prevalence of about 33% (females 36%, males 29,5%), (Table 1).

Table 1: Prevalence of thyroid diseases in 207 exposed workers. 1989-1995.

NONTOXIC GOITER:	DIFFUSE: 5(2.4%)	
	NODULAR: 23(11,1%)	MONO: 6(2.4%)
		MULTI: 17(8.2%)
DIFFUSE TOXIC GOITER: 2(0.97%)		
HASHIMOTO'S THYROIDITIS: 3(1.5%)		
		MALIGNANT 2(0,97%)
	PALPABLE:	FOLLICULAR ADENOMA 1(0.5%)
		COLLOID NODULES 7 (3,4%)
SOLITARY NODULES: 30(14.5%)		
	UNPALPABLE 20(9.7%)	
MULTIPLE NODULES: 6(2.9%) UNPALPABLE		

DIAGNOSTIC DISCUSSION

With the exemption of hot nodules that as a rule are not malignant and have not been suspected of malignancy, we found 5 groups of thyroid diseases that, representing special problems, require some considerations.

1 - **MULTINODULAR GOITER:** Two patients evaluated for single nodules were found to have additional small thyroid nodules. It is commonly stated that demostration of multiple nodule on ultrasound in a patient with a single palpable nodule makes malignancy unlikely. No carefully controlled study supports this contention, however, and the malignant potential of any nodule should be based on other criteria. In most cases, this should include a FNA biopsy.

2 - **CISTIC NODULES:** Also cystic nodules that as a rule are not cancer, have not been considered suspicious of malignancy, but since cancer is occasionally found in the wall of the cyst, it has been thought necessary the echographic surveillance of cystic lesions every periodical visit.

3 - **HASHIMOTO'S THYROIDITIS (HT):** A high prevalence of HT was confirmed. Since a patient with HT may develop, even if rarely, lymphoma of the thyroid gland, a protocol of caution for the follow up is recommended. Ultrasound should be carry out semiannually.

4 - **FOLLICULAR ADENOMA:** Considering the limits of FNA biopsy in the presurgical differential diagnosis between follicular adenoma and follicular carcinoma, we have referred to the surgeon the case of follicular adenoma. In this 1 case there was an increased chance of malignacy (large lesion over 2 cm firm nodule, young patient, values of nuclear parameters - area and perimeter - 30% over the normal.

5 - **HISTORY OF RADIATION THERAPY:** In 1 case of benign solitary nodule there was a history of radiation therapy to the neck area. Althoug any given nodule has essentially the same chances of being malignant regardless of whether there has been previous upper body radiation, caution is in order.

CONCLUSION

The case report, in particular the two papillary carcinomas, show how the diagnostic protocol suggested above could become useful also from the point of view of the secondary cancer prevention.

The diagnostic protocol by us conciliates with due economy but with the right balance, the real requirements of medical surveillance, reducing as far as possible undesiderable effects such as damage from excessive protection and patient/physician delay, which is extremely dangerous in the early diagnosis of tumours.

MEDICAL JUDGEMENT OF FITNESS FOR RADIATION WORK

As far as the medical judgement of fitness for radiation work is concerned, one has to keep in mind some main criteria, i.e., the clinical findings; the specific risk evaluation; the social, economical and psychological parameters. Thus, in his evaluation, the physician should always consider the risk/benefits balance.

ABSTRACT (See instructions overleaf)

Two successives incidents with I-131 occurred in the Radioisotope Production Facility at IPEN-CNEN/SP, contaminating areas and workers. However, no evidence cause was found, being the case still under investigation. In this paper is analysed the probable causes of how it could has been happened and the consequences, which were scanned by radiological protection measurements. Individuals internally contaminated were monitored by "in vitro" and "in vivo" bioassay. The results were used to estimate the thyroid's exposure risk reflecting the collective dose

THE IMPORTANCE OF RADIATION AND NON-RADIATION-FACTORS FOR THE STOMACH CANCER INCIDENCE IN WORKERS OF THE ATOMIC PLANT MAYAK

INTRODUCTION

Stomach cancer is one of the most widespreaded oncological diseases among the men. It is known about the increase of stomach cancer incidences and mortality among the A-bomb survivers (1) as well as among the professionals subjected to the chronic exposure to external gamma-irradiation and internal exposure due to body burden 239 Pu of high doses (2). Inasmuch as this disease is polyetiological, the determination of non-radiation factors contribution is important for more accurate estimation of the effect of ionizing radiation on its advent and for its more successful prophylaxis. With this in mind a retrospective investigation of the personal of the atomic plant MAYAK was conducted, who start their work in 1948 to 1960.

MATERIALS and METHODS

503 workers of the atomic plant MAYAK were examined that were subjected to external chronic gamma-irradiation with the total dose of 0 to 8,46 Gy and body burden ^{239}Pu 0 to 39,6 kBq. The data on individual external gamma-irradiation doses were presented by enterprise monitoring survice and data on body burden ^{239}Pu by biophysic laboratory of Branch No 1 of Biophysic Institute (the chief of the laboratory is Dr. V.F.Kchochryakov). From 1955 to 1992 stomach cancer was diagnosed by 157 persons (141 men and 16 women) morphologically confirmed (autopsy and biopsy during surgical operation). 346 persons (313 men and 33 women) without cancer served as pair control, matched on sex, age (±5 years), beginning of the work at the plant (±2 years) and profession. Besides radiation factors the effects of medical, biological and social factors were studed influencing the development of this disease (table 1). The data about the smoking and alcohol taking were received from individual interviews. The contribution of studed factors to stomach cancer incidences was estimated by odds ratio (Or_{cr}-odds ratio crude and Or_{ad} - odds ratio adjasted), calculated on base of the model of multiple logistic regression. Attributable risk (AR) was calculated for statistically significant factors, that allows to determine what part of the investigated cancer incidences is subjected to the each factor. Statistic programms SAS and BMDP were used.

RESULTS AND DISCASSION

The mean values of total and maximum doses of chronic external gamma-irradiation in the main and in the control group were significantly not different, but the part of persons with the total external gamma-dose more than 3 Gy was significantly higher in the main group (table 1). No important differences were noted between the main and the control group in ^{239}Pu content in the organism and in the frequency of previous professional contacts with chemically dangerous substances.

A significant increase of current smoker part and smoking index value was noted in the main group but in the control group the part of exsmokers was increased. The age of start smoking was the same in both groups, there were no differences in alcohol taking.

The differences in constitution between the main and control groups were characterized by mass index decrease of persons in the main group some years before tumor diagnose. The frequency of chronic hypocidity and anacidity gastritis, colitis, gallbladder diseases was significantly higher in the main group. The percent of stomach and duodenal ulcers was the same in the both groups, but there were differences in ulcer localization. The mean age of the persons fallen ill with cancer was 51.2±0.8 years and the period from the begin of the contact with ionizing radiation up to tumor diagnose was 22.1±1 years.

Table 1

COMPARISION OF STOMACH CANCER CASES AND NON-MALIGNANT CONTROL

	Risk Factors		Mean or percentage ± error		"P" value
			case	control	
			n = 157	n = 346	
	Matched variables				
1	Sex (% men)	%	89,8 ± 2,4	90,5 ± 1,6	> 0,05
2	Years of birth	yr	1924,0 ± 0,8	1925,5 ± 0,5	> 0,05

4	Part of worker's profession	%	79,6 ± 3,2	76,3 ± 2,3	> 0,05
	Professional factors				
5	Total external γ-irradiation	Gy	126,9 ± 13,6	104,3 ± 5,9	> 0,05
6	Total external γ-irradiation > 3 Gy	%	12,7 ± 2,7	5,8 ± 1,3	< 0,01
7	Maxim.. years rate γ-irradiation	Gy	48,4 ± 6,7	35,7 ± 2,6	< 0,1
8	^{239}Pu body burden	kBq	1,32 ± 0,32	0,76 ± 0,11	< 0,1
9	Previous professional contacts with chemically dangerous substances	%	14,0 ± 2.8	8,4 ± 1,5	< 0,1
	Social factors				
10	Smoking: current smoker	%	62,4 ± 3,9	44,8 ± 2,7	< 0,001
	exsmoker	%	13,4 ± 2,7	27,2 ± 2,4	< 0,001
	never smoker	%	24,2 ± 3,4	28,0 ± 2,4	> 0,05
11	Age of smoking's start	yr	17,5 ± 0,6	17,6 ± 0,8	> 0,05
12	Smoking's index	cig/d	700,0 ± 37,8	559,0 ± 22,1	< 0,01
13	Alcohol taking: regularly	%	22,3 ± 3,3	17,6 ± 2,0	> 0,05
	occasionally	%	57,3 ± 3,9	57,5 ± 2,7	> 0,05
	rarely	%	20,4 ± 3,2	24,9 ± 2,3	> 0,05
	Medical and biological factors				
14	Body height	cm	169 ± 0,6	169 ± 0,4	> 0,05
15	Body weight	kg	70,4 ± 0,8	72,5 ± 0,5	< 0,05
16	Quetlete's index	kg/m^2	24,6 ± 0,3	25,5 ± 0,2	< 0,05
17	Chronicle hypoacidity gastritis	%	18,5 ± 3,1	8,4 ± 1,5	< 0,01
18	Chronicle anacidity gastritis	%	26,8 ± 3,5	6,4 ± 1.3	< 0,001
19	Chronicle hyperacidity gastritis	%	1,9 ± 1,1	3,8 ± 1,0	> 0,05
20	Stomach and duodenal ulcer:	%	11,5 ± 2,5	11,0 ± 1.7	> 0,05
	stomach ulcer	%	7,6 ± 2,1	0,3 ± 0,3	< 0,001
	duodenal ulcer	%	3,8 ± 1,5	10,7 ± 1,7	< 0,01
21	Stomach polyps	%	2,5 ± 1,3	0,3 ± 0,3	<0,1
22	Chronicle colitis	%	12,7 ± 2,7	6,6 ± 1,3	< 0,05
23	Gallbladder diseases	%	24,8 ± 3,4	14,5 ± 1,9	< 0,01

The influence of 13 potential risk factors on stomach cancer incidence were studied by multiple analysis based on logistic regression model. 5 significant factors were resolved, OR_{ad} was calculated for each of them (table 2): for the external gamma-irradiation with the total dose more than 3 Gy OR_{ad} = 2,1; for anacidity gastritis OR_{ad} = 8,0; for hypoacidity gastritis OR_{ad} = 5,2; for current smokers relative exsmokers and never smokers OR_{ad} = 2,7 (table 2). By the calculation of attributable risk it was shown that among all studied cancer incidence only 5% were cased by external gamma-irradiation with the dose more than 3 Gy; the main

part of cancer incidences - 29 % is connected with chronicle stomach disease and 24% of them are caused by current smoking.

Besides the study of independent influence of different factors on cancer incidences the evaluation of their interaction is made. In this case it was noted that the interaction between external gamma-irradiation with the total dose more than 3 Gy and gastritis is

Table 2.

DEPENDENCE of STOMACH CANCER of VALUE DIFFERENT RISK FACTORS

Factors	Range	Frequency (n)		OR_{cr}	OR_{ad}		AR and
		case	control		Point est	95% CI	95% CI
Total external γ-irradiation (Gy)	0-3 > 3	137 20	326 20	2,4*	2,1	1,01-4,4	5,2% (0,7%-9,4%)
Hypoacidity gastritis	no yes	128 29	317 29	2,5**	5,2	2,45-11,0	7,8% (2,3%-13,0%)
Anacidity gastritis	no yes	115 42	324 22	5,4**	8,0	4,4-14,6	16,1% (9,7%-22,0%)
Stomach ulcer	no yes	145 12	345 1	28,6*	41,2	5,2-328	5,1% (2,1%-8,2%)
Stomach polyps	no yes	153 4	345 1	9,0

* - $P < 0.05$, ** - $P < 0,01$

submultiplicative and the interaction between gamma-irradiation and smoking, alcohol taking is multiplicative.

In such a way as a result of the conducted study it was determined, that the chronic external gamma-irradiation causes the statistically significant increase of stomach cancer incidences by the total dose more than 3 Gy. It is known, that the significant increase of cancer risk by the dose more than 200 rad was noted by the A-bomb survivors in the group with the age of irradiation moment that corresponded to the age of MAYAK workers at the moment of the first contacts with ionizing radiation /1/.

Among the examined persons more higher probability of cancer incidence was noted for current smokers relative to never smokers and exsmokers and the value of smoking index hadn't any great importance, that is the main importance had just the fact of current smoking. The data from references on this problem are different but the many authors doesn't find correlation between the stomach cancer and smoking. In our case cheap sorts of papirosen with high content of toxic substances and without filter were taken chiefly and just that fact could promote cancer. It was not found direct correlation between stomach cancer and alcohol taking. This is in accordance with literature data but it must be noted, that the examined persons could give incorrect information from social reasons about the quantity of alcohol taking, specially lowing it.

The most high probability of stomach cancer was noted among the workers with chronicle stomach diseases. In this connection we are studying now the problem on the possible influence of ionizing radiation on the incidence of them and , if such an influence will be confirmed, the stimation of the contribution of ionizing radiation to the stomach cancer incidences among the personnel could be changed.

ABSTRACT (See instructions overleaf)

EVALUATION OF HEALTH IMPACTS IN HUMAN CHRONIC LOW DOSE, LOW DOSE RATE γ-IRRADIATION EXPOSURE.
Chang WP, Wang D, Wang JC, Hwnag BF, Chan CC, Hwang JS, Wang JD.

More than 6,000 residents and primary school or kindergarten students in Taiwan have been identified to have received continuously excessive low dose γ-ionizing radiation (cumulative 0.5 to 100 rems) from various environmental sources, including radioactive apartments and radioactive classrooms containing Co-60 contaminated steel rebars or window frames, since 1983 to 1995 (Lancet, 342:1544). Several correlated studies have been undertaken in order to understand the health effects of such exposure in human, including exposure dose assessment by the time-activity-based environmental monitoring (a joint program with the National Institute of Occupational Safety and Health, U.S.A.), a systemic and comprehensive medical surveillance program, the growth and development evaluation in children borne and grown up in the apartments, and the cytogenetic monitoring in their peripheral lymphocytes. The risk of various health effects will be demonstrated and compared with those of current risk coefficients employed by the International Commission on Radiological Protection(ICRP). This report will be an update of

THE ESTIMATE REPRODUCTIVE HEALTH STATUS OF POPULATIONS EXPOSURED IN LOW DOSES IN RESULT OF CHERNOBYL DISASTER.

A.M. Ljaginskaja, P.W. Izhewskij, O.V. Golovko

State Research Centre of Russia - Institute of Biophysics, Moscow.

One of the indices characterising the health of the population is the reproductive period including such estimations as birth rate, the health status of pregnant women, the frequency of untoward outcomes of pregnancy, the health status of newborns. In accordance with these evidence one may judge about the health status not only of the present but also of the future generations.

One of the major manifestations of impairment of the reproductive health is stochastic effects in the offspring of the exposed parents. The stochastic effects having their origin in gonads can be reproduced and revealed in the form of inherited impairments in the offspring of an exposed person. Such effects may become apparent in many generations. The dominant mutations dispeay mainly in the first and second generations after exposure while the recessive mutations add genetic following generations. In addition to the effect in parents' gonads, the radiation may the affect the embryo and fetus. Within the period from three weeks after the conception to the outcome of the pregnancy the stochastic effects seem to be able to appear.

The epidemiological investigation (1980 - 1992) reproductive health status of the population exposed due to the Chernobyl accident was performed in two districts of Bielorussia (Gomel and Mogilev) and in two districts of Russia (Briyansk and Riyazan) having different levels of territory contamination with ^{137} Cs and ^{90} Sr as well as different levels of dose loading of summary (external and internal) radiation.

In order to estimate the reproductive health, the data of the questionnaires of women living in the mentioned districts, the long-term data of regional medical statistics as well as the epidemiological data of medical help to pregnant women and newborns according to the chosen criteria were used.

In Gomel and Mogilev districts of Belorussia and in Briyansk and Riyazan districts of Russia the doses of external and internal radiation determined by the counting method were from 0,4 sZv to 15,2 sZv by 1992, and the doses for thyroid gland - from 15 sZv to 450 sZv.

The study of the long-term dynamics of frequencies of alive births and medical abortions in Gomel, Mogilev and Briyansk districts revealed the decrease of the frequency of alive births during post-accident period followed by the growth of the frequency of medical abortions. This process was typical both for the exposed population and for the control one.

The analysis of the long-term dynamics of the frequency of the spontaneous abortions in the radioactive contaminated districts beginning from 1987 to 1992 showed their growth from 4,1% in 1987 to 8,1% in 1992.

The average annual summary frequencies of untoward outcomes of pregnancy during the pre-accident period (from 1980 to 1985) were 9,6 ± 0,9% as to the post-accident period (from 1986 to 1992) they were 13,4 ± 1,0%.

In the control population the frequencies of untoward outcomes of pregnancy were 4,8 ± 1,2% and 4,3 ± 0,4%, respectively.

Thus, the above mentioned index is positively higher for the population of the contaminated districts during the post-accident period compared to the same index for women of the control population.

So, in the contaminated districts, on the one side, the decrease of birth rate and the increase of the frequencies of medical abortions are observed that may be considered the consequence of the stress situation and regarded as conscious regulation of the family structure under the conditions of radiophobia; on the other side, the growth of the frequencies of untoward outcomes of pregnancies and increase of morbidity among newborns that may be regarded as the increase of the pressure of the mutagen factor are revealed.

The frequencies of untoward outcomes of pregnancies (UPO) depending on the doses received by the population are determined. Their average annual meanings are as follows:

9,4 ± 0,6% (1 - 3 sZv); 8,2 ± 0,5% (3 - 5 sZv);

8,9 ± 0,9% (5 - 10 sZv); 13,2 ± 1,2% (above 10 sZv).

The frequency of toward outcomes of pregnancy is positively higher only in the total dose above sZv and on the territories with the density of the ^{137} Cs contaminated soil with 5 - 15 Ci/km^2 or more.

The analysis of the epidemiological data in Riyazan and Briyansk districts (the level of ^{137} Cs contaminated from 1 Ci/km^2 to 5 Ci/km^2 and from 5 Ci/km^2 to 15 Ci/km^2 , respectively) revealed the tendency of the decrease of the reproductive health of the population common tot the contaminated and controlled territories outlined since 1980. The impairment of the reproductive health is in the decrease of the birth rate in 1,13 - 1,2 times, in the growth of incidence of spontaneous abortions from 5% to 10%, in the increase of the morbidity of the pregnant women, in the growth of the frequency of the prematurely born children, in the increase of the frequency of the sick newborns.

The most distinct tendency of decreasing the reproductive health both in the contaminated and in the control districts was observed since 1989 that is likely to be connected with worsening the general economic situation in the country. In the contaminated areas of the Riyazan district the most district negative dynamic of the indices analysed than during the pre-accident period was observed. The intensive indices (the coefficient of negative dynamic) of the general morbidity of the pregnant women increased from 1,2 to 1,41 (18%), of the general frequency of the UPO from 1,51 to 1,93 (28%), of the general frequency of morbidity of newborns from 0,98 to 1,2 (22%), of the prematurely born children from 0,85 to 1,17 (38%).

In the contaminated areas of the Briyansk districts with density of ^{137} Cs contaminated soil the change of the positive dynamic in to the negative one during the post-accident period in comparison with the pre-accident period was observed in two indices: the frequency of congenital anomalies (the coefficient changed from 0,66 to 1,41, that is 214%) and the frequency of stillbirths (the coefficient changed from 0,66 to 1,39, that is 210%).

In general the results achieved show that in the population living on the territories contaminated with radionuclids the most distinct negative dynamic of reproductive health than in the control areas is observed dourly the post-accidental period. The highest intensively of the negative dynamic and for certain the lower (than in the control) absolute indices of the reproductive health are revealed in the population living on the territory with ^{137} Cs contamination from 5 Ci/km^2 to 15 Ci/km^2 . Under the equal conditions of ^{137} Cs contamination of soil the most distinct decrease of indices of the reproductive health was revealed in the areas with the most original level of the reproductive health that witness about the important role of the original level of the reproductive health in forming the effects of the exposure of the population. In the structure of the chosen indices of the reproductive health the loading place according to the intensively of the negative dynamic takes the indices characterising UPO and the status of the newborns, that is the indices reflecting the somatic stochastic effects of radiation influence.

ABSTRACT (See instructions overleaf)

The Chernobyl radiation risks: theoretical estimates and actual data (1986-1995)

V.Ivanov, A.Tsyb
Medical Radiological Research Centre of RAMS, Obninsk, Russia,
fax (095) 255-24-86

Immediately after the Chernobyl accident the Registry of exposed persons had been established in the former USSR. At present time the National Chernobyl Registry of Russia set up at the Medical Radiological Research Centre of RAMS, Obninsk, is working. Medical and dosimetric information on 435 thousand of individuals exposed to radiation including 160 thousand of liquidators is kept at the Registry.

Analysis of demographic and dosimetric information of the Registry related to liquidators allowed us to estimate the attributive risk of mortality caused by malignant tumors as 2.8%. This estimation has been confirmed by available actual data of the Registry for the period from 1986 to 1995. At the same time we have established that there is the statistically significant relationship between the dose of exposure and incidence rate of malignant tumors for liquidators.

By results of epidemiological analysis of thyroid cancer cases performed in Bryansk Oblast by the "case-control" technology it was possible to estimate the relative risk of this type of diseases as 7.15 (1.52; 33.8) at the dose of 1 Gy.

The results obtained allow us to say that theoretically expected estimates and actual data correlate well.

ABSTRACT (See instructions overleaf)

The Chernobyl radiation risks: theoretical estimates and actual data (1986-1995)

V.Ivanov, A.Tsyb
Medical Radiological Research Centre of RAMS, Obninsk, Russia,
fax (095) 255-24-86

Immediately after the Chernobyl accident the Registry of exposed persons had been established in the former USSR. At present time the National Chernobyl Registry of Russia set up at the Medical Radiological Research Centre of RAMS, Obninsk, is working. Medical and dosimetric information on 435 thousand of individuals exposed to radiation including 160 thousand of liquidators is kept at the Registry.

Analysis of demographic and dosimetric information of the Registry related to liquidators allowed us to estimate the attributive risk of mortality caused by malignant tumors as 2.8%. This estimation has been confirmed by available actual data of the Registry for the period from 1986 to 1995. At the same time we have established that there is the statistically significant relationship between the dose of exposure and incidence rate of malignant tumors for liquidators.

By results of epidemiological analysis of thyroid cancer cases performed in Bryansk Oblast by the "case-control" technology it was possible to estimate the relative risk of this type of diseases as 7.15 (1.52; 33.8) at the dose of 1 Gy.

The results obtained allow us to say that theoretically expected estimates and actual data correlate well.

INCIDENCE OF CONGENITAL ABNORMALITIES AMONG THE NEWBORNS FROM BUCHAREST AFTER THE NUCLEAR ACCIDENT FROM CHERNOBYL

Irina Marinescu[1], Alexandru Popescu[2], Raluca Gheorghe[1]

[1]Institute of Hygiene, Public Health, Health Services and Management
[2]Clinical Hospital N.G. Lupu

INTRODUCTION

The nuclear accident at Chernobyl has resulted in an important environmental contamination.

In order to assess the health effects of the accident on the newborn children an incidence study was conducted during the period October 1986 - December 1987.

MATERIALS AND METHODS

Data on natality, perinatal deaths, congenital abnormalities and deaths during the first 6 days after birth were collected. These data were compared to those obtained from the statistical centre of the Ministry of Health regarding a similar period before the accident. In addition, a questionnaire regarding the developpement of pregnancy was administered to the mothers.

RESULTS AND DISCUSSIONS

The data were analysed separately for those exposed during the foetal period and for those exposed during embryonic period. The incidence of congenital abnormalities was 2% (130 cases out of 6484 newborns) for those exposed during the foetal period and born beetween 1 October 1986 - 31 December 1986, and 2% (127 cases out of 6220 newborns) for those exposed during the embryonic period and born beetween 1 January 1987 - 31 Mars 1987 (table 1).

The incidence of congenital abnormalities was 2.1% during 1 January 1987 - 31 December 1987 against 2.6% during 1 January 1985 - 31 December 1985 (the period before the accident).

The proportion of stillbirths registered during the study period were: 1.3% for those born during the interval 1 October 1986 - 31 December 1986 and 0.9% for the interval 1 January 1987 - 31 December 1987; the proportion of stillbirths for the period prior to the accident (1 January 1985 - 31 December 1985) was 0.7%.

The mortality during the first 6 days of life was 1.4% for the period 1 October 1986 - 31 December 1986 and 1.1% for the period 1 January 1987 - 31 December 1987, as compared to 0.5% for the period 1 January 1985 - 31 December 1985.

Also, the incidence of the various types of malformations during the study period is not significantly different from the incidence during the reference period.

No significant differences were shown beetween the incidence of the studies outcomes for the period before the accident as compared to the interval following the accident, except the mortality during the first 6 days of life which was significantly increased (test "U").

The increased number of deaths during the first 6 days of life is probably due to the other factors than exposure to radiation: life conditions, work conditions, difficult pregnancy (table 2).

The exposure for the period 1 May 1986 - 31 December 1987 was estimated to 1.2 mSv to representing the committed effective dose equivalent for an adult from Bucharest.

The value was computed by the group of physicists working in our institute.

We lack the data on the dose delivered to embryo and foetus.

CONCLUSIONS

1. No significant differences were shown beetween the incidence of the studies outcomes for the period before the accident as compared to the interval following the accident.

2. The increased number of deaths during the first six days of life is probably due to the other factors than exposure to radiation.

Table 1. Number of cases found for the study periods (intervals).

	1October1986 - -31December1986	1January1987 - -31Mars1987	1January1987 - -31December1987	1January1985- 31December1985
Newborns alive	8673	6200	26.596	36.255
Newborns alive with malformations	156	127	640	942

CHILDHOOD LEUKAEMIA IN ROMANIA AND THE CHERNOBYL ACCIDENT

Rodica Tulbure[1], C. May[1], E. Barbulescu[1]

[1] Institute of Hygiene, Public Health, Health Services and Management

INTRODUCTION

During the days of April 29 and 30, and May 1, the direction of the contaminated cloud from the Chernobyl Nuclear Power Plant has changed, resulting in a contamination of the atmosphere in our country. Several reports have been presented on the probable long term consequences upon the populations living outside the area of close vicinity to the Plant[1,2,3] . These reports suggest that the possible excess of cancer due to the exposure to ionising radiation would be impossible to distinguish from the background incidence. Following the WHO recommendations, we focused our study on short-term consequences of the Chernobyl accident on childhood leukaemia[2] . The present study was designed to show whether the frequency of leukaemia has increased during the time period following the nuclear accident[4] . We studied the frequency of childhood leukaemia, its geographical distribution in Romania, and the possible changes of this distribution after the Chernobyl accident.

MATERIALS AND METHODS

The study population consists of children 0 to 14 years old, by 5-years age-groups. Since the cancer registry could not provide proper data on the incidence of leukaemia, we decided to include mortality in the study; the death certificates seldom specify the type of leukaemia, therefore we considered deaths from all types of leukaemia. The study included all children from the 41 districts of Romania. The study periods two equal time periods: before the accident (1981-1985), and after the accident (1987-1991). Data on deaths from childhood leukaemia were collected from the Central Commission for statistics (Ministry of Internal Affairs); data on the population 0-14 years of age, for 5 years age-groups, for each of the 41 districts and for each year of the study periods, were drawn from the Centre of Medical Statistics (Ministry of Health). Estimates of radiation doses due to the nuclear accident were taken from the UNSCEAR 1988[5] . Cumulative mortality was computed for each district over the two time periods (1981-1985 and 1987-1991), using as denominators the population for the midyear of each interval.

RESULTS

For the period before the accident (1981-1985), the distribution of the cumulative mortality from leukaemia is shown in Figure 1. The mortality for the entire country was 13.54/100,000 for all age-groups (14.92 for the 0-4 years old age group, 15.68 for the 5-9, and 10.13 for 10-14). After the Chernobyl accident, the geographical distribution of cumulative mortality from childhood leukaemia has somewhat changed (Figure 2). The rate for the entire country was 13.24/100,000 (13.72 for 0-4 years old, 16.64 for 5-9 years old, and 9.83 for 10-14 years old). Four districts showed a greater increase of the mortality rate (Figure 7). The age distribution of the mortality in these districts during the two time periods, is shown in Figures 3, 4, 5, and 6.

DISCUSSION

For the entire study period, the mortality from childhood leukaemia was a little higher in the southern and south-eastern part of Romania. Before the accident, the distribution was quite uniform, and changed somewhat after 1986. The southern and south-eastern parts of the country, where mortality rates are higher, overlap with the area with medium dose of radiation received during the period following the nuclear accident. They are also the areas where agriculture has been most intensive, and where chemical industries (oil processing plants, fertilisers) are most frequent. Four districts have shown an increase of the frequency of deaths from childhood leukaemia, of which only one is located in the area with high radiation doses due to the Chernobyl accident, one is located in the low dose area, and two in the medium dose area.

CONCLUSIONS

Further information are needed, both on the radiation doses due to the nuclear accident, and on the other factors that might induce an increase in the frequency of leukaemia, before valid conclusions can be drawn on the possible influence of the Chernobyl accident on the frequency of childhood leukaemia.

MAJOR SCIENTIFIC TOPIC NUMBER

Indices of reproductive health (RH) were studied in persons exposed by long-term radiation during the living at the radiation contamination areas after the accidents in Chernobyl and Southern Urals. 8 RH indices were studied in dynamics. 40,000 people were under surveillance at the territories of Cs-137 radiactive fallout density in the range of 1 to 15 Ci/km^2, where external exposure doses were in the range of 7 to 68 mSv. Control regions population did not have additional irradiation and Cs-137 radiationuclide content in soil was less than 1 Ci/km^2.

The investigated Southern Urals population demonstrated 40-85 thousands of people to have annual radiation doses of 0.71, 7.6, 0.49, and 0.53 mSv for the 1st, 18th, 28th, and 38yh year after the nuclear facility start-up, respectively.

It was found that such RH indices like birth rate, general morbidity of newborns, frequency of hereditary development abnormalities, mortal birth rate were the higher, the larger radiation doses comparing to control and these indices were found more frequently, than that were found for lowest contamination levels caused by Chernobyl accident. Such indices like general morbidity rate in pregnant women, the rate of unfavourable outcomes of pregnancy, early delivery, newborn body mass do not correlate to doses and radioactive fallout levels.

Medical consequences analysis for living in critical zones of Southern Urals demonstrted the confidently positive correlation coefficient (increasing with the elevation of dose) for mortal birth rate and infant mortality. Otherwise, the rate of of hereditary development abnormalities and consequent mortality rate demonstrated the negative correlation to dose.

Revealing of some RH indices conditions can be used as criterion of deterministic effects of low doses of chronical radiation exposure, if other aggrevative influences were accurately taken into account.

POSSIBLE GENETIC CONSEQUENCES FOUND IN THE RESIDENTS OF BELARUS AFTER CHERNOBYL NUCLEAR ACCIDENT

Long-time study of the dynamics of embryonal anomalies found in the residents of Belarus using genetic monitoring system for medical abortuses (the analysis of more than 30,000 samples) and genetic monitoring system for newborners (annual control of about 80,000 births) showed

1/ 59% increase in the incidence of embryonal anomalies registered in the abortuses from the areas with Cs-137 contamination of more than 15 Cu/sq km for the period of 1987 to 1993;

2/ 79% increase in the incidence of malformed newborners for the same period in the same areas;

3/ no correlation between the growth of embryonal anomalies and total and individual doses of population exposure.

MAJOR SCIENTIFIC TOPIC NUMBER 2.2..... (see page 7)

ABSTRACT (See instructions overleaf)

After a radiological accident, epidemiological studies should be carried out in order to assess its health impact especially but not only on cancer risks. The implementation of studies on cancer raises various questions such as : what site of cancer should be followed or studied, will a cancer excess be detectable, what should be the kind and/or the size of a study ? The preparation of epidemiological plans should help to answer these questions for a variety of possible situations. For practical reasons, these plans will be based on a restricted number of « typical situations ».

Radiological accidents wich occured in the past and accident simulations on nuclear installations or transport of nuclear material were used to build up a set of accident scenarios. For all of these, numbers of exposed people, expected dose distributions, sites and numbers of excess cancers were calculated with appropriate tools. These parameters were then used to characterize and select the so called « typical situations » which are presented in this paper.

In some of these typical situations, the predicted cancer excesses are very low, under the level of statistical detectability. In others, the predicted excesses for specific sites of cancer are higher. Plans based on typical situations will provide guidance to define the objectives of epidemiological studies (e.g. description of cancer occurrence or cancer risk quantification), select the target population groups and choose the kinds of studies (mortality, morbidity) taking into account statistical power considerations.

The Impact of the Human Genome Project on Risk Assessment

Katarzyna Doerffer , Paul Unrau

Atomic Energy of Canada, Radiation Biology and Health Physics, Chalk River, Ontario, Canada K0J 1J0

INTRODUCTION

The radiation protection approach to risk assessment assumes that cancer induction following radiation exposure is purely random. Present risk assessment methods derive risk from cancer incidence frequencies in exposed populations and associate disease outcomes totally with the level of exposure to ionizing radiation. Exposure defines a risk factor that affects the probability of the disease outcome. But cancer risk can be affected by other risk factors such as underlying genetic factors (predisposition) of the exposed organism. These genetic risk factors are now becoming available for incorporation into ionizing radiation risk assessment. Progress in the Human Genome Project (HGP) will lead to direct assays to measure the effects of genetic risk determinants in disease outcomes. When all genetic risk determinants are known and incorporated into risk assessment it will be possible to reevaluate the role of ionizing radiation in the causation of cancer.

The distribution of genetic risk determinants in time and space is governed by the biological and social processes involved in reproduction, such as the extent of inbreeding (endogamy) . We know already that endogamy causes the genetic risk determinants to be non-randomly distributed in populations [1]. These non-random distributions of genetic risk factors need to be considered in explaining cancer "hot-spots" observed by epidemiology.

Genetic determinants of cancer risk can be defined because the relevant phenotypes and their genotypes are being mapped and sequenced. Of 6456 genetic disorders identified in Online Mendelian Inheritance in Man (OMIM), 641 are associated directly, indirectly, or by implication with cancer. These cancer risk genes, when fully described, will define the list of genetic cancer determinants for use in risk assessment. Examples which impinge upon present risk assessments include cancer prone syndromes associated with ionizing radiation sensitivity.

ANALYSIS OF GENETIC DISORDERS ASSOCIATED WITH CANCER

Rapid developments in the HGP is leading to detailed knowledge about genes, providing information about genetic risk determinants. This information is stored in molecular biological databases which mirror the current knowledge of genetics and molecular biology. Information about those genes associated with cancer seems to be most relevant to risk assessment, as cancer risk is of most concern.

OMIM is the on-line version of V.A. McKusick's Mendelian Inheritance In Man [2]. OMIM describes all known genetic disorders and traits. The access interface uses Information Retrieval Experiment (IRX) software [3]. The Genome Data Base (GDB) is directly linked to OMIM. GDB collects genetic and physical chromosome maps, information about genes arranged by chromosome location, polymorphisms (normal and mutant gene variants), probes and associated information. GDB also provides accession numbers for links to nucleotide sequence repositories such as GenBank.

Because these databases can be interconnected, it is possible to link the phenotypic description of a particular disorder with molecular mutation at the DNA level and the detailed protein changes causing the disorder. This

allows us to define in molecular terms the genetic risk determinants we need to consider in ionizing radiation risk assessment. We built a set of computer tools to access these databases, analyze the data, and use it to evaluate hereditary contributions to radiation risk. Our goal was to define a set of all known phenotypes (physical manifestations of genotypes) and genotypes (underlying genetic blueprints) and all described biochemical events associated with cancer. Such a list is expected to contain the bulk of presently known or suspected genetic risk determinants; it is from this list that the targets of molecular epidemiology will be selected for analysis.

We operationally distinguished three major sorts of genetic effects as predisposing to cancer:
.1 direct associations,
.2 indirect associations and,
.3 molecular biological traits (biochemical events) associated with cancer.

Direct associations are those genetic disorders, in which a specific gene is involved, which when mutated manifests as cancer of a particular type. The primary outcome of mutation in such a gene is a cancer itself. Examples include Retinoblastoma (MIM# 180200) and Thyroid Carcinoma (MIM# 188550) which is also associated with ionizing radiation. This group includes phenotypes in which tumor suppressor genes and proto-oncogenes are involved.

Indirect associations include genetic disorders in which, for example, DNA repair is less accurate, leading to somatic mutation manifested as an increased incidence of cancer. Examples include Bloom syndrome (MIM# 210900), Neurofibromatosis (MIM# 162200), and Ataxia Telangiectasia (MIM# 208900) which is also associated with ionizing radiation sensitivity. This group includes phenotypes in which modulator genes are involved.

Molecular biological traits are a group of OMIM entries that describe all known molecular biological events leading to or associated with cancers. Examples include the Tumor Suppressor Gene, Hela Cell Type (MIM# 191181), Oncogene MYC (MIM# 164840), Transformation Gene: Oncogene AMV (MIM# 189990), Carcinoembryonic Antigen (MIM# 114890), and the DNA Damage Inducible Gene (MIM# 126335) which is induced by ionizing radiation.

We separated the 641 OMIM entries associated with cancer into direct, indirect, and trait subsets. The results are summarized in Table 1.

Table 1

type of association with cancer	# of disorders	# of known gene locations	# of detailed gene maps	# of sequenced genes
direct	94	53	27	15
indirect	107	52	24	20
traits	440	390	166	218

In Table 1 the number of disorders of any category were defined by reading the entries, checking for linkage to GDB, and determining the details of mapping and sequence data. The entries reflect progress in the HGP; mapping at increasing resolution is followed by sequencing the actual gene. Increasing numbers of genetic disorders associated with cancer are becoming known, and genes and map locations are being determined with increasing precision. The sequence information is what is ultimately required to develop molecular assays for the presence or absence of variants of this class of genes in individuals. All these disorders are in some way connected with cancer risk; the precise nature of the connection is one of the major outputs of the HGP.

Ultimately, all genetic disorders will be tied to mapped, sequenced genes. At this interim period, however, the 253 sequenced genes are primary targets of molecular epidemiology . Thus, we are primarily interested in those

mapped and sequenced genes whose phenotypes include sensitivity to ionizing radiation.

In risk assessment, the value of having a list of genes affecting cancer risk lies in the ability to combine molecular biological assays and epidemiological methods to define cancer risk sources in individuals and thus populations. Knowing the genes and their sequences gives us the potential for direct measurement of genetic risk determinants. By measuring doses and determining genetic risk factors, a better understanding of the ionizing radiation component of cancer risk will be obtained. Thus the presence or absence of genetic risk factors in individuals will affect the risk assessment process. Ultimately it will be possible to determine risk on the individual level and tie the risk to real causes.

Consider an example of a genetically determined, ionizing radiation sensitive disorder which is expected to affect risk assessment. Ataxia telangiectasia has long been a model human genetic disease for studies in radiation research, and ultimately in risk assessment. It belongs to the indirect set of cancer associated genes. AT is described in detail in a number of recent publications [4,5,6,7,8]. Cancer predisposition in heterozygotes, who carry one mutant copy of the AT gene, is estimated to be about 3 - 4 fold higher than the general population, and breast cancer risk in carrier women may be five-fold higher than non-carriers. It has also been hypothesized that breast cancer risks in irradiated carriers may be further increased [9].

While AT is a rare disease, up to 1.5% of the world population may be carriers of one defective copy of the gene. The relevance of AT to risk assessment is that heterozygotes, or carriers, may show both cancer predisposition and moderate radiation sensitivity. This means that up to 1.5% of individuals may be significantly more radiation sensitive than other members of the population, and at altered cancer risk, owing to carrying a mutant copy of the AT gene. Non-carriers will not have the risk determinant nor the attributable risk.

Remember that AT is only one of the 641 genetic risk determinants found in our search, and can account for only a proportion of genetically mediated or influenced cancer risk. Assays to measure the actual genetic risk determinants at the DNA sequence level are required to define the presence or absence of genetic risk determinants in individuals. Such direct assays for the presence or absence of gene variants linked with cancer predisposition, susceptibility, or expression will lead to a new understanding of the magnitude of ionizing radiation risk.

The distribution of genetic risk determinants in the individuals who make up populations is governed by biological processes. We have discussed two indicators of endogamy which are associated with non-random distribution of genetic risk determinants, namely ethnicity and consanguinity [1]. The genetic consequence of endogamy is that genetic risk factors located on DNA shared between group members is more likely to lead to observed genetic disorders. The AT variants described to date show that both ethnicity and consanguinity affect their temporal and spatial distribution, and their associated cancer risks in populations.

Acquiring the ability to assay genes directly, to determine both their relationship to disease and their distribution in populations will increase the certainty of the risk assessment process by identification and direct measurement of its deterministic genetic risk factors. At the same time it will reduce the uncertainty of risk assessment by decreasing the probabilistic components of the process.

The genetic consequens of exposure.

Izhewskij P.W.

State Research Center of Russia - Institute of Biophysics. Moscow

The results of the study of genetic consequences of external gamma-irradiation of man and animals to 1 Sv are given. The investigation was performed in 3 groups under different conditions of exposure of the population:
- among the people of Russia and Bielorussia exposed due to the Chernobyl accident;
- among the people living on the Tetscha river basing in the South Urals;
- among the occupational contigent of "Mayak" and the members of their families;

The experimental estimation of genetic consequences was made on the offsprings of the white male rats.

The male rats were irradiated dayly for 10 -1 5 days with external gamma- radiation of different dose power. The range of the doses received by the animals was approximated to the conditions of the exposure of man to the interval from 4 to 79 cSv for a year.

It was shown that:
- the most distinct effects were observed in the groups "237" cSv and "158" cSv;
- the main contribution into the remote effects of radiation action on the reproductive function of the males gives the loss on the preimplantation stage of pregnancy. The statistically reliable increase in group "237" cSv of the stillbirths incedence and the increase (very important, to 25% compared to the control) of dominant lethality incedence attract attention. In addition, the decrease of the fertility and the decrease (not very significant) of the number of litters and first of all because of the decreased number of males in the litters
were reveated;
- the statistically reliable growth of the birth weight of the newborns in groups "237" cSv and "158" cSv that is preserved in the following periods of development;
- the influence in the dose range investigated doesn't bring the increase of the mortality of offspring or the impairment of forming sensoro- motor reflexes in any group;
- the reliable impairment of development of locomotor function in offspring of the animals in group "237" cSv and the impairment of curious behaviour at the age of 30 days in groups "237" cSv and "158" cSv;
- the change of the rat conduct in the crest- line labyrinth in the offsprings of animals received summary absorbed dose 237, 158 and 48 cSv.

Thus, when estimating the remote genetic effects of the exposure it is necessary to take into account, first of all, the integral indices.
It's reasonable to study the effects on the large number of animals with the most detailed dosages in the range to 100 cSv and using more sensitive methods. It's absolutely necessary to be supported financially for the new experimental study.

With the purpose of studying the possible unfavogable outcomes of the exposure of the population due to the Chernobyl accident, the investigation was performed in the Mogilev, Gomel and Briyansk regions. The summary doses of exposure of the man living in 226 villages examined during the period from 1986 to 1992 were estimated. The doses of external radiation varied from 0,31 to 11,0 cSv. The doses of internal radiation varied from 0,08 to 4,19 cSv. The summary doses were from 0,39 to 15,19 cSv.

The frequencies and the structure of untoward pregnancy outcomes (UPO), in general, were studied. The frequencies of UPO reflecting the character of reproduction in the population living on the contaminated territories. It's necessary to point out that the frequencies of UPO in the populations living on the territories contaminated with radionucleids are reliably higher (13,4 c 1,03 per 100 pregnant women) compared to the control population (4,31 c 0,35 per 100 pregnant women).

When studing the UPO frequencies in the dose groups (group 1 - to 3 cSv; group 2 - from 3 to 5 cSv; group 3 - from 5 to 10 cSv & group 4 - more 10 cSv), it was revealed that they received the meaning 8,0 c 1,36 per 100 pregnant women (in group 2) to 13,5 c

1,2 per 100 pregnant women (in group 4). The UPO frequencies was reliably higher only in the summary dose more than 10 cSv.

The study of antropometric indices of newborns showed the decrease of the number of children with the optimal weight at the birth. The specific weight of such children was during the preaccident period 32,3% & 34,8%, and during the postaccident period 24,1% & 26,9%, in girls and boys respectfully.

The adaptation of the the newborrns to the enviroment during the first six years after the accident was decreased. Thus, the meanings of the indices reflecting the background medico- genetic situation during the preaccident period and during the first years after Chernobyl accident were dermined.

The untoward pregnancy outcomes was studied in the families exposed due to the breaks of radionucleids waste products into the Tetscha river in the South Urals. The study showed that at the average dose on the gonads of the parents to the moment of the conception equal to 12 - 15 cSv, the UPO frequency when only the father was exposed was 11%, when the mother was exposed was 9%, when the both parents were exposed was 6,1%. The UPO frequency in the control was 5,8%.

The most reliable data were in the families of the personal at the atomic industry plant "Mayak" in the South Urals, where not only the UPO frequencies but also the offspring mortality from the moment of the
birth to the age of 45 years old were taken into consideration. The average doses on the gonads of the fathers were 144 cSv, on the gonads of the mothers were 142 cSv. The average doses during the pregnancy period varied from 0,1 cSv to 233 cSv, with the mean one 19 cSv.

In the investigation the UPO frequency increase and the growth of the offspring mortality correlated with the increase of the gonad dose of the external gamma-radiation of the mother (1.04 cases per 1 Sv). The constant of the doubling gonad dose of the mather exposure was 1,4 Sv.

Thus, the material evidence of the remote genetic effects of the human exposure was, for the first time, received and the estimate of the doubling dose on the gonads when the mother is exposed was determined to be 1,4 Sv.

IN ESTIMATE OF THE HEALTH STATUS OF THE OFFSPRING OF INDIVIDUALS SUBJECT TO OCCUPATIONAL EXTERNAL GAMMA-EXPOSURE

Nadezhda P. Petrushkina, Olga B. Myssatkova

Biophysics Institute Branch N: 1, Chelyabinsk-65, Russian Federation

The assesment of genetic effects of radiation exposure is one of the critical and important problems. It is known that normal postnatal development is genetically determined. Health status indices (physical development, stability to environmental factors and other) are under the control of many genes functioning in close interaction with each other. The injury of genes may lead to the disorder in health status occuring in the offspring of irradiated individuals. But on the other hand child's development may be subjected to negative actions of external and internal factors on the different levels of development regulation.

The purpose of the present investigation was to give a complex estimate of the health status of grandchildren of individuals subjected to chronic occupational radiation exposure before the conception and to estimate the contribution of radiation factor to the occurence of revealed defects in the children with regard to a large complex of various non-radiation factors.

The main group consisted of 1557 grandchildren of individuals occupationally exposed to chronic irradiation previous to conception. Three groups were chosen depending on which of the grandparets had come into contact with sources of ionizing radiation. The first group is represented by 830 grandchildren, who had irradiated grandfathers. The 259 children whose grandmothers had been subjected to radiation exposure were included in the second group. The 468 children whose both grandparents (grandfather and grandmother) had been irradiated were included in the third group. Total doses accumulated in the gonads by the time of conception of the parents of the observed children were calculated (table 1).

Table 1

Dose characteristic of grandparents occupationally exposed to external gamma-exposure

Group	On the side of the child	Dose before conception, mSv: Dose range	Mean equivalent dose	Percetage of persons who had exposed with doses more 1000 mSv	Dose during pregnancy, mSv: Dose range	Mean equivalent dose
Grandfathers	mother	14-4934	566 ±59.7	14.9	none	none
	father	11-8823	673± 7.7	18.9	none	none
Grandmothers	mother	13-1106	173 ±42.1	3.3	3-281	45±11.1
	father	15-2000	375± 84.4	16.6	4-660	85±25.2
Grandfathers	mother	07-5440	904±158.5	28.7	none	none
and	father	06- 6754	953± 190.0	27.0	none	none
grandmothers	mother	03-0995	267± 37.5	0	2-2184	80±49.9
	father	01-5196	588 ±179.5	13.6	1-63	19±3.0

Most of the grandmothers (77.8-81.7%) were subjected to irradiation not only before conception but also during pregnancy. The parents of observed children in some of the cases also worked at the nuclear plant. Total doses of gamma-exposure at the time of conception did not exceed the maximum permissible doses.

The control group consisted of 466 children of similar age belonging to the second generation of individuals who lived in the same town during the analogous period of time but had no occupational exposure to ionizing radiation. The children were born in same maternity hospital and visited the same preschool esteblishments, and were under observation by the same physicians as the children of the main group.

The complex estimate of the observed grandchildren's health state included dynamic study of physical development (anthropometric indices, harmonizing, age dynamics and distribution of physical development disorders) the terms of biological maturation (terms of first dentition and its exchanges; development of psychomotor skill; forming of secondary sexual characters; assessment of school maturity), the range of morphofunctional characters (state of cardiovascular system; state of peripheral blood; size of thyroid gland, ets.) the age dynamics of disease level and structure, the level and structure of congenital malformations. For the ranging of the influence of professional exposure and other non-radiation factors multufactorial analysis was used (claster, rank correlation and logistic regression). Prognostic coefficients for each index were calculated by stepwise logistic regression, and the probability of revealed disoders in observed children was found. The observed children, both the main and control groups, were born in the favorable state of the health and had no significant pathology in the neonatal period.

Anthropometric data served as a basis of estimate of the physical development. A standartized technique was used to assess height and body weight. Mean values of body weight, height and chest circumference in male and female children were calculated in every age group in period from newborn to 15 years age. Height was categorized according to the age specific mean and standard deviation. Special attention was given to the correlation between the main anthropometric values. The degree of discrepancy between actual body weiht and the height-related average weight in disharmonious physical development was calculated in percentages, and children with hypotrophy, overweight and obesity were identified.

Average anthropometric indices in children of the main group did not differ from those in children of the control. The comparison of levels and harmony of physical development in children of the main and control did not revealed significant differences either. Age dynamics of antropometric indices in grandchildren of occupationally irradiated grandparents coincided with those of controls. The range of observed disorders (intrauterine hypothrophy, obesity, overweght and hypotrophy at the age of 1-15 years) was similar in the main and control groups.

There was no relationship between occurence of disorders in the physical development of the observed children and occupational irradiation of their parents and grandparents by means of the multifactorial analysis. The relationship between the incidence of the hypotrophy and a number of non-radiation factors was confirmed. Thus, impaired uteroplacental blood circulation during pregnancy gives rise to disorders in fetus feeding and, consequently, results in intrauterine hypotrophy, specifically: increased abortion risk, combined gestosis and anemia of mother in pregnancy. The presence of number cardiovascular disease as well as the mother's age at giving birth, being below 20 or above 30 years is unfavorable. A ralationship was found between the development of hypotrophy at the age of 1 year and pathologic course of pregnancy (threatening abortion, pharmacotherapy in the second half of pragnancy), as well as with an indication on previous artificial abortions in the mother's anamnesis.

No differences in disease incidence level, structure of the morbidity, per cent of often being ill children, frequency and structure of the congenital malformations between the main and control groups were found. Acute respiratory diseases during the second year of life occurred more frequently in children whose grandparents had contact with ionizing radiation sources than in control. In other age groups no significant differences between the main and control groups were found. Increased disease incidence during the second year of life coincided with the begining of the children's visits of preschool esteblishments and the period of adaptation for the new microsocial conditions. The study of the frequency and structure of congenital malformations among grandchildren of the observed cohort did not reveal significant differences between the main and control groups (table 2).

Table 2

Rate and structure of congenital malformations (in case on 1000 children of observed cohort)

Types of malformations	Main group	Control group
Number of children	1557	466
All congenital malformations	54.6	81.5
Defects of osteomuscular system	27.0	40.7
Defects of urogenital system	20.5	23.6
Defects of gastroenteric system	2.6	2.1
Defects of cardiovascular system	2.6	8.6
Defects of skin and its appendages	0.6	2.1
Defects of neurous system and sense organs	1.3	0
Defects of face and neck	0	4.3

For the ranging of the influence of professional exposure and other non-radiation factors multifactorial analysis was used. There was no relationship between occurence of anomalies in the health state of observed children and occupational irradiation of their parents or/and grandparents. The role of factors of non-radiation character has been confirmed. The relationship of acute respiratory disease incidence at early age with a number of non-radiation factors was established: (1) low or high age of the mother at birth; (2) indications on earlier abortions; (3) gestation age of the newborn - premature or overmature; (4) occurence of allergic diathesis; (5) rachitis in infants; (6) artificial feeding in the first year of life. Inflammatory diseases of genitals of infectious etiology and late toxicosis of mothers in pregnancy predisposed to more severe course af acute respiratory diseases. Occurence of intrauterine hypotrophy, allergic diathesis and rachitis resulted inull a high rate of acute disease in children. Such 'maternal' factors as early placentation, pharmacotherapy and threatening abortions as well as early additional feeding and unfavorable living condition contribute to early sensibilization with development of signs of allergic diathesis in the first year of life. There was no relationship between of congenital malformations in observed children and occupational irradiation of their grandparents by multifactorial analysis. Such factors as low or high age of the mother at the time of the labors, chronic diseases ot mother and congenital malformations of the uterum and vagina predisposed to occurence of malformations in observed children.

Biological age of each child was estimated on the basis of level of morphological criteria development (length of body, body mass and permanent dentition development) was compared with passport age. In a half of children at age 6 years and 1/3 of children at age 7 years the biological age was detained in comparison with passport age. The differences between the main and control groups were not found. The terms of apperance of secondary sexual characters in boys and girls who were grandchildren of persons exposed to occupational radiation did not differ from those in children of control group and accorded with normal development criteria. The cases of changing the rate and terms of puberty among children of examined cohort were not found.

Thus, in dynamic observation during their 15 years of life of children whose grandparents had been subjected to occupational external gamma-exposure, it was found that the range and structure of revealed pathologies coincided with those in the control groups and corresponded to national statistics data. Analogous results were obtained when evaluating the morphofunctional status of the children examined. Occupational gamma-exposure of grandparents had no significant influence on the health status of observed children. The importance of social, biological and medical factors in the development of observed disorders was confirmed.

USE OF COSYMA IN THE DESIGN OF EPIDEMIOLOGICAL STUDIES IN CASE OF RADIOLOGICAL ACCIDENTS

H.Mansoux, P.Verger, A.Thomassin

Institut de Protection et de Sûreté Nucléaire, Département de Protection de la santé de l'Homme et de Dosimétrie, Service d'Evaluation et de Gestion des Risques, IPSN, BP n° 6, 92265 Fontenay aux Roses Cedex, France.

I. INTRODUCTION

In case of a radiological accident, the epidemiological assessment of health effects in exposed populations is necessary to verify risk predictions, to detect any unexpected effect and to improve the knowledge on the effects of low protracted doses of ionizing radiation (in some accidental situations, most of the people would be exposed to such low doses). This assessment is also useful to determine health needs of exposed populations, to adapt health care resources and to provide the "media" and the public with independent and validated information.

The Chernobyl accident demonstrated the necessity of a preparation for the implementation of epidemiological studies in such circumstances, in order to get the most accurate information on the health consequences. Although effects may appear years after the accident (e.g. cancers), the lack of early data collection on exposure and the number of people lost of follow-up make the evaluation of cancer excess risks very difficult. By simulating various radiological accidents with the code COSYMA [1] and predicting cancer risks for all of them, it is intended to calculate the key parameters that are necessary for the prompt implementation of effective epidemiological studies.

II. GENERAL OBJECTIVE

This study focuses on the assessment of post-accidental cancer risks. For this purpose, when designing epidemiological studies, the scientist has to answer the following questions :

* what types of cancer are mostly expected after the accident ?
* what population groups should be followed and how many subjects could or should be included in a study ?

The following parameters should be assessed for the entire population as well as for various groups (e.g. children who are more radiosensitive) :

* average doses to various organs (e.g. thyroid gland, bone marrow...) and to the whole body,
* number of exposed people in various dose intervals,
* number of expected spontaneous and predicted excess cancers for various organs and tissues in the exposed group,
* statistical power of any planned study on cancer, that is its probability to detect an excess risk.

Then, the epidemiologist has to define a dose level to classify the subjects in two groups: those with significant doses who will be considered as "exposed" and those with lower doses, "not exposed". The choice of this level could be optimized according to statistical power criteria. This means that one has to compromise with the expected risk in the followed group and the size of this group in order to be able to detect the excess risk statistically.

The work presented here aims at calculating the above parameters and the statistical power for various radiological accident scenarios. From the results, a typology of epidemiological studies will be constructed which could be used to guide the early collection of relevant data if a real accident occurred.

III. METHOD

The study was carried out as follows:

1. definition of a set of radiological accident scenarios;
2. for each scenario, simulation of N accidental situations and estimation of dose distributions, sites of expected cancers, and associated risks;
3. classification of the N accidental situations according to health effects and epidemiological criteria (number of exposed people, distribution of whole body and organ doses, types of expected cancers, excess risk values) ;
4. extraction of n typical situations among the N simulated ones;
5. statistical power calculations for the n situations to assess the probability to detect cancer excesses by epidemiological studies.

IV. DEFINITION OF A SET OF SCENARIOS

The list of possible scenarios of radiological accidents should be as exhaustive as possible. The characterization of an accidental situation is based on the type of accident (power reactor, reprocessing plant, transportation), the amount of radioactivity and the kind of radionuclides released into the environment (source term), the location of the accident (local meteorology and demography), and the set of countermeasures undertaken (evacuation, sheltering, stable iodine distribution, relocation). For plant calculations, three typical french sites were selected: one PWR located in the Loire valley, another one located in the Rhone valley, and the reprocessing plant of La Hague. The main characteristics of these sites are presented in Table 1. For transportation accident calculations, there is no particular location, and by looking at the routes of transportation a few rural and urban sites for potential accidents can be defined.

V. USE OF COSYMA IN SIMULATIONS

COSYMA was chosen among the various accident consequences assessment codes because of its power and flexibility. It performs all the calculation steps from activity release and dispersion to cancer risks, for any site of interest, using specific data input and allowing the retrieval of non-standard outputs. As a probabilistic code, COSYMA realizes a large number of simulations for one accident in the same run just by changing the weather sequence.

PWR source terms were constructed using the inventory of the COSYMA users intercomparison exercise [2] and release fractions for french nuclear reactors S1, S2, S3 (Table 2) [3]. For the reprocessing plant, two source terms were chosen arbitrarily, based on the actual radioactive materials present in the plant and on the radioactive decay of reprocessed PWR fuel (1g Plutonium and 0.01g Curium releases, Tables 4 and 5). For the transportation scenarios, several source terms still need to be defined, according to the materials transported, the modes of transportation, and the types of packaging. The post-accidental scenario has identical main options for all installations and source terms. The ingestion pathway was not treated in this study because of its unsatisfactory modeling in COSYMA. The intervention levels for the various countermeasures were drawn from ICRP 40 recommendations (Table 3) [4]. Both low and high levels were used for evacuation, sheltering and stable iodine prophylaxis. For long term actions, only the low intervention level was applied.

For the epidemiological calculations, the execution procedure of COSYMA was modified to save two non-standard output files. These files contain the individual organ doses and the individual risks for the late health effects calculated for all weather sequences. A program was written to extract the data from these files for one chosen weather sequence; it calculates the distribution of whole-body and organ doses in the population and performs statistical power calculations for prospective studies. Figure 1 shows the statistical power of a cohort study (prospective follow-up of an exposed group) as a function of the dose level defined above, for one accident in the nuclear power plant of the Rhone valley with wind oriented north. In this example, a maximal statistical power is observed for a dose level between 10 and 40 mSv. Under 10 mSv risks are low and could not be detected despite a large number of exposed subjects. When the dose level exceeds 40 mSv, the statistical power decreases despite higher risks, as the number of exposed subjects has become too low. A statistical power of 0.8 is generally accepted to conduct an epidemiological study.

VI. CONCLUSION

COSYMA is a powerful code for the assessment of a wide range of accident consequences. It has been satisfactory because of the possibility to get access to the code itself and to change options like release duration or outputs. COSYMA is a probabilistic code, but, in this application, it has been used in a deterministic way by extracting the results for one weather sequence only.

From an epidemiological standpoint, a few issues limit the use of COSYMA. Following a radiological accident, some tumors are expected, like thyroid cancers or leukemias. For these tumors, survival rates are rather good and therefore, to assess the health impact in epidemiological studies, morbidity data should be preferred to mortality data as those used in COSYMA. Indeed, the count of incident cases instead of deceased cases would increase the statistical power which is a critical parameter for the study of low protracted dose effects. In addition, it would be of great interest to look at different age classes and different periods of follow-up. It is not feasible by COSYMA which evaluates only cancer risks for the lifetime and the general population, since population and risk data are not detailed enough in the code.

ABSTRACT (See instructions overleaf)

The report is based on the information obtained as a result of a 40-year period of follow-up of people exposed to radiation due to discharges of radioactive wastes from "Mayak" industrial facility into the Techa river. The doses to the red bone marrow (RBM) ranging from several mSv to 4,000mSv. The registry of the exposed population (26,437 exposed people, 3,091 prenatally exposed persons, and 22,158 children of exposed parents), the registries of mortality (6,439 death certificates during the period 1950-82) and registry of cancer morbidity serve as the basis for conducting epidemiologic cohort studies. The leukemia risk estimated on the basis of the linear model of absolute risk was 0.85 (0.24-1.45) per 10,000 person-y Gy of the dose accumulation in RBM, and solid cancer risk, estimated using linear model of relative risk, was 0.65 (0.27-1.03) per Gy of dose accumulated in soft tissues. Estimates of gonadal doubling doses were made based on the incidence of stillbirth, miscarriages, early neonatal mortality and congenital lethal developmental defects. The dose range proved to be as wide as 0.2-4.8 Sv.

ABSTRACT (See instructions overleaf)

"Mayak" Production Association is the first in Russia nuclear enterprise for weapon plutonium production, that was put into operation in the Southern Urals in 1948. The registry includes 14099 male and 4776 female workers, who began working at the main plants (nuclear reactors, radiochemical plant, plutonium production plant) in 1948-1972. Vital status is known for 89% of the workers included in the registry. Epidemiologic study is being carried out among the workers with known vital status and available dosimetry data. Film badge dosimetry data are available for 10881 males and 3261females. Average cumulative external gamma dose for them is 87 cGy. Dose distribution is given in the paper. Data on internal doses from plutonium are available for 3239 males and 1097 females. 3372 male and 645 female workers died of all causes. The highest mortality is among those, who began working in 1948-1958, because of higher representation of elderly people. Preliminary epidemiologic analysis among these workers has revealed increased leukemia mortality in male workers caused mainly by external radiation exposure, increased mortality from lung cancer and liver neoplasms (in particular haemangiosarcoma) caused predominatingly by internal exposure from plutonium.

PRESENTING AUTHOR (IF DIFFERENT)

MAJOR SCIENTIFIC TOPIC NUMBER 4.3 (see page 7)

ABSTRACT (See instructions overleaf)

Subject of report is the epidemiological study for the critical group of the Chelyabinsk-65 residents including children born in 1974-88. The children of the same age living in Chelyabinsk-70 will be included in the controlling group. The study will be realized with continuous method on the basis of registers including near 30000 children from the two towns. The study of children diet and animal and vegetable products contribution, evaluation of the critical components of children diet as radioactivity will be realized. Radiogenecal risk assessment will be based on the analysis of the general and the oncological infant mortality using the model of the linear dependence of incremental relative risk from the dose. The effective doses to children will be calculated with respect to the amount of the radioactive materials released to the atmosphere using the model of radionuclide distribution in the environment.

CHILDHOOD LEUKAEMIA AND LOW-LEVEL RADIATION - ARE WE UNDERESTIMATING THE RISK?

Richard Wakeford

British Nuclear Fuels plc, Risley, Warrington, Cheshire, WA3 6AS, UK

INTRODUCTION

In November 1983 a television documentary claimed that the number of cases of childhood leukaemia which had occurred in the coastal village of Seascale, situated next to the nuclear complex at Sellafield in Cumbria, England, was around 10 times the number of cases expected in the period since the start of nuclear operations at Sellafield in 1950. This report was based upon just 6 cases of childhood leukaemia. The television programme generated public concern in the UK and the Government ordered an independent inquiry into the claim. In summary, this official inquiry confirmed that an excess of childhood leukaemia cases had occurred in Seascale, although the cause of this excess could not be identified (1). The inquiry recommended that a programme of scientific research should be undertaken to investigate the possible causes of the Seascale childhood leukaemia "cluster". This research has led to a variety of suggested explanations for the Seascale "cluster" and the history of these investigations illustrates the great care with which "cluster" reports need to be interpreted.

THE PROBLEMS OF EPIDEMIOLOGICAL INFERENCE

Epidemiology is the study of patterns of disease in groups of humans with the objective of identifying the causes of disease. It is an observational (i.e. not an experimental) science and as a consequence the findings of epidemiological studies must be interpreted with considerable caution. Although a statistical association between a disease and some factor may be indicative of an underlying cause-and-effect relationship, alternative explanations must always be considered. These explanations are that the association could have been produced through the effects of chance, or that certain biases are present within the study such that the association is an artefact, or that the association is due to confounding so that an underlying causal factor is related to both the disease and to the non-causally associated factor identified in the study.

The problems of interpretation of epidemiological associations have generated a considerable literature over the years. The eminent British epidemiologist, Sir Austin Bradford Hill, suggested nine criteria of causality against which epidemiological associations could be judged, and these are still used today in the scientific assessment of associations (2). Among the more important of the Hill criteria are the strength of the association, the consistency of the association across a variety of studies, evidence for a dose-response relationship (a "biological gradient"), and the evidence of biological plausibility.

The results of the studies carried out in the wake of the Seascale "cluster" must be viewed in the light of the nature of epidemiological research. They are a cautionary tale for those interested in the interpretation of epidemiological findings.

A PLETHORA OF "CLUSTER" REPORTS

The Seascale "cluster" generated other reports of childhood leukaemia "clusters" in the vicinity of nuclear installations in the UK, apparently indicating consistent evidence for a raised risk of childhood leukaemia around nuclear sites. These reports generated considerable publicity and independent investigations were conducted as a consequence. Closer examination of these findings, however, reveals that the evidence is not as persuasive as would appear at first sight (3,4). A number of the studies would seem to have been conducted on the basis of some prior knowledge of the pattern of childhood leukaemia in the vicinity of the particular installations investigated, and this prior knowledge

complicates the interpretation of results. As a consequence, secure statistical and epidemiological inference is lacking. Indeed, a recently published study of childhood leukaemia around nuclear installations in England and Wales which did not suffer from these sorts of inferential problems found that, apart from Sellafield, the evidence of any general spatial relationship between nuclear installations and childhood leukaemia was "extremely weak" (5). The "cluster" investigations carried out around nuclear sites do demonstrate the need for particular care in the design and execution of epidemiological studies carried out on an issue which is receiving wide publicity, with the consequent pressure on researchers to produce results.

POSSIBLE EXPLANATIONS

Direct Exposure to Ionising Radiation

Initial reactions to the report of the Seascale childhood leukaemia "cluster" were that the excess cases were due to an unpredicted effect of exposures to radionuclides discharged from Sellafield, or that the risk of radiation-induced childhood leukaemia had been underestimated. However, detailed radiological assessments have consistently demonstrated that the radiation doses received as a consequence of Sellafield discharges were too small by at least a factor of 100 to account for the observed excess of cases (6). By the end of the 1980s, it was widely acknowledged that direct exposure to radiation was most unlikely to be the cause of the Seascale "cluster" (7,8). This conclusion was reinforced by a recent comprehensive reassessment of radiation-induced leukaemia risk in Seascale (9).

Indirect Exposure to Ionising Radiation

In February 1990, the initial results of the West Cumbria leukaemia and lymphoma case-control study were published which suggested that the cause of the Seascale "cluster" might be indirect rather than direct exposure to ionising radiation (10). The study found a statistical association between childhood leukaemia and the radiation dose received by fathers while employed at Sellafield before the conception of their children. The authors suggested that the association was sufficient to account for the excess of childhood leukaemia in Seascale. This study received appreciable publicity and generated anxiety among radiation workers; but the association was based upon just 4 cases of leukaemia and the scientific support for a causal interpretation of association was, at best, weak. Nevertheless, this study led to one of the largest trials concerned with a personal injury claim to be heard in the English courts (11).

Evidence which has accrued since 1990 has demonstrated that the association is confined to those offspring of the Sellafield workforce who were born in Seascale, and does not extend to the great majority of the children of Sellafield workers who were born outside this village (12,13,14,15). Further, the association has not been found in any of the substantive studies carried out elsewhere (16). A causal interpretation of this association has now effectively been abandoned by scientific authorities (17,18). It would seem that this is an example of a statistical association which has been generated by the play of chance.

Population Mixing

One fascinating consequence of the Seascale "cluster" report is the series of studies conducted by Kinlen and his colleagues into the effect of unusual population mixing upon the risk of childhood leukaemia, which suggests an infective basis for childhood leukaemia. Sellafield is a large industrial complex sited in a remote rural area, and the employment demands of the site have generated unusual population movements in its vicinity. Kinlen has proposed that the consequent population mixing has produced an unusual pattern of infections which could elevate the risk of childhood leukaemia. He has now produced compelling evidence from a variety of detailed studies involving unusual population mixing in areas not associated with nuclear installations that such mixing does raise the risk of childhood leukaemia (19,20). This would appear to be the explanation for the Seascale "cluster"

which carries the most convincing scientific support. Kinlen's studies illustrate just how important it is to consider confounding as a possible explanation of an epidemiological association.

CONCLUSIONS

The Seascale childhood leukaemia "cluster" can be interpreted as indicating that the risk of childhood leukaemia arising from low-level exposure to ionising radiation has been underestimated. Indeed, several variants of such an interpretation have been advanced. These include exposure to particular radionuclides, an underestimation of the radiation risk coefficient for childhood leukaemia, and the existence of a previously unrecognised risk of childhood leukaemia from the preconceptional irradiation of fathers. However, the scientific assessment of epidemiological associations is a complex matter, and such associations must be interpreted with caution. It would now seem most likely that the Seascale "cluster" does not represent an unanticipated effect of the exposure to ionising radiation, but rather the effect of unusual population mixing generated by the Sellafield site which has produced an increase in the infection-based risk of childhood leukaemia. This episode in the history of epidemiological research provides a timely reminder of the need for great care in the interpretation of novel statistical associations.

NUCLEAR INSTALLATIONS AND CHILDHOOD LEUKAEMIA - TESTING THE HYPOTHESES, EXPLORING THE IMPLICATIONS - A REVIEW

Andy Slovak
British Nuclear Fuels plc, Risley, Cheshire, WA3 6AS

INTRODUCTION:

Two hypotheses have, since 1983, been pursued in relation to nuclear installations and childhood leukaemia. One is environmental, the other occupational. The transition from one to another and the segregation of one from another have often been unclear as have been the implications to be drawn from one as opposed to the other. Examination of the evolution of the two hypotheses demonstrates a number of phenomenological patterns common to modern health scares which makes them comparable to other such events. The scientific and public policy inferences which may be drawn from these events are considered by examining the processes concerned with testing these hypotheses.

ANALYSIS OF PUBLISHED STUDIES

The sentinel reports relevant to both hypotheses derive from population sets in the vicinity of the Sellafield nuclear generating and reprocessing complex in West Cumbria[1,2]. The later occupational hypothesis derived from multiple analyses of a geographical subset (Seascale) which was being examined in pursuit of the environmental hypothesis. Thus it was drawn from what was occupationally a "sub" sub-population. In each case a similar cycle of studies was pursued in exploration of the theories. Figures 1a and 1b show the secular trends in observed/expected or in relative risks and associated confidence intervals relevant to the two hypotheses. Both sets of data show a similar pattern of regression to the mean after the sentinel study.

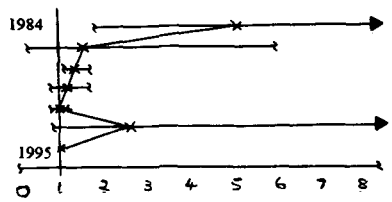

Fig. 1a Childhood leukaemia and the "environmental" hypothesis, summary of studies. O/E or RR and CIs. Unweighted. Highest exposed group in each study.

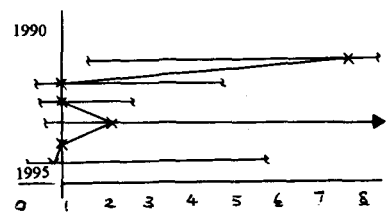

Fig. 1b. Childhood leukaemia and the "occupational" radiation hypothesis, summary of studies. O/E or RR and CIs. Unweighted. Highest exposed group in each study.

When considering the characteristics of the studies that were performed to test the two hypotheses, there is a strikingly similar pattern. Scientific work in the UK was initially concentrated on nuclear establishments in three areas, Sellafield[1], Dounreay[3] and Aldermaston/Burghfield[4]. In the geographical studies, significant excesses of childhood leukaemia were observed in all three studies. However the discharge history of the sites differed by orders of magnitude although derived doses were, by comparison with background, minute in all cases. By contrast the occupational studies carried out at Dounreay[5] and Aldermaston/Burghfield[6] did not support the preconceptual paternal irradiation (PPI) hypothesis but had vanishingly small power anyway.

Later and larger environmental (geographical) studies in the UK and elsewhere have continued to demonstrate a pattern of regression to the mean. For a number of reasons this is somewhat surprising. Firstly because the regression has continued despite the discovery of a slightly elevated risk of childhood leukaemia round potential nuclear sites generally historically. Secondly and paradoxically because such excesses of childhood leukaemia might actually be expected, at least from time to time, if an alternative, population mixing hypothesis were to be plausible.

Difficulties in discerning the crucial nature of the transition and separation of the environmental and occupational hypotheses may most relevantly be addressed by examining the key paper initiating the transition, that of Gardner[2]. This paper omitted to identify the critical importance of its derivation of the occupational hypothesis from a "geographical" sub-population of the Sellafield workforce who happened to live or to have lived in the village of Seascale. This turned out to be about 7% of the workforce and, on average, they had a slightly lower radiation dose than other workers. Thus it was left to others to infer that the most apposite test of the PPI hypothesis was by re-examining it in the whole of the population of Sellafield radiation workers from a subset of whom it had been derived[7]. When eventually performed, this test was negative. As with this study, other tests of the occupational hypothesis were uniformly negative.

The population mixing hypothesis, attributable to Kinlen, proposed that childhood leukaemia was the rare consequence of processes initiated by common viral infections and thus an excess of leukaemia would manifest in situations of "unusual" exposure to infection[8]. Specifically this would be unusually common occurrence of infection or particular liability to exposure to new strains of infection. The hypothesis was derived a priori and then tested initially in "new towns" (areas of rapid, mass resettlement) in the UK, and then in relation to military camps, wartime evacuation etc. The phenomenology is illustrated in Fig 2 and may be contrasted with Figs 1a and 1b. Of particular relevance to the nuclear debate are two other studies by Kinlen in pursuit of the mixing hypothesis. The first of these examined the temporary and recurrent migration patterns of Scottish workers serving the development of the Shetland oil industry[9]. This provided a plausible alternative explanation of the Thurso (Caithness) leukaemia cluster previously attributed to Dounreay. Similarly Kinlen's examination of large greenfield industrial, construction sites demonstrated the striking similarity of the pattern of excess of childhood leukaemia for these; including Sellafield when considered as a greenfield site[10]. It should perhaps be explained that Sellafield, in many ways, has been not so much a greenfield site but a series of greenfield sites with a rapidly turning over, serially migrant but constantly present large contractor population throughout many years of its existence.

DISCUSSION

In retrospect the leukaemia/nuclear installation debates have been characterised by early, small positive studies with a rapid fall off in positivity in later studies, large and small.

The phenomenology of the leukaemia/nuclear installation studies thus shows a pattern of secular regression to the mean similar to that seen in a number of health scares, as exemplified by the VDT - miscarriage data. This latter is shown in Fig. 3. In contrast this pattern is not seen in studies testing the population mixing concept (Fig. 2).

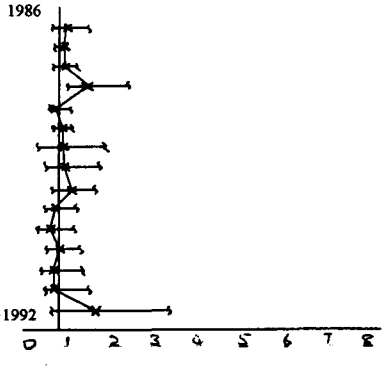

Fig. 3 Work with VDTs and spontaneous abortions, summary of studies. RR and CI for highest exposed group in each study.

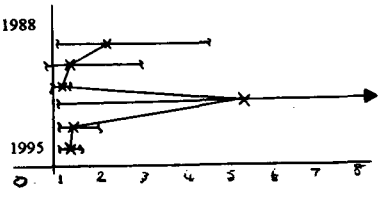

Fig 2. Tests of the childhood leukaemia population mixing hypothesis, summary of studies. O/E or RR and CI for highest "at risk" population group in each study.

The inference that may be available from the foregoing is that the population-mixing hypothesis may be describing events more plausibly than the hypotheses linked to radiation. The recognition of the phenomenology, that is the temporal trend or history of the studies relevant to a particular theory is of interest in itself but is more importantly a prescription for redoubled caution in progressing scientific research and delineating public policy in relation to it.

In scientific terms it is first necessary to re-emphasise the primarily hypothetical nature of case referent studies. Additionally, it is important to have higher regard to the long established criteria for inferring causation as propounded, among others, by Bradford-Hill. Thus it is prudent to show proper scientific caution by exercising due regard for the null hypothesis and similarly to view with caution the dissonances discernible in the biological and general scientific plausibility of novel ideas (especially across different scientific disciplines). Further it may be necessary to form a detached view of how much science should actually be done and completed before speculation is reasonably regarded as being ended and replaced by some degree of certainty. Finally, and this passes over into public policy also, the science that is done might usefully be planned so that it may be optimally focused and reorganised to serve the public interest.

In public health scares, initial "official" caution about a new hypothesis is discernible until a threshold of concern, often modulated by media attention, is overcome. A second characteristic is the subsequent caution manifested before the previously alien hypothesis, then adopted, is discarded and abandoned. It is suggested that such features, being generic, are capable of generic solution perhaps by effectively separating expert scientific advice from policy making based on that advice. Also, although this may be a counsel of perfection, some attempt might be made to avoid stigmatisation of a putative "guilty" party and putative populations at risk during the investigative phase.

By such more rigorous scientific criteria the population-mixing hypothesis performs quite well but still needs to meet a number of "robustness" requirements. Thus it is of importance to its viability that biological agents of effect be identified as well as the process by which the effect might be manifested. Further tests would usefully include the capacity to explain the Seascale cluster, demonstrate some form of dose response relationship and attempt to explain the negative findings reported round many nuclear installations.

CONCLUSIONS

The main thesis of this paper has been to demonstrate the particular phenomenology of the nuclear installations/childhood leukaemia sagas and to infer the scientific and public policy implications of the experience of investigation of these hypotheses and their confounders. If, as appears to be the case, we live in a period where science policy is more populist and thus liable to be impacted more directly and immediately by "public concern" issues, it follows that there may also be new challenges for public information and understanding and new requirements for the operation of the process of public science policy.

ARE THERE RISKS FROM EXPOSURE TO LOW LEVEL RADIATION?

D J Higson

260 Glenmore Road, Paddington, NSW 2021, Australia

ABSTRACT

For doses up to at least 50 mSv received at a high rate in a single event by adults (or 10 mSv for exposure of the embryo and foetus) and up to at least 15 mSv per year received routinely, there is no proof that radiation increases risks of cancer. One reason for this may be that there are beneficial or protective effects of radiation which tend to offset and perhaps dominate over the harmful effects at low levels of exposure. Another reason is that the effects are too small to be measured. It is not necessarily in the best interests of individuals or of society to assume that the linear hypothesis should be used to estimate risks throughout this range.

INTRODUCTION

With the resumption of nuclear weapons testing by France, there has been much in the news and "on the streets" in Australia about the dangers of exposure to radiation. We continually hear and read statements to the effect that there is no safe level of exposure and, regrettably, our profession has to bear some of the responsibility for this misconception.

Elsewhere in the world, a great deal of dissent and concern is being expressed regarding radiation protection regulations and practices which are based on the view that no level of radiation dose is free of risk. The first sixteen pages of the Health Physics Society's Newsletter of June 1995 provides examples. Particular concerns have been expressed that such regulations impose high costs on industry without achieving demonstrable benefits. It has even been suggested that some providers of radiation protection services have a vested interest in this situation.

Central to both issues is the ICRP's recommendation that risks of radiation induced cancers should be assumed to be proportional to dose without thresholds (1), the "linear hypothesis". It needs to be stressed that the linear hypothesis is an assumption, not a proven fact or a law of nature. Its application to low levels of radiation needs to be placed in perspective. This should not be taken as support for nuclear weapons testing or as opposition to the assessment and regulation of radiation protection practices. It simply reflects the need to apply a scientific approach to the question of risk at low levels of radiation exposure.

RISK ESTIMATION IN PERSPECTIVE

The linear hypothesis was formulated for the purpose of assessing radiation protection practices, not for estimating risks to individuals from low levels of radiation. The risk coefficients recommended by the ICRP (1) are based on the observed health effects of high doses received at high dose rates, e.g. by atomic bomb survivors at Hiroshima and Nagasaki. Radiation is more likely to be harmful when delivered at these high rates rather than spread over a protracted period. However, even at the highest rates which have been experienced, statistically significant increases in the incidence of cancers have not been observed at dose levels less than about 50-200 mSv for adults (1-2). For exposure of the embryo and foetus, detectable health effects have been observed at dose levels down to about 10-20 mSv.

The extent to which the linear hypothesis and the recommended risk coefficients apply

at lower doses and dose rates is questionable. As explained below, this is not so much a matter of thresholds as of the relative importance of different effects. However, the ICRP does not rule out the possibility that thresholds may exist (1).

It appears to be well established that radiation has beneficial or protective effects on living cells and organisms, as well as harmful or potentially harmful effects (2,3). Determination of the net effects on humans (such as changes to life expectancies or risks of cancer) requires properly designed epidemiological studies. At low levels of exposure, net effects may be too small to discern, i.e. because of statistical difficulties of measuring them against variations not caused by radiation. Hence, although biologically positive effects (sometimes called "hormesis") have been demonstrated in the form of adaptive responses of cells and organisms to damage from radiation, these effects cannot be reliably expressed as reductions in the incidence of cancer (2). On the other hand, there has been no detectible excess of cancers attributable to radiation for the same conditions of exposure.

PROTRACTED EXPOSURE TO RADIATION

A recent study (4) of protracted occupational exposures in the nuclear industry has shown that there is "no evidence of an association between radiation dose and mortality from all causes or from all cancers". At 100 mSv, there are dose-related increases in mortality from some cancers but these appear to be balanced by dose-related decreases for some other types of cancer.

The average rate of protracted public exposure to background radiation is about 2 mSv per year in Australia. In other parts of the world, it varies from less than 1 mSv per year to more than 15 mSv per year (2). Local populations living above some mineral deposits incur lifetime doses well in excess of 1,000 mSv from natural background radiation. The ICRP risk coefficient of 5×10^{-5} per mSv applied to a dose rate of 2 mSv per year gives a risk rate of 10 fatalities per hundred thousand per year, which is about 5% of the total rate of fatal cancers from all causes in Australia.

There are many variable factors other than radiation which affect the incidences of cancers. Nevertheless, on the basis of a linear extrapolation from figures in the foregoing paragraph, it would be expected that differences of dose rate over its range of natural variation would cause substantial differences in the total rates of cancers in the exposed populations. In fact, no correlation has been established between background radiation and rates of cancer (or genetic effects) in humans, suggesting that the ICRP recommendations do not apply to routine exposures within the range of background radiation rates. Effects, if they exist, are so small that they cannot be measured.

Even if radiation in the natural environment is having effects, it might be inappropriate to describe these effects as harmful. Human evolution has taken place in the presence of naturally occurring radiation and it is a fundamental tenet of evolutionary biology that organisms adapt to their environment (5). This means that, within the range of natural background, levels of survival and fitness should be expected which are optimum with respect to radiation.

APPLICATIONS OF RISK ESTIMATES IN RADIATION PROTECTION

The practice of radiological protection is concerned mainly with two of its three general principles - compliance with dose limits and the optimisation of radiation protection practices. Compliance with these principles can reasonably be equated with "safety", because the total absence of risk is fundamentally not achievable in the practice of any potentially hazardous activity and therefore cannot be a legitimate objective of regulation.

The linear hypothesis is the basis for the establishment of individual dose limits and is

intentionally conservative for this purpose. Dose limits recommended by the ICRP (1) are actually at levels where the risk can only be estimated hypothetically. These dose limits provide a high level of protection for individuals whose exposures are reliably known.

However, the postulation of the linear hypothesis has given rise to the belief that any dose of radiation, no matter how small, increases the risks of cancer and other adverse health effects. In fact, there is no evidence to support this belief except for the linear hypothesis itself, which is an assumption, and radiation appears to have biologically positive (beneficial) effects which may predominate at low dose levels. When dealing with the effects of low doses, estimated in accordance with the linear hypothesis, optimisation may thus involve balancing real costs against hypothetical benefits which are too small to be demonstrated and might well be non-existent. This application of the linear hypothesis should be viewed with caution.

Applications of the linear hypothesis to justification, the third general principle of radiological protection, should also be viewed with caution. The justification of a practice requires that it produce sufficient benefit to offset the radiation detriment it causes (1). This goes far beyond the scope of radiological protection. Clearly, however, many of society's concerns about the justification for uses of nuclear energy relate to risks, and hence to detriments, which have been overestimated - perhaps greatly overestimated. Decisions made on this basis may not be in society's best interests.

CONCLUSIONS

For doses up to at least 50 mSv received at a high rate in a single event by adults (or 10 mSv for exposure of the embryo and foetus) and up to at least 15 mSv per year received routinely, there is no proof that exposure to radiation increases the risk of cancer. Biologically positive and negative effects of radiation have been demonstrated in this range. However, because of statistical difficulties of measurement, they cannot be evaluated quantitatively in terms of changes to rates of cancer incidences. It is not likely that there is a discontinuity or cut-off to any of these effects at either high or low levels of exposure. The assumption that effects observed only at high doses and dose rates can be extrapolated to low doses and dose rates, to the exclusion of other effects, is questionable. It is not necessarily in the best interests of individuals or of society to make this assumption.

MAJOR SCIENTIFIC TOPIC NUMBER 2.3, 3.1-3.5 (page 7)

The experience and results in dose and risk assessment for Ukraine population after the Chernobyl accident are generalized. Four affected groups are considered: (i) *clean-up worker* (liquidators), (ii) *population* of the contaminated territories, (iii) *people had been evacuated* from Prip'jt and 30-km zone, (iv) *children with exposed thyroid gland.* Main results are follow :
(i) The exposure of *liquidators* (130 thousands persons worked in Chernobyl NPP in 1986) were estimated as 0.02-6 Sv; 6-15% of them received the doses higher than 0.25 Sv. Average individual dose of liquidators (in 1986) is 0.12 Sv.
(ii) Average ten-years individual doses of *general population* from contaminated territories are 10-160 mSv. Levels and relations of internal and external exposure pathways strongly depend on the initial radioactive deposition, type of soil, agriculture practice and diet traditions.
(iii) Doses of *evacuated people* (before the evacuation) are 1-50 mSv.
(iv) *Radioiodine thyroid exposure of children* had been reconstructed based on the some thousands of direct thyroid activity measurements made in 1986. The interval of estimated dose ranges from less than 10 mSv to more than 10 Sv. The map with the different children thyroid dose zones within Ukraine is demonstrated.

The calculations of the late health effects induced by different exposure sources for different age-groups were made. These estimations are compared with the really observed levels of oncomorbidity and mortality. The only statistically significant radioinduced effect is thyroid cancer among children exposed in 1986. All the results are presented in form of tables and maps.

DOES THE EXPOSURE FROM THE CHERNOBYL ACCIDENT ASSOCIATE WITH CANCER DEATHS IN GREECE ?

C.Papastefanou

Nuclear Physics Department, Aristotle University of Thessaloniki
Thessaloniki 54006,Greece

INTRODUCTION

Exposure of the population occurs via three main pathways: external irradiation from material deposited on the ground, inhalation of airborne material and ingestion of contaminated foodstuffs. The population dose associated with these exposure pathways was evaluated just for one year, i.e. the first year after the Chernobyl accident (May 1986 - April 1987) for the following reasons: i) the specific activities of I-131, Ru-103 and Cs-134 + Cs-137 in air were peaked on May 5-6,1986. A month later, the specific activities of the above radionuclides in air declined by a factor of 1000 (1) reaching the level of 1 mBq /m3 or lower, ii) the specific activity of the long-lived Cs-137, which remained until today, significantly decreased in the foodstuffs a year after the Chernobyl accident, i.i. by a factor of 1000.

EXPERIMENTAL PROCEDURES

From the beginning of May 1986, the Nuclear Physics Laboratory of Aristotle University of Thessaloniki (Greece), initiated different measurements on fallout of the radioactive debris transported from Chernobyl.

Alpha, beta and gamma radiation monitoring systems were set into operation in order to measure the radioactivity in air, precipitation (rainwater from any rainfall event), soil, grass, milk and a large number of items of contaminated foodstuff.

All the samples were measured for radioactivity using a Ge-Li high resolution spectrometer (resolution 2 keV at 1.33 MeV) in a standard geometry 40 g plastic can of 6 cm in diameter or in a Marinelli beaker of 1 litre (volume) or about 1 kg (mass). The gamma spectroscopic system was calibrated using standard reference sources in both cases, the overall efficiency being known to accracy of better than 5 % for the plastic can geometry and about 12 % for the Marinelli beaker geometry.

EXPOSURE OF THE POPULATION

Taking into account the concentrations of the following radionuclides: I-131, Ru-103 and Cs-134 + Cs-137 in all the samples of air, precipitation, soil, grass, milk and various items of contaminated foodstuff as well as the dose conversion factors, it was estimated that 17.7 μSv was due to external irradiation from contaminated ground, 98.14 μSv was due to internal dose from inhalation of airborne material and 2.04 mSv was due to internal dose from ingestion of contaminated foodstuffs. The total dose enhancement for the first year after the Chernobyl accident was 2.16 mSv. It is concluded that 94.4 % of the total dose enhancement was due to internal dose from ingestion of contaminated foodstuffs.

RADIOLOGICAL IMPACT

Taking into account the risk factor, wich is of the order of 10^{-5} per mSv for deaths by cancer (2), the total dose enhancement, i.e. 2.16 mSv (216 mrem) would be expected to lead to 214 cases of cancer deaths appearing in Greece over a period of 15 years or more in a population of 10 million people. This predicted increase in total cancer deaths would be difficult to detect, as it is very small relative to the number of cancer deaths from all other reasons (except Chernobyl) which should be about 330000 up to the year 2001 as derived from the data of Fig.1. It is therefore not achievable to distin-

guish any cancer death due to the Chernobyl accident from cancer deaths due to all other reasons.

The collective dose is the individual dose multiplied by the population. Based on our data, an approximate estimate gives about 20000 person Sv for the annual collective dose, assuming ≈2 mSv as the annual individual dose and 10 millions the population of Greece in accord with the last census of 1991 (3).

As a consequence of the exposure to radioactivity due to fallout from the Chernobyl accident cancer deaths are expected at the digestive system, the respiratory system and the hematopoietic system. No clear rise was observed in the monthly variation of cancer deaths in all of the above mentioned cases since the Chernobyl accident, see Fig.2.

In Fig.1 the annual number of cancer deaths in Greece was presented for the period 1968-93. The increase of cancer deaths from the year 1992 to the year 1993, just one year, was 2.5 %. That percentage was the maximum since the Chernobyl accident. The data of Figures 1 and 2 originated from the Monthly Statistical Bulletin of the National Statistical Service of Greece.

ABSTRACT (See instructions overleaf)

The comparison of the effects of high and low LET radiation exposure in man has been the subject of much debate over the years. Although the cohort of Japanese atomic bomb survivors has for a long time been the main source of data for the direct estimation of the effects of γ-rays, since the introduction of the DS86 dosimetry it has not been possible to draw any conclusions about the risks from neutrons. However, there is now growing evidence that the DS86 dosimetry needs further revision, which could result in an increase in neutron doses by up to a factor of 10 at distances beyond 1000 m in Hiroshima (Straume, et al., 1992, Health Physics, 63, 421-426, Straume, et al., 1994, Radiation Research, 138, 193-200). If the neutron doses were revised upwards in the manner suggested, the excess relative risk (ERR) for cancer incidence from low-LET radiations is likely to remain relatively unchanged. However, such a revision should make it possible to estimate the risks from neutrons. Using the recently released Japanese incidence data and assuming the dose responses are linear for both neutron and gamma radiation, it is estimated that the ERR per gray of neutrons will most likely be between 2.5 and 8.5 for all cancers except leukaemia. These values correspond to a relative biological effectiveness (RBE) of neutrons compared to gamma radiation of 5 and 15 respectively. These values are in broad agreement with the current ICRP neutron quality factors and radiation weighting factors for the energy range 0.1 keV - 2.0 MeV relevant to the Japanese bomb survivors (ICRP Publication 60, 1991).

ABSTRACT

The contribution of radon and its short-lived decay products amounts to as much as 80% of the indoor background radiation in Russia and other republics of the FSU. No less than 10% of the lung-cancer risk in human populations may be ascribed to the radon radiation. The lung-cancer annual mortality-rate risk for adults follows the double exponential distribution function. To explain this law, the reliability-theory approach has been developed [Grodzinsky et al., 1987; Koltover, 1995]. This approach enables explanation of the kinetics of the mortality growth with age together with evaluation of effects of exposure to radon progeny. Apart from the quantitative constructing of mortality curves, the theory of reliability may also serve as the basis of investigation of molecular mechanisms of radon effects. In part, the hormetic effects of low-dose exposure to radon can be explained as resulting from its mild stress-action upon the neuro-endocrine system that trains the organism's adaptive possibilities. The analysis of fluctuations of physiological parameters is suggested as the prognostic method for testing the reliability of bio-systems while exposed to radon and its decay products.

AN EXPERIMENTAL MODEL FOR RISK ASSESSMENT OF COMBINED EXPOSURE TO RADON AND OTHER AIRBORNE POLLUTANTS

G. Monchaux, J.P. Morlier, M. Morin and R. Maximilien
Laboratoire de Cancérologie Expérimentale
CEA-DSV-DRR, BP 6, 92265 Fontenay aux Roses Cedex

INTRODUCTION

Combined exposure to radon and its progeny and various occupational or environmental airborne pollutants may lead to synergistic effects for lung cancer induction. In humans, an increased incidence of pulmonary neoplasia has been observed in different groups exposed to radon and its daughters, including uranium miners (1), iron miners (2) and other miners (3) especially cigarette smokers (4). These findings suggest that co-carcinogenic mechanisms may be involved in the pathogenesis of lung cancer. In laboratory animals, a co-carcinogenic effect results in increased tumour rates after combined administration of the potential carcinogens (5). A standardized protocol has been developed in Sprague-Dawley rats to identify potential co-carcinogenic agents. In this, rats are exposed to 1000 WLM of radon followed by exposure to the agent to be studied (6). Exposure to 1000 WLM of radon alone results in a lung cancer incidence of 20%. About 30% of the tumours are squamous cell carcinoma, 50% adenocarcinoma and 20% bronchioloalveolar carcinoma. In these lifespan studies, after exposure, rats were allowed to live until they died or were moribund and then killed and the latency period for tumour induction was about 700 days. The effects in rats of combined exposure to radon and various environmental or industrial airborne pollutants such as cigarette smoke, mineral fibres, diesel exhausts, minerals associated with metallic mine ores and chlorinated compounds are reviewed in relation with the possibility of combined exposure for workers in different industries.

RESULTS

Combined exposure to radon and tobacco smoke

The first experiments were carried out to investigate the effects of inhalation of radon and its daughters at various cumulative doses, before or after various passive exposures to tobacco smoke (7), using cigarettes with and without filters. For a 1000 WLM radon exposure, the incidence of lung carcinomas was slightly lower in rats exposed to tobacco smoke before radon exposure than in rats exposed to radon alone, but the distribution of the different histological types of tumours were similar in the two groups. In contrast, a highly significant excess of lung carcinomas, mainly of the squamous cell type, was observed in the group exposed to tobacco smoke after radon exposure. In this group, the incidence of lung carcinomas was almost four times greater than in the group exposed to radon alone.

The results of further studies in which rats were exposed to cigarette smoke following exposure to radon showed that for the same tobacco smoke exposure, the incidence of lung carcinomas increased with the cumulative dose of radon. In the same way, for an identical cumulative dose of radon and its daughters, the incidence of lung carcinomas increased with the cumulative exposure to tobacco smoke.

The induction of lung carcinomas was less efficient in rats exposed to tobacco smoke produced by filter cigarettes than in those exposed to cigarettes without filters. The incidence of lung carcinomas were higher, but not statistically significant in the groups exposed to radon and tobacco smoke combined than in the group exposed to radon alone and the proportion of lung carcinomas was lower in the group exposed to filter cigarettes than in the group exposed to unfiltered cigarettes. The increased incidence of lung carcinomas in the group exposed to radon and non filter cigarettes was mainly related to an increased incidence of squamous cell carcinomas. These findings suggested a stronger synergistic effect of radon and non filter cigarettes compared to that of radon and filter cigarettes.

In rats exposed to radon and tobacco smoke combined, for the same radon exposure, the incidence of lung carcinomas was greatly increased in the group exposed to radon and tobacco smoke compared with the group exposed to radon only. Tumours observed in the

groups exposed to radon and tobacco smoke were larger and more invasive than in the groups exposed to radon alone. These tumours also spread more to the pleura and the presence of intrapulmonary metastases or of multiple tumours in the lung was observed. For the same radon exposure, the mean latent period for lung carcinomas was shorter in the group exposed to radon and then to tobacco smoke compared with the group exposed to radon alone. For an identical tobacco smoke exposure of 350 hours, the mean latency period was inversely related to the cumulative radon dose. All these results showed a clear co-carcinogenic effect of exposure to radon and radon daughters and tobacco smoke in rats.

Combined exposure to radon and mineral fibres and other industrial or environmental airborne pollutants

The experimental protocol described above was used to study the potential co-carcinogenic effects of radon and mineral fibres. Acid leached chrysotile fibres were shown to exhibit less carcinogenic activity *in vivo* than untreated fibres (8). Since mesothelial cells are considered to be the target cells for the induction of tumours by mineral fibres, this experiment was designed to investigate the potential synergistic action of different kinds of unleached or acid leached asbestos fibres and other mineral dusts injected into the pleural cavity of rats after previous inhalation of radon and its daughters. In these experiments, 60 rats exposed to radon were used as controls. Ten groups of 10 rats each were exposed to the same dose of radon and then, 2 weeks later were injected intrapleurally with 2 mg of mineral dust, unleached or leached asbestos fibres, glass fibres and two varieties of quartz. No rats were exposed to mineral fibres alone. The results are summarized in table 1.

Table 1. Combined effects of radon and other environmental or industrial airborne pollutants

Experiments	Results	Conclusion
Radon + Cigarette Smoke	Increased incidence of lung carcinomas up to 4 times greater than in rats exposed to radon alone	**Multiplicative effect**
Radon + Mineral Fibres	1 / 3 Lung carcinomas 1 / 3 Pleural mesotheliomas 1 / 3 Combined pulmonary pleural tumours in excess	**Additive effect**
Radon + Diesel Exhaust	Slight non significant excess of lung carcinomas	**No clear synergistic effect**
Radon + Minerals from Metallic Mine Ores	Slight non significant excess of lung carcinomas	**No clear synergistic effect**
Radon + Methylene chloride	No excess of lung cancer	**No synergistic effect**

The potential carcinogenic or co-carcinogenic role of 4 minerals present in the ores of metallic mines was also investigated. These included, nemalite (a contaminant of Quebec chrysotile), biotite (present in many granites and in the French uranium ore), iron pyrites (present in various iron and gold ores), and finally iron-rich chlorite (present in iron, tungsten and gold ores).

The use of diesel-powered vehicles is steadily increasing worldwide. Among diesel-exhaust exposed populations, only a case control study and a retrospective cohort study in railroad workers (9), showed a significant association between diesel exhaust inhalation and lung cancer, suggesting that occupational exposure to diesel exhausts results in a small but significant excess risk of lung cancer. Experimentally, some evidence of a carcinogenic effect has been previously reported in rats after exposure to diesel exhaust containing high concentrations of diesel soot particles for periods of up to 2 years (10). The potential synergistic effects of diesel exhaust were investigated in rats after previous exposure to radon and radon daughters.

Chlorinated compounds are widely used in a variety of commercial forms for industrial and medical applications. Exposure to methylene chloride induces lung and liver cancers in mice. The aim of this study was to test the potential carcinogenic or cocarcinogenic effect of methylene chloride in rats, acting either alone, as a complete carcinogen, or as a promoter after local pulmonary irradiation by inhalation of radon.

The results of these different studies are summarized in table 1.

CONCLUSION

These results demonstrate the potential co-carcinogenic action of various environmental or industrial airborne pollutants combined with radon exposure, showing either a multiplicative, an additive or nul effect. The strongest co-carcinogenic effect was shown by combined exposure first to radon and then to tobacco smoke and resulted in an increased incidence of lung carcinomas, mainly of the squamous cell type. These results also indicated the possible application of this "radon model" to the investigation of possible interactions between exposure to two occupational and/or environmental pollutants. The importance of such an experimental model for risk assessment should be emphasized since human industrial occupational or environmental exposures are nearly always not single but multiple.

A MOLECULARBIOLOGICAL MODEL FOR THE DOSE-EFFECT RELATION FITTING DIFFERENT EPIDEMIOLOGICAL DATA

Carl M. Fleck, Markus Kottbauer, Helmut Schöllnberger
Atominstitut der österreichischen Universitäten, Wien, A-1020

The effect of radiation hormesis can be observed in an increasing number of epidemiological studies investigating the cancer rate at different levels of background radiation. At this low level dose rate the mortality rate for several types of cancers decreases with increasing dose rate while others do not. With the Random Coincidence Model (RCM), a new model concerning the dose-effect relation, /1/, /2/, it is possible to explain the radiobiological effect of radiation hormesis and to give conditions when hormesis takes place and when it does not. This model describes the formation of cancer caused by a multistage process of mutations in the critical regions of tumor associated genes such as proto-oncogenes or tumor suppressor genes. The central thesis of the model says that a point mutation not only occurs by a causal coincidence of two base lesions or a misrepair of one base lesion or a DSB but also by a random coincidence of two base lesions or two single strand breaks of complementary DNA strands during the repair time of the first base lesion or single strand break.

As the random coincidence predominates the results of the RCM, the basic equations of this mechanism will be discussed now. The probability for a single base lesion or a single strand break per second (S) on each location of the DNA is the sum of the probabilities of a chemically induced nucleotide lesion ($C\alpha$) and a radiologically induced nucleotide lesion ($D\beta$)

$$S = (C\alpha + \dot{D}\beta) \tag{1}$$

The probability per second that the complementary nucleotide (or a nucleotide close to the complementary nucleotide) is also damaged before or during the repair of the first nucleotide, making the repair ineffective is described by the equation:

$$S_{fixed} = (C\alpha + \dot{D}\beta)^2 \tau \tag{2}$$

This is the fixation rate of point mutations or a misrepair of DSB caused by a randomly coincident destruction of both complementary bases or a randomly coincident caused double strand break. The coincidence takes place during the repair time. Equation (2) leads to a synergism between radiation and chemical noxes as a mixed term that does not arise if we just add the terms of both damage mechanisms:

$$S_{fixed} = \left[C^2\alpha^2 + 2C\alpha\dot{D}\beta + \dot{D}^2\beta^2\right]\tau \tag{3}$$

It is well known that cells have a response mechanism which reacts on irradiation. Works from Eckardt-Schupp /3/, Boothman /4/, Woloschak /5/, Sankaranarayanan /6/ and many others have shown this in detail. The elimination of low-dose hypersensitivity in Chinese Hamster V79-379A cells by pretreatment with x rays or hydrogen peroxide was recently shown in a work from B. Marples and M.C. Joiner /7/.

The RCM model implies that the rate of damage fixation depends on the repair time of the first base lesion or single strand break. The repair time is a function of the repair enzyme concentration as indicated by the Michaelis-Menten relation /8/. Recently Livneh /9/ gave the experimental evidence of the mutagenic pathway described above.

In the lowest dose rate region we assume a linear correlation between the mean dose rate $\dot{D}$ applied to tissue and the enzyme concentration increasing after this irradiation:

$$[E] = [E_0] + \delta' \dot{D} \tag{4}$$

$[E_0]$ is the concentration of repair enzymes in the absence of radiation and [E] is the concentration after a stimulation caused by radiation /3-7/. The factor δ' describes the extent of the production of additional repair enzymes caused by radiation and so does δ which is defined as $\delta := \frac{\delta'}{[E_0]}$. This leads to

$$\frac{[E]}{[E_0]} = 1 + \delta \dot{D} \tag{5}$$

For low dose rate irradiations as regarded in the data fits of B.L. Cohen's radon data and in those fits related to background radiation (ARIP), we refer to the equilibrium of enzyme production: the production of repair enzymes by chemicals and radiation is as large as their decay. The search for lesions by means of repair enzymes is a diffusion controlled process. In other words: the more repair enzymes are available, the faster is the finding of lesions and the higher is the velocity v of the repair process: v is proportional to the enzyme concentration and it is indirectly proportional to the repair time, thus we obtain

$$\tau = \frac{\tau_0}{1 + \delta \dot{D}} \tag{6}$$

Combining equations (3) and (6) we get equation (7), for which each term is plotted separately in Fig.1.

$$S_{fixed} = \underbrace{\frac{C^2 \alpha^2 \tau_0}{1 + \delta \dot{D}}}_{\text{term 1}} + \underbrace{\frac{2C\alpha \dot{D} \beta \tau_0}{1 + \delta \dot{D}}}_{\text{term 2}} + \underbrace{\frac{\dot{D}^2 \beta^2 \tau_0}{1 + \delta \dot{D}}}_{\text{term 3}} \tag{7}$$

Fig.1 shows the most important influence of the Random Coincidence Model on the discussion of the linear dose-effect relationship versus radiation hormesis at small dose rates. Fig. 1 clearly shows that both parties are right:

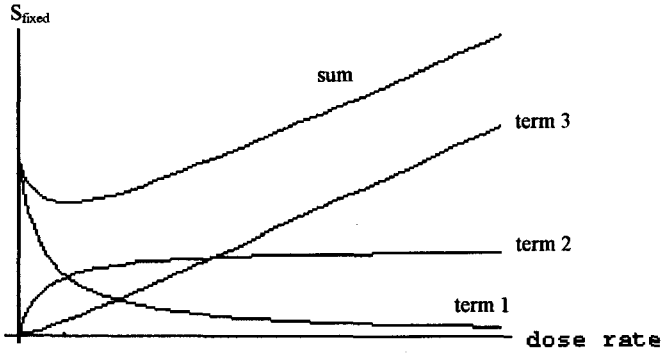

Fig.1

1) The direct radiation induced transformation rate (term 3) increases as a function of dose rate very close to linearity.

2) In addition to that, the radiation stimulated production of repair enzymes is able to reduce oxidative impact of radicals of the natural cell metabolism (term 1) and therefore causes a decrease of the natural transformation rate.

3) Of course there is a synergism of chemical and radiation impact (term 2), which indicates that under certain circumstances a multiplicative dose-risc relationship will dominate the dose-effect relationship.

4) Only if the impact of chemicals or the natural cell metabolism on the DNA is larger than the radiation induced one, the reduction of the oxidatively induced lesions is able to dominate over the increase of radiologically caused lesions: hormesis takes place (sum).

In other words: radiation hormesis can only exist if the oxidatively induced transformation rate is larger than the radiation induced one.

For experiments on radiation adaption the working principle is the same as in hormesis, just the part of the dominating oxidative and chemical impact is taken over by the "challenge dose": the increase of the repair stimulating damages due to the "inductive dose" is much more than compensated by the large decrease of those damages caused by the "challenge dose" and this decrease is a consequence of the stimulation of the repair system by the priming dose.

The Random Coincidence Model describes two different ways of the formation of point mutations:

a) point mutations where the damage of the complementary base (nucleotide) occurs before or during the repair of the first base (we talk about a random coincident fixation of the damage because the damage of the complementary base happens randomly and coincidently within the repair time τ before the first base is repaired)

b) point mutations where the damage of the complementary base (nucleotide) occurs immediately after the damage of the first base (we talk about a causal fixation). Both complementary bases (nucleotides) are damaged by the same particle or by the same cloud of radicals resulting from one particle.

For those point mutations described under a) the formalism of the model contains an expression for the chemically induced rate of point mutations ($C^2\alpha^2\tau$), one for the synergism between radiologically induced and chemically induced rate of point mutations ($2C\alpha\dot{D}\beta\tau$) and one for the coincidently occuring radiation induced rate $\dot{D}^2\beta^2\tau$ (equ.3). For point mutations described under b) we use the expression for causal damages ($\frac{1}{f_{nuc}} z_F \dot{D}\beta^2$), changing equation (3) into

$$S_{fixed} = \frac{\left[C\alpha + \dot{D}\beta\right]^2 \tau_0}{1 + \delta\dot{D}} + \frac{1}{f_{nuc}} z_F \beta^2 \dot{D} \qquad (8)$$

where the relation between the term for causal damages and the term for random coincidences can be derived by the help of microdosimetry, where z is the frequency mean specific energy per event departed by the radiation in a critical volume.

There is much epidemiological and experimental evidence that malignant change is a process which results from multiple genetic alterations. Several lines of evidence suggest that changes to more than one proto-oncogene are involved in tumors /10/. In a few human tumors, for example, changes to more than one proto-oncogene have been found /11/. Another evidence for the involvement of multiple oncogenes comes from studies in which the malignant transformation of non-immortal cell strains is facilitated by the introduction of two different oncogenes /12/. Therefore equation (8) is the source term in a system of linear differential equations, where each of the equations describes one transformation step in the successive process of carcinogenesis.

The explanation of B.L. Cohen's radon data and the low-LET ARIP-data with the Random Coincidence Model

Helmut Schöllnberger,[1] Bernard L. Cohen,[2] Carl M. Fleck,[1] Markus M. Kottbauer[1]
[1]Atominstitut der Österreichischen Universitäten, A-1020 Wien
[2]University of Pittsburgh, Pittsburgh, PA 15260

Abstract The Random Coincidence Model (RCM) describes the formation of cancer if caused by a multistep series of point mutations in the critical regions of tumor associated genes such as proto-oncogenes or tumor-suppressor genes. It is the central thesis of the model that a point mutation mainly occurs through the random coincidence of two base lesions or two single strand breaks of complementary DNA bases (strands) during the repair time of the first base lesion or SSB.

Introduction The effect of radiation hormesis can be observed in an increasing number of epidemiological studies investigating the cancer rate at different levels of background radiation. At this low level dose rate the mortality rate for several types of cancers decreases with an increasing dose rate while others do not. In his epidemiological investigations, B.L. Cohen (1) measured the average radon level in homes in 1730 counties of the USA and correlated these data with lung cancer mortality. He found a clear tendency of decreasing lung cancer mortality with an increasing radon dose. Years ago N.A. Frigerio (2) got the same results for background radiation (terrestrial- and cosmic γ-radiation, K-40).

The RCM proposes the randomly coincident destruction of the complementary DNA base (nucleotide) before or during the repair of the first damaged base (nucleotide). Random coincidence means that after the first base (nucleotide) lesion the second damage on the complimentary base (nucleotide) occurs randomly before the repair of the first base (nucleotide) lesion is finished and coincidently within the repair time. This approach implies that the rate of damage fixation depends on the repair time of the first base lesion or SSB. The repair time is a function of the repair enzyme concentration as indicated by the Michaelis-Menten relation. To explain radiation hormesis we have to assume that the repair enzyme concentration and the concentration of scavengers, radical detoxification systems, is direct proportional to the dose rate.
Wallace has recently reviewed the nature of the DNA lesions caused by active oxidizing species produced both naturally and by low-LET radiation (3). Oxidizing radicals and especially OH radicals resulting from either cause produce similar types of DNA lesions (3-5). The enzymes involved in their repair are similar no matter whether the DNA damage is produced spontaneously or by radiation (6).
We therefore explain radiation hormesis as a result of the reduction of the spontaneous (chemical) damage probability by a small dose rate of ionizing radiation causing an additional genetic expression of repair enzymes and scavengers.

The Model $C\alpha$ is the chemical damage probability per second and nucleotide, caused by the natural cell metabolism and by chemical carcinogens. $\dot{D}\beta$ is the radiological damage probability per second and nucleotide. $\dot{D}\beta$ includes the possibility that radiation directly interacts with the nucleotide or indirectly by radicals.
The probability per second that the complementary base (nucleotide) is also damaged before or during the repair of the first base (nucleotide) is described by the equation:

$$S_{fixed}=(C\alpha + \dot{D}\beta)^2 \tau \qquad (1)$$

This is the fixation rate of point mutations caused by a randomly coincident destruction of both complementary bases or a randomly coincident caused double strand break. The coincidence takes place during the repair time.
v is proportional to the enzyme concentration and it is indirectly proportional to the repair time τ:

$$\tau = \frac{\tau_0}{1+\delta\dot{D}} \qquad (2)$$

with $\delta \cdot \dot{D}$ describing the additional genetical expression of repair enzymes.
Besides the three terms in equation (3), describing a randomly coincident fixation of base lesions or a randomly coincidently caused double strand break, we also have to take into account that both nucleotides may be damaged immediately one after the other by the same particle or by the same cloud of radicals originating from one particle. In this case no repair of the complementary base (nucleotide) is possible and therefore there is no τ in

the corresponding term, which is $\vartheta\dot{D}$. $\kappa(\dot{D})$ represents the probability that cells are killed by radiation in high dose regions. κ is the cell killing probability. Killed cells cannot become tumorigenic.

$$S_4=\left(C^2\alpha^2+2C\alpha\dot{D}\beta+\dot{D}^2\beta^2\right)\tau+\vartheta\dot{D}-\kappa(\dot{D}) \tag{3}$$

The following differential equation describes the time dependent behaviour of the arising of the first step in the successive process of damage.

$$\frac{dM_1(t,C,\dot{D})}{dt}=(B_0M_0-B_1M_1)\left(\left(C\alpha+\dot{D}\beta\right)^2\tau+\frac{1}{f_{nuc}}\bar{z}_F\beta^2\dot{D}-\kappa(\dot{D})\right) \tag{4}$$

$M_1(t, C, \dot{D})$ is the number of cells per individuum at time t which are in the first transformation step, i.e.: which have one point mutation on a critical, tumor relevant gene locus caused by a chemical carcinogen with concentration C or by a dose rate $\dot{D}$. M_0 is the number of all human cells which are not yet transformed. Equation (4) describes the first step necessary for a complete carcinogenesis. The number of steps necessary for the induction of cancer defines a system of coupled differential equations. Each transformation is represented by one differential equation. B_0 is the number of critical DNA bases (nucleotides) in critical codons of all tumor associated genes per cell. B_1 is the number of critical DNA bases (nucleotides) in critical codons of all tumor associated genes per cell after the first transformation.
The first sink on the right side of equation (4) ($-B_1M_1$ ...) is due to the fact that cells which have reached the first step of damage are a source term for the second step. M_1 is several orders of magnitude smaller than M_0. Therefore this sink can be neglected. In the case of constant chemical and radiological influences (C=const., $\dot{D}$=const.), the coefficients of the differential equation (4) are time independent and the equation can be directly integrated:

$$M_1(t)=B_0M_0\left(\left(C\alpha+\dot{D}\beta\right)^2\tau+\frac{1}{f_{nuc}}\bar{z}_F\beta^2\dot{D}-\kappa(\dot{D})\right)t \tag{5}$$

For $M_n(t)$ we get with $A_1:=B_0B_1B_2\ldots B_{n-1}M_0\frac{1}{n!}$

$$M_n(t)=A_1\left(\frac{C^2\alpha^2\tau_0}{\left(1+\delta_S\dot{D}\right)^2\left(1+\delta\dot{D}\right)}+\frac{2C\alpha\dot{D}\beta\tau_0}{\left(1+\delta_S\dot{D}\right)\left(1+\delta\dot{D}\right)}+\frac{\dot{D}^2\beta^2\tau_0}{1+\delta\dot{D}}+\frac{1}{f_{nuc}}\bar{z}_F\beta^2\dot{D}-\kappa(\dot{D})\right)^n t^n \tag{6}$$

where δ_s describes the extent of the production of additional scavengers caused by radiation. The term $\kappa(\dot{D})$ is approximately zero because cell killing is not a relevant effect in the low dose regions refered to in the data which are used for regression analysis. For an anambiguous data fit this equation has to be slightly transformed and we can only determine $\frac{\beta}{C\alpha}$ and $\delta=\delta_s$. For τ_0 we take 40 minutes /7/. $\frac{1}{f_{nuc}}$ can be derived as approximately 3.3 /8/. For a critical volume with a radius of 4.66 µm, the average radius of a bronchial epithelial cell nucleus, D.R. Fisher, V.P. Bond et al. /9/ received $\bar{z}_F$=0.5 Gy. Data fits are done with all 1601 data points using the Levenberg-Marquardt algorithm and the Nelder-Mead simplex search method. For n, the number of transformations, we take 4, which was received by a data fit of age dependent ARIP data for I.C.D. 140-205 (all cancers).

OH WUNDER!
THE INVERSE DOSE-RATE EFFECT IS QUELLED BY THE EFFECTIVE THRESHOLD

Otto G. Raabe

Institute of Toxicology and Environmental Health
University of California, Davis, California 95616 USA

ABSTRACT

Three-dimensional dose-rate/time/response mathematical surfaces describe radiation effects in lifetime studies of beagles after intake by injection or inhalation of selected radionuclides (including α-emitters ^{226}Ra, ^{239}Pu, ^{238}Pu, and ^{241}Am and β-emitters ^{90}Sr, ^{91}Y and ^{144}Ce) and in people after intake of ^{226}Ra. For each effect $t_m = K_m \bar{d}^{-s}$, where t_m is the median elapsed time to death with the specified effect after intake, $\bar{d}$ is the time-weighted average absorbed radiation dose-rate to the target organ, K_m is the median distribution coefficient, and s is the negative slope parameter. Using maximum likelihood survival regression methods, s was found to be ⅕ for α radiation and ⅔ for β radiation. The relationships of competing risks of death associated with radiation injury, radiation-induced cancer, and natural aging after initial exposure or intake are graphically portrayed using three-dimensional illustrations of these dose-rate/time/response surfaces. At the higher dose rates (larger organ burdens of radionuclide) the principal deleterious effects are those associated with radiation-induced injury while at intermediate dose rates radiation-induced cancer predominates. For cancer induction, lower dose rates have a higher relative dose effectiveness than higher dose rates (*inverse dose-rate effect*) for either low LET β radiation or high LET α radiation. However, at the lower dose rates the long latency time required for development of radiation-induced cancer may exceed natural life span, yielding a *life-span effective threshold* for death associated with radiation-induced cancer at a lifetime cumulative absorbed dose to the target organ of from about 0.08 to 1.4 Gy for α irradiation or from about 28 to 130 Gy for β irradiation. The beagle results were scaled to predict human bone cancer risks for internally-deposited ^{226}Ra and the predicted life-span effective threshold of about 2.1 Gy agreed well with the U.S.A. human ^{226}Ra data. The predicted occurrence of human lung cancer from inhaled $^{239}PuO_2$ yielded a life-span effective threshold of about 1.4 Gy..

INTRODUCTION

In this report, radiation risk from internally deposited radionuclides is described by an independent risk model in which radiation risk is superimposed in time upon the natural lifetime causes of death and competing risks. In its simplest form there are three separate fatal risk distributions: (a) deaths associated with natural life span and aging including the background incidence of various types of fatal cancer; (b) those deaths associated with radiation-induced cancer; and (c) deaths associated with exposure-related non-neoplastic injury (1-7). Precise data obtained in lifetime studies utilizing beagles provide the basis for understanding these phenomena. Raabe et al. (8-9) used life-span normalization to scale response relationships from laboratory animal species to human risks.

METHODS

Selected data were reviewed from published reports of life-time studies of internally deposited radionuclides in young adult beagles at four laboratories: University of California, Davis (10), Lovelace Inhalation Toxicology Research Institute, ITRI (11), University of Utah (11), and Battelle Pacific Northwest Laboratory, PNL (12). Throughout this report, doses refer to average absorbed target organ doses from parent and decay products, where all x ray and gamma emissions are ignored, and beta emissions are also ignored where alpha emitters predominate. Because of an observed pattern of linearity between the logarithm of time to radiation induced cancer deaths and logarithm of lifetime average dose rate to the target organ, standard log-linear survival models and maximum likelihood regression methods were used to describe the response functions (4). In terms of the natural logarithms, ln, the log-linear regression line is thus given by:

$$\ln t_m = \ln K_m - s \ln d \rightarrow t_m = K_m d^{-s} \quad (1)$$

where $\bar{d}$ is the time-weighted average dose rate, t_m is the regression value of median survival time, s is the negative slope of the regression line for the specified effect, and K_m is the median risk coefficient.

RESULTS AND CONCLUSIONS

The results are summarized in Figure 1. Alpha emitting radionuclides all yielded cancer risk distributions with slopes of -1/3 and the beta emitting radionuclides all yielded cancer risk distributions with slopes of -2/3, indicating that two beta particles are required to effect the same cellular transformations effected by one alpha particle such as two-strand DNA breaks (6). In addition, the underlying slope of -1/3 indicates that the distance between these events controls the response as a function of survival time as discussed by Raabe (3).

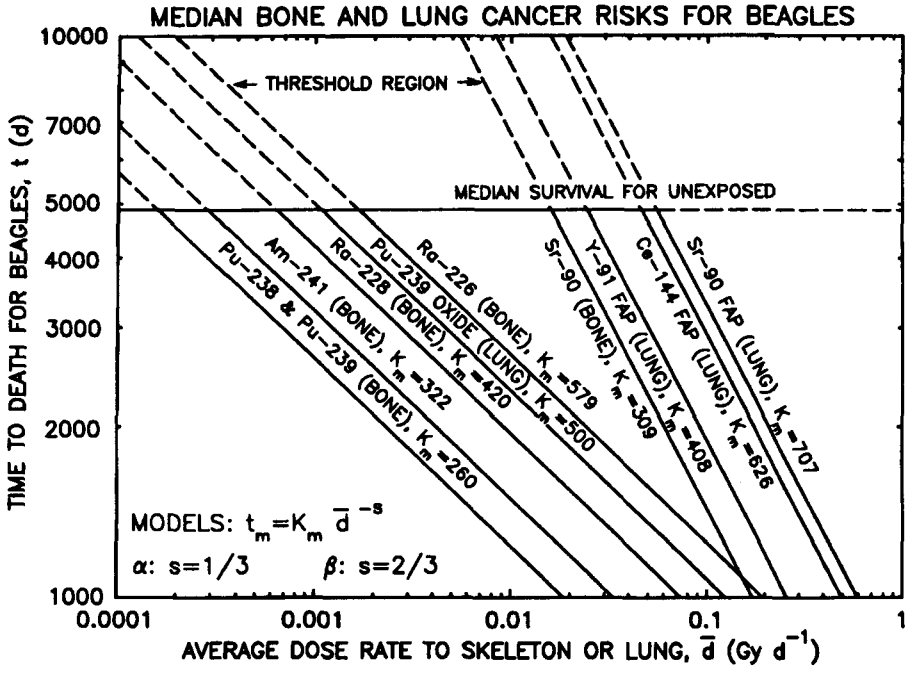

Figure 1. Median bone and lung cancer risks for beagles.

Because of the negative slopes of these distributions, the cumulative absorbed dose required to yield a specified level of cancer risk is less at lower dose rates than at higher dose rates (*inverse dose-rate effect*), but the time required for tumors to manifest tends to be much longer at lower dose rates and can exceed the natural life span, yielding a *life-span effective threshold* for fatal radiation-induced cancer. In other words, *Oh Wunder!* The old-age-related death of the individual preempts the development of radiation-induced cancer. For young adult beagles, this threshold occurs at about 0.08 Gy for ^{238}Pu and ^{239}Pu in bone, 0.2 Gy for ^{241}Am in bone, 0.5 Gy for ^{228}Ra in bone, 0.9 Gy for ^{239}Pu in lung, 1.4 Gy for ^{226}Ra in bone, 28 Gy for ^{90}Sr in bone, 70 Gy for ^{91}Y in lung, 110 Gy for ^{144}Ce in lung, and 130 Gy for ^{90}Sr in lung. Effective thresholds are predicted for human exposures using life-span normalization (8-9). For example, it is about 3.5 Gy for ^{226}Ra in bone; there were no cases of bone cancer for any cumulative dose less than 10 Gy in U.S. radium cases (13). Likewise, the predicted human occurrence of radiation-induced lung cancer (Figure 2) from inhaled $^{239}PuO_2$ has an effective threshold of about 2 Gy (8).

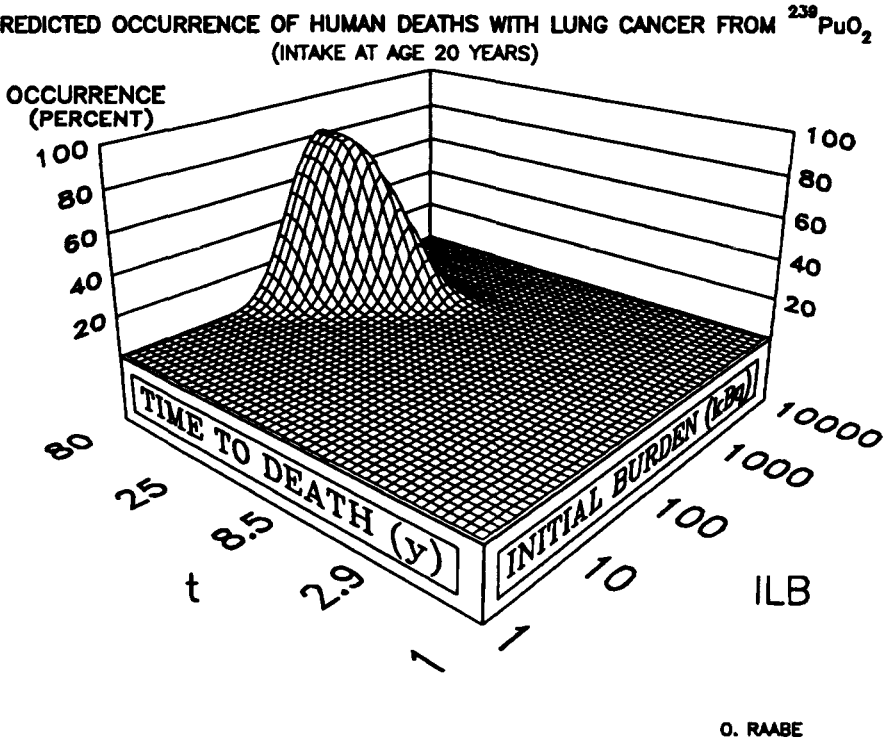

Figure 2. Predicted lung cancer from inhaled $^{239}PuO_2$ by initial lung burden (ILB).

ABSTRACT (See instructions overleaf)

The suggested model can be used for constructing of the objective number measure of the rising risk of the definite degree of the damage.The effect of such action is described by the binary index when taking two values **e=0** ("no" effect) and **e=1** (presence of the effect).The effect **e=e(r,a)** is the function of two arguments, where **a**-the dose(intensivity of radiation action), **r**-the resistance. In the simplest case the function **e(r,a)** may be set by the formula:

$$e=e(r,a)=\begin{cases}0, & a \le r\\ 1, & a > r,\end{cases} \text{ where } r,\ a \in [0,\infty).$$

According to this formula the resistance **r** has a meaning of the "threshold", i.e. the effect is absent as long as the action **a** will not exceed the meaning **r**. The probability $P\{r'<r\}$ of **r'** being smaller than the fixed resistance **r** is given by the function of distribution $P\{r'<r\}= F_{r'}(r)$. The randomized action of doses **a'** is introduced by the analogy with randomized resistance **r'**. It is described by the function of distribution $F_{a'}(a)$: $P\{e'(r)=1\} = 1-P\{e'(r)=0\} = 1 - F_{a'}(r)$. The randomized effect **e'(a)** can be given in the following way:

$$e'(r) = \begin{cases}0, & \text{with the probabililty } F_{a'}(r);\\ 1, & \text{with the probabililty } 1-F_{a'}(r).\end{cases}$$

"Dose-effect" curve deduced from these relations implies the next information about the action of irradiation: 1) Coinciding with the function of distribution $F_r(r)$, the "dose- effect" curve describes the distribution of meanings of the radioresistance threshold among the individuals of the studied population; 2) The "dose-effect" function being the probability of appearing of the effect **e=1** at the random taken organism determines the fraction **m(a)** of the individuals with the observed effect **e=1** under the action of the dose **a**; 3) The "dose-effect" function being the mathematical expectation of the effect value observed after the dose **a** is the measure of the mathematical expectation of the individual damage weight among the population irradiated with dose **a**.

A MATHEMATICAL FORMULATION OF RADIATION RISK

Kazuaki KATOH

Ibaraki Prefectural University of Health Sciences, Ami, Ibaraki 300-03 Japan

INTRODUCTION

The purpose of radiation protection (RP) is self-evident but is not so easy to establish a target for it. The aim of RP has been set to prevent the so-called deterministic effects and also to suppress the stochastic effect to some acceptable limit. We have learnt through our experience of more than thirty years with this subject that under provision of the ordinary measures to achieve the latter aim, the former is usually automatically carried out.

Thus, the measure of the stochastic effect, radiation risk, is one of the most important two quantities in the causality relation, indispensable to radiation protection as a science. The quantity of cause is of course the radiation dose.

In this paper, issues of the definition and mathematical formulation of the radiation risk are discussed.

THE STATUS QUO

The term risk is widely used not only in the field of RP but also in many other fields. However, definition or significance of the word is not the same. In the field of RP, the word is often used to mean the probability of loosing an individual's life or mathematical expectation of the whole loss of lives in a population when it is used as the name of a quantity. While in some other fields including nuclear safety, risk is used as a synonym for the mathematical expectation of the magnitude of the undesirable consequence of event.

The risk defined as a synonym for the probability of incidence of lethal cancer, for example, is frequently understood as the rate of death due to cancer of an individual and expressed in the form of a percentage. Arithmetic treatment of this quantity we find unconvincing because total of these rates is fixed as one and the rate of carcinogenecis cannot be changed without in principle reshuffling other rates. Moreover, appearance of new death factors or increase in value of an existing other factor makes the value of the radiation risk decrease. When social desasters such as famine or AIDS occurs, the radiation risk decreases as result. Thus the risk of radiation defined with the probability is not suitable to discuss the risk of an individual.

ICRP introduced a concept of risk coefficient, risk per unit (effective) dose, which is used in the present system of radiation protection. However, as is well known, harmful stochastic effects of radiation on individuals depend on the age of exposure and their appearance accompanies stochastic "latent periods." On the other hand, risk of an exposure at time t_0 in the past ($t_0 < 0$) for the time passed is deterministic and for the future is stochastic. The function of life existence can have values of either one or zero for the past, while it can have a value of a positive real number between zero and one. Thus, even with the same exposure, evaluated risk depends on the time of evaluation even if the character of the population is stable. Therefore, the ICRP risk coefficient is not so useful for the purpose of discussing the risk to an individual.

Shortening of the mean residual life span of a population is often used as an expression of risk. This is a mathematical expectation. Extinction or depletion of the species is also important as a harmful effect of radiation on human beings and this quantity is useful for considering this problem. However, it is not suitable for discussing an individual's risks, because its value depends on the size of the population.

A MATHEMATICAL FORMULATION OF RADIATION RISK

In order to overcome the above-stated difficulties of the present situation, a reformulation of the radiation risk is tried on the premise of linear proportionality between the dose and the effect and on the newly specified concept of radiation risk.

We define the risk accompanying an act of receiving some amount of radiation dose as the expected value of shortening of the residual life span of a hypothetical standard man (or woman) at the time of exposure. The standard man (or woman) is a hypothetical individual characterized by the statistical data, i.e., the mortality rate as a function of age, $\lambda(\tau)$, with a population of interest. The data is obtained from a national census or such. His or her residual life span at age τ, $\rho(\tau)$, is calculated with the mortality function $\lambda(\tau)$ by the following relations;

$$-dN(\tau)/d\tau = \lambda(\tau)N(\tau) \tag{1}$$

$$\rho(\tau_0) = \int_{\tau_0}^{\infty} \tau\, \sigma(\tau_0, \tau)\, d\tau - \tau_0 \tag{2}$$

where τ_0 is the present time (age) and $\sigma(\tau_0, \tau)$ is the probabolity of maintaining life of an individual at age τ,

$$\sigma(\tau_0, \tau) = 1 \qquad \text{for } \tau \le \tau_0$$

$$\sigma(\tau_0, \tau) = N(\tau)/N(\tau_0) \qquad \text{for } \tau > \tau_0 \tag{3}$$

$N(\tau)$ is the population of the standard men (or women) of age τ.

Now the risk brought by unit amount of instantaneous dose is expressed as follows:

$$r(\tau, \tau') = \rho(\tau) - \rho'(\tau, \tau') \tag{4}$$

where $\rho'(\tau, \tau')$ is the new function or curve of the expected residual life span for an instantaneous exposure of unit amount of dose at the time (age) of τ'. The function $\rho'(\tau, \tau')$ can be evaluated if the data on the distortion of the function $\lambda(\tau)$ for an instantaneous exposure of unit amount of dose at time of τ' is available.

$$\dot{\varepsilon}(\tau) = \delta(\tau'), \tag{5}$$

where $\delta(\tau)$ is the Dirac's delta function and $\varepsilon(\tau)$ is a time spectrum of the dose,

$$\dot{\varepsilon}(\tau) \equiv dE(\tau)/d\tau$$

Thus the risk (for the future only by nature) evaluated at the time τ for the past exposure $\dot{\varepsilon}(\tau')$ is expressed as

$$R(\tau) = \int_{\tau}^{\infty} r(\tau, \tau')\, \varepsilon(\tau')\, d\tau' \tag{6}$$

Here, the risk or expected shortening in residual life span is proportional to the dose is assumed. That for the past is zero due to the fact of survival at the time of evaluation.

CONCLUSION

Risk for radiation exposure is defined as the expectation of the shortening of the residual life span. With this definition, the concept of risk is only for future life, since the fact of main-

taining life at the time of evaluation negated the possibility of losing the life in the past.

A mathematical formulation is shown under the premise of the linear proportional relation between the dose and the end effect (newly defined risk) and on the new concept of "Standard Man/Woman" whose characteristic on mortality is the same of the population of interest.

USE OF RISK PROJECTION MODELS FOR THE COMPARISON OF MORTALITY FROM RADIATION-INDUCED BREAST CANCER IN VARIOUS POPULATIONS

Dominique HUBERT[1], Thierry SCHNEIDER[2]

[1]Service de Radioprotection - EDF, 3 rue de Messine, 75008 Paris, France.
[2]CEPN, BP 48, 92265 Fontenay-aux-Roses Cedex, France.

Lifetime risk estimates for radio-induced fatal breast cancer were compared in Japanese, North American and French populations for several epidemiological studies. In the case of breast cancers, some differences appear between the epidemiological studies according to the reference population. Thus, this comparison aims at pointing out how this affect the lifetime risk estimates when Japanese and Occidental populations are used.

METHODS

Six studies on mortality from breast cancer after irradiation were selected (Table 1.).

Table 1. Characteristics of epidemiological studies on breast cancer after irradiation

The risk coefficients have been transferred to the 3 studied populations (Japan, USA, France), using demographic data from the 3 countries, risk projection models (additive or multiplicative), and assuming an individual acute exposure of 10 mSv. The calculations have been performed with the PC-based software "Assessment System for the Quantification of Radiation Detriment" (ASQRAD).

RESULTS

The excess lifetime risk from radiation-induced breast cancer was compared between the 3 populations, using the risk coefficients either from the Japanese A-bomb study (Table 2) or from the study based on the Canadian fluoroscopic examinations of patients treated for tuberculosis (Table 3).

Table 2. Number of lifetime excess deaths from breast cancer per 100,000 persons individually exposed to 10 mSv acute radiation (Shimizu et al. 1990) for France, USA and Japan demographic data

Age at exposure (y)	Japan 1988	USA 1987	France 1987
Additive model			
10	13.5	12.9	13.3
20	6.1	5.8	6
30	6.3	5.9	6.2
45	0.48	0.44	0.46
Multiplicative model			
10	18.5	75	71.8
20	9.5	38.8	37.1
30	9.4	39.6	38.1
45	0.6	2.9	2.8

Table 3. Number of lifetime excess deaths from breast cancer per 100,000 persons individually exposed to 10 mSv acute radiation (Miller et al. 1989) for France, USA and Japan demographic data

Age at exposure (y)	Japan 1988	USA 1987	France 1987
Additive model			
10	36.7	35	36
20	15.5	14.6	15.1
30	7	6.6	6.9
45	3.3	3	3.2
Multiplicative model			
10	27.3	111	106
20	6.1	24.7	23.7
30	1.9	7.9	7.6
45	0.54	2.7	2.6

The lifetime risk estimates are similar in the 3 populations when the additive projection model is used because of the similarity of the life tables of the 3 countries. However, using the multiplicative model, large differences appear due to the discrepancies in the baseline breast cancer rates between the Japanese and Occidental populations. For this reason, transfer of risk coefficients fitted on the Japanese population data must be considered with caution when applied to an Occidental population. The risk projections obtained from different epidemiological studies have been compared in the French population (Table 4). Lifetime risk estimates are largely dependent on the risk coefficients considered. Nevertheless, for each source of data, they are higher with the multiplicative one.

Table 4. Number of lifetime excess deaths from breast cancer per 100,000 persons individually exposed to 10 mSv acute irradiation (French demographic data, 1987) for additive and multiplicative models

Age at exposure (y)	Shimizu et al. (1990)	UNSCEAR (1988)	Darby et al. (1990)	Davis et al. (1989)	Miller et al. (1989)	BEIR V (1990)

45	38.1	36	37.5	17.2	7.6	5.6
	2.8	30.8	32	14.7	2.6	2.9

CONCLUSION

The choice of a transfer model is all the more difficult that mechanisms of radiation-induced cancer are not yet well understood. If breast cancer death rates are higher in the American population than in the Japanese one because Americans tend to be exposed to more breast cancer initiators early in life and if radiation also acts as an initiator, then the additive model might be expected to fit well. On the other hand, the multiplicative transport model would be more appropriate if the difference between populations could be due to differential exposure to promoters later in life. As far as breast cancer is concerned, the characteristics of the reference population, where the risk coefficients have been defined through epidemiological studies, are of particular importance when these risk coefficients are transferred to another exposed population. This is due to the possible large variations in breast cancer rates between various populations.

ABSTRACT

Heavy ion tracks distribution up to 2 GeV / amu in bone tissue was simulated in order to assess the biological effects of the radiation. Calculation of ion tracks distribution in the target was materialized using the code TRIM (1).
Average energy transferred by ion tracks in nuclear as well as in atomic collision is obtained and pattern of ion tracks is analyzed for comparison. The computer program provides particularly high computer efficiency, when a new analytical formula used in determining nuclear scattering angles (2). Heavy ion therapic parameters, such as the width of the spread-out Bragg peak (Figure 1), Q values and H dose equivalent are obtained and compared with existing data (3).

Biological effects of the combined impact of low radiation doses & chemical agents

Rolevich Igor V.
1st Deputy Minister
Ministry for Emergencies & Population Protection
from the Chernobyl NPP Catastrophe Consequences
Minsk, Belarus

This report examines biological effects of the combined and separate impact of low ionizing radiation doses on the organism and molecular levels. Synergetic effects were found. Radiation effects of thyroid hormones synthesis, peroxide oxidation of lipids, formation of proteins are examined.

THE DOSE RATE AS A MODIFIER OF BIOLOGICAL EFFECTS IN CONDITIONS OF THE COMBINED ACTION OF RADIATION-CHEMICAL FACTORS

S.Sushko, T.Kuzmina, A.Malenchenko

Institute of Radioecological Problems of the Academy of Science of Belarus

INTRODUCTION

The proper evaluation of the risk of the delayed effects in the case of equal absorbed doses but different dose rates in the conditions of the additional impact of the factors of nonradiation nature is a complicated biological and mathematical problem.

Insufficiently correct evaluation of the multi-factor effect of harmful substances on organizm and ascribing the registered negative aftereffects only to the impact of the radiation can result in both the overestimation of the radiation danger and the inefficient investments of funds into the system of countermeasures for reduction of risk of irradiation [1].

Taking into account the real character of the impact of the set factors of the radiation and nonradiation nature on organism, the effect of the dose rate has been studied in the conditions of additional influence of chemical compounds on the process of structural damages of chromosomes and induction of lung adenoma. Nitrogen oxides (one of the dominating atmospheric pollutants) and urethan, which is the pulmonotropic mutagen, have been chosen as chemical substances.

MATERIALS AND METHODS

The studies have been carried out using the mice of Af line in two series differ in the method of irradiation. In the first series mice have been exposed to the whole body single irradiation of Co gamma rays at a dose of 0.35 Gy and a dose rate of 1.0 Gy/h. In the second series the mice have been irradiated at a total dose of 0.35 Gy, but at a dose rate of 0.008 Gy/h (0.0389 Gy · 9 days).

Each series consisted of 8 groups: 1 - control, 2 - irradiation, 3 - inhalation of nitrogen oxides at a concentration of 120 mg/m^3 for 30 minutes, 4 - administration of urethane intraperitoneally (1 mg/g weight), 5 - inhalation of nitrogen oxides followed by administration of urethan an hour later, 6 - inhalation of nitrogen oxides in the same concentration an hour later after irradiation, 7 - administration of urethan an hour later after irradiation, 8 - the mice have been exposed to the action of three factors in the following sequence: irradiation + nitrogen oxides + urethan.

The cytogenetic analysis has been carried out on marrow cells in line with methods given in [2,3]. The cancerigenic effects have been determined according to the number of the induced lung adenoma in 20 weeks after the impact [4].

In groups of the combined effect of the factors, the coefficient of synergy (SC) has been determined with correction for the background [5].

RESULTS AND DISCUSSION

Chromosome aberrations (ChA)

The change of the frequency of the chromosome aberrations is shown on fig.2.

The spectrum of ChA has been presented by the fragments (single and pair), intrachromosome (cyclic rings) and interchromosome (symmetrical translocation) exchanges. The cells with multiple damages has also been registered.

The analysis of the spectrum has shown, that deletions have been the dominant type of aberrations in all experimental groups. The largest quantities of fragments have been found in the groups of the combined effect under a single exposure to radiation (up to 95% of all types of aberrations).

With prolongation of the dose, the fraction of simple deletions has been smaller and accounted for 75%. In the groups of the combined effect with lower dose rate, the aberrations of the chromosome type dominated. The number of the cyclic rings in case of the action of three factors against the background of the prolonged exposure to radiation has been four times as many as in the case of a single exposure to radiation under the same combination of factors (18.5% - 4.8% of the total number of ChA, respectively). In addition, the cells with multiple aberrations (more than 6) have been registered in this group.

The stable aberrations (total symmetrical exchange) have been under the three-factor effect with the background of prolonged exposure to radiation. The fraction of these aberrations in the total number of ChA has been 2.7% and 7.4% of the total number of ChA, respectively.

Lung adenoma

The induction of lung adenoma is shown on fig.2.

The effect of nitrogen oxides on mice under a single exposure to radiation was manifested as the inhibition of the process of adenoma formation in comparison with the separate effects. On the contrary, the prolongation of radiation exposure dose with inhalation oxides has been characterized by the increase of the frequency of adenoma - 2.06 (SC = 1.73).

In the group with combination of a single exposure to radiation and administration of urethan, the number of adenoma has reached the maximum value 14.06 adenoma/mouse, and SC = 4.46. The administration of urethan after the prolonged exposure to radiation has increased the cancerigenic effect, but the number of adenoma has been lower in comparison with the group of a single exposure to radiation, amounting to 4.31 (SC = 1.44).

In the group of three-factor effect and a single exposure to radiation, the number of adenoma/mouse has amounted to 6.67 (SC = 1.82). The prolonged exposure to radiation has increased these figures to 10.73 adenoma/mouse, and SC up to 3.48. With three-factor effect, SC in the group with the prolonged exposure to radiation has exceeded the indices of the similar group under a single exposure to radiation by a factor of two, and the growth of adenoma - by 1.6 times.

The treatment of the mechanisms of aberrations found out under the combined effect of radiation-chemical factors is significantly more complex as in the formation of ChA and tumor induction both the direct damage of DNA and the efficiency of functioning of the reparation system of a cell are important. The effect of the additional factors at this period can both strengthen the processes of restoration and facilitate its retardation especially in the cases, when the coefficient of synergy exceeds unity. The latter evidences the inclusion of additional mechanisms into the realization of registered changes, which are out of the scope of the additivity mechanisms.

The following mechanisms can be supposed as the above mentioned:

- Apart from the direct effect of each of the agents able to induce the DNA damage, possible additional influence on latent damages, which have been induced by the effect of the first agent, should be taken into account, including their transfer into the cytogenetically registered form, that is, ChA under the effect of the second agent [6, 7].
- Formation of a new substance from the active chemical compounds possessing mutagenic and cancerigenic properties intensifying the effects of precursors [8, 9].
- Stimulating effect of the ionizing radiation on the synthesis of carcinogenic agents [10].

It follows from the obtained data, that under the multi-factor effect, the reduction of the dose rate can result not in the increase, but in the decrease of frequencies of tumors. Therefore, the delayed consequences, associated with the dose effects, in particular, the processes of cancerigenesis, can be underevaluated in the real ecological conditions. Presently available observations on the alteration of the sensitivity of the irradiated organism to the effect of the nonradiation factors, as well as the radiation-chemical synthesis of mutagens from the containing in organism and the entering precursors confirm the possibility of existence of such a process [11, 12, 13].

Unsufficient evaluation of the modifying effect of radiation on the changes of the sensitivity of organism to the action of the chemical compounds, the level of which are considered to be safe, and attributing the registered modification only to the affect the scale and the direction of the countermeasures on elimination of the radiation risk.

ASSESSMENT OF AGE-SPECIFIC RADIATION RISKS TO PATIENTS WITH NON-UNIFORM DOSE DISTRIBUTION

T.Komppa and A.Servomaa

Finnish Centre for Radiation and Nuclear Safety,
P.O. Box 14, FIN-00881 Helsinki, Finland

ABSTRACT - In medical radiology, a typical radiation dose distribution within the patient's body is extremely non-uniform, and the patients' typical age distribution is clearly different from that of the whole population. The effective dose and the nominal probability coefficients, as defined in the 1990 Recommendations of the ICRP for radiological protection and for assessment of risks in general terms, apply to workers and to the whole population. For estimating the risks from a known exposure to a known population, e.g. to patients in certain X-ray examinations, it is better to use specific data relating to that exposed population.

The modified relative risk model of the BEIR V (1990) report allows assessment of the radiation risk as a function of the age at exposure and the time after exposure, separately for males and females. Fitted parameters are given for five specific organs or organ groups. The model is directly applicable if the dose distribution is uniform within each of the organ groups. Otherwise, some extra information or extra assumptions are needed for risk assessment. In this work, the BEIR V model is used with Finnish statistical data on cancer and mortality. Some approximative assumptions are presented and discussed, applied to selected X-ray examinations, and compared with uniform exposure of the population.

INTRODUCTION

In the 1990 Recommendations of the ICRP (1), average coefficients for the probability of radiation-induced fatal cancer are defined for twelve organs or tissues and for the remainder group. The tissue weighting factors and the effective dose are then defined, considering the estimated loss of life expectancy and the contributions of non-fatal cancers and genetic effects. The quantities used in the definitions are averages calculated for several populations, both sexes and a wide range of ages. Because of this averaging, there is no explicit dependence on age, time or sex in the definition of the effective dose.

The BEIR V report (2) presents a modified relative risk projection model with explicit dependence on the age at exposure, time after exposure and sex. The model can be applied together with national mortality and cancer mortality rates and age distributions, and with the age distributions of specific groups. It is one of the risk projection models used by the ICRP in preparing the 1990 Recommendations. With some modifications, it is also used by the NRPB (3). The use of the radiation risk projection models - and the associated uncertainties and problems - have been discussed by many authors (1-7). If the dose distribution within the body is strongly non-uniform, a special problem arises from the application of collective groups of organs (8,9).

METHODS

In principle, the radiation-induced age-specific excess mortality rate, R(a;e,D) is the sum of all organ-specific mortality rates, $r_k(a;e,d_k)$ caused by the organ doses, d_k:

$$R(a;e,D) = \sum r_k(a;e,d_k)$$

where a is the age, e is the age at exposure and D is a symbol for the configuration of all organ doses. In practice, certain organ-specific functions, r_k, may be available for some organs, and one or more organ groups may have given group-specific functions, r_g :

$$R(a,e,D) = \sum r_k(a,e,d_k) + \sum r_g(a,e,d_g)$$

The problem is how the group-specific doses, d_g, should be estimated if the dose distribution is not uniform within each of the organ groups. The problem can be examined within any one of the groups; in the following, the group subscripts are deleted: $r \equiv r_g$, $d \equiv d_g$, and $\sum r_k$ is the sum of organ-specific mortality rates within the group under consideration:

$$r(a,e,d) = \sum r_k(a,e,d_k)$$

In the following, some simplifying assumptions are made, and the resulting relations are presented for the absolute (A) and relative (R) risk models.

In functions r and r_k, the dose dependence is assumed to be separable;

A: $r(a,e,d) = f(d)\, g(a,e) = \sum f_k(d_k)\, g_k(a,e)$

R: $r(a,e,d) = f(d)\, g(a,e)\, r_0(a) = \sum f_k(d_k)\, g_k(a,e)\, r_{0k}(a)$

Functions r_0 and r_{0k} are the baseline mortality rates of the population, and $r_0 = \sum r_{0k}$.

The age and time dependence is assumed to be the same for all organs in the group: $g_k \equiv g$;

A: $f(d) = \sum f_k(d_k)$

R: $f(d)\, r_0(a) = \sum f_k(d_k)\, r_{0k}(a)$

A simple linear dose response function, $f = \alpha d$ and $f_k = \alpha_k d_k$, is assumed for all organs in the group;

A: $\alpha\, d = \sum \alpha_k d_k$

R: $\alpha\, d\, r_0 = \sum \alpha_k d_k r_{0k}$

If the dose distribution is uniform, $d_k \equiv d$ for all organs;

A: $\alpha = \sum \alpha_k$

R: $\alpha\, r_0 = \sum \alpha_k r_{0k}$

These relations apply to any dose configuration because the risk coefficients, α and all α_k, are independent of the organ doses. For practical calculations, more information or extra assumptions about the unknown α_k coefficients are needed. The four equations above are then solved simultaneously with the extra relations.

First assumption: All coefficients within the group are the same, $\alpha_k \equiv \alpha'$;

1A: $\alpha = n\, \alpha'$ and $d = \sum d_k / n$ (n is the number of organs in the group)

1R: $\alpha = \alpha'$ and $d = \sum d_k r_{0k} / r_0$

If, in the R model, the absolute risk coefficients are required to be equal ($\alpha_k r_{ok} = C$) then

1R': $\alpha\, r_0 = n\, C$ and $d = \sum d_k / n$

Second assumption: The ratios of the coefficients are furnished with specific weighting factors, w_k ;

$\alpha_k = w_k \alpha'$ and $\sum w_k = 1$

2A: $\alpha = \alpha'$ and $d = \sum w_k d_k$

2R: $\alpha\, r_0 = \alpha' \sum w_k r_{0k}$ and $d = \sum w_k r_{0k} d_k / \sum w_k r_{0k}$

If, in the R model, the absolute risk coefficients need to have constant ratios ($\alpha_k r_{ok} = w_k C$), then

2R': $\alpha\, r_0 = C$ and $d = \sum w_k d_k$

In the following examples, the BEIR V relative risk model is applied to Finnish demographic data, mortality and cancer mortality rates, patients' age distribution, and estimated organ doses in a typical chest CT examination. The lifetime risk projections are calculated using two of the assumptions above: 1R and 2R'. The weights, w_k for the 2R' case, are calculated from the nominal probability coefficients of ICRP 60 (1). For comparison, the same lifetime risk quantities are also calculated from a hypothetical uniform dose distribution corresponding to the effective dose of the same chest CT examination.

RESULTS

The most prominent organ doses (in mSv) in the chest CT examination are: lungs 18; breasts 16; red bone marrow 2; digestive organs: oesophagus 15, stomach 2, liver 3, gall bladder 1, pancreas 3, spleen 3; and other organs: adrenals 3, kidneys 1, skin 5, thymus 25, thyroid 7, muscles 5, bones 9 mSv. According to the ICRP 1990 Recommendations (1), the remainder organ dose is 13 mSv, and the effective dose 6 mSv. These values are rounded averages of a sample collected from Finnish hospitals. The weighted group-specific doses according to the 2R' case are 3.2 mSv for the digestive organs and 7.5 mSv for the BEIR V group of other organs.

The lifetime risk projections: the excess lifetime risk (ELR), the risk of exposure-induced death (REID), and the loss of life expectancy (LLE) are calculated according to Thomas et al. (4). The REID values, calculated as a function of age at exposure, are shown in Figure 1. The mean values of REID and LLE, according to the relevant age distributions, are presented in Table 1.

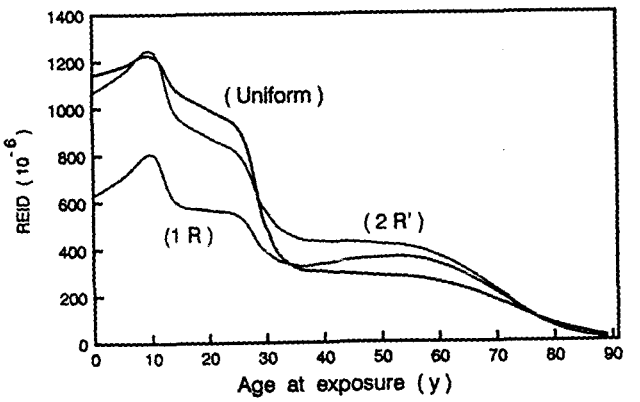

Figure 1. The REID for Finnish females in chest CT examinations, calculated using two different assumptions (1R and 2R' as defined in the text) and a uniform dose distribution for comparison.

Table 1. Mean REID (10^{-6}) and LLE (10^{-6}y) for Finnish females in chest CT examinations and with uniform dose distribution.

Target group:	CT Patients		CT patients		CT patients		Population	
Assumption:	1R		2R'		Uniform		Uniform	
Quantity:	REID	LLE	REID	LLE	REID	LLE	REID	LLE
Leukaemia	16	200	16	200	47	590	37	740
Breast cancer	44	910	44	910	16	340	32	790
Respiratory	180	2090	180	2090	60	700	50	660
Digestive	50	480	70	660	130	1240	270	2720
Other cancers	40	420	110	1250	90	1000	170	2120
All cancers	330	4100	420	5100	340	3870	560	7030

DISCUSSION

The problem of assessment of the group-specific dose is eliminated if the dose distribution is uniform, but its significance increases with increasing non-uniformity. The problem is closely related to the problems in the definition of the effective dose with respect to the group of remainder organs (1,8,9). The difficulties arising from the definition of the remainder (8,9) may be emphasized if the dose distribution is strongly non-uniform. For example, in CT examinations of the head, the dose to the brain is by far the highest organ dose. The brain is one of the remainder organs, and the interpretation of the definition of the remainder has a strong influence on the effective dose and risk assessment. The goals in the risk assessment of specific groups differ in some respects from the goals in defining the effective dose; it may be appropriate to modify the rules defining the remainder according to the purpose, rather than to apply them literally.

The Black Committee report on the raised incidence of childhood cancers in West Cumbria revealed the paucity of data on the effects and sensitivity of the mammalian embryo/foetus to high LET radiation exposure in-utero.

Uniquely in this study, mice were exposed at low activities to isotopes of plutonium chronically throughout pregnancy to model possible environmental contamination. Animals exposed to ^{241}Pu-citrate were used to investigate the uptake and distribution of the radionuclide. These biokinetic data were used to estimate radiation doses in a life-span study of the offspring of 255 female mice exposed to (0-89 kBq.kg^{-1}) ^{239}Pu-citrate. A range of activities known to result in leukaemia in adult mice. Distribution studies showed that only 0.1% of infused activity was incorporated into the pups at birth. Autoradiographs prepared of pups in-utero showed localisation of activity in the foetal yolk sac, placenta, foetal liver and skeleton. Activity and concentration increased in the foetal liver, the major site of embryonic haemopoiesis, throughout gestation despite increasing organ mass. Doses were estimated to the foetal liver and bone in-utero and for lifespan.

No significant differences due to plutonium exposure were observed in numbers of animals born or litter survival. Full independent (blind) pathological analysis was undertaken on dead animals and those killed when moribund. Kaplan Meier analysis showed no significant differences in lifespan. Analysis was also undertaken by tumour type and significant differences were not observed. One case of myeloid leukaemia was observed which is not significantly different to previously reported control incidences.

The major findings of this work are:- i) no increased cancer incidence as a result of alpha particle exposure at low levels throughout gestation was observed, ii) chronic exposure results in tenfold less uptake than single injection studies, iii) the contribution of the lactation pathway to neonatal uptake was higher than in previous studies, and iv) no mass effect, as previously reported by others, was seen. The significance of these results in the context of environmental plutonium contamination is discussed.

ABSTRACT (See instructions overleaf)

At the IRPA8 meeting in 1992, Lawrence Livermore National Laboratory (LLNL) presented a new method for obtaining calibration factors for radiation measurement systems used to measure internally deposited radionuclides *in vivo*. This method utilizes Magnetic Resonance Imaging (MRI) to determine the anatomical makeup of an individual. Monte Carlo methods are then employed to simulate the transport of radiation throughout the phantom. A supplemental interface code entitled MRIPP (Magnetic Resonance Image Photon Phantom) has been developed and tested to determine applicability for generating efficiency factors for in vivo measurement systems. MRIPP assists in modeling the detection equipment of the *in vivo* measurement system into the Monte Carlo code, allows for the modeling of several different phantoms and phantom/source configurations, and provide calibration factors. MRIPP provides a useful tool for the calibration of in vivo measurement systems, enhances evaluation of different sized phantoms and detection configurations, and reduces the cost involved in procuring surrogate human structures. This presentation will demonstrate the use of MRIPP and provide results demonstrating the degree of accuracy that can be achieved using MRIPP.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract No. W-7405-Eng-48.

INVESTIGATIONS ON FREQUENCY DISTRIBUTION OF WHOLE-BODY RETENTION PARAMETERS OF CAESIUM IN HUMANS

A. Andrási

KFKI Atomic Energy Research Institute, Budapest, Hungary

INTRODUCTION

The fission product caesium radionuclides, ^{137}Cs and ^{134}Cs, play an important rule in internal dose received by members of the population as the consequence of reactor accidents or nuclear weapon tests. Better knowledge on the biokinetic parameters of these radionuclides leads to more realistic dose estimate. Since these parameters, apart from their age and sex dependence have also individual variability, it is worth to investigate quantitatively and characterize statistically these variations.

METHOD

In this study the individual variability of the parameters of the systemic retention function were investigated which has the following form according to the ICRP Publ. 30 and 56 recommendations:

$$R(t) = a \exp [- 0.693\ t/T_1] + (1-a) \exp [- 0.693\ t/T_2]$$

where the coefficient a and the half lives T_1 and T_2 are independent parameters to be investigated.

The study was based on whole-body potassium measurements assuming the validity of close correlation between potassium content and the above given retention parameters of caesium according to a predicting model suggested by R.W. Leggett [1]. The basic investigated data set was obtained by measurements of the whole-body counter of our institute. Altogether the whole-body counting results of 286 adult male and 84 adult female subjects were investigated together and separately in two age groups. namely from 20 to 40 and above 40 years of age. The frequency distribution of the three independent parameters of the given two-exponential function was studied by fitting normal and log-normal distributions. According to the goodness-of-fit in most cases slightly better fit were obtained when log-normal distribution was assumed, however the differences were not significant.

RESULTS

The most characteristic results of these statistical investigations obtained for the three parameters as mean values and for their standard deviations assuming normal distribution together with the ICRP recommended parameter values are shown in the following table:

Table 1. Caesium retention parameters and their found uncertainties

Sex	Age-group [year]	a	σ_a [%]	T_1 [day]	σ_{T1} [%]	T_2 [day]	σ_{T2} [%]
m	20-40	0.091	25	1.5	29	113	12
m	40-	0.104	25	1.7	29	106	12
f	20-40	0.160	24	4.8	15	102	16
f	40-	0.160	18	4.8	12	101	13
ICRP	adults	0.1	-	2	-	110	-

As it is seen the calculated mean values of the three parameters are quite close to the ICRP recommended values and their standard deviations varied from 12% to 25% depending on the investigated age and sex groups.

The investigated data sets represented the final results of whole-body counter measurements which contained the spread of data of different origin. To consider the contribution due to the applied scanning WBC technique (reproducibility, geometry, counting statistics, body size, etc.) and of the short term variation of whole-body potassium to the total frequency distribution pattern, the data obtained by repeated measurements on selected individuals were also investigated. The measurements of 5 male and 10 female subjects have been repeated 15-27 times within a relatively short time period in which no significant age and weight variation could be expected. The frequency distributions were investigated and spread of retention parameters was characterized by their standard deviations. The averaged standard deviations are shown in the next table:

Table 2. Averaged standard deviations of empirical distribution of retention parameters determined by repeated measurements of single individuals

Sex	σ_a [%]	σ_{T1} [%]	σ_{T2} [%]
m	13	14	6
f	13	8	9

These figures are characteristic to our measuring conditions (scanning bed technique, least squares spectrum resolution, etc.), while another whole-body counting method can provide another feature of these data. For instance the data measured by a four detector stretcher arrangement on selected individuals in Karlsruhe show about half of the values of the above given Table 2 [2]. However considering even our data this source of error is reducing the parameter total uncertainties (see Table 1) by 2-5% only. On this reason due to the biological

variability the data given in Table 3 are more realistic figures for adults disregarding age dependence:

Table 3. Derived uncertainties of retention parameters attributed to biological variability

Sex	σ_a [%]	σ_{T1} [%]	σ_{T2} [%]
m	21	25	10
f	16	11	12

For comparison we investigated data sets measured on adult subjects from the territory of the previous Soviet Union measured by the WBC laboratory of GSF Frankfurt using single detector chair technique [3]. The standard deviations of the caesium retention parameters derived by the given method are shown in the next table.

Table 4. Uncertainties of retention parameters determined in Frankfurt on adults from the former Soviet Union

Sex	σ_a [%]	σ_{T1} [%]	σ_{T2} [%]
m	21	23	12
f	21	13	16

The figures in Table 4 are quite close to the values obtained by using our measurements, which confirm the validity of the outcome of our investigations. It is to be mentioned that G. Schwarz and D.E. Dunning found much larger values for these distribution parameters that is 40, 32 and 27 percent for σ_a, σ_{T1} and σ_{T2} respectively [4].

European Intercomparison of *in vivo* Monitoring Systems

M. Thieme, E. L. Hunt, K. König, A. Schmitt-Hannig, R. Gödde

Institut für Strahlenhygiene des Bundesamtes für Strahlenschutz, D - 85762 Neuherberg

1. INTRODUCTION

With the implementation of the Internal Market workers are guaranteed freedom of movement within the European Union. With regard to the practical application of the Council Directives on the Basic Safety Standards [1] and on the operational protection of outside workers exposed to ionizing radiation as a result of their work in controlled areas, the so-called 'Outside Workers' Directive [2] lays down that internal doses shall be included in the Union's radiation monitoring system (Art. 4, annex I, part III). Therefore it is especially important to ensure a common quality standard in performing measurements to attain consistent results and facilitate effective interpretation. Furthermore, article 25 of the Basic Safety Standard Directive requires that measurement instruments for radiation protection are regularly checked and tested to ensure their effectiveness and correct use. One of the established methods for the fulfillment of this requirement is by intercomparison, normally performed at a national level. International intercomparisons provide the opportunity to harmonize radiation protection measures at a wider level. The European Commission has therefore decided to fund an Europeanwide Intercomparison of *in vivo* Monitoring Systems which is organized and carried out by the Institut für Strahlenhygiene (part of the German Bundesamt für Strahlenschutz, BfS). Taking part in this intercomparison are 44 institutions in 19 states (the 15 Member States of the European Union and Hungary, Czech Republic, Switzerland and Norway). In addition to the purely technical part of the intercomparison, the methods and underlying assumptions of deriving dose estimates from the measured activities are also examined. The institutions are asked to calculate doses on the basis of given (but not complete) information on fictitious *in vivo* measurements and state the assumptions and equations used. To complete the overview, the various regulations regarding incorporation monitoring are also reported.

2. OBJECTIVES OF THE INTERCOMPARISON

The study seeks to compare aspects of *in vivo* dose evaluation between the nominated representatives of the 15 European Union member states and 4 non-EU countries.

The primary objective of this study is to compare the performance of European whole body counters under normal working conditions. To carry out this intercomparison, each participating institute measures a phantom filled with unknown, mixed radionuclides. Paramount to the success of the study is that the normal measurement routine for humans is used at all times, in particular that the normal measuring time is not exceeded. A representative of the BfS is therefore travelling with the phantom to supervise the measurement routine and to ensure that the phantom is assembled in the correct way. In addition to the whole body measurement, the following aspects of dose evaluation are considered in this study: (i) the measurement of I-125 and/or I-131 in a thyroid phantom (optional), (ii) the calculation of committed dose for cases where either full or partial work history is known (case studies), and (iii) the legal mechanisms in each country which regulate detection and measurement of incorporated radionuclides in the workplace.

3. THE PHANTOMS USED FOR THE INTERCOMPARISON

3.1 WHOLE BODY PHANTOM

The Whole Body Phantom used for this intercomparison was developed by the 'Research Institute for Industrial and Sea Hygiene' and produced by the 'Scientific and Technical Centre -Protection Ltd.-' both in St Petersburg, Russia. The St Petersburg phantoms are made from up to 120 small, interchangable, plastic bricks, held together with hollow aluminium connection pieces. The plastic bricks are supplied in two sizes representing 1 kg and 0.5 kg of body mass. Four holes are drilled through the length of each brick so that rods containing known amounts of user defined radionuclides may be inserted (see Fig. 1).

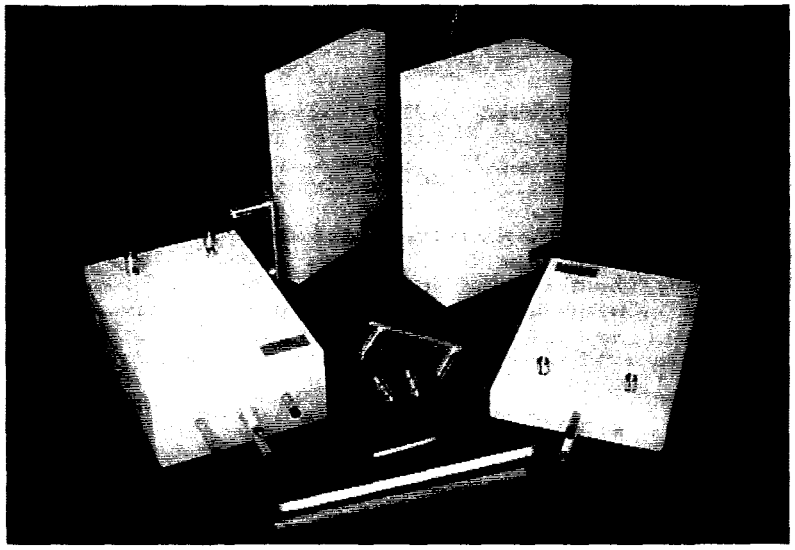

Fig. 1 1 kg and 0.5 kg bricks showing rods and connecting pieces

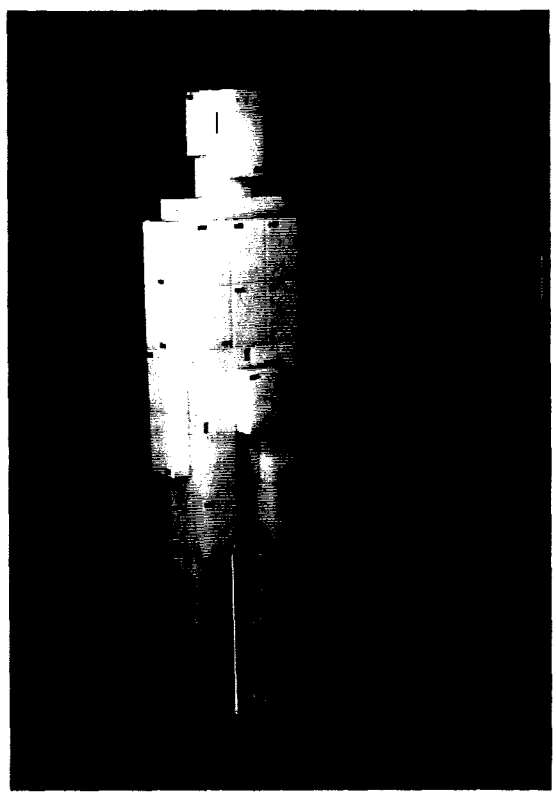
The St Petersburg Phantom can be assembled into representations (in terms of scattering) of 12 kg, 24 kg, 50 kg, 70 kg, 90kg and 110 kg persons (P1, P2, P3, P4, P5 and P6 respectively) in either stretch, chair or bending geometry. The stretch geometry may also be used in a "standing" position, when supported by a custom built aluminium stand. For the ongoing intercomparison, the St Petersburg phantom P4 is being used, representing the 70 kg reference man (Figure 2).

Fig. 2: Phantom P4 standing geometry



3.2 THYROID PHANTOM

The acrylic glass thyroid phantom which is made available to the participating institutions was developed as part of a research project on intercomparison of iodine counters in Germany funded by the German Federal Ministry of Environment, Nature Conservation and Nuclear Safety [3]. Intensive test measurements led to the conclusion that the chosen design provides an accurate representation of the thyroid gland for the purpose of measuring radio-iodine.The phantom was involved in a German intercomparison, and has been used by the majority of German iodine counters for calibration. The phantom is made of acrylic glass and incorporates 6 holes into which iodine samples may be placed. The holes are positioned in three pairs of two and each pair, representing the two lobes of the thyroid gland, is a specified distance from the surface of the phantom. For this intercomparison, the holes which are 20 mm from the surface of the phantom (smallest neck thickness) are used. The vials provided to the participating institutions are smaller in diameter than the holes in the phantom, and so acrylic glass tubes are used to maintain a uniform measurement geometry. The four holes which are not used during a measurement are filled with acrylic glass blocks.

4. RESULTS

More than half the measurements have been carried out and preliminary results show that most participating institutions measured the activities within 20% of the actual values. However, some institutions could not identify all radionuclides in the phantom.
The experimental part of the intercomparison is expected to continue until mid 1996. The analysis of the results and the evaluation of the answers to the questionnaires on legal requirements and dose assessment should be concluded by the end of 1996 and will be presented in spring 1997.

ABSTRACT (See instructions overleaf)

In 1992, the U.S. Department of Energy (DOE) performed a pilot study to determine the feasibility of performing an internal dosimetry intercomparison[1]. An intercomparison was performed because a conventionally true value for an internal dose evaluation is not available. Intercomparison of results using a common set of test questions provides a measure of the consistency of internal dose calculations, and DOE facilities are encouraged to participate in internal dosimetry intercomparisons. Participants were asked to evaluate five actual exposure scenarios. Results of this study demonstrated that the relative standard deviation of the internal doses was approximately 30-50% (about 180% in one case) of the mean values. Factors contributing to the significant discrepancies were identified to include: 1) the interpretation and statistical treatment of the bioassay data; 2) the biokinetic models applied; and 3) the computational tools used. This study pointed to the need for further intercomparisons to fully evaluate the problem of internal dose assessment consistency. A second intercomparison study is currently underway, and it is planned that similar intercomparisons will be performed every three years. Test exposure scenarios that have been used in the present study are directly related to the current operations taking place in DOE facilities. They cover different single and multiple intakes of plutonium, chelation treatments and other realistic exposure situations. Results of this study, along with the improvements that have been made in the intercomparison technique, will be reported.

DIRECT INTERNAL DOSIMETRY - A NEW WAY FOR ROUTINE INCORPORATION MONITORING OF γ-EMITTING RADIONUCLIDES

H. Doerfel

Forschungszentrum Karlsruhe GmbH, Karlsruhe, FRG

INTRUDUCTION

The conventional procedures for *in vivo* monitoring of γ-emitting radionuclides involve the determination of body or organ burdens using whole body counting techniques and the subsequent estimation of intake and committed dose equivalent, respectively. For these procedures many information are required, such as time and pathway of intake, physical and chemical form of incorporated materials, metabolism etc. At routine monitoring these information are hardly available, thus resulting in significant uncertainties for the estimation of intake and committed dose equivalent. Besides, it is extremely difficult or even impossible to define general criteria such as lower limit of detection or confidence interval for intake and committed dose equivalent, respectively. Thus it is problematic to define minimum requirements for incorporation monitoring devices or to compare different monitoring procedures with respect to the quality of their dose estimates. In order to meet these difficulties, at Karlsruhe Research Center a new method for direct internal dosimetry has recently been developed.

MEASURING PRINCIPLE

The method refers especially to those radionuclides which commonly are detected with standard whole body counters, i.e. radionuclides emitting γ-rays with relative high abundancy (>10 %) and relative high energy (>100 keV) If such a radionuclide is deposited in some organ or region of the body, there is a well defined correlation between the photon flux at particular points of the body surface and the dose equivalent rate due to the incorporated radionuclide. This correlation may be used for direct dose assessment with an adequately designed detector system according to the following general equation:

$$H'_{eff}(S) = C(S) \cdot \sum_{i=1}^{n} [\alpha_i \cdot R_i(S)] \qquad \text{with} \qquad C(S) = \frac{\sum_{T} [w_T \cdot SEE(T,S)]}{\sum_{i=1}^{n} [\alpha_i \cdot \varepsilon_i(S)]}$$

$H'_{eff}(S)$	effective dose equivalent rate due to a given radionuclide deposition in the source organ S
$C(S)$	calibration factor of the detector system consisting of n detectors at well defined measuring points for the same deposition in S
$R_i(S)$	response of the detector i for the deposition in S
α_i	weighing factor for the detector i ($\sum\alpha_i=1$)
$SEE(T,S)$	specific effective energy for the source organ S and the target organ T according to ICRP 30
w_T	weighing factor for T according to ICRP 30
$\varepsilon_i(S)$	counting efficiency of detector i for the deposition in S

In general the calibration factor C(S) defined by the above equation depends both on the radiation emitted by the radionuclide and on the pattern of the deposition in the body. This dependence, however, can be minimized by adequate optimization of the detector system, i.e. optimization of type, number, arrangement, size and lateral shielding of the detectors, material and thickness of radiation entrance windows, electronic settings of amplification and discriminator levels etc.

„INDOS" DETECTOR SYSTEM

The INDOS detector system has been developed both for routine incorporation monitoring and for special monitoring at incidents or accidents. Thus, the following practical aspects were taken into account:

- The measurement should be performed with a simple counting detector system without spectrometry.
- The measurement should be performed automatically without the need of any trained staff.
- The measuring time should be very short (≤ 20s), thus allowing for monitoring a large number of persons with a high frequency (1 measurement/week).

The detector system which meets these conditions is shown schematically in Fig. 1. The main components of the system are four plastic scintillation detectors, being positioned in front of the thyroid (detector 1: 6.5 x 6.5 x 10 cm^3), in front of the respiratory tract (detector 2: 16 x 16 x 10 cm^3), over the thighs (detector 3: 20 x 20 x 10 cm^3) and under the gastro-intestinal tract (detector 4: 20 x 20 x 10 cm^3). The detectors are operated by standard electronics consisting of a high voltage power supply. a preamplifier and a main amplifier with a single channel analyzer. The detector pulses are fed into four counting channels of a PC. The PC is connected to a chip card unit for input of personal data (i.e. personal identification, body weight, body height, chest circumference) and for output of measuring results. For individual adjustment of the measuring geometry the seat of the detector system can be moved by computer controlled stepping motors in the horizontal and vertical direction according to the subjekct's body proportions (chest circumference for horizontal movement and body height for vertical movement, respectively). The individual adjustment allows for measurement of all subjects with body heights ranging from 150 cm up to 200 cm.

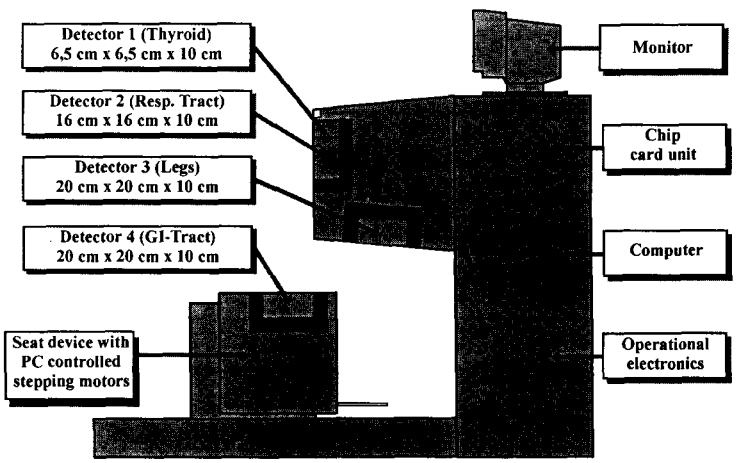

Fig. 1:
The INDOS
detector system

In order to use the detector system for dose estimations in any meausuring geometry, a mathematical calibration procedure was applied. This procedure is based on a set of semi-emprical formulas for the calculation of the detector response as a function of the photon energy of the source, the coordinates of the source position and of the thickness of the tissue between the source and the detectors. The measurements in general are performed using calibration factors for the reference man having a body weight of 70 kg and a body height of 170 cm. Since the SEE values of ICRP Puplication 30 also refer to the reference man, this procedure will yield realistic results for all persons having simaler body propertions. Moreover, this procedure will also yield very good results for persons with different body proportions, because the calibration factors and the SEE values show a very simaler dependence on the body size. Thus, this method of internal dosimetry to some extend has a built-in correction of the body size effects. This is an important advantage of the direct method.

The background counting rate is governed by radiation emitted from the natural radionuclides, i.e. K-40 contained in the materials of the environment of the detector system. The contribution of the natural airborne activity is relatively small and so the background of the detector system is very stable when counting is done susequently without subject in the same environment. When counting with a subject, however, the background of all detectors is reduced significantly due to the absorption of the environmental radiation in the

body. The absorption effect has been studied on the basis of more than 300 measurements with about 40 male and 20 female subjects with different body proportions. These measurements show the backgrount counting rate to be in very good approximation a linear function of the body weight (detector 1 and 4), the chest circumference (detector 2) and the body height (detector 3), respectively. The mean deviation of the measured background counting rates from the respective fit values are ±26 cts/20s (detector 1), ±115 cts/20s (detector 2), ±142 cts/20s (detector 3) and ±140 cts/20s (detector 4), these values being less than twice the standard deviation due to counting statistics.

EVALUATION

For evaluation of the measurement, first the individual background counting rates of the four detectors are calculated on the basis of the biometric parameters of the subject. These hypothetical background values are subtracted from the measured counting rates. If the resulting net counting rate of any detector is significant larger than the respective standard deviation (>3.29σ), the net counting rates of all four detectors are analyzed with a special logic algorithm in order to select one of the four deposition cases listed in the first column of Tab. 1. As can be seen from Tab. 1, the measured dose qanatities are the effective dose equivalent in the first two deposition cases, the lung dose equivalent in the third deposition case and the thyroid dose equivalent in the fourth deposition case, respectively. The calibration factors and the values for the lower limit of detection refer to Co-60 in the first three cases and I-131 in the last case. For unknown mixtures of radionuclides the choice of these standard calibration factors result in a mean calibration error of about 50 %. Otherwise the calibration error amounts to about 20 %.

Tab. 1:
Parameters for evaluation of the measurement and corresponding values of the lower limit of detection for one 20 s measurement (95 % confidence level)

Deposition case	Measured dose quantity	Weighing factors ($/\alpha_1/\alpha_2/\alpha_3/\alpha_4$)	Calibration factor (μSv/d per cps)	Lower limit of det. (μSv/week)
Homogenious whole body deposition	Effective dose equivalent	0/0.34/0.33/0.33	0.018	1.6
Inhomogenious trunk deposition	Effective dose equivalent	0/0.14/0.36/.50	0.062	6.3
Dose relevant lung deposition	Lung dose equivalent	0/1/0/0	0.72	9.6
Dose relevant thyroid deposition	Thyroid dose equivalent	1/0/0/0	4.7	140

CONCLUSIONS

The INDOS detector system offers the following advantages with respect to routine incorporation monitoring:

- The measurement is performed automatically and there is no need for trained staff.
- The measuring time is short und thus a relative large number of persons may be monitored with a relative high measuring frequency.
- First estimates of the individual effective dose equivalent rate are available immediately after the measuremt.
- The direct determination of the dose equivalent in principle is more precise than the conventional procedures for internal dosimetry, because (i) the retention of radionuclides in the body may be measured explicitely and (ii) the dependence of the dose equivalent on the body proportions is corrected implecitely.
- The measuring procedure is comparable to the external dosimetry with respect to accuracy and lower limit of detection. Thus, the results of internal and external dosimetry can be summed up in an easy and reasonable manner.
- The detector system can be installed in any building; it also can be installed as a mobile unit in a car or a container for long distance transportation by aircraft or train.
- Last but not least, the cost for monitoring with INDOS is much lower than for the conventional monitoring procedures using whole body counters.

The Canadian National Calibration Reference Centre for *In-Vivo* Monitoring and the United States Department of Energy's International *In-Vivo* Intercomparison.

INTRODUCTION

The Canadian National Calibration Reference Centre for *In-Vivo* Monitoring (1) and the United States Department of Energy (DOE) collaborated to offer an intercomparison program to whole body counting facilities in 1993. The HML fabricated the phantom shell and Battelle Pacific Northwest Laboratory filled the shell with radioactive tissue-substitute polyurethane to simulate a uniform fission-product distribution in soft tissues.

The choice of the four-year-old phantom (2) was made for two important reasons: following the Chernobyl reactor accident monitoring many children was necessary and it follows that any whole body counter that has to be used in emergencies should have a good range of calibrations for it to be effective; costs- the smaller phantom required much less tissue-substitute to fill it and the shipping costs were also lower for this small phantom.

The phantom contained ^{137}Cs 4.487 ± 0.076 kBq, ^{88}Y 18.90 ± 0.54 kBq and ^{40}K 851 ± 43 Bq (01-May-93, 1200 PST). Performance of the participating facilities was evaluated according to ANSI N13.30 "Performance criteria for radiobioassay" (3) which states that "For testing purposes ...(bias) shall be within -0.25 to 0.50" and "The relative precision ... shall be in absolute value less than or equal to 0.4".

PARTICIPANTS

The program began with 27 facilities in the intercomparison program; however, this number grew as word of the program spread. As a result, the original 27 facilities enrolled in the program grew to 35. Each counting system was coded so some facilities had multiple codes, for a total of 43. Some participants counted the phantom on several different whole body counters. For example, one facility had seven codes assigned to it.

Time estimates for the length of the program were made assuming that it would take one week to perform measurements and two weeks for shipping/handling the phantom to the next facility. Thus, the length of the intercomparison was estimated to be 86 weeks. The program began in April 1993 and should have ended in December 1994; however, such factors as shipping delays, equipment breakdown, and customs contributed to the lengthening of the program. The program officially ended on 1-Aug-95, when the phantom arrived back at the HML from the last participant's laboratory.

RESULTS

The phantom, designated as P4C (Phantom 4 year old, item C), was filled with soft-tissue substitute material and an unknown quantity of multiple radionuclides. The activity in the phantom was homogeneously distributed throughout all sections and was proportional to the volume of that section. The phantom also contained ^{40}K homogeneously distributed in an amount similar to a Reference Child, to produce an accurate Compton background in the resulting spectra.

Each facility was asked to determine the identity and amount of the radionuclide(s) in the energy range 200 - 2000 keV. Each facility was asked to make an estimate of the "worst case" precision (WCP) (4) and estimate their Minimum Detectable Activity (MDA).

DISCUSSION

All facilities correctly identified the radionuclides in the phantom although some facilities did not report the activity for ^{88}Y as they had no calibration factors for this radionuclide. Most did not report an activity value for ^{40}K. Selected results are shown in and the Figs. 1 - 3. The complete set of data can be found elsewhere (4). The average shipping time was 6.3 days and the average time at a facility was 16.3 days; however, this time is not realistic due to the downtime of the counting system at one facility. If the 187-day layover at one facility is

replaced with the actual time taken to do the measurements (seven days), the average facility time becomes 11.3 days. Total shipping plus facility time was 17.6 days, which is less than the assumed three weeks used for planning purposes. The 21-day time-frame will be used for the next intercomparison scheduled for early 1996.

Bias results: Fig. 1 shows the bias results for ^{137}Cs as a function of counting geometry. Other data showed that size dependency was not a simple function of the type of counting geometry but must be a mixture of factors such as distance of the phantom from the detector(s), scan length (where applicable), size of detector, calibration coefficients etc. A similar analysis was performed on the ^{88}Y results (not shown) and the same trends were seen.

It is interesting to note that most of the facilities overestimated the activity in the phantom; however, when size corrected calibration factors were applied the results (not shown) become much more normal for ^{137}Cs. Most facilities underestimated the ^{88}Y when using size corrected calibration factors. The data in the final report (4) will be useful for facilities that wish to redefine their calibration factors.

Fig. 1 shows that no one type of counting geometry appeared better than another. Representatives of all counting geometry types fell within the N13.30 acceptable limits mentioned above.

Precision results: Fig 2 shows the WCP results for ^{137}Cs. Normal precision values for these facilities will be much less than the values reports here. All facilities fall within the N13.30 guidelines for precision. Similar to the bias results, there appeared to be no one counting geometry that was superior to another.

MDA results: Figure 3 shows the MDA as a function of counting geometry. As the photon energy rises both the counting efficiency and the background count rate drop. Therefore, one would expect the ^{88}Y MDA's (not shown) to be lower than the ^{137}Cs values. The data showed this to be true for most facilities; however, for a few facilities the reverse was true, and the ^{88}Y MDA was higher than the ^{137}Cs value. As before, there was no correlation with counting geometry. One would have expected to see a correlation between ^{137}Cs MDA and counting time; however, the data showed that this was not true. Although there was a general drop in MDA as counting time was increased there was much scatter in the data. The data clearly showed that there was a large difference between ambient background count rates and/or detector shielding at the participating facilities (4).

THE NEW WHOLE-BODY COUNTER AT THE NRIRR, BUDAPEST

Andor Kerekes

National Research Institute for Radiobiology and Radiohygiene, Budapest, H-1775
P.O.B. 101

INTRODUCTION

A CANBERRA Model 2270 whole-body counter equipped with NaI(Tl) detectors in chair geometry operates at the NRIRR since 1981. This counter is suitable mainly for screening of internal contamination in body and thyroid of occupational origin because of the relatively small size of detectors and the poor shielding (1). However the counter was also used to determine the ^{137}Cs body burden of population living in the region of Budapest following the Chernobyl accident (2). The experiences gained from this study and preparations for the investigation of contamination due to accidental releases from a NPS made clear, that beside the improvement of shielding a new whole-body counter should be equipped with high resolution HpGe semiconductor detectors too. The new shielding was made from steel of thickness of 15 cm with the inner sizes of 1.6, 2.0 and 2.0 meters allowing the operation in scanning geometry too, with moving detectors under and over the bed.

METHODS

The requirements of moving and positioning of detectors, i.e. quasi continuos controlled linear driving, manual setting of vertical and rectilinear position could have been satisfied most simply by the use of step motor and chain driving of the detector holder stand. The detection limit of the measurements can be reduced by the summing up of the spectra taken by the detectors moving under and over the bed simultaneously. However, to obtain good result the complete co-operation of the two detector systems, conformity of amplification and linearity are essential.

The calibration of the new whole-body counter was performed by homogeneous phantoms built from 1 L plastic bottles for the gamma-energies from 22 up to 1836 keV and for body masses of 15, 30, 45, 60, 75 and 90 kg for both standing above the chest and scanning detectors. Neck phantoms made from different materials (plastic and wood) and having different absorbent layer thickness (10-19 mm) were used for the calibration of thyroid geometry.

RESULTS

The efficiencies of the two-detector system for different gamma-energies and for the most common scanning geometries can be seen in Fig. 1. The highest efficiency was observed at 122 keV energy, while the efficiencies at very low and high energies (22 and 1836 keV) are less by a factor of 4 to 5. The total efficiency is lower for the 90 kg, 35 cm (bed-detector distance) geometry than the 15 kg, 25 cm one by a factor of about 3. The efficiencies for the detectors standing above the chest are higher than of the similar scanning geometries by a factor of 1.3 to 1.4, because of the shape and activity distribution of the phantoms.

The efficiencies of the thyroid geometry are illustrated in Fig. 2. The observed ratio between the highest (plastic, 10 mm absorbent layer, 1 cm neck-detector distance) and lowest efficiencies (plastic, 19 mm absorbent layer, 5 cm neck-detector distance) was higher than 3 .The results on the effect of the material and thickness of the absorbent layer and of the detector-neck surface distance on the efficiency yield valuable information for assessing the uncertainties of measurements of human thyroids as well.

The typical ranges of the detection limits derived for scanning and standing whole-body and thyroid geometries for the measuring times of 1000 and 1500 s can be seen in Table 1. The highest LLD was estimated for ^{40}K, because this natural radionuclide is present also in the background.

The retention of ^{134}Cs radioisotope for two radiation workers (KA 42 yr., 65 kg; SD 54 yr., 85 kg) was investigated following the ingestion of 1 kBq activity. The results of our measurements agreed well with the whole-body activities measured at the National Institute of Radiation Protection (SSI), Stockholm 7 and 10 days following the intake (Fig. 3.). The estimated components of the biological half-times were 32 and 120 days for subject KA, while in the other case a single exponential fitting was only acceptable.

RADON INFLUENCE IN THE ESTIMATION OF BACKGROUND OF WHOLE-BODY COUNTING

Nobuyuki SUGIURA, Toshiso KOSAKO, and Hoshio EGUCHI

The University of Tokyo, Research Center
for Nuclear Science and Technology, Tokyo, Japan

INTRODUCTION

Because of the existence of natural background radiation, it is important for the precise whole-body counting to keep the fluctuation of background radiation slightly. It is considered that radon and its daughters are one of the remarkable components of natural background radiation for its large fluctuation. Therefore, we investigated (a) the relationship of meteorological factors and radon concentration, (b) the effects of ventilation and filtration on radon concentration, and (c) the comparison between radon concentration and count rate of whole-body counter (WBC).

METHOD

1. Outline of WBC at the University of Tokyo

The WBC at the University of Tokyo is consisted of 20 cm thick iron shield room with 4 segments of 50x50x15 cm plastic scintillators and a 8inch ϕ x 4inch NaI(Tl) scintillator (1). Two ventilation systems are equipped; one is for an operation room (4.5m^3/min, air intake from top of the building, 21m height), the other is for an iron room (0.5m^3/min, air intake from the ceiling of iron room). The operation and iron rooms are situated at a semi basement floor.

2. Radon concentration measurement

Radon concentration was measured with PMT-TEL measurement system (provided by Pylon Co.) by the air-flow electrostatic sampling method. The air flow rate by the built-in pump was 2,000 cm^3/min. The radon concentration was averaged for 10 minutes or 1 hour. The conversion factor of count rate to concentration was 1.61 Bq/m^3/cpm from a reference manual of the system (2).

RESULTS AND DISCUSSIONS

1. Relationship between meteorological factors and radon concentration

The relationship between meteorological factors, which are temperature, humidity and atmospheric pressure, and radon concentration was investigated. As for atmospheric pressure, there was a significant correlation. Measured radon concentration level was low in case of higher atmospheric pressure. The regression equation was as follows:

$$RC = -0.270\ AP + 293$$

where RC is radon concentration (Bq/m^3), AP is atmospheric pressure (mb) (r^2=0.726). This tendency agrees with the previous report (3).

2. Effects of ventilation and filtration on radon concentration

Figure 1 shows the change of radon concentration in the operation room by the method of ventilation. When the ventilation was not operated, radon concentration reached about 40 Bq/m^3. In the case of air intake from the ground level, radon concentration remained at rather high level (about 20 Bq/m^3). When air was intake from the top of building with 21m

height, the radon concentration was kept at low level (about 10 Bq/m^3). Under this condition, HEPA filter could not work to remove radon effectively.

As shown in Fig. 2, the ventilation of the operation room decreased radon concentration effectively and it took about 6 hours to settle a stable condition from the beginning of ventilation. This tendency has a good reappearance. The averaged radon concentration in the operation room was 8.5 Bq/m^3 in case of well-ventilation. The calculated value was 10.4 Bq/m^3, obtained by the following method.

The flux density of radon, J_D (Bq/m^2/s), from one side of a wall (or a floor) was calculated by the equation (4) shown below,

$$J_D = C_{Ra} \lambda_{Rn} f \rho [D_e/(\lambda_{Rn} \varepsilon)]^{0.5} \tanh d [D_e/(\lambda_{Rn} \varepsilon)]^{-0.5},$$

where C_{Ra} is the activity concentration of ^{226}Ra in the building element (Bq/kg); λ_{Rn} is the decay constant of ^{222}Rn (2.1 10^{-6} /s); f is the emanation fraction, ρ is the density (kg/m^3); D_e is the effective diffusion coefficient (m^2/s); ε is the porosity, and d is the half-thickness (m). The ventilation rate is 4.5 m^3/min. The volume of an operation room is 197 m^3. Because air exchange through doors and other openings was not taken into account in this calculation, the actual amount of air exchange was larger. Therefore, the calculated value, 10.4 Bq/m^3, would be more small.

The comparison of the fluctuation of radon concentration in the iron room with/without ventilation of the operation room is shown in Fig. 3. The averaged radon concentrations per every ten minute were measured for 40 minutes. In the case of no ventilation, radon concentration was high (30 - 45 Bq/m^3) and its fluctuation was large. On the other hand, radon concentration was in low level and its variation was small. These results showed the air exchange between an operation room and an iron room could occur easily and only the ventilation of an iron room was not effective. Therefore, it is necessary and important to keep radon concentration in an operation room low by the ventilation of an operation room.

3. Comparison between radon concentration and count rate of WBC

The effect of radon concentration on WBC count rate with plastic scintillator is shown in Table 1. The count rate in the lower energy range below about 800 keV of WBC corresponded with radon concentration. The decreases of Bi-214 and Pb-214, which are radon daughters, by ventilation were observed in the spectrum measurement with a high-purity Ge semiconductor detector. On the other hand, there was no change of the count rate in the upper energy range above about 800 keV. That shows no consideration is needed in this high energy region on the discussion of radon influence.

CONCLUSION

The behavior of radon in WBC room was analyzed and the desirable condition of ventilation and filtration for whole-body counting was discussed.

TREATMENT OF THE X AND γ RAYS LUNG MONITORING SPECTRA OBTAINED BY USING HP-Ge DETECTORS IN CASE OF EXPOSURES TO URANIUM

P. Bérard , O. Pourret, J.P. Aussel and E. Rongier
Institut de Protection et de Sûreté Nucléaire, Département de Protection de la santé de l'Homme et de Dosimétrie, Service d'Hygiène Industrielle, I.P.S.N., BP.38, F-26701 Pierrelatte Cedex (France)

INTRODUCTION

X and gamma whole body counting examinations make it possible, when focusing to an organ, to determine the retention of radioelement. The critical organ when performing the radiotoxicological monitoring of personnel exposed to non-transferable compounds of uranium is the lung. This is true for both natural and enriched uranium because of their biological inertia and of the very high ionising power of their alpha radiation. *In vivo,* X and gamma spectrometry take advantage of the low excretion rate of these compounds to allow the quantification of the pulmonary retention of the inhaled products. These examinations are based on the analysis of the X and gamma radiation emitted by the radioelements retained in the lung and the ensuing quantification of their activity.
HyperPure coaxial Germanium detectors (HP-Ge) are used because of detection features which are specific to uranium. In the 10 keV to 400 keV energy range, these detectors combine low electronic background, satisfactory energy resolution and a high peak/background ratio. Their detection limits depend on spectrum treatment performance and on the modelling of the morphological parameters of the rib cage. For various reasons, the estimation of radioactive contamination in the lungs of a human being poses a delicate spectrometry problem: activity levels are low, a significant proportion of the radiation emitted is absorbed by the rib cage and counting time is limited for practical reasons as well as because of the equipment background effect. Consequently, for most of the spectra, the 185 keV ^{235}U absorption peak does not clearly stand out of the average level of spurious counter pulses. It is therefore difficult to affirm whether or not a peak exists, and in case of contamination, it is, *a fortiori,* difficult to estimate the number of pulses emitted by the radioelement at that energy level during the measurement operation.
The aim of our study, which calls into question both acquisition conditions and interpretation methods, is to improve the efficiency of these measurements.

MATERIALS AND METHODS

1 - The whole body counting equipment

The system consists of four LOAX detectors movable and adjustable on a rail. The coaxial N-type low background detectors are made with high purity germanium. The energy detection range extends from 3 keV to 3 MeV and covers the isotopic energies required for medical assessment in Pierrelatte facilities. Two detectors are placed along the body axis above each lung to cover as much lung area as possible. The absolute efficiency of the measuring system is calibrated with a Livermore phantom. Two background measurements are performed every day. The background measurements are made on an empty shield, the counting time being the same as for the monitoring measurements. The calculations, which take into account the morphological parameters of the worker, are made using automatic spectral analysis, peak search and specific area. The results are analysed using the sum of the counts given by the four detectors, once the background of the room has been subtracted.

2 - The method adopted

The starting point for this study was a critical appraisal of the measurement principles. It is clear that, before looking at spectrum interpretation problems, a certain number of questions need to be asked: Do the four spectra need to be summed or should they, on the contrary, be treated separately ? Can the backgrounds really be exploited ? If so, what counting time should be allotted for them ? Should lung acquisition time be increased, or can it be reduced ?

In replying to these questions, an important consideration is to take into account all the available information: the resolution of the detector, for example, is a useful piece of information since it indicates what form the eventual peaks will have. The second stage involves the analysis of the spectra. Basing ourselves, respectively, on statistical test theory and evaluation theory, we propose a method of diagnosis and a peak quantification algorithm. A computer programme written in Turbo-Pascal has been developed in order to implement the corresponding algorithms.

3 - Modelling

A whole body counting spectrum cannot be considered to be a series of regular peaks, even if the background is totally abstracted. Adjusting a Gaussian function to a peak is not a trivial affair, because the peak is the result of random phenomena. As such, in comparison with the "ideal" Gaussian function, it may contain discrepancies of varying importance.

Peak formation modelling is a random phenomenon when we consider that the number of counts that the detector - which is submitted to a certain apparent activity over a given period - shows in each of its channels obeys a Poisson distribution in which the average is equal to the product of the following numbers:

- ⇨ the apparent activity (activity x percentage of non-absorbed photons x solid detector angle fraction)
- ⇨ the counting time
- ⇨ the fraction of the theoretical Gaussian area intercepted by the channel

Throughout this study, to simplify the calculations, we have taken the numbers of pulses received in each channel as being independent random two-by-two variables. The probability of a spectrum corresponding to a given source can be calculated, thanks to this approximation, from the probabilities of the number of counts that each channel can receive.

RESULTS

1 - The background

Physical modelling of the background has to be ruled out, because there are too many possible explanations for the spurious counts. The study will accordingly be statistical, based on a two-hour long background measurement on an empty cell. Subtracting the background does not bias the measurement. However, for low counting rates, the relative error may not be negligible.

2 - Do the treatments have to be separated ?

The argument advanced to justify the summing of the four spectra is that, for cases of low contamination, it appears to be necessary to add up the spectral information. This argument holds for peak presence searches, but it is not valid in the cases where the peak area has to be quantified. Figure 1 shows the magnitude of a spectrum corresponding to a level of activity close to the equipment detection limit.

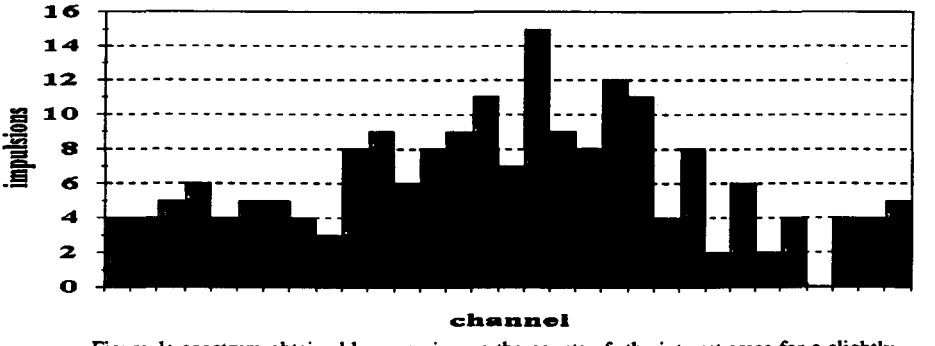

Figure 1: spectrum obtained by summing up the counts of the interest areas for a slightly contaminated worker

The peak obeys a Poisson law where the average is proportional to the resolution of the detector. Separate quantitative treatment also shows up the distribution of the contamination in the lungs.

Table 1 summarises the distribution in terms of the spectral information provided by each detector during measurement on workers whose results were higher than the detection limit. Examinations need to be studied detector by detector.

Table 1: Distribution of the areas measured on real cases in function of the detectors

detector	1	2	3	4
% of the area cover by each detector	24.2	25.4	24.2	26.2

3 - Estimating the presence of internal contamination

This analysis falls within the scope of statistical test theory. Two multiple hypotheses can be posited: the presence of spurious pulses only, or the simultaneous presence of spurious pulses and photonic uranium isotope emission. Since the numbers of pulses counted in each channel are considered to be independent variables, test theory enables us to show the existence of an unbiased, convergent Uniformly Most Powerful test, with an acceptance region corresponding to a 5 % type I error.

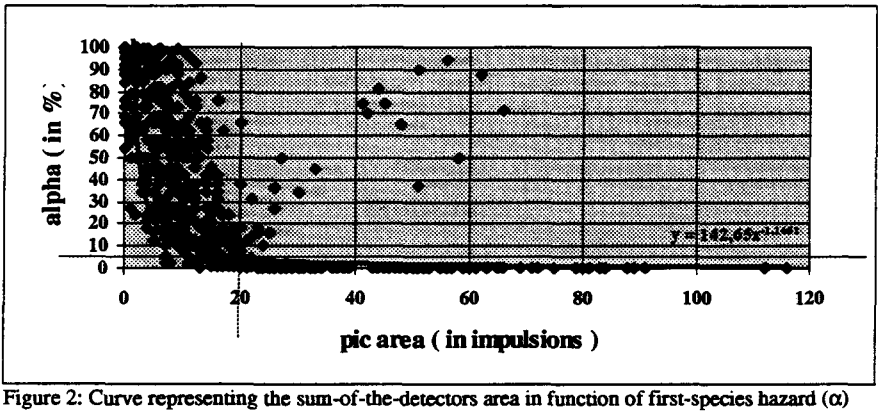

Figure 2: Curve representing the sum-of-the-detectors area in function of first-species hazard (α)

Figure 2 shows four distinct zones.
Negative results : weak area (less than 20 pulses), α between 5% and 100%
Positive results : area with more than 20 pulses, α less than 5%
Results with interferences : weak area and α less than 5%, or area with more than 20 pulses and α between 5% and 100%

CONCLUSIONS

A lung monitoring counting spectrum can be described as a random phenomenon. Channel-by-channel Poisson-type modelling was verified for cases of pure background. When carrying out spectral analysis for qualitative research, one must work with the sum of the detectors. The quantification must be calculated detector by detector. Statistical tests make it possible to certify that one or several peaks are really present in the organism.

The calculations are currently made with automatic spectral analysis, peak search, specific area, statistics and probability of the real presence of analytic photo peak taking into account the morphological parameters of the worker. The results are analysed detector by detector, with and without the background of the room. Detection limits obtained in Pierrelatte in monitoring measurement conditions were assessed for variable tissues covering the range of subjects to be examined. For each subject , the calculations are made taking into account the equivalent tissue thicknesses derived from individual morphological parameters.

This method makes it possible to quantify lung activities with a detection limit of 3.9 Bq (^{235}U; thirty minutes counting time ; reference man parameters) and to monitor exposure to the different compounds of uranium.

THE GAMMA CAMERA AS AN EMERGENCY WHOLE-BODY COUNTER FOR CONTAMINATED PERSONS

E. Wallström[1], M. Alpsten[1], and S. Mattsson[2]
[1]Dept. of Radiation Physics, Sahlgren University Hospital,S-413 45 Göteborg, Sweden
[2]Dept. of Radiation Physics Malmö, Malmö University Hospital, S-20502 Malmö, Sweden

INTRODUCTION

In case of a severe accident with release of large amounts of radionuclides into the environment there will be a great need for equipment to measure contaminated persons. Gamma cameras with large scintillation detectors are available at many hospitals. It would be of great importance if these could be used for measurements of gamma-emitting nuclides as Cs-137, Cs-134 and I-131 in the acute situation as well as in the control work which will be needed for a long period of time. The aim of this work is was to investigate the possibility of using gamma cameras in accident situations and to provide suggestions of measurement procedures. Simplicity was in this context judged to be essential.

MATERIALS AND METHODS

Two gamma cameras have been used. Camera A is an older camera with a 400 mm diameter 9 mm thick NaI(Tl) detector with the possibility to easily connect an external multi channel analyzer (MCA). Energy ranges can thereby be set even for energies above that of Cs-137 (662 keV). With the addition of an extra counterbalance the camera could be handled freely with and without a collimator. Camera B was more modern with a 400 mm diameter 6 mm thick detector and limited possibilities of setting energy ranges. No extra counterbalance could be used so the camera had to remain fixed when used without a collimator.

All calibrations were made with phantoms constructed from various numbers of 300 ml freezing sachets filled with known water solutions of Cs-137, Cs-134, I-131 and potassium. Tap water was used for background meaurements. The sachets were arranged in the form of rectangular boxes of various sizes, as well as three body-shaped phantoms simulating a four year old child (14 kg) as well as two adults of different sizes (60 kg and 90 kg).

At measurements the phantom was placed on a bed with a flat surface. The distance phantom surface - detector was 5 cm, 20 cm, and 35 cm respectively. At measurements with the body shaped phantoms the camera head was placed in two fixed positions one centered over the throat (thyroid) and one over the center of the body. At measurments with the box phantoms the camera head was fixed over the geometrical center of the phantoms.

Camera A was used with High Energy General Purpose (HEGP) collimator, Low Energy General Purpose (LEGP) collimator and without a collimator. The energy ranges investigated were 50 - 450 keV, 450 - 550 keV, 550 keV - 750 keV. Camera B was only used without a collimator and the investigated energy ranges were 50 - 450 keV and 450 - 511keV, the maximum possible energy to be pulse height analyzed for that camera.

Minimum detectable activities (MDAs) were calculated as three standard deviations of the background counts for 1 minute measuring time. In sensitivity values, cps/Bq, cps refer to the net counts from the present nuclide when background counts, from measurement with background fantom in the same energy interval, is subtracted. All MDA values, in Bq, and all sensitivity values, in cps/Bq, refer to total activity in the phantoms.

RESULTS

The highest sensitivity is achieved in the large low energy range, 50 - 450 keV, with camera A without collimator. In all three energy ranges the sensitivity decreases with increasing distance phantom surface - detector. The sensitivity for the Cs-137 phantom at constant distance phantom surface - detector decreases with increasing length, width and thickness of the phantom. The background increases with increasing distance phantom surface - detector and decreases with increasing length, width and thickness of the phantom. The variations of sensitivity and background with phantom size is larg at 5 cm distance phantom surface - detector. At 35 cm distance the variations are much smaller and for "adult" sizes of phantoms,

especially in the low energy range, almost constant. MDA values for adult phantoms are in the low energy range 400 Bq (5 cm distance) to 1000 Bq (35 cm distance). The MDA values in highest energy range, covering the Cs-137 full energy peak, are 1,3 - 1,8 times higher than in the lowest energy range. In the intermediate energy range the MDAs are higher by a factor of 3 - 4 than in the low energy range.

With LEGP collimator variations of sensitivity and background with distance phantom surface - detector, and with phantom size, are similar but more pronounced than without collimator. The level of the background values are lower, but the sensitivity values are also lower, which gives higher MDA values by a factor of 3 - 4. Values of MDA with use of the HEGP collimator are approximately 10 times higher than without collimator.

MDA values of I-131 in thyroid at measurement over the phantom throat at 5 - 35 cm distance are in the low energy interval 100 Bq - 450 Bq without collimator, 800 Bq - 2500 Bq with LEGP collimator, and 12000 Bq - 17000 Bq with HEGP collimator.

All calibration measurements of potassium show that K-40 is not detectable (refering to three standard deviations of the background counts).

The sensitivity for camera B is in the low energy interval about 20 - 40% lower for both I-131 and Cs-134,137. In the intermediate energy range 450 keV - 511 keV, compared to 450keV - 550 keV for Camera A, the sensitivity is reduced by a factor 2 to 5.

Table 1. Sensitivity, background and MDA values (1 min. measuring time) for camera A at 35 cm height above adult phantom Whole-body Cs-137 measured over the center of the phantom; I-131 in thyroid measured above thyroid. Comparison with standard measurements at the whole-body counter (WBC) in Göteborg (one - two 12,5 x 10 cm NaI(Tl) detectors).

Energy range (keV)	Collimator	Sensitivity, Cs-137 [cps/Bq]	Sensitivity I-131 in thyroid [cps/Bq]	Background countrate [cps]	MDA Cs-137 (Bq)	MDA I-131 (Bq)

DISCUSSION

The most important parameter is the background. For the normal standard gamma camera, the background constitutes the major part of the pulses in the camera, without or with a contaminated person. This makes a stable and known background extremely important. A "normal" change in background - due to changes in the general background or due to a person passing close to the camera making a shield for a part of the background or due to contaminated persons or items in the neighbourhood of the camera or due to a different body shape of the measured person or another distance person to camera head than taken into account - can alter the measured value with thousands of Bq. Lead shields around the camera will decrease the background and its variations. Moreover a lead shield under the camera head reduces the photon field from below, including scattered photons, and hence reduces the background (3).

A realistic goal is to keep the background within six SD of the mean (i.e. double MDA values). This requires stable background conditions and a background calibration measurement performed in the present outdoor contamination situation. If the background is kept within these limits an activity measurement at the MDA level means that the activity in the body is

somewhere between 0 Bq and an activity corresponding to two MDAs. Hence the accuracy of activity measurements increases with increasing activity in the body. However the MDA values are in most cases low when considering the doses achieved from internal contamination. For a person of 70 kg a constant body burden of 160 kBq Cs-137 gives a yearly effective dose of 5 mSv. For a child of 10 kg the corresponding figure is 24 kBq (4). An intake of 120 kBq I-131 giving 35 kBq at maximum in thyroid gives a thyroid dose of 50 mSv (5).

Suggested measurement procedure

To maximize the sensitivity of the gamma camera, a camera with a thick chrystal and without collimator is to prefer. The most sensitive energy interval is in all situations for all nuclides 50 - 450 keV or larger. To minimize the changes in background with various body sizes, a not to short, but fixed, distance body surface - chrystal should be used e.g. 30 - 40 cm. Since the background without phantom/person varies with distance of the camera head above the floor, the most stable condition is a fixed camera head above a flat bed possible to change in height. A gamma camera without a collimator is difficult to handle so a convenient height may be difficult to achieve without special arrangements. The person making the measurement should be placed at a fixed place at least a few meters away from the camera. No other persons should be allowed in the closest area.

For calibration it is most simple to use simple box phantoms made of larger plastic containers. The size of the phantom should be approximately, length 150 cm - 170 cm, width 30 cm - 40 cm, and height 15 cm - 20 cm. For adults one phantom for background and one for each radionuclide is sufficient. The background phantom could be filled with water or, rather, a mixture of water and 1,5 g - 2 g potassium/kg phantom. For children one or more phantoms sizes may be needed. For calibration of I-131 in thyroid a small container (appr. 20 ml) with I-131 placed under a few cm of water will be sufficient. It is necessary to make often repeated background measurements without a phantom to correct the background values measured with water phantom for changes in the background photon field.

CONCLUSIONS

The gamma camera can be a good and important tool for assessing the internal contamination of gamma-emmitting nuclides in an accident situation. The background is a large source of uncertainty and must be kept low, if possible, and known and stable at all times. To avoid variations in background and sensitivty with body size, which severely influence the accuracy of the measurements, the camera should be used without a collimator, a large low energy interval should be chosen and the distance persons surface - detector should be at least 30 cm. Measurements can then be performed with simple calibration procedures. In the case of low contamination levels near the theoretical MDA values, use of collimator, short distances measured persons surface - detector, or simultaneous measurements of e.g. I-131 and Cs-137,134, somewhat more extensive calibrations are necessary.

INTRODUCTION

In nuclear medical research and diagnosis it is often important to be able to localize small amounts of radioactivity in the human body. A complete representation of the distribution of a radioisotope in a region of the body is highly desireable but would require scans in two orthogonal planes to achieve a three-dimensional portrayal. Since most scanning devices are limited to plane portrayal we have developed an alternative technique which will be presented in this paper. Thereby we combine single longitudinale profile scans using a special detector configuration with a computer model, where we take the special geometry into account.

MATERIALS AND METHODS

Description of the experimental equipment

The detector system of the high-sensitivity whole-body counter (HWBC) used for the measurements consists of four 8" x 4" NaI(Tl)-crystals. Two of these linear scanning detectors are placed above and two below the bed and can be arranged independently in three dimensions. For an accurate measurement of the spatial distribution of the radioactivity special focussing lead collimators were designed. These multi-slit collimators can easily be brought into position in front of the four NaI(Tl)-detectors when required. This equipment is placed in a closed massive shielding chamber (total weight of the order of 74 t) to ensure a low background activity and thus a high sensitivity of the system. A central computer controls the scanning motion and the data aquisition separatly for each detector, the evaluation of energy spectra, the storage of data and the output of results.

Collimated profile scanning

To achieve spatial resolution a special detector configuration was chosen shown in Fig.1. Various point sources [^{133}Ba (355 keV), ^{131}I (364 keV), ^{22}Na (511 keV), ^{137}Cs (662 keV), ^{60}Co (1173 keV, 1333 keV)] of known activity were used to measure the counting efficiency systematically for different point source positions. Thereby each radioisotope was placed at fixed positions inside an elliptical cylindric Presdwood phantom (major axis 34 cm, minor axis 26 cm, height 50 cm). This phantom was positioned on the bed, and the profile of count rates was measured (scanning time 600 s, scanning length 190 cm) by the profile scanning system using the special measuring arrangement. The profiles thus obtained for each scanning detector expressed in cps/Bq represents the efficiencies vs. the longitudinal localization of the point source. Based on the counted efficiencies by different vertical and transversal point source positions a computational model to estimate spatial positions was developed, in which the inverse square law and the attenuation factor due to the absorbtion and

scattering processes of gamma rays in body tissue equivalent medium were taken into account. So the energy peak efficiencies for each detector can be approximated by the expression:

$$\varepsilon_D(x_p,z_p) \approx \frac{C}{r(x_p,z_p)^2} \cdot e^{-\mu(E)\cdot s(x_p,z_p)}$$

ε_D	detector efficiency [cps/Bq]
C	scaling factor [cm^2 cps/Bq]
r	distance between source and detector [cm]
μ(E)	attenuation factor [cm^{-1}]
s	thickness of the scattering medium (Preswood phantom) [cm]
x_p	transversal position of the source [cm]
z_p	vertical position of the source [cm]

This model allows to determine the unknown position of a point source inside the Presdwood phantom and its accuracy was verified for various radionuclides over a wide gamma energy range. The energy peak efficiencies of the detectors for ^{131}I (364 keV) are shown in Fig.2. as a function of vertical point source location with/without transversal displacement within the phantom. Also the geometrical and arithmetic means are indicated and it can be seen that a almost complete independence of response on the depth of the point source was obtained for the geometric mean. The variation of sensitivity with depth is largly compensated by the use of opposite detectors. Because of the attenuation, when a radioisotope in a tissue equivalent phantom is scanned, the sum of the counts from all detectors showes a minimum for the source at the mid point of the phantom. Similar results have been obtained for other gamma energies but the absolute values of the averaged energy peak efficiencies may differ considerably.

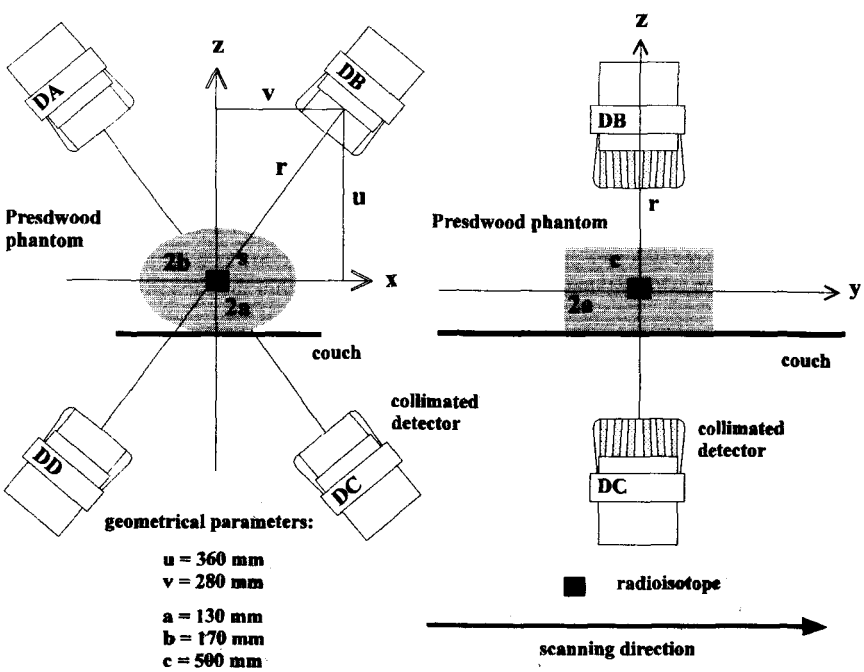

Fig.1. Measuring arrangement using a Presdwood phantom.

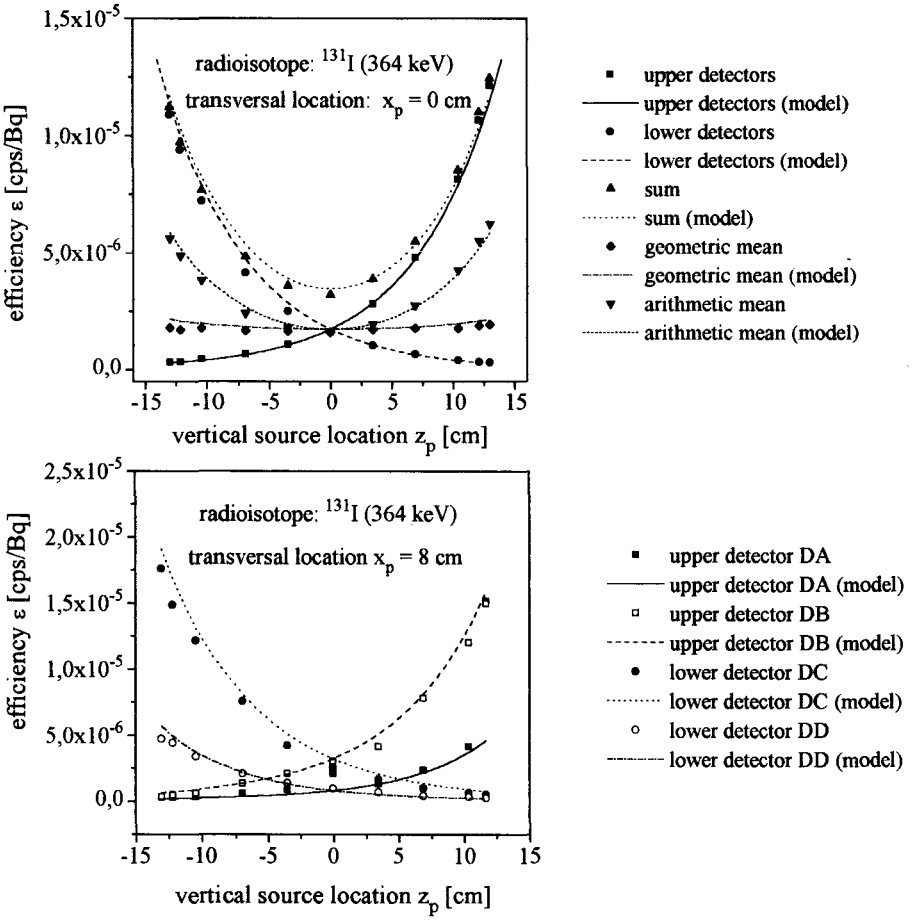

Fig.2. Lower and upper detector efficiencies and their combinations as a function of vertical point source location with/without transversal displacement within the Presdwood phantom.

DISCUSSION

By the usually used method (linear profile scanning) only the distribution of radioactivity in one dimension can be visualized. Perpenticular to this plane there is no resolution. To achieve a complete representation of distribution in the human body a model based on the detector configuration was developed. The computational model presented in this paper was crosschecked for various radionuclides over a wide gamma energy range. Because of the excellent agreement between the measured and the model calculated efficiency values and the fact that the geometrical mean of the efficiency values for all detectors is almost independent from the actual position of the distribution of radioactivity it is possible to calculate the centre of the radioactivity from the detected counts.

The importance for medical applications of this method follows from the combination of the possibility to localize radioactivity and the typical characteristics of the HWBC. So count rates can be directly attributed to organs of the human body and it is possible to study the metabolism. In this connection the HWBC over a wide energy range (60 keV - 2 MeV) ensures a very high accuracy even when lowest activities are provided.

ABSTRACT (See instructions overleaf)

An European intercomparison study (Gibson,1992) uses the bioassay data for 5 cases of contaminations by inhalation, wound or injection with 7 radionuclides to estimate the initial intakes and doses in 9 laboratories (U.K., Germany, France, Spain and Switzerland).

To extend the area of this intercomparison we made a study to establish the degree of fitness for several computer codes currently used for estimation of initial intakes and doses at Lawrence Livermore National Laboratory (LLNL), USA. This study provided equivalent results within the inherent errors of the data and the method of dose estimation. In our initial intake assessments, the results are more constrained, showing that the model parameters were the roughly the same, while in the European study model parameters were independently chosen by the dosimetrist. The range of the coefficients of variation for the dose estimates show that the choice of the dose conversion factors was fairly consistent among the European laboratories and U.S. dosimetry codes.

To show that it is possible to fulfill a gap in the interpretation of the bioassay measurements, we made at the LLNL a short "demo computing program" to use the US Nuclear Regulatory Commission data and recommendations (CR4884 and DG8009). We present the algorithms, inputs and outputs for our new "Windows" program for the interpretation of radioactive bioassay measurements.

Work partially performed under an I.A.E.A. fellowship at the LLNL.

ABSTRACT (See instructions overleaf)

A high sensitivity whole body counter has been installed at the Centre for Radiation Protection and Hygiene (CPHR-Cuba).The detectors system consists of a 8"x4" NaI(Tl) and a 3"x3" NaI(Tl) scintillation detectors located in a low background room. The room is made of low intrinsic radioactivity steel plates (less than 1 Bq of ^{60}Co per kg of steel), with internal dimensions 2500 mm w by 2500 mm l by 2600 mm h and plate thickness of 162 mm. Internal walls are lined with 3 mm of Pb, 1.8 mm of Sn and 1.5 mm of Cu for background reduction between 10 keV and 3 MeV. The gamma ray spectra are analyzed automatically using a special purpose software package and a personal computer. In order to calibrate the detection system for high energy photon emitters a structure based on the BOMAB phantom which comprise ten elliptical containers was assembled. This structure approximate the physical shape of a human body for 5, 10, 15 years old and an adult person. Phantoms are filled with plastic bags containing radioactive solution of ^{57}Co, ^{22}Na, ^{137}Cs, ^{226}Ra, ^{134}Cs, ^{54}Mn, ^{133}Ba, ^{60}Co, ^{40}K, simulating an uniform distribution. Each photon was measured with NaI(Tl) 8"x4" detector using a tilted chair geometry. Detection efficiency, FWHH and minimum detectable activity as function of energy, for counting time of 30 minutes was calculate for each radionuclide. The calibration factors as a function of weight of the phantoms were calculated too.

3.1 Internal Dosimetry

ABSTRACT (See instructions overleaf)

The metabolism of carbon has been extensively studied and is well known. Despite this, models currently being used to describe intake, distribution, and retention following a pulsed intake are not adequate for internal dosimetry. Carbon-14 is encountered in the nuclear industry primarily as CO_2, and in nuclear medicine and biomedical research as organic carbon compounds. Environmental ^{14}C will become bound in a variety of hydrocarbons. On occasion, ^{14}C will exist as an insoluble aerosol (inhalation Type S). The dose per unit intake from these different compounds will have a large range, as will the relationship between intake and excretion. This paper describes a physiologically based pharmacokinetic (PBPK) model that has been developed for use with bioassay to evaluate the dose from an intake of ^{14}C. The model has been used to calculate committed effective and equivalent dose following inhalation intakes of compounds containing ^{14}C as gases and vapors, and as Type F, M, and S compounds, as well as from ingestion intakes. Data useful in relating measurable quantities (chest contents, and urine and fecal excretion) to organ contents are given.

RESTRICTIONS FOR APPLICATION OF EFFECTIVE DOSE IN RADIATION SAFETY

Vladimir A. Kutkov

Russian Research Center "Kurchatov Institute", Moscow, Russia

INTRODUCTION

ICRP in Publications N 26 (1) and N 30 (2) recommended to calculate the annual limit on intake (ALI) of a radionuclide as the smallest value of the annual intakes corresponding to committed effective dose of 50 mSv or committed organ dose equivalents of 500 mSv. Recently ICRP don't limits the value of committed equivalent dose in organs and tissues on ALI calculations. The recommendations of ICRP Publication 61 (3) are the first one, where the annual limit on intake for any radionuclide is based only on a committed effective dose.

It is well known, that the effective dose, E is the sum of the weighted equivalent doses in all the tissues and organs of the body, H_T. The weighting factors for different organs have wide variation in magnitude, e.g. 0.2 for gonads and 0.01 for bone surfaces or skin (3). When one is exposed to radionuclides, uniformly spread in the body, e.g. ^{137}Cs, ^{106}Ru, equivalent doses in all organs and tissues are not different from the effective dose. When one is exposed to organotropic radionuclides irradiated only some organs or tissues (e.g. ^{93}Zr - skeleton, ^{238}U - kidneys, ^{131}I - thyroid), the effective dose become the weighted equivalent dose in the only organ or tissue. In those cases the equivalent dose in organ differs from the effective dose by a factor of the inverse value of tissue weighting factor put to that organ. For ingestion of ^{131}I, as an example, committed equivalent dose in thyroid is close to 200 mSv if effective dose is equal to 10 mSv (value of tissue weighting factor for thyroid is equal to 0.05).

METHODS AND RESULTS

Ratios between committed equivalent dose in organ and committed effective dose both for inhalation and ingestion of 1148 compounds of 383 radionuclides relevant to radiology were calculated with computer code "R-MAN" (4). Computer code "R-MAN" is based on ICRP Recommendations (Publications NN 30, 38, 48, 56, 60 (2, 5-8), publications of US Oak-Ridge National Laboratory (9, 10).

Results of the ratio calculations for some organs are presented in the tab. I. Thus, in accordance with (3), ALI is a value of the annual intake corresponding to committed effective dose of 20 mSv. The list of radionuclides for which H_T/E in some organs exceed 25 includes compounds of ^{93}Zr, ^{109}Cd, ^{113}Cd, ^{113m}Cd, ^{125m}Te, ^{146}Sm, ^{147}Sm, ^{151}Sm, ^{152}Gd, ^{171}Tm, ^{181}Hf, ^{210}Pb, ^{210}Bi, ^{227}Ac, ^{228}Ac, ^{228}Th, ^{229}Th, ^{230}Th, ^{232}Th, ^{231}Pa, ^{230}U, ^{232}U, ^{233}U, ^{234}U, ^{235}U, ^{236}U, ^{238}U, ^{237}Np, ^{238}Np, ^{238}Pu, ^{239}Pu, ^{240}Pu, ^{241}Pu, ^{242}Pu, ^{244}Pu, ^{241}Am, ^{242m}Am, ^{243}Am, ^{244m}Am, ^{243}Cm, ^{244}Cm, ^{245}Cm, ^{246}Cm, ^{247}Cm, ^{248}Cm, ^{250}Cm, ^{249}Bk, ^{250}Bk, ^{249}Cf, ^{250}Cf, ^{251}Cf, ^{252}Cf and ^{254}Es.

One mast to expect in relation to the data presented in the tab. I that intake of radioactivity equivalent to ALI of some organotropic radionuclides may result in a committed equivalent dose of 920 mSv in bone surfaces or 520 mSv - in kidneys or 400 mSv

Table I: Comparison of the committed equivalent and effective doses for inhalation and ingestion of 383 radionuclides

Target organs and tissues	Fraction (%) of radionuclides for which H_T differs from E by factor of between:						Maximum of H_T/E ratio, in brackets - the inverse value of tissue weighting factor
	0 and 2	2 and 4	4 and 8	8 and 16	16 and 32	32 and 64	
Bone Surfaces	77	4.7	3.1	3.7	8.4	3.1	46 (100)
Kidneys	91	3.0	2.3	2.3	1.4	0	26 (40)
Thyroid	95	2.0	0.6	0.8	1.6	0	20 (20)
Spleen	98	1.4	0.4	0	0.2	0	20 (40)
Bladder	96	3.2	0.7	0.2	0	0	12 (20)
Liver	87	6.3	6.2	0.5	0	0	10 (20)
LLI wall†	61	15	22	2.0	0	0	8.3 (8.3)
Lungs	56	11	27	6.0	0	0	8.3 (8.3)
Pancreas	99.6	0.3	0.1	0	0	0	7.8 (40)
Red Marrow	86	11	3.0	0	0	0	6.6 (8.3)

† Wall of lower large intestine

- in thyroid and spleen or 240 mSv - in bladder or 170 mSv - in lower large intestine wall and lungs or 160 mSv - in pancreas or 130 mSv - in red marrow.

CONCLUSIONS

It stands to reason that correct applying of effective dose is bounded by share of permissible equivalent doses (*PED*) in some organs:

1/50th of PED in bone surfaces;

1/25th of PED in kidneys;

1/20th of PED in thyroid or spleen;

1/10th of PED in liver or bladder wall;

1/8th of PED in lower large intestine wall, lungs or pancreas.

Therefore, the annual limit for effective dose of 20 mSv is in good agreement with the permissible equivalent dose for any internal organ of 100 mSv established by ICRP Recommendations 1990 (8).

STOCHASTIC APPROACH TO THE ESTIMATION OF RADIONUCLIDE BODY BURDENS

B.S. Prister; L.I. Shpinar; I.I. Yaskovets; V.A. Girij
Institute of Radioecology, St.Tolstoy 14, 252033, Kiev, Ukraine

It is common for estimation of radiation body burdens to use a compartment model. In these models are proposed the following simplified assumptions: 1) it is may introduced a good determined metabolism coefficients α_{ik} for each radionuclide, and 2) the law of radionuclide entering γ in organism are known in detail. Then the problem reduced to the analysis of system n independent coupling differential equations in the case of model with n compartments:

$$\frac{dq_i}{dt} = \gamma_i + \sum_{k=1}^{n} \alpha_{ik} q_k, \qquad (1)$$

where q_i is radiation loading in i-th compartment , α_{ik} are metabolism coefficients between i and k compartments and i and k are a numbers of compartments (i,k = 1,...,n). The equation (1) decided under initial conditions $q_i(t = 0) = q_i^0$. Thus the such approach to this problem is deterministic.

In reality, the situation is rather complicate. As shown the measurements, the radioactivity contamination of soil on the territory due to the accident on Chernobyl plant is inhomogeneous. This inhomogeneity is due to both the circumstances of accident and just statistical regularity of nuclide's precipitation on soil surface. Therefore, the foods (of the same kind) that are work out on this territory will to have different degree of pollution. The same result is due to the reason that transfer coefficients of radionuclides from soil to plants are not well determined parameters. In this situation the entering of activity $\gamma(t)$ in living organism is not deterministic process and rather stochastic one and in the many cases it may be approximated by impulse Poisson process:

$$\gamma(t) = \sum_j \xi_j g(t - t_j), \qquad (2)$$

where a random quantity of the impulse amplitudes ξ_j are statistic independent and characterised by a certain probability density function $w(\xi)$, and the random time moments t_j distributed on consider time interval (0,T), so that their number N is distributed according to Poison law with the parameter $\langle N \rangle = \nu T$. The function $g(\tau)$ ($g(\tau) = 0$ if $\tau < 0$) describes the form of impulse and is not random one.

Another factor that determines the stochastic of activity entering in a critical organ is temporal fluctuations in parameters α_{ik} that determine the process of metabolism. The such fluctuations may be due to random variations of organism state. In this case the dynamic of nuclides distribution on organism compartments is essentially determines by both relations between the characteristically times $t_{ik} = \alpha_{ik}^{-1}$ of nuclides transfer between compartments and times t_f, that characterise the temporary length of this fluctuations and the value of such fluctuations $\delta\alpha_{ik}$ of the metabolism parameters.

The above mentioned is shown that it allowed to speak only about the probability W(C(t)) that the amount of radionuclides entered in organism (organ) at moment t is equal to C(t). The quantity W(C(t)) is very useful one since it permits to find the probabilities of radionuclide body burdens in the given interval (C_1,C_2) and probabilities of $W(C_1 < C < C_2) = \int_{C_1}^{C_2} W(C)dC$ radioactivity loading on an inhabitant above, for example, the middle loading for reference man.

Then it may to obtain in the pair correlation approximation:

$$\frac{\partial P_t(x)}{\partial t} + \sum_k \frac{\partial}{\partial x_k}\{\sum_i \alpha_{ki} x_i P_t(x)\} + \sum_i \langle \gamma_i \rangle \frac{\partial}{\partial x_i} P_t(x) = \sum_i \sum_k \frac{\partial^2}{\partial x_i \partial x_k}\{\langle \delta\gamma_i(t)\delta\gamma_k(t)\rangle P_t(x) \quad (3)$$

This equation describes a distribution of burdens on all n compartments. The initial conditions for equation (10) are $_{t=0}(x) = \langle \prod_{i=1}^{n} \delta(x_i - q_i^0) \rangle$, where the sign <...>denotes the average on the ensemble of the all possible realisations of the dependencies $\gamma(t)$.

The (3) is equation of Einstein-Fokker-Plank type that describe the temporary evolution of burden on compartments in diffusion approximation. Since the equation (3) has coefficients that linear dependent on coordinates x_i it is may to claim that the system of random quantities x_i are obey the normal law of distribution and consequently for the unknown function P may to write down:

$$P_t(x_1,\ldots,x_n) = \frac{1}{\sqrt{(2\pi)^n \det(\lambda_{jk})}} exp\{-\frac{1}{2}\sum_{j=1}^{n}\sum_{k=1}^{n}\Lambda_{jk}(x_j - \xi_j)(x_k - \xi_k) \quad (4)$$

where the elements of correlation matrices $\lambda_{jk} = \lambda_{kj}$ and $\left(\Lambda_{jk}\right) = (\lambda_{jk})^{-1}$. The averages $\xi_i = \langle x_i \rangle$ and correlation coefficients λ_{jk} depend on variable t only. For determination of ξ_i and λ_{jk} we have the following equations ($\gamma_i = \langle \gamma_i \rangle(1 + \delta\gamma_i)$, $<\delta\gamma_i>=0$):

$$\frac{d\xi_l}{dt} - \sum_k \alpha_{lk}\xi_k = \langle \gamma_l \rangle ; \qquad \frac{d\lambda_{lm}}{dt} - 2\sum_k (\alpha_{lk}\lambda_{km} + \alpha_{mk}\lambda_{lk}) = 2\langle \delta\gamma_l \delta\gamma_m \rangle,$$

Let us to consider a simple example of compartment model, namely two- compartment model that used for describing of ^{137}Cs, ^{90}Sr and ^{131}I metabolism[1]. In this case $\alpha_{12} = k_1$, $\alpha_{21} = k_2, \alpha_{11} = -(k_2 + \lambda_p)$, $\alpha_{22} = -(k_1 + k_3 + \lambda_p)$ and $\gamma_1 = 0$, $\gamma_2 = \gamma$. Here k_1 and k_2 are the coefficients of exchange by matter between compartments 1 and k_3 is the coefficient of coming out. λ_p is constant of radioactive decay. For the long-life nuclides ($\lambda_p^{-1} \geq t \geq k_i^{-1}$) we have: $\langle q_1 \rangle \approx {}^{\langle \gamma \rangle k_1}/_{k_2 k_3}$. For the distribution function $P(q_i)$ of burden in compartment 1 we obtained:

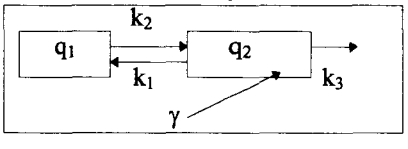

Fig.1. Two-compartment model of metabolism

$$P_t(q_1) = \left[16p^3 L_{22}\det(l_{ik})\right]^{-1/2} \exp\left[-\frac{1}{2}\frac{\det(L_{ik})}{L_{22}}(q_1 - \langle q_1 \rangle)^2\left[1 + \mathrm{erf}\left\{\sqrt{L_{22}}\left[\langle q_2 \rangle - \frac{L_{12}}{L_{22}}(q_1 - \langle q_1 \rangle)\right]\right\}\right]\right],$$

where $rf(\eta) = \frac{2}{\sqrt{\pi}}\int_0^{\eta} e^{-t^2} dt$. In order to obtain the distribution function $P_t(q_2)$ it is sufficient to change the index 1 on 2.

Given real radioactive contamination of foods, with this method it is possible to calculate the distribution of body burdens among inhabitants. For example, knowing contamination of milk in Olevsk (Ukraine), we are calculated the distribution body burdens among inhabitats in this village. This distribution is very close to experimental data(see [2]).

In the case of temporal fluctuations in parameters of metabolism the quantity k_i it is convenient to present in the following manner:

$k_i = <k_i>(1 + \delta k_i)$, $<\delta k_i> = 0$,

here the sign <...> denote the average on the ensemble of the all possible realisations of the random processes γ and k_i.

The role of fluctuations in parameters k_i at the small time in the process of accumulation of radionuclides is negligable. The contribution of fluctuations k_i is essential at the time $t \geq \langle k \rangle + \min\{\alpha_{ik}\}$, that is at the times which are comparable with the times of the establishment of stationary state in considered dynamic system. We are found that the relative body burden in compartment of deposition, that is conditioned only by fluctuations of parameters k_i, is:

$$\Delta\langle q_1 \rangle = \sum_k \langle k_k \rangle \left[\frac{\sum_i \langle k_i \rangle \varepsilon_{ik} - \langle k \rangle \varepsilon_{1k}}{\langle k \rangle + \tau_{ik}} \right] \left[\langle k \rangle - \sum_i \sum_k \frac{\langle k_i \rangle \langle k_k \rangle \varepsilon_{ik}}{\langle k \rangle + \tau_{ik}} \right]^{-1} \qquad (i,k = 1,2)$$

This expression is obtained in the case of long-life radionuclides $\lambda_p << \langle k_1 \rangle + \langle k_2 \rangle + min\{\alpha_{ik}\}$. In this expression $\varepsilon_{ik}=<\delta k_i(t)\delta k_k(t)>$, and τ_{ik}^{-1} is correlation radius in cross-correlation function $<\delta k_i(t)\delta k_k(t')>$. As will readily observed, the fluctuations $\delta k_i(t)$ with small τ_{ii} has a dominant role in $\Delta\langle q_1 \rangle$. Fig. 3 gives a presentation about $\Delta\langle q_1 \rangle$ (axis z) as function of fluctuations δk_1 (axis x) and δk_3 (axis y) in the case of radionuclide I^{131} (k_1=0.04, k_3=0.09, k_2=0). Thi example is illustrated that temporal fluctuations in parametrs of metabolism effect the radiation body burdens in depot of

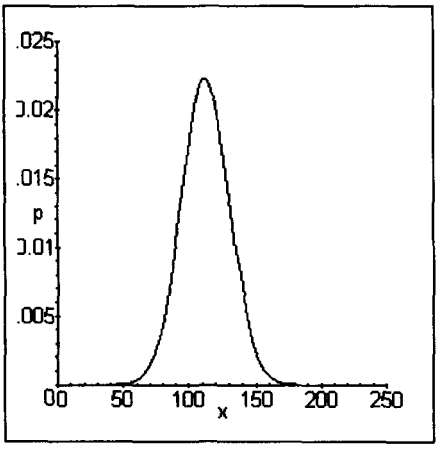

Fig.2.Distribution of body burdens among inhabitants in Olevsk.

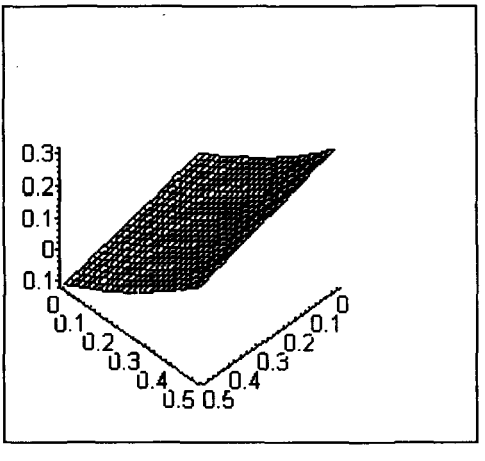

Fig.3. $\Delta\langle q_1 \rangle$ as function of fluctuations δk_1 and δk_3

radionuclides deposition. The change in body burden may be essential in the case of other nuclides (for example: ^{90}Sr, ^{45}Ca, etc.).

OBSERVATION OF SOME ANOMALIES IN THE ICRP METABOLIC MODEL OF URANIUM

H.S. Dang and V.R. Pullat
Health Physics Division, Bhabha Atomic Research Centre,
Bombay 400085, India.

A simple and sensitive analytical method was developed for determining the concentrations of uranium (^{238}U) in biological and environmental samples. The minimum detection limit (M.D.L) of 0.08ng uranium (0.1 Bq of ^{238}U) in a sample was obtained with this method. Data on daily intake (through diet, drinking water and air), the excretion (through urine) and organ burdens of uranium were obtained for human subjects living in Bombay (India), and were employed to obtain important human metabolic parameters of U such as, gastrointestinal absorption factor(f_1), excretion ratio and biological half-lives of uranium retained in various human organs. The study showed that the f_1 factor for uranium available to humans at dietary level (0.5-5ug.d^{-1}) is 0.016, which is much lower than 0.2 suggested in ICRP 30. The biological half-lives, of uranium stored in kidney and muscles were estimated to be much longer than those proposed by ICRP.

INTRODUCTION

The large variations reported in the uranium concentration of similar human tissues and body fluids for subjects with comparable intakes of uranium, underline the need for the developement of sufficiently sensitive and accurate analytical method for uranium determination (Wrenn et al.1985, Dang 1993). The consistently lower concentrations of uranium in human tissues and body fluids reported by different workers in recent years (Eisenne et al., 1987, Igarashi et al., 1987, Wrenn etal., 1985, Dang et al., 1992, 1993, 1995) in comparison to the values reported in ICRP 30 (1979) also indicated that the ICRP metabolic model for uranium, may need revision.A program was initiated at Bhabha Atomic Research Centre (India) with the main objectives: 1) to develop a sensitive and reliable analytical method (with extremely low reagent blank) for the determination of uranium in biological and environmental samples, 2) employ the method to obtain the daily intake, excretion and organ burdens data on human subjects, 3) to use these data for evolving various important human metabolic parameters of uranium, 4) to compare the metabolic parameters thus obtained with those proposed by ICRP..

MATERIALS AND METHOD

The human tissue (obtained at autopsy), diet and body fluids (urine and blood serum) samples were obtained from population living in natural background area of urban India (Bombay). The samples of air and drinking water were also collected, for uranium analysis. While collecting samples, it was ensured that various samples were obtained from subjects with similar social background, food habits and that all the subjects were living in Bombay City for long duration of time.

The tissue, diet and blood serum samples were homogenised, freeze-dried and powdered before analysis. Urine and drinking water samples were first digested in nitric acid and, then the U present in the samples was co-precipitated with calcium phosphate. The procedure is described in detail by Dang et al (1992). The air samples obtained from various parts of the city were directly analysed along with the filter paper used for air sample collection.

The freeze dried samples and calcium phosphate precipitate were sealed and then irradiated for 24-36h in a nuclear reactor in neutron flux of = 10^{13} n cm^{-2} sec^{-1}. The neutron irradiation converted the uranium present in the samples to neptunium (^{238}U (n,)^{238}U-----^{238}Np). The uranium standard (200 ng of uranium nitrate solution dried on ashless filter paper) was also sealed and taken up for irradiation along with the samples. The irradiated samples containing ^{238}Np were digested in acid and then the ^{238}Np was chemically separated by two step chemical separation, using first DOWEX-1 (an anion exchange resin)and then its co-precipitation with barium sulphate precipitate. ^{237}Np was also used as tracer for the chemical yield determination. The gamma activity (227.5 keV and 278 keV gamma rays) of ^{238}Np was counted using 54 CC Hyperpure Germanium detector coupled to 4096 channel analyser. The uranium standard was also processed in the same way and counted, to compare the activities of sample and standard for the quantification of U. The details of analytical procedure are given elsewhere (Dang et al.,1992 Dang et al., 1993). The reliability of the analytical method was tested using the Standard Reference Materials.

RESULTS AND DISCUSSION

The total daily intake of uranium by adult Indian subjects are shown in Table 1. The daily urinary excretion levels of uranium are also included in the same Table.

Gastro-intestinal absorption factor(f_1)

The uranium entering the blood stream (transfer compartment) after absorption through the gastrointestinal tract, gets deposited in various systemic body organs such as, kidney, skeleton, muscles. Because of the relatively short biological half-lives of U deposited in various organs, as compared to the average age of the subjects (45Y), an equilibrium between the uranium entering and leaving the organs could be assumed. The U leaving the organs is excreted through the kidney into urine. Contribution of air was <2% of total intake. The f_1 factor was estimated to be 0.016 from the daily urinary excretion and intake of uranium.

Excretion Ratio

The excretion ratio is the fraction of uranium excreted daily in urine from the uranium present in the transfer compartment which is assumed to be the blood serum. Table 2 gives the uranium burdens for some of the body organs and total uranium in blood serum. The burdens were calculated from the concentrations of uranium determined in tissues obtained from these organs and average weight of the organs of an adult Indian. Employing the daily urinary excretion of 12.2 nanogram and the 30 ng of U in total serum pool, the excretion ratio was worked out to be 41%. Th excretion ratio is quite close to the clearance fraction of 54% proposed by ICRP. The excretion ratio studied in the present work could provide a guideline for an upper limit which may be used for screening the subjects for any impending kidney malfunction.

Biological half-lives of uranium retained in some organs

The organ burdens calculated on the basis of daily intake of uranium, the gut absorption factor obtained in the present study and the ICRP distribution factors (f_2) for these organs are also shown in Table 2 along with the measured values.

Table 1. The daily intake and urinary excretion (ug d^{-1}) of uranium for an adult Indian population group.

Source of intake	No. of samples analysed	Daily intake Range	Mean ± SD
Duplicate Diet	18	0.24 - 1.3	0.64 ± 0.4
Drinking Water	10	0.05 - 0.39	0.14 ± 0.1
Air	9	0.002 - 0.03	0.01 ± 0.1
Total Intake			0.79 ± 0.2
Daily Urinary Excretion (ng.d^{-1})	28	4.0 - 52.0	12.3 x 2.2

Daily Intake of water 2.6L, and Air 20M^3 Daily Urine vol. 1.3L
Daily Urinary excretion is based on Geometric mean (GM) conc. of U.

The calculated and measured values for skeleton are comparable, but for kidney and muscle, they are 4 and 70 times lower, indicating that the true biological half-lives for uranium retained in kidney and muscle may be much longer. As the concentration of U in muscle is extremely low,the longer biological half-life may not have significant effect on human health the longer biological half-life of uranium deposited in kidney (upto four times longer than that proposed in ICRP metabolic model) however, may warrant the reduction in the annual limit if soluble class (D&W) of uranium..

Table 2. Organ burdens of kidney, skeleton and muscles and blood serum of Indian subjects

Organ	Organ Weight (g)	Measured Uranium Burden (ug) Range	Geometric Mean (GM)	calculated
Kidney	230	0.02 - 0.58	0.13	0.03
Skeleton	7000	0.70 - 11.4	2.18	2.18
Muscle	21000	0.06 - 1.54	1.20	0.03
Blood Serum	2300	0.02 - 0.06	0.03	-

CONCLUSIONS

The f_1 factor 0.016 for uranium incoporated in diet, obtained in present sudy, is much lower than 0.2, as reported in ICRP 30. This study also showed that the biological half-life of uranium for kidney may be upto four times longer than that is proposed in ICRP model. The excretion ratio obtained in the present study may provide a useful guideline for screening the occupational workers handling uranium for any impending kidney damage.

ABSTRACT

A new uranium enrichment facility using laser isotopic separation generates aerosols consisting of U_{metal} + UO_2 with traces of U_3O_8. Results of lung absorption to blood showed that the U_{metal} + UO_2 transportability was appreciably greater than for other industrial forms of UO_2. Taking into account the new ICRP human respiratory tract model, the data were used as a basis for assessing the dose coefficient, for the dust sampled at the workplace.

INTRODUCTION

A new method for uranium enrichment, developed in France, is based on laser isotopic separation (1-2). In this process uranium metal is vaporised to be selectively photoionised by laser beams. During the removal of condensed uranium from graphite collecting plates, workers may be exposed to different types of uranium aerosols. The aerosols formed have been previously identified as consisting of a mixture of U_{metal} + UO_2 with a highly variable ultrafine component (1-20 % by activity) (1-2).

Only a paucity of data are available on the physico-chemical characteristics and absorption to blood of aerosols formed from uranium metal (1-6).The aim of the biokinetic study with rats described here was to provide specific experimental data for assessing dose coefficients ($Sv.Bq^{-1}$), and due consideration has been given to the new respiratory tract model of ICRP 66 (7) and to the most recent recommendation of ICRP 60 on annual dose limit of 20 mSv for workers (8).

MATERIALS AND METODS

Physico-chemical characteristics of dust : The dust used for the biokinetic study was produced by the SILVA process and collected at Pierrelatte. Physico-chemical analyses carried out by X-Ray diffraction show that trace amount of U_3O_8 were present. Electron Energy Loss Spectrometry (EELS) show that the particles consisted of a natural uranium metal core oxidised at the surface to uranium dioxide.The activity median aerodynamic diameter (AMAD) of the dust measured at the workplace varied between 5 and 10 µm (σ_g=2.5). However the dust contains clusters of particles of about 0.1 µm which represent between 1 and 20 % of the total radioactivity. The density of the dust was 7.2 g. cm^{-3} and the specific surface area 1 $m^2.g^{-1}$.

Sample preparation : To obtain particles of respirable size for the animal study, the dust sample was sedimented in ethanol. The AMAD of the particles was controlled using high resolution particle size analyser (API Aerosizer, Malvern Instrument Ltd., Malvern, Worcs, UK) was 1.61 µm (σ_g=1.29).

Administration of dust : The rats used were females of the HMT strain (NRPB, Chilton). A saline suspension was administered to a group of 35 rats by intratracheal instillation, using a procedure described previously (9) and the initial lung deposit was 86 µg of natural uranium

Tissue analysis : To assess the lung retention and transportability characteristics of uranium, groups of 5 rats were sacrificed at 1, 3, 7, 14, 28, 84 and 168 days after exposure. The lungs, liver, kidneys, carcass (excluding the gastrointestinal tract) and urine were ashed at 500°C and the uranium content determined by the delayed neutron counting technique. These experiments on animal were performed by scientists certified by the French Ministry of Agriculture for carrying out these procedures.

Interpretation of data : Publication 66 of ICRP recommends to determine the specific dose per unit of intake ($Sv.Bq^{-1}$), as a function of the following three main experimental parameters : particle size distribution of dust measured at the workplace, physico-chemical properties and calculation of dissolution fractions and rates obtained from animal experiment. SILVA process is still being a pilot process, so it reasonably seems now time to compare calculated doses with the recommended ICRP 60 annual dose limit , for occupational exposure, and to assess a specific ALI calculation resulting from this study.

The absorption rates into blood obtained from the experimental animal data must be scaled in order to obtain the human data on particle clearance and excretion, using a graphically-interactive parameter-fitting personal computer program (GIGAFIT) (10), and then available in LUDEP (11) application. The dose coefficients of the dust were obtained using the computer program LUDEP which is designed to implement the new respiratory tract model of

ICRP 66. In this program, besides default absorption parameters for type F (fast), M (moderate), and S (slow) materials, specific experimental data can be implemented.

RESULTS

The tissue distribution and excretion data obtained from the animal study, expressed as a percentage of the initial alveolar deposit, are given in Table 1.

Table 1. Tissue distribution and retention of uranium after intratracheal instillation of $U_{metal} + UO_2$.

			% Initial	Lung	Deposit[a]		
Time days	Lungs	Kidneys	Carcass	Total Body[b]	Urine	To blood[c]	Faeces + GIT[d]
1	60.8 ± 2.7	2.8 ± 0.4	5.9 ± 0.4	69.5 ± 2.8	15.2 ± 0.9	23.8 ± 1.1	15.3 ± 2.9
3	47.1 ± 4.6	2.8 ± 0.4	6.1± 1.1	56.0 ± 4.7	20.8 ± 0.7	29.7 ± 1.4	23.2 ± 4.7
7	43.0 ± 2.9	1.0 ± 0.11	4.9 ± 0.4	48.9 ± 2.9	24.8 ± 1.2	30.7 ± 1.3	26.3 ± 3.1
14	41.5 ± 3.8	0.46 ± 0.05	4.9 ± 0.2	46.9 ± 3.8	27.8 ± 1.3	33.2 ± 1.3	25.3 ± 4.0
28	31.3 ± 3.1	0.44 ± 0.06	5.3 ± 0.4	37.0 ± 3.1	30.8 ± 1.3	36.5 ± 1.4	32.2 ± 3.4
84	12.6 ± 1.9	< 0.28[e]	5.6 ± 0.6	18.5 ± 2.0	36.8 ± 1.5	42.7 ± 1.6	44.7 ± 2.5
168	7.5 ± 1.9	< 0.28[e]	4.5 ± 0.3	12.3 ± 1.9	38.2 ± 1.5	43.0 ± 1.5	49.5 ± 2.4

a: Mean ± se, 5 animals per group, ILD = 600 ng ^{235}U (86 µg natural uranium)
b: Sum of uranium in tissues, excluding liver (undetectable)
c: Kidneys + carcass + urine; absorption from gastrointestinal tract (GIT) f_1 was ignored
d: ILD -(total body + urine)
e: Minimum detectable activity; all livers were in this category

They show that the uranium is highly transportable; 24 % and 43 % of the initial alveolar deposit is absorbed into the blood by 1d and 168d respectivly after exposure. Using the computer program GIGAFIT, 27 % of the amount deposited in the alveolar region was rapidly cleared with a rate of 1.01 d^{-1} and the remainder with a rate of 0.0093 d^{-1} . The fraction rapidly absorbed to blood was calculated to be 33.7% with a rate (s_r) of 1.42 d^{-1} and the remainder was absorbed with a slow rate (s_s) of 0.0048 d^{-1}. After absorption, uranium is excreted preferably in urine, eg. 64%, 80% and 90 % after 1 d, 7 d and 168 d respectively. The main site of retention in systemic tissues was the skeleton (carcass); the amounts present in the liver were trivial.

Calculations of dose coefficient (Table 2), using the computer program LUDEP, were based on a mean breathing rate of 1.2 $m^3 .h^{-1}$, a measured particle density of 7.2 $g.cm^{-3}$, and were also made for particles with an AMAD of 5 µm and 0.1 µm. The absorption rates were calculated from the experimental data using the GIGAFIT computer program . For comparison, the dose coefficients were also calculated for aerosols of 5 µm AMAD using the default absorption parameters for type M (10% at 10 min and 90 % at 140 d), and for type S (0.1 % at 10 min and 99.9 % at 7000 d).

Table 2. Dose coefficients for $U_{metal} + UO_2$ ($Sv.Bq^{-1}$) : comparison of the doses calculated with experimental values and with default values.

Compound	Final dose coefficient ($Sv.Bq^{-1}$)
Dust $U_{metal} + UO_2$ [(a)(b)]	$3.34\ 10^{-6}$
Type M	$4.43\ 10^{-6}$
Type S	$12.75\ 10^{-6}$

[(a)] Sum of the activity contribution of each isotope : ^{234}U (0.63), ^{235}U(0.07), ^{238}U (0.3)
[(b)] Aerosol generated by the SILVA process; average AMAD composition is 0.1 µm (20%) - 5 µm (80%)

DISCUSSION

This study was designed to provide an experimental basis for assessing the consequences of human exposure to a $U_{metal} + UO_2$ produced by SILVA process. Emphasis is placed on the comparative behaviour of results obtained on the same dust in a previous study (1-2) and with basic compounds such as uranium dioxide and octoxide.

The biokinetic data reported here are similar to that obtained after inhalation of $U_{metal} + UO_2$ by rats (1-2). The high urinary excretion of uranium, eg. 34 % by 21 d has been confirmed (Table 1). The absorption characteristics of the $U_{metal}+UO_2$ dust contrast sharply with those obtained for two industrial UO_2 preparations in which 3-6 % was transferred to the blood by 168 d (12). This different behaviour of uranium may be due to the rapid dissolution of the ultrafine component of the dust. However, the relatively large amounts of uranium which were absorbed after the early clearance phase, eg. 20 % of the initial lung deposit between 1 d and 168 d, suggest that the UO_2 present in the dust is more transportable than for particles which consist solely of this chemical form. It is also noteworthy that the absorption of uranium was appreciably greater than for U_3O_8 when about 15 % was transferred to the blood by 168 d after exposure in the same species of rat (6,13) After the absorption of uranium by the blood the tissue retention and excretion characteristics of $U_{metal} + UO_2$ (Table1) are similar to those obtained after the administration of very transportable compounds such as U(VI) bicarbonate or nitrate (9).

The results calculated with the experimental s_s and s_r values are very close to those obtained with the default values for a type M component. In this case, the value of the s_s rate has the most drastic influence on the specific dose coefficient. Due to the high contribution of the 0.1 µm particles to the specific dose coefficient, the amount of fine particle in the aerosol is the most important parameter to determine.

The dose coefficient for the aerosol containing 20 % of particles with an AMAD of 0.1 µm and 80 % of particles with an AMAD of 5 µm is calculated to be 3.34 10^{-6} Sv.Bq $^{-1}$. This corresponds to a specific ALI of 5980 Bq or 150 mg of uranium with a given isotopic activity composition (Table 2) , a specific activity of 39770 $Bq.g^{-1}$, and derived from the primary annual limit of 20 mSv. However in the view of the rapid absorption of uranium into the blood and hence potential damage to the kidneys, the daily intake should be limited to 2.5 mg (14). It should be emphasised that the above values may need to be revised in the light of the new ICRP 69 (15) systemic model for uranium.

CONCLUSION

The data presented in this paper show that the biokinetics of a $U_{metal} + UO_2$ dust produced by the SILVA process can differ appreciably from other uranium oxides. The results calculated with the experimental s_s and s_r values are very close to those obtained with the default values for a type M component. This uranium compound shows a highly transportable behaviour, with 24 % and 43 % of the initial alveolar deposit absorbed in the blood by 1 d and 168 d respectivly. Consequently, it is recommended that intakes of this particular dust by workers should be limited by the chemical toxicity of the uranium and assessments of such intakes based on the urine analysis. It should be emphasised that the dust used in this study has a high ultrafine component, about 20 % (due to the pyrophoricity of uranium), and further studies on the biokinetics of dusts with different compositions are needed before more comprehensive guidance on personal monitoring can be given.

ABSTRACT

ICRP Publication 61 was a temporary replacement for ICRP Publication 30. It gave ALIs but not the underlying dose conversion factors. ICRP Publication 68 has now been issued to replace Publication 61; it contains the dose conversion factors but not the ALIs, so comparison is impossible without carrying out calculations. This paper presents comparisons between the two publications and calculates the ICRP Publication 68 ALIs for some of the more common radionuclides.

INTRODUCTION

An operational health physicist reviewing a publication of the ICRP feels rather as a Catholic parish priest must feel reviewing a Papal encyclical. Not all the details of the publication are fully understood, some may be disagreed with, but in the end it is a document that will have to be accepted and used.

After the major revision of the ICRP's recommendations in Publication 60 (1) much earlier data, including the many volumes of Publication 30 (2) were no longer valid. The ICRP provided a temporary replacement for Publication 30 in the form of Publication 61 (3). Publication 61 provided ALI values for over 700 radionuclides. These ALIs were, in the normal ICRP manner, rounded to one significant figure. Because of this rounding it is not strictly possible to calculate ALIs for mixtures of radionuclides because the rounding of the input data may result in a very large error in the result of the calculation. In addition, dose calculations in accident conditions need to be made to better than one significant figure. For those needing to carry out such calculations an ICRP Publication with dose conversion factors has been eagerly awaited.

ICRP has now issued Publication 68 (4) to replace Publication 61. It provides dose conversion factors for radionuclides, using the new ICRP lung model (5) with transportability classes of F, M and S. (F = fast, M = medium and S = slow). The inhalation conversion factors are provided for aerosols with particles of an activity median aerodynamic diameter (AMAD) of 1 μm and of 5 μm, which are the default values for public and occupational exposures respectively.

IMPACT OF THE NEW LUNG MODEL

In the past an aerosol with an AMAD of 1 μm was taken as the default and a relatively simple expression was available to calculate an ALI corrected for other values of AMAD. Some organisations were able to demonstrate that typical aerosols in their industry had AMADs of 10 μm or more and justified the use of a site specific ALI. This made a considerable reduction in the calculated inhalation doses. ICRP 68 presents dose conversion factors for 1 and 5 μm AMAD aerosols but there is no longer a simple means to calculate dose conversion factors or ALIs for aerosols of other particle sizes . Contrary to the expectation of some papers presented before the publication of the new lung model, the 5 μm AMAD does not always result in the highest dose conversion factor: sometimes the 1 μ AMAD value is higher.

IMPACT ON "RADIOTOXICITY"

With the publication of ICRP 61 it became clear that previous classifications of radionuclides into groups, usually four, on the basis of their radiotoxicity would need revising. In Australia a new classification was developed (6). The publication of ICRP 68 has rendered this "new" classification out of date. The authors have used the ICRP 68 data to revise the new classification with the results presented in Table 1. The classification is based on the highest ICRP 68 dose conversion factor for each radionuclide irrespective of the AMAD or the transportability class.

Table 1. Changes in "Radiotoxicity" Group if ICRP 68 data are used in place of ICRP 61 data.

	ICRP 61	ICRP 68
Total number of entries.	757	760
Radionuclides in Group 1.	56	58
Radionuclides in Group 2.	212	243
Radionuclides in Group 3.	388	399
Radionuclides in Group 4.	101	52
No. of radionuclides that have changed group.	NA	118
Number of radionuclides that have moved to a lower group. i.e. are more radiotoxic.	NA	101

IMPACT ON THE NATURAL RADIONUCLIDE DECAY SERIES

For the mining and related industries that deal with natural uranium and natural thorium it is necessary to calculate ALIs and DACs for the mixture of radionuclides present in the natural decay series. In most mining situations the decay series is in approximate equilibrium. The authors have calculated ALI_{inh} for the natural series in equilibrium and for the separated metals. The results are presented in Table 2.

Table 2. ALI_{inh} for the Uranium-238 and Thorium-232 series.

	ICRP 30	ICRP 61	ICRP 68
Uranium 238 series ALI			
Uranium series	1200[a]	2000	2100[b]
Uranium metal	600[a]	600	2500
Thorium 232 series ALI			
Thorium series	400	600	700[c]
Thorium metal	70	120	500

a. From reference 7. b. 8000 for type S, 5 μm. c. 4600 for type S, 5 μm.

CHANGES IN ALI FOR SELECTED IMPORTANT RADIONUCLIDES

In ICRP 61 there were seven radionuclides with ALI_{inh} of 100 Bq or less; there are only two in ICRP 68. Table 3 lists those radionuclides that had ALI_{inh} less than 100 Bq in ICRP 61 and gives the ICRP 2 (8), ICRP 30 (2) and ICRP 61 values for comparison. The ICRP2 (8) values are not strictly comparable as the models and factors have changed considerably since 1959. They have been calculated from the ICRP 2 40 hour week DAC and corrected for the reduction in annual dose limit and are included as an indication of the change in recommended limits since 1959. For these seven radionuclides all the ICRP 68 ALI values are greater than the ICRP 61 values, the increase ranging from 150 % to 600 %. Changes in the most restrictive ALI_{inh} for some other radionuclides of interest are given in Table 4.

Table 3. Most Restrictive ALI_{inh} for the Most "Radiotoxic" Radionuclides

	Most restrictive ALI_{inh}			
Radionuclide	ICRP 2	ICRP 30	ICRP 61	ICRP 68
Ac-227	71	20	20	32
Th-229	not listed	30	60	200
Th-232	71	40	90	480
Pa-231	35	60	100	150
U-232	3500	300	100	570
Cm-248	not listed	50	80	140
Cm-250	not listed	not listed	10	25

Table 4. Most Restrictive ALI_{inh} for Selected Radionuclides

	Most restrictive ALI_{inh}			
Radionuclide	ICRP 2	ICRP 30	ICRP 61	ICRP 68
Co-60	1×10^7	1×10^6	4×10^5	6.9×10^5
Sr-90	1×10^4	1×10^5	6×10^4	1.3×10^5
Cs-137	2×10^6	6×10^6	2×10^6	3×10^6
Ra-226	1×10^3	2×10^4	9×10^3	1.3×10^3
Pu-239	3×10^3	200	300	430

CONCLUSIONS

ICRP Publication 68 presents dose conversion factors but leaves the reader to convert these to ALIs and DACs so is less operationally convenient than ICRP30.

Although several conference presentations gave the impression that the new lung model would make an AMAD of 5 μm the most restrictive, this is not the case. For many radionuclides a 1 μm AMAD remains the most restrictive. It is no longer easy to calculate an ALI for a site specific AMAD value.

There has been a relaxation in the ALI_{inh} for the most hazardous radionuclides by a factor of between one and a half and six. There has also been a relaxation in the ALI_{inh} for the natural decay chains. Overall, however, there is a slight reduction in the ALI values.

IN VITRO SOLUBILITY OF CHERNOBYL NUCLEAR FUEL AEROSOL WITH RESPECT TO COLLECTIVE BEHAVIOR OF ITS RADIONUCLIDES

Vladimir A. Kutkov,[1] and Olga I. Komaritskaya[2]

[1]Russian Research Center "Kurchatov Institute", Moscow, Russia,
[2]State Scientific Center "Institute of Biophysics", Moscow, Russia

INTRODUCTION

The Chernobyl accident was the first one, when big groups of peoples were affected by aerosol containing poor investigated chemical speciation of fission products – matrix-bond radionuclides. Due to uranium-oxide matrix of the spent nuclear fuel, the behavior of the nuclear fuel particle (*NFP*) radionuclides both in the environment and in the body acquires a collective character. Bound by the matrix, the radionuclides do not escape from the fuel particles until the matrix is chemically destroyed. If any nuclear fuel radionuclide tracer was found in the sample from environment or from human barrier organ e.g., lungs or skin, all another NFP radionuclides have to be expected to present in the sample too. Their normalized activities have to be closed to those from Kutkov et al. (1) having regard to the radioactive transformation.

Cuddihy et al. (2) give the results of a study on the radionuclide leaching rate from the particles found in late May 1986 on a wooden container which was about $80\,km$ from Chernobyl at the time of the accident. Approximately 90% of activity were slow to leave the particles, with a leaching half-time of about 160 days and leaching constant of about $0.004\,d^{-1}$. This was characteristic of all the fuel particle radionuclides including ^{131}I, ^{134}Cs and ^{137}Cs commonly have the relatively soluble chemical compounds. Such an effect of U substrate on leaching of radionuclides has been reported earlier by Dua et al. (3) and from our viewpoint it is the result of binding the fission products by the matrix of uranium oxides.

MATERIAL AND METHOD

The strength of a radionuclide-matrix bond in the nuclear fuel particles was studied using dialysis of an aerosol sample in Ringer's solution. Since all commonly occurring Cs compounds are soluble, 100% of the ^{137}Cs activity could be expected to pass into solution in a short time. However, Chernobyl on-site samples collected in June 1986 contained about 40% of aerosol Cs in a relatively insoluble form, probably, as part of fuel particles, the remainder being soluble (4). In 1990-1991, the "Shelter" (special entombment of damaged Chernobyl reactor) samples showed that at least 30% of Cs were still in a nontransportable form, as part of nuclear fuel particles and did not pass in 2 days into aqueous phase through a membrane with a pore diameter of about $0.5\,\mu m$.

A special investigation of longtime dialysis kinetics for "Shelter" samples was carried out in 1992. The test procedure resembled the one described by Eidson and Griffith (5). Smears from vertical surfaces with an area of up to $100\,cm^2$ were collected on ash-free aerosol filters in premises of the "Shelter". All the samples spread to contain nuclear fuel

radionuclide tracers (^{144}Ce, $^{154,155}Eu$). The activities of gamma-emitting fission products normalized to that of ^{144}Ce in the smears showed no statistically significant difference from those in the representative NFP at the time of sample measurement.

Disks of $35\,mm$ in diameter made out of filter sections chosen for the heaviest surface contamination were fixed between two membrane filters MFA-MA-12 (Russia) with a pore diameter of about $0.5\,\mu m$, fixed between closely assembled Teflon rings and placed for dialysis into thermostatic vessels containing $150\,ml$ of Ringer's solution at room temperature.

The leaching of radionuclides from samples into aqueous phase (dialyzate) was investigated on 2, 7, 21, 35, 49, 63, 77, 92, 106 by 122 days after onset of dialysis. Every time assembly extracted from a vessel, it was washed up by 10 ml of distilled water and examined by $\gamma-$spectrometry without disassembling. Every spent portion of dialyzate was acidulated by 5 ml concentrated nitric acid and examined with $\gamma-$spectrometry in parallel with sample examined. Then the total $\alpha-$activity in dialyzate was determined. After that procedure the contaminated solution was changed for fresh one and dialysis continued.

Till the ending of experiment the assemblies were disassembled, and the filters with membranes were used for determination of total $\alpha-$activity, remaining in the sample.

RESULTS

The data obtained on the levels of ^{137}Cs and total alpha emitters were used to determine a constant for the sample–solution transfer of the radionuclides. The transportability of over 70% of ^{137}Cs was found to be weak in the sample, with a leaching constant of $0.002 \pm 0.001\,d^{-1}$. The remaining Cs fraction was 20 times as transportable. For the total of alpha emitters, the dialysis constant was $0.005 \pm 0.002\,d^{-1}$. The difference between the leaching constants for ^{137}Cs and total alpha emitters is not statistically significant ($p > 0.05$). This confirms a supposition that these radionuclides have similar chemical speciation, being matrix bound. Using the summarized data on total alpha and Cs leaching, the constant for radionuclide leaching from nuclear fuel particles is estimated at $0.003 \pm 0.002\,d^{-1}$ and closed to $0.004\,d^{-1}$ from Cuddihy et al. (2).

CONCLUSIONS

It is evident that an *in vitro* experiment cannot simulate the processes of interaction between aerosol particles and intrapulmonary medium; the findings, however, evidence in favor of a hypothesis that there is an equally strong bond between the matrix of the nuclear fuel and fission products of different nature. The results are in good agreement with earlier data on the binding of fission products by U matrix from Eidson and Griffith (5) and Dua et al. (3). This led us to develop a special dosimetry model to describe the behavior of the nuclear fuel particle radionuclides in the human respiratory system (6).

It stands to reason that the NFPs are the crystals produced by fragmentation of fuel pellets. Their lattice forms a fuel matrix and strongly holds fission products and transuranium radionuclides. By analogy with uranium oxides assigned by ICRP to inhalation class Y by their transportability in the respiratory system (7), all radionuclides entering the respiratory system as a part of fuel particles should be assigned to the same inhalation class.

On penetrating the body, the matrix–bound radionuclides of the nuclear fuel particles exhibit collective behavior but in the respiratory system, the gastrointestinal tract and skin, until the bonds between them are broken due to chemical destruction of the nuclear fuel matrix that takes place in these barrier organs. Chemical destruction of aerosol particles in these organs is a fundamental process resulting in transfer of radionuclides to body fluids where they become independent.

Therefore, a model for the behavior of matrix-bound radionuclides in the body can be proposed as follows.

1. Due to the matrix, the behavior of fuel particle radionuclides in the body acquires a collective character. Matrix-bound radionuclides penetrate to "body fluids" only after a chemical destruction of the fuel matrix.

2. The matrix-bound radionuclides acquire biokinetic properties of uranium oxides, normally unusual for them, so that they should be assigned to nontransportable compounds of inhalation class *Y*. When fuel particles enter the gastrointestinal tract, the fractional absorption of matrix-bound radionuclides does not exceed that of uranium oxides.

3. Distribution and retention of radionuclides, penetrating into "body fluids" after NFP destruction has individual peculiarities and is determined by biokinetic properties of the related elements only.

RECONSTRUCTION OF THE SIZE OF NUCLEAR FUEL PARTICLE AEROSOL BY THE INVESTIGATION OF A RADIONUCLIDE BEHAVIOR IN BODY OF THE CHERNOBYL ACCIDENT WITNESSES

Vladimir A. Kutkov

Russian Research Center "Kurchatov Institute", Moscow, Russia

INTRODUCTION

As a result of the Chernobyl NPP (*ChNPP*) accident aerosol particles of dispersed nuclear fuel were released to the atmosphere. Inhalation of those aerosol became the source of internal exposure for witnesses of the Chernobyl accident.

To assess correctly internal doses from a mixture of radionuclides present in air in the form of aerosol particles one mast assign each radionuclide to a certain inhalation class by its chemical speciation in aerosol and define the airborne characteristics (the activity median aerodynamic diameter, *AMAD* and the standard geometric deviation, β_g) of that particular aerosol. Moreover, information on any particular radionuclide is useless for other components since, in such a mixture, the radionuclides are generally independent and may belong to different particles.

On the contrary, all nuclear fuel particle (*NFP*) radionuclides belong to the same particle, being matrix-bound (1). The collective behavior of the matrix-bound radionuclides in the environment and in the human barrier organs makes it possible to spread to the aerosol of NFP any estimates of AMAD and β_g obtained for any particular NFP radionuclide. This is principal feature of NFP aerosol as distinguished from a mere mixture of aerosol particles carry different radionuclides.

The information on the aerodynamic size of ChNPP in-site aerosol of nuclear fuel particles for the first postaccident days is absent. The only way to obtain it is to use the indirect methods based on the investigation into behavior of NFP radionuclides in body of persons who inhaled that aerosol in the time of the accident. With this aim two groups of ChNPP staff and firemen that witnessed the accident were investigated in 1987-1992 and one group of Gomel inhabitants was investigated in 1991-1993 (2).

MATERIAL AND RESULTS

Two groups of ChNPP staff and firemen that witnessed the accident were investigated. Analysis of ^{137}Cs kinetic in body (Method I) and analysis of ^{239}Pu distribution in body (Method II) were used for evaluation the AMAD of inhaled aerosol.

Out of the workers involved in operations on 26-27 April 1986 and measured with a semiconductor whole-body counter, the first examined group was chosen. It consisted of 264 nuclear fuel particle carriers examined at least three times from 16 May 1986 to 16 November 1986. The measurements were made by officers of the Radiation Monitoring Department in the town Chernobyl. Out of this group, we chose a few tens of individuals

that even 700-800 days after the accident had the ^{137}Cs content of the body in excess of $100\,nCi$, i.e., the average 1987-1988 value for the ChNPP personnel unemployed in emergency operations in April-May 1986. The results of intravital studies on the ^{137}Cs contamination of members of this group make up data base to be used for validation of NFP size.

In NFP cesium acquire properties of uranium oxides, normally unusual for it (1). Following intake by inhalation with NFP aerosol, biokinetics of ^{137}Cs appears to be affected by the particle size, though commonly occurring Cs compounds belong to ICRP inhalation class D (3), with kinetics in the body being, therefore, independent of aerosol particle size. Relationship between the effective half-time of matrix-bound ^{137}Cs clearance from the body of the Adult Reference Man, $T_{ef}(^{137}Cs)$, and the AMAD of nuclear fuel particles was found using the computer code *"R-MAN"* (4). As the AMAD of an aerosol increases from 1.0 to $50.0\,\mu m$ (with a constant β_g assumed to be 3.0), the value of $T_{ef}(^{137}Cs)$ drops from 600-500 to 130 days. Increased dimensions of aerosol particles change the contribution of different processes of the NFP clearance from the respiratory system to the general process of the matrix-bound ^{137}Cs retention in the body. When an aerosol with an AMAD of about $1\,\mu m$ is inhaled, the bulk of particles is deposited in the pulmonary region and the radionuclides enter body fluids through pulmonary communications where radioactive material of NFP is retained for long time, due to particle destruction. The larger particles, the higher the probability of their deposition in the nasal passage and the trachea and bronchial tree; some portion of the radionuclides penetrates body fluids almost without delay, while the bulk transits through the gastrointestinal tract and is removed from the body. In this case, a long-retained activity fraction in the lung is small and the ^{137}Cs elimination half-time appears to be close to 110 days, i.e. the half-time of ^{137}Cs removal following intake by ingestion (3). The elimination half-time of ^{137}Cs in the first group of workers ranged from 230 to 600 days, in full accordance with model predictions. For further analysis, 15 workers were chosen in this group since their legends were most likely to suggest a single intake of NFP aerosol by inhalation within the first postaccident days. For every person examined, the ^{137}Cs content of the body was normalized. The value at the time of intake was taken to be unity, using extrapolation of later individual measurements to the accident date. The normalized data are adequately described by an exponential curve with a half-time of 330 days. This value is three times as high as that recommended by the ICRP (3) to describe the Cs elimination kinetics for Adult Reference Man. According to our model, a half-time of 330 days corresponds to the ^{137}Cs behavior in the body following a single inhalation of nuclear fuel particles aerosol with an AMAD of $16 \pm 2\,\mu m$.

The distribution of the radioactive material in the body also depends on the chemical composition and the particle size of inhaled aerosols. The ratio, $R(Pu)$, of the plutonium content of the lung to that of the remaining organs is a criterion used to assess the AMAD of the relevant aerosol.

The Chernobyl workers and firemen that died of acute radiation sickness in 1986 form the second control group of examined accident witnesses. The results of postmortem studies on the ^{239}Pu distribution in the organs of members of this group make up another data base to be used for validation of NFP size. According to Popov et al. (5), the value of $R(Pu)$ for the workers that died of acute radiation sickness within 90 days after the accident ranged from 0.07 to 10.0. Using that data, we took a mean $R(Pu)$ value of 1.6 for the dead workers and, with the help of the "R-MAN" code, found expected AMAD of

nuclear fuel particles. The estimates proved to be in good agreement with those obtained for the intravital ^{137}Cs behavior in the witnesses. The mean AMAD of fuel particles estimated by $R(Pu)$ is $12 \pm 2\,\mu m$.

CONCLUSIONS

Method II was used for reconstruction of the AMAD of nuclear fuel particles aerosol inhaled by inhabitants of Gomel district, who were affected by the accident (2). That estimates are in a good agreement with the previous one. The results of the reconstruction of the size of NFP aerosol (mean AMAD $\pm$ Standard Deviation of Mean) are as follows:

AMAD, μm	Case specification
16±2	15 alive accident witnesses of ChNPP staff, examined with semiconductor body counter in 1986-87 (Method I)
12±2	23 accident witnesses of ChNPP staff, dead in 90 postaccident days and examined by autopsy (Method II)
12±3	21 accident witnesses of 125 Gomel district inhabitants, dead in 1990-91 and examined by autopsy (Method II) (2)

The obtained estimates for AMAD of nuclear fuel particles are in a good agreement with results of Rudhard et al. (6) on investigation the size distribution of NFP obtained from soil samples collected in South Germany in May, 1986. Autoradiography of that samples showed that they were contaminated with NFPs with median linear diameter of $4.5\,\mu m$, that corresponds to AMAD of 15 μm (for NFP density of 10 g/cm^3). Those values are closed to the dimension of uranium dioxides grains in the fuel pellets of Chernobyl type reactor.

INTRODUCTION

Numerous studies have been reported on the biological behaviour of different masses of ^{237}Np or ^{239}Np administered under various chemical forms and valency states by intravenous or intramuscular injections and by ingestion. In contrast with Pu, some important Np speciation informations are still lacking as well as an appropriate treatment for Np decorporation (1). To our knowledge, only three main studies have concerned the behaviour of Np after inhalation and were confined to soluble forms such as Np-oxalate of unknown valency state and Np (V) nitrate (2, 3, 4). This paper presents preliminary results obtained in rats on the behaviour of Np after inhalation of $^{237}NpO_2$ for which no experimental data is available. This physico-chemical form might be potentially used in the nuclear industry.

MATERIAL AND METHODS

Female Sprague-Dawley rats were used. Two groups of 30 animals were exposed at 3 months of age to $^{237}NpO_2$ aerosols (actual diameter 0.40 μm, σg 2.02) as previously described (5). Four to five animals per group were killed under pentobarbital anaesthezia 7, 21, 48 and 92 days after exposure. The lungs, the liver, the kidneys and the femurs were taken off for α counting by liquid scintillation. This was performed after heat mineralization, solubilization in nitric acid and specific extraction of Np reduced into Np(IV) within the organic scintillation phasis.

At this time, some animals are still alive for further studies up to 300 days after NpO_2 exposure.

RESULTS

The Np lung burden, measured 7 days after exposure were 110 Bq (n=5, sd=10) and 200 Bq (n=5, sd=15) in the 2 animal groups respectively.

Figure 1 shows the evolution of the Np lung burden as a function of time following exposure. The observed curve fits to a single exponential function of time with a half-life at about 68 days.

Figure 2 shows the relative amount of Np retained in the skeleton, the liver and the kidneys as a function of time following exposure expressed as the fraction of the Np lung burden measured on day 7. Maximal retention at about 1 % was observed in the skeleton which remained nearly constant from day 7 to day 92 after exposure. An about two-fold decrease of Np liver retention was observed between days 7 and 21 but this retention remained nearly at a constant value from day 21 to day 92 which corresponded to about 20 times less than the skeleton retention value. The Np kidney retention seemed to gradually decrease by a factor of 2 from 0.003-0.002 % to 0.002-0.001 % from day 7 and to day 92 respectively.

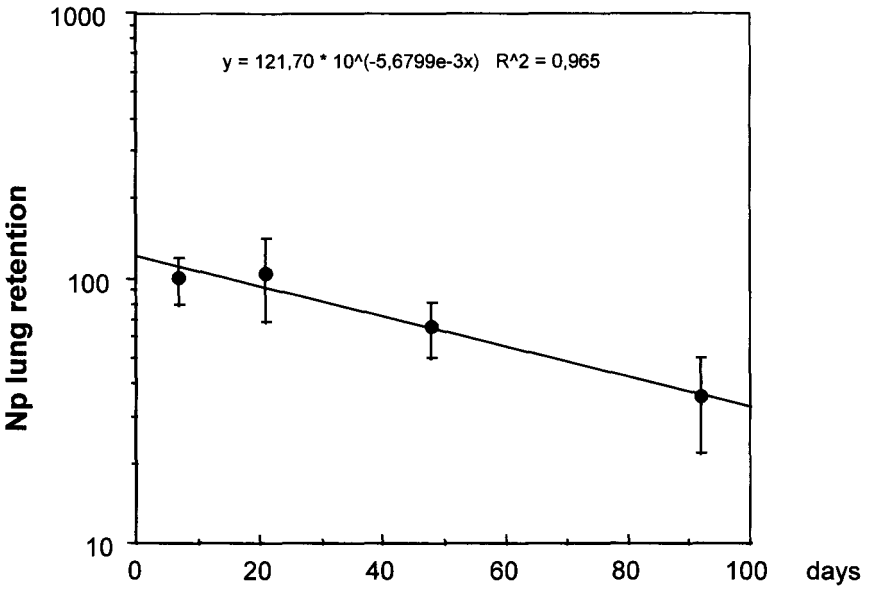

Figure 1: Np lung retention expressed as percent of the retention measured on day 7. Mean values ± sd.

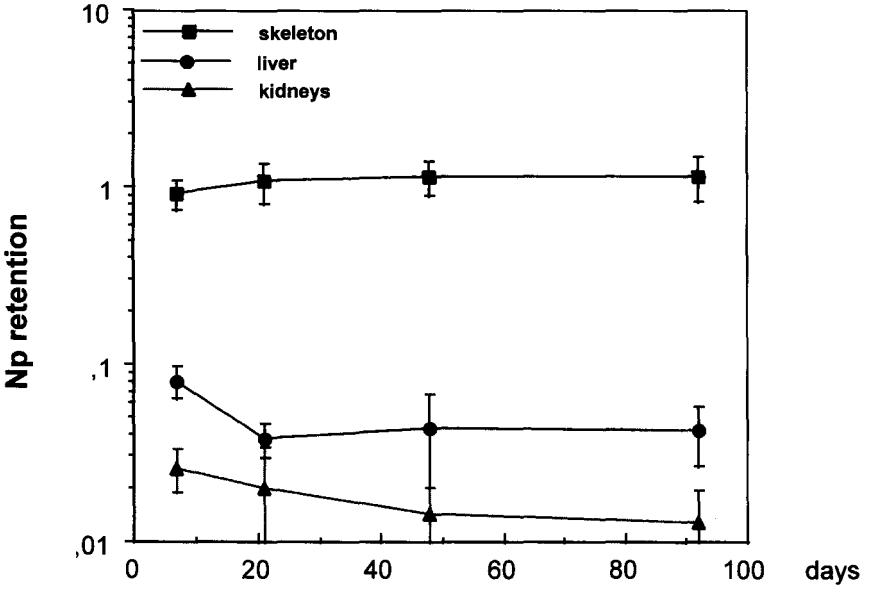

Figure 2: Np retention in different organs expressed as percent of the lung retention measured on day 7. Mean value ± sd.

DISCUSSION

Translocation of Np from inhaled NpO_2 to the other parts of the organism and Np lung clearance appear much slower than those reported for the different Np soluble forms (2, 3, 4). Our results can be directly compared to those obtained in our Laboratory after inhalation of PuO_2 or (UO_2,PuO_2) mixed oxyde containing 20 % Pu which had used the same inhalation device, the same sex, age and strain of rats and a similar α emitter counting method (6).

The half-life of Np retention in the lungs (68 days) was nearly the same as that reported for Pu after exposure to PuO_2 or (UO_2,PuO_2) mixed oxyde (66 days). These Pu exposures were performed at initial lung deposits which are not known to alter lung clearance parameters, especially alveolar macrophage motility involved in the removal of particles by cell migration via the broncho-tracheal tree on the epithelial surface. Thus, our preliminary results suggest that, for the low initial lung deposits studied, between 100 and 200 Bq, $^{237}NpO_2$ is non-toxic for alveolar macrophages and do not alter early lung clearance parameters. Further studies are in progress to characterize these lung clearance parameters as a function of the initial Np lung deposit in order to visualize a potential chemical toxicity of this actinide as compared with Pu.

The fraction of the Np initial lung burden retained in the skeleton was between those reported for Pu after inhalation of PuO_2 and (UO_2,PuO_2) mixed oxyde but close to the Pu value for PuO_2. Moreover, the retention ratio for the skeleton versus the liver appeared very similar at 15 and 20 for Pu and Np respectively. Our results suggest that Np from inhaled NpO_2 might be slightly more translocated to the extrapulmonary compartments than Pu from inhaled PuO_2. Nevertheless, the actinide distributions in the extrapulmonary compartments studied appeared similar for Pu and Np.

In conclusion, these preliminary results suggest that the biological behaviours of Np and Pu after inhalation of NpO_2 or PuO_2 are similar. Further studies are in progress to complete this work and to explain why, in these experimental conditions, Np and Pu have a similar behaviour.

INTRODUCTION

The chemical association of the transuranic elements in the liver was investigated more than 20 years ago. The numerous studies realised until now demonstrated the preferential binding of plutonium, americium and californium to lysosomes and to the cytosolic ferritin (1-3). By contrast, few studies were realised with neptunium and no clear association of this radionuclide with any subcellular structure was pointed out. Moreover, the results published until now are in apparent contradiction since some authors reported preferential binding of this radionuclide to lysosomal structures (4-5), while others claimed that the nuclei seemed to be the main binding site (6-7). The reasons involved for these dissimilarities are not yet defined and it could be interesting to test the influence of the initial chemical form of the radionuclide on its intracellular distribution. Moreover, an identification of the biological ligands of neptunium, and particularly their renewal frequency, may enable an estimation of the turnover of neptunium in the cell and should, therefore, give information on internal dosimetry. These informations should give data which could be used for specific decorporation studies. The work reported here aims to identify the biological ligands involved in the binding of neptunium as a function of the chemical form injected.

MATERIALS AND METHODS

The experiments were performed with eight 11-12-week-old, male Sprague-Dawley rats (IFFA Credo, France, 220 ± 25 g) which had free access to food and water throughout the study. These experiments on animals were performed by scientists certified by the French Ministry of Agriculture for carrying out these procedures.

The ^{239}Np was obtained from the Service de Chimie, C.E.A. Bruyères le Châtel (France) and was prepared according to a previously published method (8). Prior to administration, the solutions of Np in 0.1M citric acid and Np in 0.1M nitric acid were diluted in order to inject 17 pg ^{239}Np.kg^{-1}.

Two groups of four rats each were contaminated by intravenous injection of one of the solutions (^{239}Np-citrate or ^{239}Np-nitrate) into the saphenous vein under light anaesthesia with pentobarbital (SANOFI, France).

All the animals were sacrificed 24 hours after contamination by exsanguination under anaesthesia and the subcellular fractions of the rat livers were prepared using a previously published method (7). Briefly, the liver was perfused and then homogenized in ice-cold homogenization medium (20mM Tris-HCl, 0.25M sucrose, pH 7.4) using a Potter-Elvehjem homogenizer (clearance 0.3-0.5 mm, 280 r.p.m.). The homogenate was then subjected to ultracentrifugation at successive accelerations of 1,000g (for 10 min), 10,000g (for 20 min), 40,000g (for 30 min) and 100,000g (for 45 min). In this way, 4 pellet samples and a supernatant liquid were obtained composed of cell nuclei + unbroken cells, mitochondria + lysosomes, membranes, microsomes and cytosol, respectively. The protein content of each fraction was determined by the method of Lowry *et al.* (9). The specific activities of the marker enzymes acid phosphatase (10), cytochrome oxidase (11), 5'-nucleotidase (12) and glucose-6-phosphatase (13) were assayed spectrophotometrically.

For each animal, 5 ml of the cytosol was subjected to gel permeation chromatography. Sephacryl HS-300 was used in a column 85 cm long x 2.6 cm in diameter, surrounded by a water jacket at about 4°C. The column was operated at a flow rate of approximately 40 ml.h^{-1} and was equilibrated with 0.2 M NaCl, 20 mM Tris-HCl, pH 7.4. After elution 3.5 ml fractions were collected and analysed for absorbance at 280 nm and for neptunium content. The radioactivity of each fraction collected was determined by gamma-ray analysis.

RESULTS AND DISCUSSION

Table I lists the subcellular deposition of neptunium in the rat liver, according to the chemical form administered. This shows that nearly-half of the ^{239}Np was distributed in the soluble fraction whereas the nuclear and mitochondria + lysosomal fractions accumulated 20-27% and 16-18%, respectively, of the neptunium. The initial chemical form (citrate or nitrate) of the radionuclide has little or no effect on its intracellular distribution. The main effects were observed for the quantitative distribution of neptunium in the liver, since the organelles were three more times contaminated (in terms of Bq/mg Prot.) after injection of Np-citrate than after Np-nitrate (Table I). Nevertheless, when the results are expressed in term of Relative Specific Activities (RSA), the

This work was funded by the Nuclear protection and Safety Institute (IPSN, France)

differences between Np-citrate and Np-nitrate were not statistically significant. This is somewhat surprising since all the previous studies realised until now pointed out the importance of both the chemical form and the valency state of the radionuclide on its biodistribution (14). One explanation for the results reported here could be that the element neptunium is distributed from blood to liver bound to one protein, i.e. in a single chemical form. Blood analysis by means of ultrafiltration and liquid chromatography showed that less than 10 % of the blood Np was ultrafiltrable and that nearly all the radionuclide was bound to transferrin (15), whatever the initial chemical form injected. This fact implies that a reduction of the element from the pentavalent form to the tetravalent state occurs *in vivo* after systemic administration, but the mechanisms involved are not yet explained.

The intracellular distribution of neptunium reported in table I is somewhat different from that described by several authors, who claimed that the lysosomal structures within the liver cells were the main storage site for all the transuranic elements (1-3). The cytosolic accumulation of neptunium noticed in our study was higher from what was observed elsewhere and an attempt was made to determine the cytosolic ligands involved in the binding of the element. Fig. 1. represents the distribution of neptunium amongst proteins of the soluble fraction after gel permeation chromatography. The measurement of absorbance showed the elution of 3 main classes of proteins with MWs of 450 kd, 130 kd and 40 kd, respectively. The recovery of neptunium in the eluent was 90-92% and, 24 hours after contamination, neptunium eluted mainly in two peaks, whatever the initial chemical form administered. The first peak coincided with the elution of ferritin (15), whereas the second eluted in a region of low spectrophotometric absorbance, corresponding to compound of MW 200 kd. This last compound probably corresponds to the same protein than that described in previous studies and which was responsible for the early binding of plutonium and protactinium (16-17). The identity of this protein remains unknown and Schuppler et al. (17) postulated that this compound might be related to Calmodulin. Further investigations on this protein are needed before conclusions can be drawn.

The reasons for the preferential binding of Np in cytosol instead of lysosomal or nuclear structures remain undefined. Nevertheless, the main experiments realised until now with neptunium were done with high masses of ^{237}Np and it can be postulated that the storage of this radionuclide in the heavier structures of the cells (nuclei and lysosomes) was influenced by the mass injected. This kind of results has been previously noticed by Schuler and Taylor (18) who showed that the mass of the injected Pu in primary cultures of rat hepatocytes influenced its intracellular distribution, the nuclei being the main deposit site when high mass of Pu were used. By contrast, that hypothesis was inconsistent with the work of Seidel et al. (5) who described a lysosomal accumulation of neptunium after administration of low masses of ^{239}Np.

CONCLUSIONS

After systemic administration of neptunium-239 in a citrate or nitrate form, the radionuclide distributed in all the subcellular structures of the rat liver. Nevertheless, the early distribution occurred mainly in cytosol, where two proteins with MWs 450 kd and 200 kd, respectively were involved. The first protein was identified as cytosolic ferritin, but the identity of the second remains unknown.

The initial chemical form of the radionuclide had no significant effect on its intracellular distribution. This fact probably implied that neptunium was reduced into one single chemical form when administered in blood, and is consistent with the assumption that the circulating Np was bound to blood transferrin.

THE MEASUREMENT OF ^{241}Am IN THE BODY WITH A DOUBLE LOW ENERGY GERMANIUM DETECTOR SYSTEM

J.L. Genicot[1], J.P. Culot[2], F. Hardeman[1], J.P. Alzetta[1], H. Vanmarcke[1]

[1] SCK•CEN - Boeretang 200, 2400 Mol Belgium
[2] A.V. Nuclear Avenue du Roi, 157 1060 Bruxelles Belgium

ABSTRACT

A system based on two low energy germanium detectors has been calibrated for the investigation of internal contamination with ^{241}Am. The two detectors have a total active area of 5775 mm^2 and a resolution of 600 eV at the energy of 59.5 keV. The measurement system was calibrated with the realistic torso phantom of Livermore which was obtained from the IAEA. The detection efficiency was determined in real measurement conditions with the two detectors above the right lung. Assuming a standard tissue thickness of 25 mm, a detection efficiency of 0.083 cpm/Bq was found. For a counting time of 50 minutes this corresponds to a detection limit of 6 Bq of ^{241}Am. Applying the new ICRP lung model and assuming a typical Pu(MOX) mixture with 1.2 % (w) ^{241}Am, an inhalation corresponding to an internal dose of 20 mSv is measurable 30 days after the intake for a class M compound. In case the americium of the Pu(MOX) mixture can be classified as slow (S), a single intake corresponding to a dose of 20 mSv is detectable over a period of about six months. The subject specific background is evaluated from a background prediction region above the peak region. This system allows a fast response in case of accident. The detectors are also calibrated for the measurement of americium and plutonium in the liver, for uranium and americium in the tracheo-bronchial lymph nodes and for plutonium in the lungs.

INTRODUCTION

The in-vivo measurement of lung contamination with actinides has always been a difficult task because the low energy X-rays emitted by most of the nuclides are strongly absorbed by the tissues. Since two years, a system using two low energy HPGe detectors has been used in the SCK•CEN for this type of measurements. This system greatly improves the capabilities for the quantitative assessment of actinides in the lungs, the liver and the tracheobronchial lymph nodes. The two crystals having a total active area of 5775 mm^2 are placed over the right lung and positioned with an angle between them of about 30 degrees. The technique is based on the quantification of ^{241}Am associated with plutonium in MOX fuel particles. The counting room is made of steel plates 200 mm thick lined with thin plates of Pb (3.2 mm), Sn (1. mm) and Fe (0.5 mm).

CALIBRATION

The efficiency of the counting system has been determined with the aid of a torso phantom of the Livermore type (lent by IAEA). The calibration is made for the assessment of ^{241}Am and of pure ^{239}Pu in lungs, in liver and in tracheo-bronchial lymph nodes. Different overlayers were used for the simulation of the different morphological types. These measurements show an influence of the tissue thickness, tissue composition and distance torso-detector on the total efficiency of the system. An increase of 20 mm in the distance torso-detector results in a decrease of the efficiency of about 20%. The efficiency of our system with two detectors for a man with a tissue thickness of 25 mm is 0.083 cpm/Bq. For a counting time of 50 minutes this corresponds to a detection limit of 6 Bq of ^{241}Am. The influence of the tissue thickness on the counting rate is shown in figure 1.

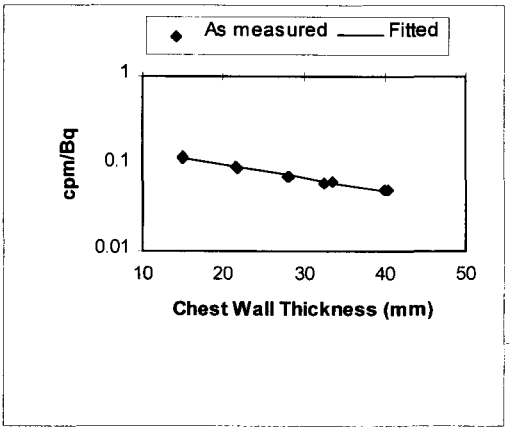

Figure 1. Decrease in counting rate with increasing chest wall thickness of a dual germanium system for the assessment of ^{241}Am in the lungs. The full line is obtained by a least square fitting including all observed values.

ANALYSIS PROCEDURE

A dispersion of 0.2 keV/channel is used for the counting. The examined zone between 59.2 and 60.0 keV, is compared to the zone between 61.4 and 64.2 keV used for the background calculation. The zone chosen for the background assessment is normally free of photopeaks in case of contamination by another radionuclide so that false negative results are minimized. Uranium, in case of contamination with mixed oxide fuel particles, because of the relative proportion of each element, will produce a negligible contribution in the 63 keV region as compared with ^{241}Am.

APPLICATION

A common bioassay tool for Pu(MOX) workers is chest counting for the ^{241}Am progeny of ^{241}Pu. An estimation of the intake requires working assumptions about the isotopic composition of the inhaled mixture and the lung's clearance dynamics. Many factors have to be considered:

- Particle size of the material: From a recent survey of the literature (1) an AMAD of 5 µm and a median geometric standard deviation of 2.56 are realistic default values for occupational exposure when the particle size distribution is unknown.
- Chemical form of the source material: The ICRP-30 and ICRP-68 designate ^{241}Am as class W or class M material. However, a minor contaminant of a matrix may exhibit the behaviour characteristics of the matrix. It could be assumed that the ^{241}Am is of class Y or S such as the plutonium in the Pu(MOX) matrix.
- Metabolic retention and dosimetric model: The new ICRP-66 lung model and ICRP-67 systemic model for Pu and Am provide a basis for the retention and dose assessments. For the density, ICRP-68 uses a default value of 3. In this work, a more realistic density of 10 is used, keeping all the other parameters of ICRP-68 (e.g. breathing rate of 1.2 m^3/h, resting for 31.3 % of the time and light work for 61.7 %, size factor of 1.5).
- Isotopic composition: In this work, a standard isotopic composition (in weight) is assumed: 1.2% ^{238}Pu, 61.1% ^{239}Pu, 23.5 % ^{240}Pu, 8.8% ^{241}Pu, 4.2% ^{242}Pu and 1.2 % ^{241}Am. The doses due to all isotopes of the mixture vary with the solubility class when 1 Bq ^{241}Am is inhaled:

	1 µm (mSv/Bq(^{241}Am))	5µm (mSv/Bq(^{241}Am))
Class M	0.23	0.13
Class S	0.20	0.11

Defining Q(20) as the measured activity in the lung that gives an effective dose of 20 mSv when

we assume the above-mentioned isotopic composition of the mixture:

Q(20)(Bq) = (20 mSv/Dose coefficient (mSv/Bq(^{241}Am)))•Fraction remaining in the lung.

We found:

	^{241}Am class S (Bq)	^{241}Am class S (Bq)	^{241}Am class M (Bq)	^{241}Am class M (Bq)
Time (d)	1μm	5 μm	1 μm	5 μm
0.5	16.4	12.9	12.8	9.8
1	16.0	12.5	12.4	9.5
2	15.6	12.2	12.1	9.2
3	15.5	12.1	11.9	9.1
4	15.3	11.9	11.8	8.9
5	15.2	11.8	11.6	8.8
6	15.1	11.7	11.5	8.6
7	14.9	11.6	11.3	8.5
15	14.0	10.7	10.2	7.6
30	12.6	9.4	8.5	6.2
45	11.6	8.5	7.3	5.2
90	9.8	7.1	4.9	3.5
180	8.3	6.0	2.7	1.9
360	6.9	5.0	0.9	0.6

This table shows that, for class S and an AMAD of 5 μm americium, an effective dose of 20 mSv could be assessed up to 180 days after an acute intake (inhalation), when the detection limit is 6 Bq. The situation is less favourable for a class M compound but better for an older Pu(MOX) mixture.

CHELATING AGENT, DTPA, CAN NOT REMOVE EFFECTIVELY INHALED-PLUTONIUM OXIDE IN RATS

Satoshi Fukuda,[1] H. Iida,[1] Y. Yamada,[1] A. Koizumi, [1] H.Sato, [1] N.Isigure, [1] T . Nakano, [1] and H. Enomoto[1]

[1] National Institute of Radiological Sciences, Chiba, Japan

INTRODUCTION

Chelation therapy is a useful method to reduce the cancer risk in the patients contaminated with transuranic elements such as plutonium and americium. Chelating agents, calcium and zinc salt-diethylenetriaminepentaacetic acid (Ca-DTPA and Zn-DTPA) are useful drugs to remove plutonium and americium effectively from the body with almost no toxicity. Although these chelating agents combine with radionuclides of ionic chemical forms such as nitrate and citrate, the effect is not expected for the insoluble form, i.e. oxide. If patients will be contaminated with plutonium oxide through inhalation, it is doubtful whether each DTPA therapy is useful or not. The present study is to clarify whether these DTPAs are useful to remove plutonium oxide from the body or not.

MATERIALS AND METHODS

Twenty female Wistar rats, 3 months of age, inhaled the particles of plutonium oxide generated by the radioactive aerosol exposure system for rodents developed in our institute (1). The inhaled dose was determined by a whole body counter for small animals (2). They were divided into four groups of five each; Group 1(G1): DTPA administration was initiated on 1st day after inhalation, Group 2 (G2): on 7th day, Group 3 (G3): on 14th day and was not administered in the no-treatment group. Chelation therapy was carried out according to the following schedule. Ca-DTPA was injected intraperitoneally with a daily dose of 150 μmol/kg for the first 5 days and subsequently Zn-DTPA was administered orally at the same dose as that of injection in drinking water up to 30 days. The 24-h urine and feces were collected for 1 day after the first Ca-DTPA injection (Table 1). The lung retention in each group was measured using a whole body counter during the experiment period (Table 1).

Table 1 Experimental design

Group	Inhalation 1	7	14	21	30	38	44days
No treatment group	WBC #	WBC	WBC	WBC			WBC+
Group 1	WBC *, #	WBC			WBC+ *		
Group 2		WBC *,#	WBC			WBC+ *	
Group 3		WBC	WBC *,#	WBC			WBC+ *

WBC: whole body count, *: chelation therapy , #: collection of urine and feces, +: sacrifice

The rats in each experimental group were killed after receiving chelation therapy for 30 days and the no treatment group was time-matched to G3. The blood was collected and then the organs such as lung, trachea, liver, kidney and femur were removed. The plutonium concentration in the blood, organs and excreta was measured by a liquid scintillation spectrometry after a wet ashing treatment.

RESULTS

The initial lung burdens in G1-3 were not different from that in the no treatment group. There were no significant differences in the lung retention of plutonium with the group (Fig.1).

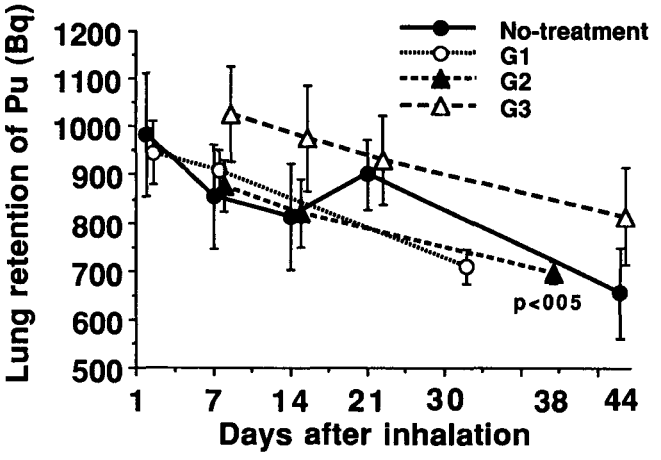

Fig. 1 Lung retention by a whole body counter in each group

The plutonium contents in each organ as well as blood, serum, spleen and ovary were not different between the no-treatment group and each group (Table 2). Also, the excreted plutonium in the urine and feces after first Ca-DTPA injection was not different between the no-treatment group and each treatment group.

Table 2 Plutonium contents (total Bq) in various organs

Organ/Group	No-treatment Group	Group 1	Group 2	Group 3
Lung	772±105	872±50	929±44	1060±144
Trachea	1.20±0.07	1.40±0.25	1.42±0.17	1.12±0.23

Femur	0.83±0.02	0.82±0.03	0.88±0.03	0.75±0.04

* significantly different from no-treatment group ($p<0.05$)

DISCUSSION

As an effective method of chelation therapy, Ca-DTPA injection for the first few days after contamination and subsequently the oral administration of Zn-DTPA is generally appreciated. The dose of 150μmol/kg of DTPAs administered here is more than the recommended human dose of 30 μmol/kg/day, but was effective to remove plutonium nitrate with almost no toxicity for rats in our previous study (3). The particles of plutonium oxide deposited in the lung, although insoluble, may change to be soluble, because the activity is determined in the serum, various organs and excreta. Therefore, the chelation therapy for contamination with plutonium oxide of the insoluble form, although slight and gradually,

may be expected to the effectiveness even if the initiation is delayed but the period is long. Although DTPA administration should be initiated immediately after contamination with the soluble form of plutonium to obtain high effectiveness.

We obtained no evidence that chelation therapy using Ca-DTPA and Zn-DTPA can remove plutonium effectively from the body in spite of initiation of chelation therapy and high dose administration for 30 days. Therefore, other treatments such as lung lavage are necessary to decrease the cancer risk with internally contaminated plutonium

EFFECTS OF NEW CHELATING AGENT, CBMIDA AND ITS ANALOGUES, ON REMOVAL OF PLUTONIUM IN RATS

Satoshi Fukuda,[1] H. Iida,[1] Y. Xie ,[2] and W. Chen [2]

INTRODUCTION

Chelating agents are important for removal of radionuclides for reduction of the risk of radionuclide-induced cancer. DTPA (diethylenetriaminepentaacetic acid) is, at present, the most effective chelating agent to remove plutonium and other actinides from the human body. However, the development of new chelating agents that are more effective with lower toxicity than DTPA is required for chelation therapy. We developed CBMIDA [catechol-3,6, bis(methyleiminodiacetic acid)] that can remove plutonium especially from bone, more effectively than Ca- and Zn-DTPA (1) and the side effects are lower or similar to those of Zn-DTPA in animals (2). Since CBMIDA was later found to have an untoward action to accumulate Pu in the kidneys, some analogues of CBMIDA were developed. The present study was performed to clarify the effect of CBMIDA and four kinds of analogues on removal of plutonium in rats.

MATERIALS AND METHODS

Thirty male Wistar rats, 3 months of age, were injected intravenously with plutonium (5.6 x 10^3 Bq of ^{239}Pu in 0.12ml of 0.008M sodium citrate solution, pH adjusted to 7.2) after bring anesthetized with a combination of ketamine hydrochloride and xylazine. The plutonium-injected rats were divided into six groups, each consisting of five animals: those receiving

(1) CBMIDA,
(2) N-(4-carboxypheylcarbamoylmenthyl)-N-phosphonomethyl glycine (C-I),
(3) 2-hydroxy-3-(N-phosphonomethyl-N-carboxymethylaminomethyl)-5-carboxy-N-phosphonomethyl-N-carboxymethylbenzenzylamine(C-II),
(4) N-carboxymethyl-N-(carboxypropylcarbamoyl-methyl)-2,3-dihydroxy-5-carbomethoxybenzylamine (C-III),
(5) 2,3-dihydroxy-N,N'-di carboxymethyl-N,N'-di-(o-carboxyphenyl-carbamoylmethyl)-1,4-benzendimethan amine (C-IV) , and
(6) physiological saline.

Each chelating agent was dissolved in distilled water and adjusted to pH 7.2 with sodium bicarbonate to make the solution 0.2 ml against the rat mean body weight of 350 g. Each rat in each group was daily given intraperitoneal injections with a dose of 100 μmol/kg CBMIDA and its analogues for 2 weeks, beginning at 1 hour after plutonium injection on the first day of treatment.

Animals were killed 2 weeks after the plutonium injection. The plasma, bone(femur), liver, kidney, spleen and testis were removed and the plutonium concentration was measured by an alpha liquid scintillation counter.

RESULTS

Table 1 shows the plutonium contents (Bq/g or Bq/ml) of the organs and plasma. There were significant decreases in the bone, liver and testis in the CBMIDA group, compared to those in the control group. There were significant decreases in the bone, liver and spleen in the C-2 group, and the bone and liver in the C-3 group. There was a significant decrease in the bone, and liver but increase in the kidneys in the C-4 group.

There were no significant differences in the body weight of rats before and after the experiment in any group. During the experimental period, no unusual clinical findings were observed. No untoward findings at autopsy were observed.

Table 1 Plutonium content (Bq/g or ml) in the organs and plasma

Group	Femur	Liver	Kidney	Spleen	Testis	Plasma
Control	159.9±15.5	23.0±3.0	15.4±1.3	34.1±7.4	7.8±0.5	4.0±0.1
CBMIDA	71.1±16.6*2	9.5±2.6*1	25.2±5.2	23.1±7.9	4.0±0.6*2	4.6±0.2
C-1	151.2±10.8*1	23.5±1.2	13.2±0.9	23.1±2.8	8.2±1.0	4.0±0.1

C-3	98.5±14.6*1	11.6±2.0*1	14.4±1.8	18.5±2.5	6.5±1.0	4.6±0.2
C-4	58.4±11.4*2	15.1±2.3	83.0±8.7*3	20.3±3.1	7.9±0.6	4.4±0.2

Values are means ± standard error. Significant difference from control:*1($p<0.05$), *2($p<0.01$).

DISCUSSION

We have demonstrated that CBMIDA can remove plutonium particularly from the bone and liver, which are the target organs, more effectively than Ca-DTPA or Zn-DTPA, either by the injection or oral administration (1, 3), suggesting that the chelating action of CBMIDA is stronger than that of DTPAs. In this experiment, the plutonium content in the bone was also reduced significantly in the CBMIDA group. Because CBMIDA increased the osteoid volume and thickness, its effect to reduce plutonium deposition in bones is attributed to the inhibition of the mineralization of the bone (4). On the other hand, the plutonium content in the kidneys increased, not significantly from that in the control group, and that in the C-4 group increased in the kidneys. These findings indicate that CBMIDA and C-4 can not be used for chelation therapy.

In the C-2 and C-3 groups, the plutonium content was decreased significantly in the bone and liver, and tended to be decreased in the kidneys, spleen and testes. These compounds improved the untoward action of CBMIDA in which the plutonium content increased in the kidneys. No unusual findings were produced by CBMIDA and its analogue groups even at the dose of 100 μmol/kg. All analogues of CBMIDA had the same toxicity as CBMIDA or lower toxicity, but further examination will be necessary on the toxicity, because a dosage of 100 μmol/kg is more than the recommended dose, for example, the daily dose of DTPA for humans is 30 μmol/kg.

In conclusion, the injection of compounds of C-2 and C-3 of CBMIDA analogues effectively removed plutonium from the body. Therefore they should be examined as drugs for chelation therapy in persons contaminated with plutonium.

MICRODOSIMETRY OF HOT PARTICLES IN LUNG INTERSTITIUM

Vladimir A. Kutkov

Russian Research Center "Kurchatov Institute", Moscow, Russia

The radiobiological significance of inhaled local α-emitting particles ("hot" particles) was the central point for number of researches. We evaluated the relative carcinogenic effectiveness of "hot" particles with the help of microdosimetry. According to microdosimetry concept the dose-dependent microdistribution of deposited energy in irradiated tissue, $f_D(z)$ is the physical base for prediction of stochastic tissue response on irradiation of different quality. The method of moments was used to approximate $f_D(z)$ in case of α-irradiation of lung interstitium (*LI*) (1). Two sets of sources were investigated. The first one is the set of randomly distributed stationary local emitters ("hot" particles). The second one is the set of α-emitters spread uniformly in LI (the case of uniform irradiation of the tissue). The penetration of α-particles through LI was examined with computer model of 3-d stochastic structure of lung interstitium (2). For the purposes of this model one describe the lung alveoli as a spherical shell with fluctuated inner diameter and thickness of wall.

The term of dispersion of $f_D(z)$, which is affected by spatial correlation of points of α-decay was found (3). For the set of local emitters that term depends on their average activity, energy of α-particles and spatial structure of irradiated tissue. According to our results the spatial microdistribution of α-emitters in irradiated LI affects the dose-response relationship for radiation induced cancer at low doses. In some instances at the same organ dose high local concentration of α-radioactive material in "hot" particles found greater effective carcenogenically than α-emitters spread uniformly. That fact conflicts with judgement of ICRP Recommendations 1990 (4) about relative hazard of the nonuniform irradiation.

The quantitative definition of notion "hot particle", based on microdosimetry approach is proposed.

ABSTRACT (See instructions overleaf)

Experience gained in developing and using the PLUTO[1] program for assessing plutonium exposure from urinalysis data has been applied to produce an entirely new code PuMA:- Plutonium Maximum-likelihood Assessment.

PuMA allows the assessment of complex plutonium exposure histories from urine sample data sets of variable reliability and containing large numbers of samples recorded as being below the minimum detectable activity. During it's development the PLUTO program was moved from a mainframe to a PC environment and this left it with an outdated interface. PuMA is being developed for the PC and this has permitted the development of a new user-friendly interface. The increased processing power now commonly available on PCs has enabled a more sophisticated implementation of the maximum-likelihood fitting technique to be utilised in the new program. A modular approach to program design will make it easy to implement new biokinetic models and allow future adaption to assess exposure to other nuclides.

BIOKINETIC MODELLING OF SKELETAL LABELS FROM PU-239

E. Polig

Forschungszentrum Karlsruhe, Hauptabteilung Sicherheit/ Strahlenschutz, Postf. 3640, D-76021 Karlsruhe, Germany.

INTRODUCTION

Biokinetic models of the radionuclide distribution in the human body are not only useful for estimating intakes from excretion analysis or calculating committed effective doses. They also may be used for modelling and predicting intra- organ distributions in such cases, where a non- uniform deposition is a characteristic feature of an organ's anatomy and physiology, and such a non- uniformity essentially determines the radiation detriment. This is the case for the deposition of the actinides in the skeleton.

In the following a biokinetic model of the distribution of ^{239}Pu in the human skeleton after systemic intake is discussed. With regard to the non- skeletal parts the model is identical to the one proposed recently by the International Commission of Radiological Protection (1). The skeletal compartments were rearranged to achieve agreement with basic autoradiographic data obtained from animal experiments and human injection cases.

MODEL STRUCTURE

The skeletal compartments of the model are shown in Fig. 1. According to our present knowledge, actinides are bone surface- seekers and only deposit in bone volume by way of new bone formation at remodelling sites. The concentration of these volume labels is determined by the radionuclide concentration in blood at the time of mineralization of the organic matrix. Therefore the compartments representing volume labels are directly connected to the blood (transfer) compartment. Of the radioactivity in blood 43% enters the skeleton with partitioning among the skeletal compartments as shown in Fig.1. This partitioning of the flow from blood to skeleton can be calculated using the concept of affinity ratios. One is the cortical/trabecular affinity ratio (q_{ct}), which specifies the ratio of the fractional flow per unit bone surface to trabecular and cortical bone compartments. The other is the resting/forming affinity ratio (q_{rf}), which specifies the ratio of the fractional flow per unit bone surface to forming (new bone) or resting bone surfaces. Both ratios can be determined autoradiographically and have been chosen as 1/3.

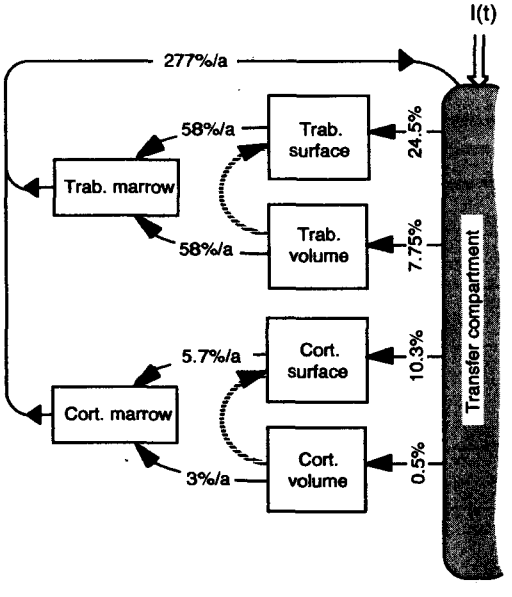

Figure 1. Skeletal compartments of biokinetic model.

Although the turnover rate of the trabecular bone volume is only 26%/year, it can be shown that surface turnover rates are higher (58%/year). Trabecular volume labels are resorbed at the surface turnover rate, cortical volume labels are resorbed according to the volume turnover rate (Fig.1). The model may take into account "internal recirculation", i.e. the direct re-deposition of radioactivity resorbed from volume labels onto neighbouring surfaces (dashed arrows in Fig.1) without entering the blood compartment. However, as specific data from experiments are lacking, this feature presently is not being used.

The question of how much of a surface- seeker remains on bone surfaces after extended burden times is of importance with regard to the relative toxicities of surface- and volume- seeking radionuclides. Volume- seekers such as ^{226}Ra are generally less toxic, because mineralized tissue shields much more of their radiation from reaching endosteal target cells, than is the case for surface- seekers. One can show that an upper limit for the fraction of the trabecular activity (F_{vol}) deposited in volume labels is given by:

$$F_{vol} < \frac{1}{1 - q_{rf} + \frac{q_{rf} MWT\, S_{vt}}{F_{vt}\, \sigma_R}} \qquad (1)$$

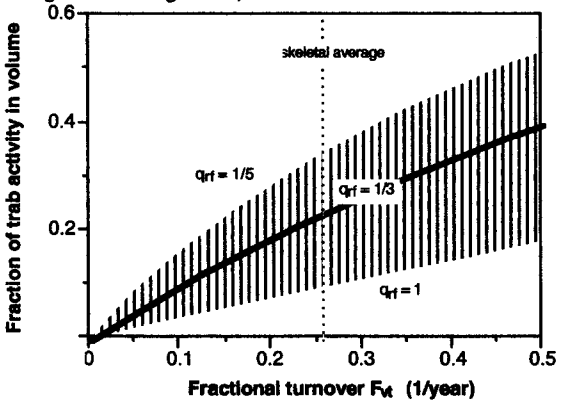

Figure 2. Fraction of total trabecular radioactivity of ^{239}Pu which is deposited in bone volume.

The mean wall thickness (MWT) and the surface/volume ratio (S_{vt}) are two morphological parameters of bone structure. F_{vt} is the (volume-) turnover rate of trabecular bone. F_{vol} decreases with increasing resting/forming affinity ratio (q_{rf}). Fig.2 shows that even for a trabecular turnover as high as 50%/year and a small ratio q_{rf} = 1/5 not more than 50% of the trabecular activity can be in bone volume. For typical values of the human skeleton only about 20% of the ^{239}Pu activity should be found in volume labels. A relationship similar to Eq. 1 holds for cortical bone. The upper limit for F_{vol} in cortical bone slowly increases from about 5% immediately after intake to 15% at 50 years.

LABEL CONCENTRATIONS

In Fig. 3 the average concentrations of ^{239}Pu in trabecular surface labels are plotted for single or continuous systemic intake of 1 kBq. The continuous intake is assumed to occur at a constant rate up to the time read off from the graph. The intake mode has a significant effect on label concentrations with the single intake resulting in lower concentrations than the continuous intake. According to model predictions, the influence of the intake mode on cortical surface labels should be less pronounced. The calculations show that cortical surface concentrations exceed trabecular concentrations after two or five years for single or continuous intake, respectively. Also indicated in Fig. 3 are autoradiographic measurements (2) of trabecular surface concentrations in the axial skeleton of a human injection case (3) who died 17 month after injection. Fig. 3 shows the concentration averaged over all existing surfaces. As formation and resorption sites do not have a surface label, average concentrations over sites where a surface label really exists are obtained by multiplying values of Fig. 3 with the factor 1.11. Cortical surface concentrations reach a maximum of about 4 mBq cm^{-2} (for 1 kBq intake) at 10 or 20 years after intake, for single or continuous intake, respectively.

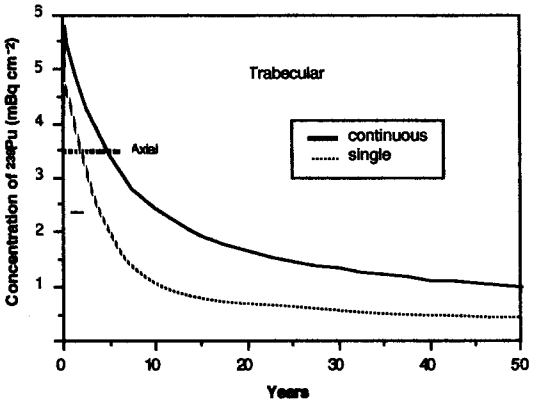

Figure 3. Concentration of ^{239}Pu on trabecular bone surfaces after single or continuous systemic intake of 1kBq.

Assuming random remodelling of bone structure, the fraction of bone surfaces carrying an adjacent volume label (f_{vol}) can be calculated according to

$$f_{vol}(t) = 1 - (1 - \sigma_F F_s)\, e^{-F_s t} \quad (2)$$

where σ_F is the bone formation interval and F_s the surface turnover rate. Eq. 2 may be used to estimate that 99% of all trabecular or cortical surfaces will have an adjacent volume label after 7.8 years or 80 years, respectively. As Fig. 4 shows, cortical volume labels are not influenced very much by the uptake mode. Concentrations of ^{239}Pu in trabecular volume labels are always significantly higher than in cortical labels. The dashed horizontal line in Fig.4 indicates measured concentrations in burial sites of the axial skeleton from the aforementioned human injection case (2).

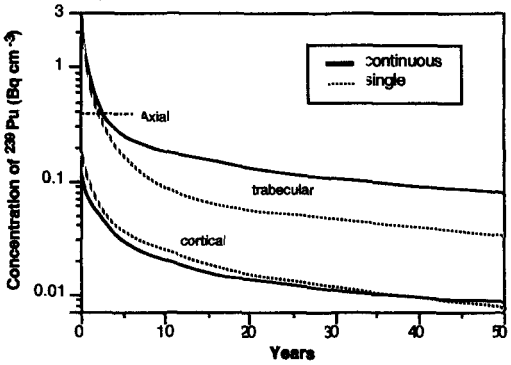

Figure 4. Concentration of ^{239}Pu in bone volume labels after single or continuous systemic intake of 1 kBq.

Because of the rapid clearance of the marrow compartments (Fig.1) they are in quasi- equilibrium with the corresponding volume and surface compartments. This means a nearly constant percentage of 17% of the total trabecular and 2% of the cortical activity is found in the trabecular and cortical marrow, respectively. The dosimetric importance of marrow deposits for the irradiation of the endosteum is small compared to bone volume deposits. Trabecular marrow concentrations are about eight time and cortical marrow concentrations more than two times lower than the respective volume concentrations.

In addition to calculating skeletal averages of surface and volume label concentrations, this model also is able to predict concentrations in formations sites for any chosen time after intake, it quantitatively explains characteristic concentration profiles in formation sites ("buried hot lines") observed in autoradiographs of contaminated human and animal bones, and it describes the kinetic behaviour of labels at individual skeletal sites undergoing the remodelling cycles of resorption, formation and quiescence. One of its major advantages may be its ability to provide estimates for the variability of label concentrations throughout the skeleton.

The main purpose of the model presented here is to provide the basis of a refined dosimetric model for estimating radiation doses to the endosteum and red bone marrow, which are considered to be the principal target tissues of the skeleton.

CONCLUSIONS

- Most of the ^{239}Pu radioactivity in surface labels remains or will be re-deposited on bone surfaces even after extended burden times. There is no complete transformation into volume labels, and thus the radiation risk from actinide depositions remains elevated compared to ^{226}Ra and other bone volume- seekers.
- Intake modes may significantly affect the level of label concentrations and their change in time.
- The model presented is able to describe qualitatively and quantitatively the major features of the microdistribution of actinides as observed in autoradiographic studies of human and animal bones.

DOES INITIAL LUNG BURDEN AFFECT THE ALVEOLAR LUNG CLEARANCE OF INHALED $^{239}PuO_2$?

N. Ishigure, T. Nakano, H. Enomoto, H. Sato and J. Inaba

National Institute of Radiological Sciences, 9-1, Anagawa 4, Inage, Chiba 263, Japan

INTRODUCTION

The objective of this study is to establish alveolar lung clearance curves in rats for inhaled $^{239}PuO_2$ of various initial lung burdens (ILB), which are essential for lung dosimetry in the study to define the shape of the dose-response curve.

EXPERIMENTAL

Aerosol generation and inhalation

Stock solution of $^{239}Pu(NO_3)_4$ was treated by the same chemical procedures as described by Raabe et al.(1), which resulted in colloidal $Pu(OH)_4$ suspended in HCl solution. This colloid was nebulized and the resultant droplets were passed successively through a heated tube at 300℃ to dry the droplets and then on to a high temperature furnace heated to 1150℃ to oxidize the dried particles(2). The size of the PuO_2 particles was between 0.4 and 0.5 micron in AMAD and the geometric standard deviation was about 2.

Young adult female Wistar rats were used. The inhalation was conducted using a multiport nose-only exposure chamber without anesthesia. Immediately after the exposure the skin around the nose of the rat was wiped with a sheet of wet thin cloths to reduce surface contamination.

In vivo counting of Pu in rat lung

To follow the lung retention of plutonium, *in vivo* counting of low energy L X-rays (average energy 17 keV) with thin NaI(Tl) scintillation detectors was applied at various intervals up to 1 year after the inhalation (see **Figure 1**). The details were described elsewhere(3,4).

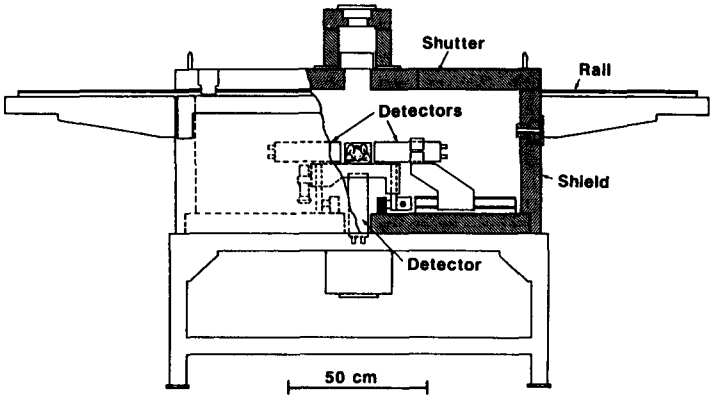

Figure 1. Schematic diagram of the whole-body counter.

The counting system was calibrated by measuring counting efficiencies for rats of various body weights that had been sacrificed for different experimental purposes and then plotted the measured counting efficiencies against the body weight (see **Figure 2**).

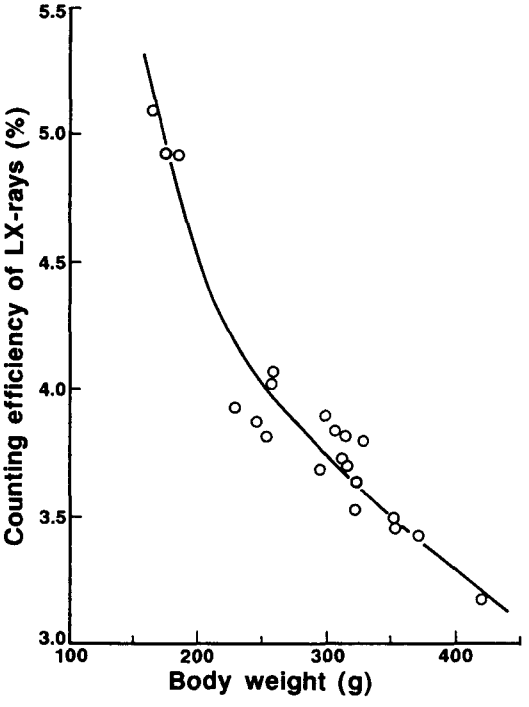

Figure 2. Counting efficiency of L X-rays for the rats of various body weights.

RESULTS AND DISCUSSION

Lung retention of Pu followed in the rats inhaled with various ILB is shown in **Figure 3**; the ILB were 0.28 kBq, 0.72 kBq, 1.37 kBq and 2.4 kBq. The master retention function obtained using five rats of their ILB between 1.99 kBq and 2.96 kBq was:

$$Y(t) = 0.766\exp(-0.0131t) + 0.234\exp(-0.000873t)$$

where $Y(t)$ is the relative Pu content in lungs at time t days after exposure(5), which is shown in the figure as curves. The present result shows that the alveolar lung clearance of $^{239}PuO_2$ was independent of ILB between 0.28 kBq and 2.4 kBq, which does not agree to the recent data of Pacific Northwest Laboratories (PNL) which claimed the alveolar lung clearance inversely proportional to ILB of 0.4-3.9 kBq (6).

The physicochemical characteristics of the aerosols used in these two laboratories were not the same. Considering the present methodology, our aerosol generation system is designed to produce PuO_2 particles that are spherical and of small sizes, compared with those of PNL. Therefore we only give an answer that there are PuO_2 particles whose ILB does not affect the alveolar lung clearance of inhaled PuO_2.

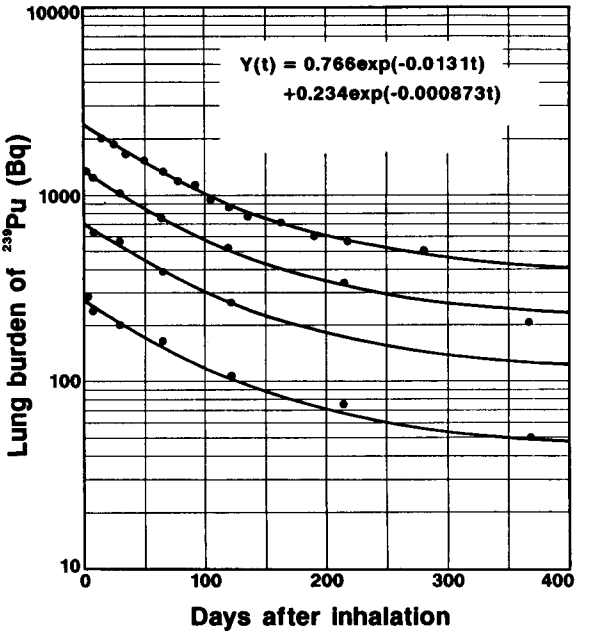

Figure 3. Lung retention of Pu of rats following inhalation of aerosols of PuO_2

INTRODUCTION

The kinetics of the transfer of radionuclides from mother to embryo is still a matter to be solved. After the Chernobyl accident, we had the possibility to study the transfer of Cs^{137} from mother to embryo, in the case of a continuous and variable Cs^{137} intake of the mother. The study was carried on for a period of three years after the accident. Our group performed also measurements of transfer from mother to embryo, in the case of a continuous, prolonged, but rather constant intake. The results of this study will be presented in future papers.

MATERIALS AND METHOD

During April 1986 - September 1989 we have determined Cs^{137} content in 96 human embryos, aged between 5 and 11 weeks at the moment of prelevation, as well as Cs^{137} dietary intake and urinary excretion of the mother, while they were in hospital for the abortion. All the subject mothers were living in Bucharest, and were aged between 17 and 44 years.

In order to do this, embryos of different ages were prelevated from the hospitals, as well as dietary intake and urine samples from their mothers, within the entire period of study.

The Cs^{137} content of the embryos and of the dietary and biological samples was performed by radiochemical separation [1], followed by beta counting with a low-level, high-efficiency counter.

RESULTS AND DISCUSSION

Within the period of study, the average Cs^{137} content in embryos increased from 97.3 mBq/g tissue in 1986, to 137.9 mBq/g tissue in 1987, then it decreased to 10.3 mBq/g tissue in 1988. In 1989, the content in embryos was very small; in many cases, it was bellow the minimum detectable activity (MDA). Those variations are presented in Fig. 1, where the peak Cs^{137} content in embryos can be observed, in March 1987.

Since April 1986 until December 1986, 44 embryos of different ages were prelevated monthly, as well as dietary intake and urine samples from their mothers, and we measured the Cs^{137} content. Among the 44 embryos studied, 16 were 7 weeks old, 11 were 6 weeks old, and the other covered the other ages from 5 to 11 weeks.

Table 1: Cs^{137} content in embryos, with respect to the average value

Cs^{137} content in embryos (mBq/g tissue)	Age of the embryos (in weeks)					
	6	7	8	9	10	11
> 97.3	45.45%	56.25%	60%	-	66.66%	100%
< 97.3	54.55%	43.75%	40%	100%	33%	-

The average value of the Cs^{137} content in the embryos analysed in 1986 was 97.3 mBq/g tissue (for all the ages). Considering this value as reference value for that period, we have separated the Cs^{137} content in embryos in two groups: "high Cs^{137} content", when it exceeds the average value, and "low Cs^{137} content" when it is lower than the average. The percentage distribution of the Cs^{137} content in embryos, considering this reference value and the age of the embryos, is presented in Table 1.

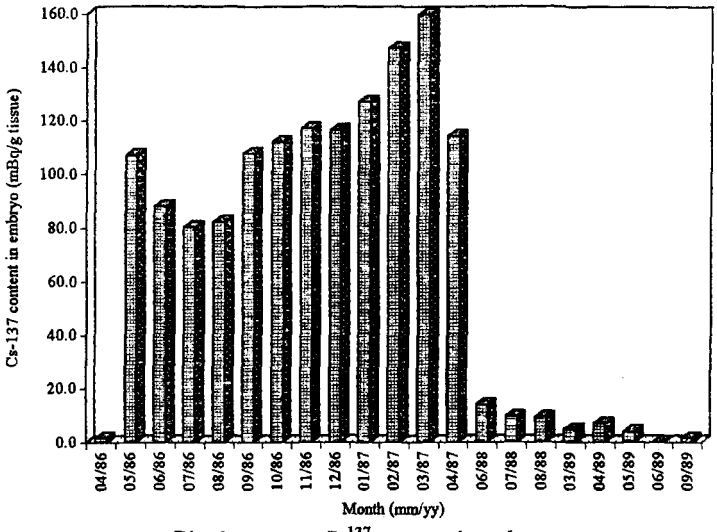

Fig. 1: Average Cs^{137} content in embryos

It appears that, the older are the embryos, the higher the number of cases with increased Cs^{137} content (with one exception: 9 weeks embryos). This indicates that Cs^{137} content tends to increase as the age of the embryo increases.

Cs^{137} intake of the mothers took values between 61.5 and 127.2 Bq/day, in 1986, with an average value of 90.16 Bq/day. The percentage distribution of embryos with Cs^{137} content higher than 97.3 mBq/g tissue, with respect to Cs^{137} intake of the mother, is as presented in Table 2. The table bellow seems to point out that there is a step value for the mother intake (103.5 Bq/day) above which the percentage of embryos with "high Cs^{137} content" is directly dependent of the quantity of Cs^{137} ingested by the mother no matter how old is the embryo.

Table 2: Cs^{137} content in embryos with respect to Cs^{137} of the mother

Cs^{137} content in embryos	Cs^{137} intake of the mother (Bq/day)							
(mBq/g tissue)	40.3	61.5	70.4	93.8	103.5	105.6	119.0	127.2
> 97.3	20%	75%	-	-	80%	66.6%	80%	85.7%
< 97.3	80%	25%	100%	100%	20%	33.4%	20%	14.3%

Cs^{137} content in embryos prelevated during January 1987 - April 1987 was the highest among all the considered periods.

The 16 embryos studied in 1987 had ages between 6 and 10 weeks, the number of embryos of a certain age being variable (from one embryo aged 10 weeks, to 6 embryos aged 7 weeks) imposed an overall discussion of the values for all the embryos. In 1987, the percentage distribution of embryos with Cs^{137} content higher than the annual average was the following:

Table 3: Cs^{137} content in embryos, in 1987

Cs^{137} content in embryos (mBq/g tissue)	Age of the embryo (weeks)				
	6	7	8	9	10
> 137.9	25%	83.3%	50%	100%	100%
< 137.9	75%	16.7%	50%	-	-

It can be seen that, while only 25% of the 6 weeks embryos have Cs^{137} content higher than the average, all the 9 weeks and 10 weeks embryos have higher Cs^{137} content than the average. Cs^{137} intake of the mothers during January 1987 - April 1987 ranged between 92.6 and 134 Bq/day. From the results obtained it seems that the content in embryos increases as the intake of the mother increases.

Cs^{137} content of the 17 embryos studied in 1988 was lower than in the precedent years, and ranged between 6.7 and 15.8 mBq/g tissue, with an annual average of 10.3 mBq/g tissue. Performing the same analysis as before, we have obtained the following data for the percentage distributions of "high Cs^{137} content" with respect to the age of embryos:

Table 4: Cs^{137} content in embryos, in 1988

Cs^{137} content in embryos (mBq/g tissue)	Age of the embryo (weeks)					
	5	6	7	8	9	10
> 10.3	50%	50%	66.66%	66.66%	33.3%	100%
< 10.3	50%	50%	33.3%	33.3%	66.6%	-

In this case too, the Cs^{137} content seems to be higher in older embryos than in younger embryos.

Cs^{137} intake of the mother during January 1988 - August 1988 took values between 6.5 Bq/day and 11.5 Bq/day. In this case, the data were not sufficient to allow us to make any correlation between the mother intake and the content in embryo.

In 1989 Cs^{137} content in embryos was extremely low, 32% of the embryos having Cs^{137} content bellow MDA, and the average Cs^{137} content in embryos was 3.35 mBq/g tissue (for all the embryos analysed), and 6.31 mBq/g tissue (for the embryos with Cs^{137} content above MDA). Because of the low Cs^{137} content in embryos, any attempt of correlating the Cs^{137} content with the age of the embryos or with the intake of the mother is very difficult.

CONCLUSIONS

The data discussed above seem to poin to two conclusions:

- Cs^{137} content in embryos increases as the age of the embryo increases
- there is a step value for the Cs^{137} intake of the mother, above which the content of the embryo increases with the intake of the mother

The present data did not allowed us to corelate the Cs^{137} content of the embryo with the age of the mother.

INTRODUCTION

On the 26th of April, 1986, a major accident occurred at the fourth reactor of the Chernobyl nuclear power plant, in Ukraine. The meteorological conditions lead to important fallout over our country. The most important radionuclides carried by the radioactive plume over Romania were I^{131}, Cs^{134}, Cs^{137} and Sr^{90}. After the decay of I^{131}, and of the other short-lived radionuclides, Cs^{137} and Sr^{90} remained the most important contaminants on the Romanian territory. The principal route of intake for these two radionuclides is considered to be the ingestion of contaminated foods. Therefore, we have measured Cs^{137} and Sr^{90} content in dietary intake for a group of adult subjects. The data for dietary intake were used to determine the effective doses committed annually, with the dose factors recommended by ICRP 67 [1].

MATERIALS AND METHOD

All the samples were prelevated since April 1986 until April 1995, during nine years after the Chernobyl accident, in the Bucharest area.

The population group selected for this study was a group of adult men, aged between 25 and 40 years, without any health problems, hard labourers. The food samples were prelevated from the cafeteria of the factory, where their were all taking their meals. Usually, the food was prelevated in the second part of every month.

For all samples, Cs^{137} and Sr^{90} content was determined by radiochemically separated, using standardised methods (HASL-300), followed by beta counting with a low-level high-efficiency counter.

RESULTS AND DISCUSSION

During the nine years of our study, the quantity of ingested Cs^{137} varied a lot from one year to another. As expected, the Cs^{137} intake had the highest value in the first year after the accident. The peak of the Cs^{137} intake was reached in May 1986, when the average daily ingested quantity was 408.5 Bq. Beyond this date, on the background of a continuous decrease of Cs^{137} intake, other two peaks occurred, for reasons presented in previous papers [2]. The experimental data are very well fitted by the following "dietary intake function":

$$I(t) := 1.84 \cdot 10^{-2} \cdot t^{4.31} \cdot \exp(-0.16t) + 184 \cdot \exp\left[-\left(\frac{t - 220.52}{186.56}\right)^2\right] + 23.27 \cdot \exp\left[-\left(\frac{t - 683.4}{193.5}\right)^2\right]$$

with t - the time elapsed after the accident, in days.

As it can be seen in figure 2, there is a strong variation of Sr^{90} intake during April 1986 - March 1995. To begin with May 1986, Sr^{90} dietary intake increased continuously, until it reached 1.485

Bq/day in October 1986 (Fig. 2). Strontium intake remains at high values until April 1987, then it decreases continuously.

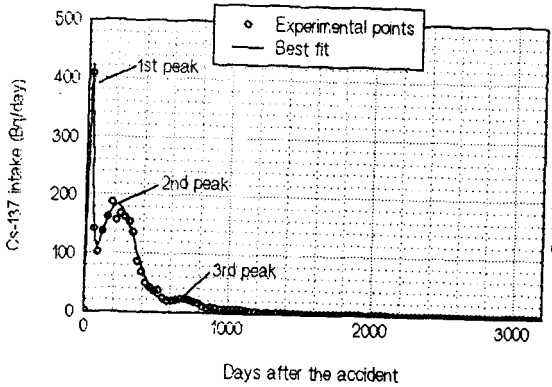

Fig.1: Cs^{137} dietary intake, during nine years after the accident

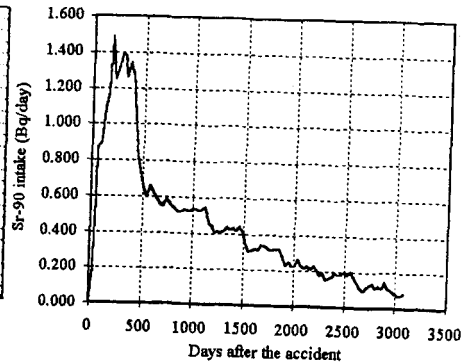

Fig. 2: Sr^{90} dietary intake, during nine years after the accident

The effective doses committed annually due to internally deposited Cs^{137} are presented in Fig. 3, while the effective doses committed due to Sr^{90} dietary intake are presented in Fig. 4 (to red marrow, bone surface, and their sum).

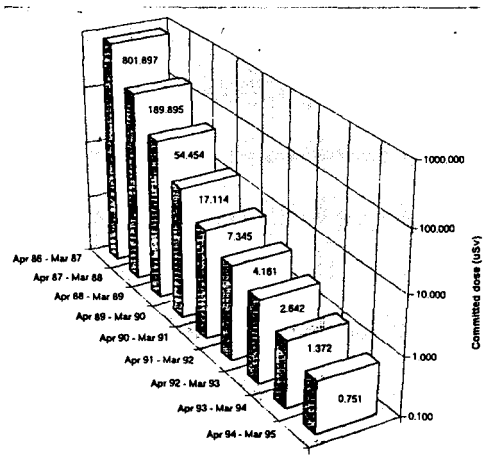

Fig. 3: Effective doses committed due to Cs^{137} intake

As it can be seen, in the first year after the accident, Cs^{137} intake lead to an effective dose commitment of 801.9 μSv. This value decreased quite fast, as the amount of caesium intake decreased, and reached 7.3 μSv five years after the accident, then 0.75 μSv in the ninth year after the accident. A comparison of the doses committed due to Cs^{137} and Sr^{90} intake is presented in Fig. 5.

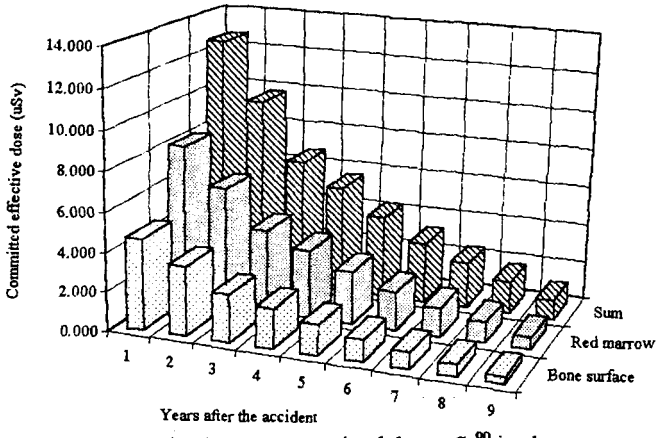

Fig. 4: Doses committed due to Sr^{90} intake

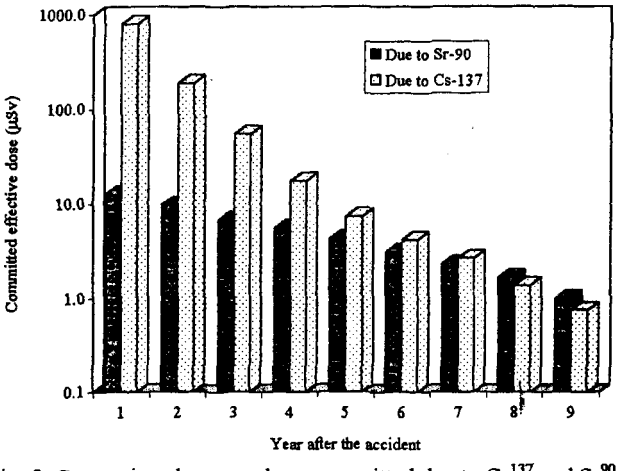

Fig. 5: Comparison between doses committed due to Cs^{137} and Sr^{90} intake

CONCLUSIONS

The effective dose committed by the adults in then first year after the accident, due to Cs^{137} dietary intake was 801.9 μSv while the dose committed due to Sr^{90} intake was 12.69 μSv (bone surface and red marrow). The doses committed annually are continuously decreasing, so that in the eight year after the accident the dose due to Sr^{90} is higher than the dose due to Cs^{137}. The effective dose committed by the adults in the nine years elapsed from the accident were 1079.6 μSv due to Cs^{137}, while due to Sr^{90} the doses were 16.978 μSv (to the bone surface) and 29.814 μSv (to the red marrow).

MAJOR SCIENTIFIC TOPIC NUMBER 4.3

ABSTRACT

A major problem after the Chernobyl accident was to asses the effects of the irradiation for different age groups, especially children. Our group has measured Cs^{137} and Sr^{90} dietary intake and urinary excretion for children having different ages (between 4 and 12 years), during different time intervals. From the intake data, a trend of the annually committed effective doses was deduced. The paper presents the dose values for different age groups, and their evolution in time. A comparison with the doses committed by adults living in the same conditions as the children is presented.

ASSESSMENTS OF INTERNAL DOSES BY INGESTION OF RADIOACTIVE FOODSTUFFS IN BANGLADESH

A. S. Mollah

Institute of Nuclear Science and Technology, Ganakbari, Savar, Bangladesh.

ABSTRACT

The internal radiation dose to a man from the consumption of foodstuffs was estimated on the basis of the measured radioactivities in the foodstuffs in Bangladesh. The total annual internal effective dose equivalent was found to be 454.56 μSv. The dose from intake of radionuclides by foodstuffs (ingestion dose) in general is so low that no harmful effects will occur directly.

INTRODUCTION

Exposure of man to ionising radiation can cause harmful effects. The extent of these effects is dependent on the dose. The possible exposure pathways to individuals include direct radiation from an airborne radioactive plume, inhalation of radioactive gases and aerosols, external radiation from the contaminated ground, and internal dose from ingestion of contaminated food. Food intakes is one of the important pathways for long term health considerations. There may be a variety of radionuclides of artificial as well as natural origins which normally get entry into human body through foodchain and other pathways and deposited in the critical organ(s) causing internal irradiation (1,2). Artificial radioactivity comes mainly from nuclear weapon testings, major nuclear power accidents and radioactive wastes. Among the naturally occurring radionuclides, ^{40}K and the products of the ^{232}Th and ^{238}U decay series are the most important ones. To assess the radionuclide intake by man thourgh food consumption, it is necessary to measure the radioactivity in different foodstuffs. This study was undertaken to determine the radioactivity levels in foodstuffs in order to estimate the effective dose equivalent from dietary intakes of radionuclide-contaminated foodstuffs in Bangladesh. In this study, ^{238}U, ^{232}Th, ^{40}K and ^{137}Cs radionuclides have been considered.

RADIOACTIVITY IN FOODSTUFFS

Food samples representing the major dietary habits of local people were collected from the local markets. This included cereal, vegetable, milk, fresh fish, fresh meat, fresh fruit, etc. All samples were cleaned, processed and dried at room temperature (3,4). About 1 kg dry sample was used in a Merinelli beaker, which is then sealed for more than 30 days to allow for a radium-radon equilibrium to be reached before further measurements (5). The gamma spectrum of each samples was determined with a HPGe detector connected to a 4096 channel analyzer. The effective volume of the detector was 72.4 cm^3 and its energy resolution was 2.1 keV from 1.33 MeV gamma line of ^{60}Co. Samples and standard were counted in identical containers. Details of the counting and efficiency calibration have been given in earlier reports (3-5). The radioactivity was determined from the counting rate under respective photopeak areas and the efficiency of the detector for respective energies. The photopeaks at 609 keV (^{214}Bi due to ^{238}U), 583 keV (^{208}Tl due to ^{232}Th), 1460 keV (^{40}K), and 662 keV (^{137}Cs) were used for the determination of radioactivity in foodstuffs.

RADIONUCLIDE INTAKE AND DOSE ESTIMATES

The intake of radionuclides with food is dependent on the concentration of radionuclides in the various foodstuffs and on the food consumption. It is obvious that food consumption depends on many factors, some of which concern the individual while others are group related. Information on the range and amounts of foods consumed regularly by individuals is required. Types of food consumed are related, of course, to the specific geographical, as well as the cultural, economic, social and even political, conditions within and amongst countries (6).

The risk associated with an intake of radionuclides in the body is proportional to the total dose delivered by the radionuclides while staying in the various organs. In general it is assumed that stochastic effects occur linearly with dose and usually the effective dose equivalent H_e is used to define this risk. So H_e is a parameter for the biological effect. Intake to effective dose equivalent conversion factors are needed in order to convert the intake into dose on ingestion of radionuclides into the body. The intake to dose conversion factors (50-year period) cited in the ICRP publication no.51 for the members of the public (adults) were used. The factors used for estimation of doses are (1,7,8): 6.2×10^{-9} Sv/Bq for ^{238}U; 7.4×10^{-7} Sv/Bq for ^{232}Th; 5.0×10^{-9} Sv/Bq for ^{40}K; and 1.2×10^{-8} Sv/Bq for ^{137}Cs. Radioactivity levels in foodstuffs were used to estimate internal effective doses. Internal doses were estimated from the foodstuffs by multiplying the average concentrations of ^{238}U, ^{232}Th, ^{40}K and ^{137}Cs by the yearly food intake and ingestion dose coefficients.

RESULTS AND DISCUSSIONS

The content of ^{238}U, ^{232}Th, ^{40}K, and ^{137}Cs radioactivity in foodstuffs varies from 0.16 to 1.28 Bq/kg, 0.22 to 1.12 Bq/kg, 95.22 to 220.54 Bq/kg, and 1.19 to 3.89 Bq/kg, respectively. The average concentration of ^{238}U, ^{232}Th, ^{40}K, and ^{137}Cs in foodstuffs, grouped according to their food type, are listed in Table 1.

Table 1. Average radioactivity in foodstuffs in Bangladesh.

Name of foodstuffs	Activity (Bq/kg)			
	^{238}U	^{232}Th	^{40}K	^{137}Cs
Cereal	1.28	1.12	150.27	2.25
Roots & tubers	0.32	0.22	120.51	3.89
Vegetables	0.16	0.36	180.07	3.49
Fish	0.26	0.45	109.11	1.82
Meat	0.37	0.29	95.22	4.65
Fruit	1.11	0.95	188.56	1.57
Milk	1.19	0.88	220.54	1.19
Total	4.69	4.27	1064.28	18.86

Based on the food consumption rates (6) and radionuclide concentration given in Table 1, the annual intakes of ^{238}U, ^{232}Th, ^{40}K and ^{137}Cs are estimated. The total annual intakes of ^{238}U, ^{232}Th, ^{40}K and ^{137}Cs are estimated to be 337.13 Bq, 295.23 Bq, 45240.45 Bq and 686.87

Bq, respectively. Table 2 gives the daily intake of various food items and the daily intake of various radionuclides through the above foodstuffs.The intake rates for Bangladeshi foodstuffs were taken from the food consumption statistics data given in the report (6). Internal doses were estimated from the foodstuffs by multiplying the average concentrations of ^{238}U, ^{232}Th, ^{40}K and ^{137}Cs by the yearly food intake and ingestion dose coefficients. The estimated internal doses are also included in the last column of Table 2. A person receives about 226.24 μSv/y from ^{40}K, 2.09 μSv/y from ^{238}U, 218.01 μSv/y from ^{232}Th and 8.22 μSv/y from ^{137}Cs. The total ingestion dose from the consumption of radioactive foodstuffs due to ^{238}U, ^{232}Th, ^{40}K and ^{137}Cs is estimated to be approximately 454.56 μSv/y.

Table 2. Average annual intakes of radionuclides in the foodstuffs and estimated annual effective dose.

Type of food	Consumption (g/day)	Annual intake of radionuclide (Bq)				Estimated annual effective dose (μSv/y)
		^{238}U	^{232}Th	^{40}K	^{137}Cs	
Cereal	631.7	295.12	258.24	34647.75	518.78	183.20
Roots & tuber	44.8	5.23	3.60	1970.33	63.60	10.67
Vegetables	26.9	1.57	3.54	1768.28	34.27	9.28
Fish	20.3	1.93	3.33	808.51	13.49	4.24
Meat	10.8	1.46	1.14	375.17	18.32	2.11
Fruit	39.6	16.04	13.73	2724.69	22.69	14.09
Milk	36.7	15.94	11.79	2955.23	15.95	15.14
Total	810.8	337.29	295.27	45249.96	687.10	454.56

It should be pointed out that these individual dose estimates are based on measured dietary concentrations of ^{238}U, ^{232}Th, ^{40}K and ^{137}Cs radionuclides, taking into account the assumed dietary habits of the general population in Bangladesh. The contributions of other radionuclides to the individual effective dose equivalent can be considered negligible since their concentrations in foodstuffs were found to be less than the lower detectable activities. The dose from intake of radionuclides by foodstuffs (ingestion dose) in general is so low compared to natural external radiation (2000 μSv/y) that no harmful effects will occur directly.

EVALUATION OF ACTUAL LEVEL OF ^{90}Sr AND ^{137}Cs IN URINE AS INDICATOR FOR INTERNAL CONTAMINATION OF HUMAN BODY IN THE CASE OF NUCLEAR ACCIDENT

LUMINITA ALBULESCU
INSTITUTE OF HYGIENE AND PUBLIC HEALTH
1 - 3 DR. LEONTE, RO - 76256 BUCHAREST, ROMANIA

ABSTRACT

In this work it was determined the urinary contamination with ^{90}Sr and ^{137}Cs as indicator of the exposure of population from Bechet zone to the risk of nuclear accident, created by C.N.E. Koslodui-Bulgaria. Two lots of persons were selected, the first from Bechet zone, situated within 30 km area from Koslodui, and the second from a central zone, Melinesti, situated far at 200-300km from Koslodui. Every lot was formed by 35 healthy persons, males and females, and was structured in this way: of 7 to 9 years old, of 13 to 14 years old, of 17 to 18 years old and after 25 years old. The results obtained and the conclusions that can be drawn about the distribution of these isotopes in urinary daily excretion function by age, sex or distance from C.N.E. Koslodui are presented below.

INTRODUCTION

The twenty years fonction of Nuclear Power Station Koslodui - Bulgaria, situated within 30 km from Bechet - Romania zone, determines a permanent risk of nuclear accident, for the population who lives there (1).

That is why in april 1994, our laboratory was recolted total daily urines samples, from two selected lots of population, one from Bechet zone and the second from the Melinesti control zone, situated far from Koslodui and were determined by radiochemical analysis (2),(3), the daily urinary level of ^{90}Sr and ^{137}Cs, as indicator for internal contamination of human body (4),(5).

RESULTS AND DISCUSSION

It's known, the human internal contamination is a result of environmental contamination, that is why we must specifiy the Chernobyl major nuclear accident (april 1986) who afected our country, Melinesti zone higher and Bechet zone lower.

In this circumstances, the human body contamination and also the urinary contamination with ^{90}Sr and ^{137}Cs must have a same direction in case Nuclear Power Station Koslodui - Bulgaria, was not poluante and Bechet zone was not affected.

Indeed, the results of the determinations presented in table 1 + 4, proves the same report exested after Chernobyl, the urinary contamination with Sr-90 and Cs-137 in the lot of population from Melinesti zone, was higher comparatively with the lot of population from Bechet zone.

So, the ponderate mean value for Sr-90 was in Melinesti population 0,123 Bq/day for female and 0,084 Bq/day for male, comparatively with Bechet population 0,071 Bq/day for female and 0,075 Bq/day for male.

For Cs-137, the ponderate mean value was, in Melinesti population 0,505 Bq/day for female and 0,364 Bq/day for male, comparartively with Bechet population; 0,291 Bq/day for female and 0,207 Bq/day for male.

Also, at all the group of age, the urinary levels of Sr-90 and Cs-137 was higher at Melinesti zone comparatively with Bechet zone.

CONCLUSIONS

The conclusion of the work is, the fonction of C.N.E. Koslodui - Bulgaria, was not modified significant the human body contamination with ^{90}Sr and ^{137}Cs, the urinary level of these isotopes, proved it.

But, also we consider it is necessary to establish a permanent supervise program, determine the urinary contamination with Sr-90 and Cs-137 in Bechet population, special in young people and in children, as indicator for internal contamination of human body, parallel to food and drinking water program.

POOLING TECHNIQUES FOR BIOASSAY SCREENING[1]

L.C. Sun, J.W. Baum, E. Kaplan, and A.R. Moorthy

Brookhaven National Laboratory, Upton NY 11973-5000

ABSTRACT

Pooling techniques commonly are used to increase the throughput of samples used for screening purposes. While advantages of such techniques are increased analytical efficiency and cost savings, the sensitivity of measurements decreases because it is inversely proportional to the number of samples in the pools. Consequently, uncertainties in estimates of dose and risk which are based on the results of pooled samples increase as the number of samples in the pools increases in all applications. However, sensitivities may not be seriously degraded, for example, in urinanalysis, if the samples in the pools are of known time duration, or if the fraction of some attribute of the grab urine samples to that in a 24-hour composite is known (e.g., mass, specific gravity, creatinine, or volume, per 24-h interval). This paper presents square and cube pooling schemes that greatly increase throughput and can considerably reduce analytical costs (on a sample basis). The benefit-cost ratios for 5x5 square and 5x5x5 cube pooling schemes are 2.5 and 8.3, respectively. Three-dimensional and higher arrayed pooling schemes would result in even greater economies; however, significant improvements in analytical sensitivity are required to achieve these advantages. These are various other considerations for designing a pooling scheme, where the number of dimensions and of samples in the optimum array are influenced by: 1) the minimal detectable amount (MDA) of the analytical processes, 2) the screening dose-rate requirements, 3) the maximum masses or volumes of the composite samples that can be analyzed, 4) the information already available from results of composite analysis, and 5) the ability of an analytical system to guard against both false negative and false positive results. Many of these are beyond the scope of this paper but are being evaluated.

INTRODUCTION

Often a large number of samples must be analyzed to screen them for any possible high values. If the costs of analysis are high, it may be cost-effective to combine (pool) several samples and analyze the pool, or a fraction of it, to decide if specific analyses of the individual samples in the pool are justified. In 1987, a fission track analysis (FTA) method was developed at Brookhaven National Laboratory (BNL) (1) and used for plutonium urinalysis for the Marshallese (2,3). Although sample analysis using the FTA method is expensive, because of the FTA's ultra-low level of detection sensitivity, pooling methods given in this paper can be used to increase the throughput of samples, saving both time and money.

POOLING SCHEMES AND TECHNIQUES

In the same available time, square and cube pooling schemes allow a significantly larger throughput of samples than making individual analyses, and hence can considerably reduce analytical costs (on a per sample basis). For a square matrix composite method, a total of N^2 (N is an integer) individual samples can be pooled in batches of 2N single composite samples; the composite samples are pooled from the corresponding rows and columns, respectively. Once all composite samples have been analyzed, no further testing is needed for determining individual dose levels. In a square composite pooling scheme, all rows' and columns' test samples can check and verify for each other. This thesis applies also to a multidimensional pooling scheme. Therefore, the additional advantage of using a square matrix or multidimensional pooling scheme over a simple composite pooling method is reducing the probability for false positive and false negative results.

In a square pooling matrix, the probability of two composite samples, from an intersecting row and an intersecting column, being false positive is p^2. There is a 10% probability of false positives in the existing BNL FTA system established for plutonium dose assessments; therefore, the chance of generating positive results in both a column and row composite urine is reduced to 1% (0.1^2). Similarly, if spike (e.g., calibration) samples are used in a pooling scheme, then the probability of false negative results also can be improved because positive results in each intersecting composite must be identified and be traceable for all spiked samples. Overall, the final

[1]This work was supported by the U.S. Department of Energy under contract No. DE-AC02-76CH00016.

positive results are only accepted as positive, for example, using a square matrix method, when both the row and column composite results are positive simultaneously, and both results also are within a factor of two of each other. The criterion of 2 can be changed according to the precision required of the measurements and the mass balance of plutonium activity in the samples. Therefore, all "non-coincident" row and column or array composite results are to be treated as false positive outcomes and should be eliminated for dose calculations. These include the following three cases: 1) only one out of the ten test samples is positive, 2) only multiple row (or columns) composite test samples are positive, 3) all imbalanced (greater than outside preset limits) plutonium activity in all positive coincident rows and column results.

The square matrix composite pooling approach can be generalized further to three and higher dimensions. Significant improvements in analytical sensitivity would be required for four-dimensional and higher arrays. Table 1 illustrates several options including square, cube, and four (quad) dimension arrays. For example, a 3x3x3 array would allow 27 individual urine samples to be linked using 9 composites, with portions of 9 samples in each composite. Each sample is uniquely identified at the intersection of three composites. Further, the benefit-cost ratios in a 5x5 square matrix and a 5x5x5 cube schemes are 25/10=2.5 and 125/15=8.3, respectively. Three-dimensional arrayed pooling schemes and higher ones would result in even greater economies, as the last column of Table 1 shows. However, significant improvements in analytical sensitivity are required to achieve these advantages. The probability of accepting false positives is reduced as p^n, where n is the dimension of the pooling array. Although we do not expect improvements in the probabilities of avoiding false negatives for screening the maximum individual outcomes, this is unimportant for the FTA system.

Table 1. Multidimensional Pooling Options

Array		No. of Samples	Samples per Composite	Volume of Each Urine Sample	Composites Analyzed	Benefit-Cost Ratio
Dimensions	**Size**					
Square	5x5	25	5	1/5	10	25/10=2.5
Square	10x10	100	10	1/10	20	100/20=5.0
Cube	3x3x3	27	9	1/9	9	27/9=3.0
Cube	4x4x4	64	16	1/16	12	64/12=5.3
Cube	5x5x5	125	25	1/25	15	125/15=8.3
Quad	4x4x4x4	256	64	1/64	16	256/16=16

The number of dimensions and samples in the optimum array is influenced by: 1) the MDA of analytical processes, 2) the maximum masses or volumes of the composite sample that can be managed in the analytical process, 3) the information available from results of previous composite analyses, and 4) the criteria that the analytical system must meet to guard against both false negative and false positive results. Many of these, and other, considerations are beyond the scope of this paper, and are being evaluated for application in future pooling methodologies.

CONCLUSIONS

The main advantage for pooling urine samples (grab or 24-h) for bioassays is increased analytical efficiency and cost savings. The sample's screening power is inversely proportional to the duration of collection of a grab sample, and may be derived from a recommended guideline or a specific protection standard. Using a larger fraction of the collected individual sample lowers the screening goal. In cases where it is necessary to ensure that the dose rate of the maximally exposed individual in the pool is below some fixed value, pooling samples can be a viable option. It must be recognized that interpretations of the results of short-term samples are based on assumptions which require further verification (e.g., a constant rate of diurnal excretion; the ability of approximating the duration of grab samples using measurements of specific gravity or creatinine). There also may be no opportunity for analytical verification because small grab-sample volumes can be quickly depleted in the preliminary stages of pooling.

In general, for designing a pooling scheme, the optimum screening plan will depend on the following parameters: 1) the total number of samples to be analyzed, 2) the sensitivity (MDA) of the analytical method to be used, 3) the cost per sample to be analyzed, and 4) desired screening goals or acceptable sensitivity limit. We are making further studies to optimize this multidimensional approach.

ASSESSMENT OF THORIUM EXCRETION IN URINE BY MEANS OF ICP-MS

INTRODUCTION

Thorium is a primordial element with only radioactive isotopes. It is quite ubiquitous in the earth's crust and small amounts are present in foodstuffs and also in the human body. Whereas ingestion is the main pathway of uptake in non-exposed subjects, incorporation due to occupational exposure occurs most probably by inhalation. A number of industrial applications of thorium are known e.g. in heat resistant materials, welding rods, gas mantles, Mg/Th alloys, thermistors, catalysts etc. Therefore, adequate monitoring of exposed workers is required. Due to its physical characteristics as alpha-emitter and its biokinetic behaviour following incorporation, ^{232}Th is considered as one of the radionuclides with the highest radiotoxicity. Among the methods available for monitoring of the internal thorium content, whole body counting or urine analysis by alpha spectrometry proved to be inadequate to comply with the required detection limits. Interpretation of results of faecal analysis is aggravated by the variation of thorium excretion from natural intake. Up to now, basic data on dietary thorium content and in particular its biokinetics in humans is rather limited. E.g. for the intestinal uptake, the ICRP has adopted an f_1-value of $2 \cdot 10^{-4}$ in its publications N°30 (1) and N°54 (2) and of $5 \cdot 10^{-4}$ in its publications N°56 (3) and N°69 (4). But combining data of Beyer (5) and Riedel (6), for Germany an f_1-value of at least $4 \cdot 10^{-3}$ has to be assumed even under neglect of any endogenous faecal excretion or body accumulation of thorium in adults.

ICP-MS provides a tool for rapid measurement of very low concentrations of thorium in biological fluids. Therefore, in this study the feasibility and sensitivity of ICP-MS for the assessment of renal thorium excretion was investigated. Variation of urinary thorium content was studied in a group of non-exposed persons as well as its day to day variation in a particular subject.

SUBJECTS

A total of 18 healthy volunteers (7 males: mean age 46 ± 11 years (MV ± SD), range 30 to 57 years; 11 females: mean age 42 ± 23 years, range 17 to 84 years) were included in the study. None of them had a history of previous occupational exposure to thorium. The subjects were asked to collect urine for 24 hours under normal habits in polyethylene bottles. After addition of 50 ml/l conc. HNO_3 the urine was stored at 4°C until measurement. Additionally, in one of the subjects complete urine was collected for 6 consecutive days.

PROCEDURE

For the measurements an ICP mass spectrometer ELAN 5000 (Perkin Elmer Sciex) coupled to an AS90 sample changer (Perkin Elmer) was employed. Unprocessed urine was

pumped at a rate of about 0.9 ml/min to a Ryton Chamber. In all measurements a conventional GemTip cross flow nebulizer was used. The plasma flow was set to 15 l/min, the nebulizer flow to 0.95 l/min and the auxiliary flow to 0.8 l/min. Rhenium (^{103}Rh) was taken as internal standard. Standard solutions for thorium and rhenium were obtained from SPEX Ind./USA. Only ultrapure water (Milli-Q, Millipore) and nitric acid distilled by subboiling were required for the analysis. For the determination of thorium concentrations in the urine samples the method of standard additions was employed. Under these conditions a detection limit (3 SD of background signal) of 4 μBq/l urine was achieved for ^{232}Th.

RESULTS

The mean urine volumes obtained for males and females of 1.6 ± 0.5 l and 1.3 ± 0.7 l respectively were in the expected range. For all subjects investigated the mean daily ^{232}Th excretion is 25 ± 14 μBq/day, for males it is 33 ± 14 μBq/day (range 17 to 54 μBq/day) and for females it is 21 ± 9 μBq/day (range 9 to 42 μBq/day). The difference between males and females is statistically not significant. Moreover, the results obtained so far show no clear dependence of ^{232}Th excretion on age (Fig.1). The day to day variation of renal thorium excretion in one subject during 6 consecutive days is shown in Fig.2. The values obtained range from 21 to 52 μBq/day with a mean of 35 μB/day.

DISCUSSION

The interpretation of data obtained for excretion analysis of workers occupationally exposed to primordial radionuclides requires basic knowledge on the natural content and its variation of these radionuclides in faeces and urine. Due to the low f_1-value almost all thorium ingested with food is excreted in faeces i.e. faecal monitoring of occupational thorium exposure is limited by the fluctuations of Th intake from natural sources. Because of the biokinetic behaviour of Th the urinary excretion seems to be more closely related to the Th body content and may therefore be a better measure of occupational Th incorporation. But up to now, only few data are available on urinary Th content of non-exposed persons. Applying 48 h urine collections and alpha spectrometry with 10,000 minutes measuring time, Riedel (6) could obtain a mean excretion of 30 μBq Th per day in normal urine which is in good agreement with the data found in this study. Concentration of ^{232}Th was measured by Dang (7) in the urine of 11 non-exposed subjects by means of neutron activation analysis. From his data a mean daily excretion of 16 ± 6 μBq Th can be derived if a mean volume of 1.4 l urine per day is assumed. The same technique was applied by Hewson (8) on five subjects without history of occupational thorium exposure. While for two of the subjects the urinary thorium concentration was below the detection limit of 4 μBq/l, the mean daily urinary ^{232}Th content of the other three subjects can be estimated at 29 μBq.

Both methods i.e. alpha spectrometry and neutron activation analysis require careful sample processing. They are time-consuming techniques. In contrast, measurements by means of ICP-MS are carried out within few minutes without sample work-up. Moreover, the method shows a good sensitivity and reproducibility for the assessment of thorium concentration in urine. Therefore, the application of ICP-MS offers an attractive alternative for monitoring of thorium body burdens in occupationally exposed subjects and also in larger groups of the general population.

ABSTRACT — Secondary Ion Mass Spectrometry (SIMS) allows a rapid detection of stable or radioactive elements. Based on the erosion of samples by ion bombardment, this technique makes possible the localization and the quantitative assessment of trace elements in biological samples. We have been investigated the feasibility of SIMS to measure long-lived alpha emitters at low concentrations of relevance to the individual monitoring of workers. Special attention has been paid on the preparation of the sample on a thin specimen which was found a critical parameter for this method of analysis. Our preliminary results show that ^{238}U specimen activities below 10^{-4} mBq can rapidly be measured compared with alpha spectrometry.

INTRODUCTION.

For the individual monitoring of workers exposed to the risk of contamination by actinides, conventional methods of analysis are based on the use of nuclear counting techniques, mainly alpha spectrometry. Because of the small range of the alpha particles and their low probability of emission, the use of these methods for the analysis of trace actinides implies a heavy chemical treatment to purify the sample and prepare it on a thin source. Whereas this approach was proved very efficient, a long counting time is generally necessary to reach the low detection limits required. To lower the time of measurement represents a challenge for research to improve routine analysis and especially to provide adequate methods for investigations of accidental situations.

This work was carried out to investigate the feasibility of Secondary Ion Mass Spectrometry (SIMS) as an alternative method for long-lived actinides analysis. This method was developed by R. Castaing and G. Slodzian (1). The application of SIMS is well established in the fields of solid state physics and metallurgy; its application in biomedical research was initially proposed by P. Galle (2). The detection principle is based on the erosion of a sample by ion bombardment which sputters atoms and groups of atoms from its surface. Some of the particles are ejected as charged ones. These secondary ions are collected by an electrical sector and eventually analyzed by a magnetic sector according to their mass charge ratio (Fig.1).

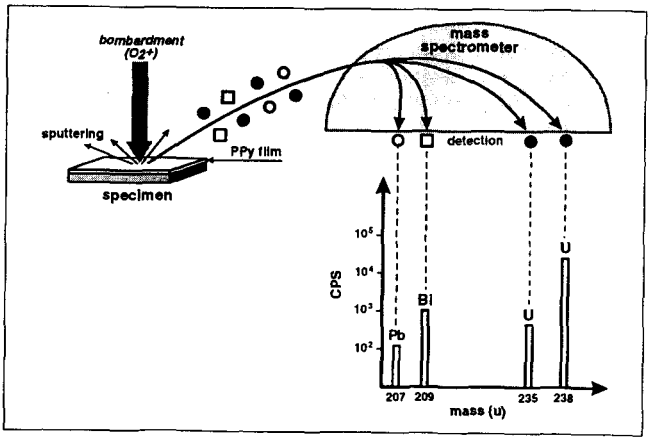

Figure 1 - Schematic representation of SIMS physical principles.

As a major advantage, SIMS is usually coupled to ion microscopy that makes possible to study the localization of a given nuclide in tissue sections. However, as a pure mass spectrometer, it provides also an accurate analytical method. Its mass resolving power, in particular, makes possible accurate determination of the isotopic ratio. In the present work therefore, as a first step to investigate the feasibility of SIMS for bioassay analysis, the isotopic ratio of sources prepared with known amounts of uranium was accurately determined. The performance of SIMS is discussed with respect to alpha spectrometry by comparing the results obtained using both methods for the same specimens.

MATERIALS AND METHODS

Specimen Preparation. Due to the erosion process by ion bombardment, the performance of SIMS critically depends on the properties of the specimen such as chemical composition and thickness. Common problems of mass interference and surface charging effects are respectively related to these two characteristics. Hence, the preparation of the specimens is the first important step for the analysis by SIMS. The use of conventional techniques based on electrodeposition was tested in preliminary experiments and showed inappropriate. In these methods indeed the specimen thickness was too thin for the erosion process to be efficient. Alternative methods needed therefore to be found.

Recent works of M. Carrier et al. (3) and O. Stéphan et al. (4) have demonstrated the viability of the use of functionalized polypyrrole (PPy) films for the preparation of alpha sources. Their method permits the synthesis of PPy films with different thickness to allow sufficient erosion ratio and signal stability. This polymer was selected because of its good incorporation yield for uranium by ion-exchange. For the present work different specimens were produced containing either natural uranium or depleted uranium.

The films was synthesised by electrochemical polymerisation following the same protocol as in reference 3, leading in our conditions to a film thickness of 250 nm. After the electrochemical process, the films, air-dried, were cut in rectangular pieces of 1 cm^2. The films fixed on its support were placed into a solution of 10 ml of oxalate of ammonium acid 10^{-2} M containing known uranium quantities. In this case, the incorporation of uranium is made by anion-exchange with the ammonium groups contained in the PPy.

Alpha Spectrometry. The specimens were previously analysed by alpha spectrometry using silicon surface barrier detector (Eurisys, France). The alpha spectrometry was used to evaluate the incorporation yield of uranium in the PPy films. The specimens measured for the present work contained mass of natural uranium and of depleted uranium in the order of 10^{-8} and 10^{-6} g respectively.

Secondary Ion Mass Spectrometry. A SIMS apparatus (Cameca, France) type IMS 300 was first investigated. This system had a mass resolving power of 300. It was used at the beginning to verify the quality of the specimens and the signal stability for isotopic ratio measurements. However, a system type IMS 4F of a newer generation allowed a mass resolving power better than 1,000. Moreover, the IMS 4F permitted a rapid switching between the masses due to its double-focusing mass spectrometer which allowed a better statistical treatment.

The primary ion beam used oxygen ions O_2^+ with energy of 5 keV to scan a maximum field of 250 μm in diameter. For the measurement of isotopic ratio, a good agreement was observed between measured and theoretical values after up to 5 different scan for a given specimen. A single scan per specimen was therefore assumed sufficient for the present experiments. During such a scan, the mass range of interest was covered several times, the isotopic ratio being obtained as the average over five such cycles. This process provides simultaneously a depth profile of the specimen. This capability was not available using the IMS 300.

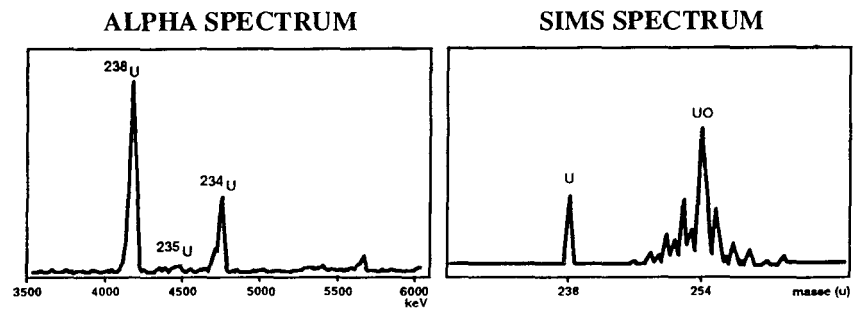

Figure 2. Alpha and mass spectra of the same specimen : depleted uranium with an activity of 17 mBq.

RESULTS

Figure 2 compares the alpha spectrum of a PPy specimen containing 17 mBq of depleted uranium with the mass spectrograph obtained with the IMS 300 for the same specimen. The counting time was 5 days and 1 min for the alpha spectrometry and the SIMS measurement respectively. The standard spectrograph given by the IMS 300 represents the average intensity of the secondary ions. It was sufficient in a first attempt to emphasise the emission of uranium either as monoatomic positive ion ^{238}U (99.6 % in mass) or as a positive ion cluster ^{254}UO. However the peaks of ^{235}U (0.4 %) et ^{234}U (0.0029 %) are not shown on the figure.

Figure 3 shows the depth profile obtained by the IMS 4F for a specimen containing natural uranium (^{238}U=99.28 %, ^{235}U=0.711 %, ^{234}U=0.0059 %) with activity of 0.75 mBq (3 x 10^{-8} g). The IMS 4F is more sensitive due to higher ion collection and transmission efficiencies which permitted the analysis of the three isotopes. Using the switching between the masses of 235 and 238, the average value of the isotopic ratio $^{238}U/^{235}U$ was measured equal to 138.9 in excellent agreement with the theoretical value (139.6). The depth profile shows that this isotopic ratio remains relatively constant with the analysis cycle although the intensity rapidly decreased. Further measurements are currently carried out to assess the overall accuracy of the isotopic ratio measurement depending on the set up of system parameters such as cycle time and primary ion beam energy. As derived from the Figure, the detection of ^{234}U, present in the specimen with the lowest concentration, indicates the low activities which can be analysed with SIMS. To give an order of magnitude, the isotopic ratio ^{234}U / ^{238}U equal to 6 x 10^{-5} lead to a detection limit below 10^{-4} mBq, independent of the isotope.

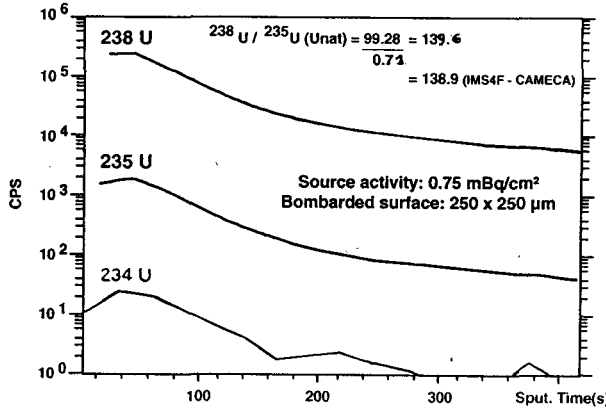

Fig 3 - Depth profile obtained from a specimen containing natural uranium with an activity of 0.75 mBq .

CONCLUSION

This investigation has shown the rapidity of detection using SIMS compared with alpha spectrometry. Whereas further investigations are required to demonstrate the feasibility of this analytical method for accurate determination of specimen activities, the isotopic ratio observed on specimen with known activity and isotopy was found very close to the theoretical value. This indicates the possible application of an internal tracer. Therefore, there is a potential interest for application of the SIMS technique for assessments of internal contamination by analysing long-lived alpha emitters in bioassays. Studies are currently carried out to test the method for analysis of uranium and plutonium in urine samples.

ACKNOWLEDGEMENTS —The authors are grateful to M. Carrier and M. Stéphan (INSTN, France) for the implementation of the PPy technique and are grateful to M. Renard (Cameca, France) for his technical assistance.

ABSTRACT

The design and performance characteristics of a thyroid counter using two NaI(Tl) detectors, with 5.08x5.08 cm and 5.08x0.2 cm crystal sizes, respectively for measuring ^{131}I and ^{125}I are described in this paper. Two neck phantoms and a series of standard sources of each radionuclide were applied for efficiency calibration as well as to investigate the effects of thyroid depth in the neck and the source activities on the responses. The results are reported and discussed.

INTRODUCTION

Internal contamination monitoring of persons occupationally exposed to radioiodine, particularly ^{131}I and ^{125}I, is of great concern in radiation protection. The most common method is thyroid counting by applying different techniques either by using a single NaI (Tl) gamma ray detector connected to a scaler or a multichannel analyzer; or by using two NaI (Tl) detectors operating separately or in a coincidence counting mode for ^{125}I (1-6). Due to a need for a thyroid counter system for monitoring of some workers and a high cost to purchase such a system as well as the availability of the components required, a thyroid monitoring system was designed and constructed at the National Radiation Protection Department (NRPD) of the Atomic Energy Organization of Iran (AEOI). In this paper, the design and performance characteristics of this thyroid counter are presented and discussed.

MATERIALS AND METHODS

Two NaI(Tl) detectors of different sizes including a 5.08x5.08 cm detector (I) with 1.6 mm thick Al window (SPA-3, Eberline) and a 5.08x0.2 cm detector (II) with 0.025 mm Al window (PG-2 Eberline), a scaler (MS-2 Eberline), a collimator and its carrier and a chair were used in this study. The detectors were connected to a single channel analyzer and a scaler. The detector I has been mainly used for ^{131}I although its performance for counting ^{125}I photons has also been studied. The detector II has been used only for measuring ^{125}I. The collimator was designed and constructed in our laboratory, as shown in Figure 1, with a wall thickness of about 2.5 cm of lead except at the front side and lined inside with 1 mm of copper sheet. The calibration of the detectors was carried out by a neck phantom made according to ANSI specifications (7). This phantom is a plexiglass cylinder of 12.7 cm diameter and 12.7 cm height whhich has a cylindrical hole for inserting a polyethylene vessel of 30 ml, as shown also in Figure 1, simulating the thyroid gland. The depth of the vessel inside the phantom is 2.2 cm. The distance between the collimated detector and the phantom surface (counting distance) is 5 cm for both detectors. However for the calibration of the detector II for ^{125}I, an extra distance of 10 cm was used by drawing the detector back in the collimator to investigate the effect of counting distance on the detector response. To evaluate the detector efficiency as a function of the amount of activity in the thyroid, for selected counting distances, a series of standard sources of each nuclide with a range of activities from 0.03 to 200 kBq for ^{131}I and from 0.7 to 320 kBq for ^{125}I were used. To evaluate the influence of the thyroid depth in the neck on the counting efficiency, at selected

counting distances, a cylindrical vessel made of plexiglass with dimensions similar to ANSI phantom and filled with water was applied. The depth of thyroid simulator in this water phantom was ranged from 1.9 to 3.4 cm in 5 mm intervals.

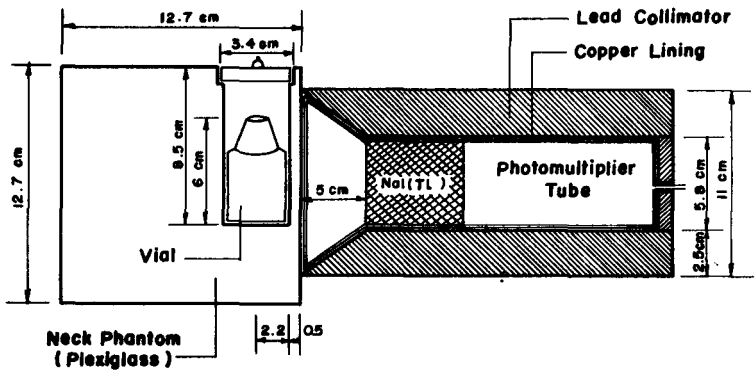

Fig. 1 The schematic diagram of the detector inside the collimator designed and constructed at the NRPD, AEOI.

RESULTS AND DISCUSSION

Figure 2 shows the calibration curves of the detectors for ^{131}I and ^{125}I. Each curve represents the net count rate of the detector as functions of the activity in polyethylene vessel in the neck phantom. The net count rate due to a minimum detectable activity (MDA) for the detector and nuclide of interest is also shown as the first starting point in each curve. The MDA values are calculated based on statistical error of the background count rate of the detectors in counting windows of interest, with a 95% confidence level and 5 minute counting period. As shown in Fig. 2, the calibration curve for each detector and nuclide of interest is linear up to a certain amount of activity (nearly 60 kBq for ^{131}I and 100 kBq for ^{125}I for a 5 cm counting distance). Increasing the counting distance of detector II from 5 to 10 cm, as shown in Fig. 2, resulted in a significant extension of linearity of the calibration curve for ^{125}I from 100 to 320 kBq. The use of stronger sources than those specified in the calibration curves, particularly for 5 cm counting distance, resulted in gradual reduction of counting efficiency of the detectors for both radionuclides. It appears that the reductions are due to dead-time losses in the count rates of the detectors which are not corrected by the scaler. Also as shown in Fig. 2, the MDA value for ^{125}I with detector II due to a higher efficiency and much lower background count rate is about 12 times lower than that of the detector I, for the same counting conditions.

Figure 3 shows the variation of the counting efficiency of the detectors for both radionulides as functions of the depth of the polyethylene vessel in the water phantom, as well as the efficiency values for average depth. Such variations, as shown in Fig. 3, are of more significance for ^{125}I than those for ^{131}I particularly for the 5 cm counting distance (nearly 20% for ^{125}I against 5% for ^{131} I for a 3 mm relative to average depth). In addition, increasing the counting distance from 5 to 10 cm for detector II for ^{125}I results in the reduction of efficiency variation with source depth in the phantom. So, it can be concluded that the use of relatively large counting distances makes the response of detector less dependent on the anatomical features of the thyroid including its depth in the neck as well as the amount of activity in the gland; i.e. the measurement accuracy can be very much improved. Of course the efficiency and therefore measurement sensitivity will be reduced with increasing the distance.

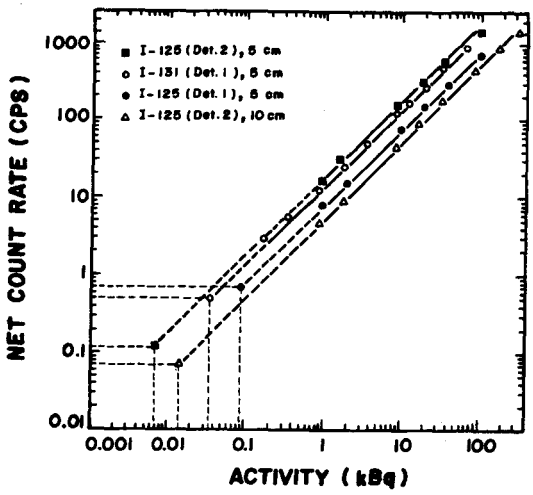

Figure 2. Calibration curves of the detectors for ^{131}I and ^{125}I.

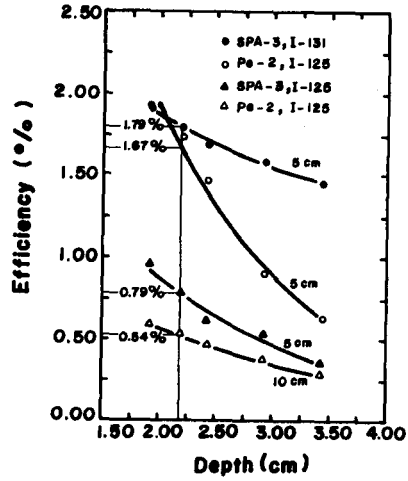

Figure 3. Efficiency of the detectors as functions of vessel depth in the phantom.

CONCLUSION

The above studies show that among the two detectors, detector I and II are respectively appropriate for ^{131}I and for ^{125}I. The use of relatively short counting distances although is appropriate from efficiency point of view, it makes the efficiency of the detectors more dependent on anatomical variations of the thyroid among the individuals particularly for ^{125}I. Therefore, the use of very large counting distances over 10 cm improves the measurement accuracy. Of course for ^{131}I, this problem is not very critical. This monitoring system in general showed to be very practical for our applications and it has been in routine use for near 2 years the results of which will be reported elsewhere.

DEVELOPMENT OF THYROID MONITORING SYSTEM FOR RADIOIODINE IN THYROID GLAND

Hideki HANGAI and Seiichi MIZUSHITA

Japan Atomic Energy Research Institute
Tokai-mura, Naka-gun, Ibaraki-ken, Japan

ABSTRACT

A thyroid monitoring system consisting of a high-purity germanium (HPGe) detector and a spectrometry unit has been developed for measurement of thyroid radioiodines which could be released in nuclear accidents.

We report the characteristics of the system and results of the calibration experiment used realistic neck phantom and ORINS type IAEA phantom.

INTRODUCTION

In the early stage of the nuclear accidents, several radioiodines, such as ^{131}I, ^{132}I, ^{133}I, ^{134}I, and ^{135}I could be released together with other radionuclides. The mixture of these iodines varies from dependency on the time after the accident, fuel type, burn-up of fuel and protective measures of a reactor. These radioiodines in the thyroid are predominant cause of the exposure to the public in the early stage, and countermeasures such as sheltering or iodine prophylaxis should be considered. So, the evaluation of thyroid dose is very important for the risk assessment and medical treatment in point, and it is necessary to measure the thyroid burden of each radioiodine for individual dose estimates. The monitoring of iodines in the thyroid are made using lots of portable counters, such as NaI(Tl) thyroid detector (or even GM counters) in hospitals or nuclear institute. These counters should be calibrated correctly for these nuclides, and then the precise monitor for this calibration purpose is needed to be introduced and studied.

EXPERIMENTS

We developed a thyroid monitoring system consisting of a high resolution HPGe detector and a spectrometry unit in portable size as illustrated in Figure 1, and the spectrometry unit makes it possible to transport the system to monitoring places, hospitals and sheltering places. The HPGe detector is surface barrier type with 2 inch diameter and 2cm thickness for low energy photon detection, which is housed in a designed lead collimator of cylindrical shape of the 1 inch thickness. This collimator shields effectively background radiations from the body excluding a thyroid, and it makes the counting response of the detector uniform.

The high resolution detector makes it possible to identify gamma rays from the above nuclides separately and then to estimate the reasonable thyroid doses caused by these isotopes which offer a proper calibration factor the other counters such as GM counter used for actual thyroid iodine measurement of people. The energy resolutions obtained for gamma rays of 122 keV for ^{57}Co, 284 keV and 364 keV for ^{131}I are 0.67 keV, 1.18 keV and 1.25 keV respectively. Figure 2 shows characteristics of the isoresponce curve for different size collimators.

The present study for the calibration of the monitor is made using two phantoms, realistic neck phantom and ORINS type IAEA phantom of adult size. The realistic neck phantom (Photo 1) is made of tissue equivalent substitute for gamma rays and the thyroid model is made of plastic vessel of 20 ml volume for adult size. The obtained detection efficiency for ^{131}I is compared with 3 inch NaI(Tl) detector as shown in Table 1 for two different adult thyroid phantoms, in which 364 keV gamma ray used for evaluation and the distance between detector surfaces and neck surfaces is 5 mm.

CONCLUSION

Nevertheless its relatively low efficiency compared with NaI(Tl) detector, the HPGe detector has an advantage of high resolution which enables to get the proper calibration factor for mixed radioiodine in accident cases, and supports the monitoring of thyroid iodine of the people. Comparing the results for the two phantoms, we found that ORINS phantom is adequate enough for such a monitoring purpose.

ABSTRACT

ICRP-67 gave the age-dependent dose coefficients to the members of the public from ingestion of most radiologically significant radionuclides taking into account the various anatomical and physiological characteristics of ICRP Reference Man, Child and Infant. In this regard, Indians differ significantly from their ICRP counterpart. In this paper, efforts have been made to estimate effective dose from ingestion of some radionuclides viz. ^{95}Zr, ^{95}Nb, ^{132}I and ^{134}Cs taking into consideration the organ weights of Indian adult and children of various age groups. The effective dose estimates have been found to be marginally higher as compared to the corresponding values for their ICRP conterpart.

INTRODUCTION

Radiation dose to members of the public from ingestion of most radiologically significant radionuclides, that might be released to the environment due to various human activities are given in ICRP - 67 (1). The ingestion dose coefficients for various organs and tissues have been computed taking into account the various anatomical and physiological characteristics of ICRP Reference Man, Child of various age groups and Infant. In this regard, Indian population differs significantly from their ICRP counterpart (2-4). In the present study, efforts have been made to estimate effective dose from ingestion of some radionuclides viz. ^{95}Zr, ^{95}Nb, ^{132}I and ^{134}Cs for Indian adult and childern of various age groups. These effective doses have been compared with the corresponding values as given by ICRP-67.

METHODOLOGY

The weight of five organs, namely, brain, kidney, liver, lungs and spleen was obtained from postmortem records of 3000 accident death cases in Indian population including children of various age groups (3). These organ weights were utilised to estimate dose coefficients in Indian population of various age groups namely 1y, 5y, 10y, 15y and adult by computing the dose transformation factors (DTF) for different organs using the method

suggested by Yamaguchi (5). The dose coefficients to various organs as given in ICRP-67 are multiplied by the corresponding dose transformation factors to give the revised dose estimates for the organs in the Indian population. In the present study, the effective dose has been estimated from ingestion of four radionuclides viz. ^{95}Zr, ^{95}Nb, ^{132}I and ^{134}Cs. The dose transformation factors for the various organs have been estimated for the principal gamma energy emitted by these radionuclides. Thymus is taken as a surrogate to oesophagus. The contribution to the effective dose from thymus as one of the remainder organs is not taken into account as its contribution has been already included while considering contribution from oesophagus. The equivalent dose to colon and gonads is computed in the manner similar to that adopted by ICRP-67 (1).

The effective dose was computed from ingestion of various radionuclides for Indian population utilising the transformation factors as computed for five selected organs mentioned above. For the other organs, if the weight of the organ is less than or equal to 20 g, DTF is taken as 1 and for the others, DTF has been computed considering the organ masses to be proportional to the body weight. For comparison, the relative difference between the E values for ICRP population to that of Indian counterpart has been worked out and expressed as %age change.

Table 1. Effective dose from ingestion of radionuclides

Effective dose(Sv/Bq)	Age at Intake				
	1y	5y	10y	15y	Adult
^{95}Zr					
E_1	5.7E-9	3.1E-9	1.9E-9	1.2E-9	9.6E-10
E_2	6.4E-9	3.7E-9	2.4E-9	1.4E-9	1.1E- 9
^{95}Nb					
E_1	3.2E-9	1.8E-9	1.2E-9	7.4E-10	5.9E-10
E_2	3.5E-9	2.1E-9	1.4E-9	8.4E-10	6.7E-10
^{132}I					
E_1	2.4E-9	1.3E-9	6.2E-10	4.2E-10	2.9E-10
E_2	2.5E-9	1.4E-9	6.7E-10	4.5E-10	3.1E-10
^{134}Cs					
E_1	1.6E-8	1.3E-8	1.4E-8	1.9E-8	1.9E-8
E_2	1.7E-8	1.4E-8	1.5E-8	2.0E-8	2.0E-8

E_1 : Effective dose as given by ICRP-67 (1)
E_2 : Effective dose estimates for Indian population

Table 2. Relative Difference in Effective Dose Estimates for Indians to that of ICRP Population (%

Radionuclide	Age at Intake				
	1y	5y	10y	15y	Adult
^{95}Zr	10.9	19.4	26.3	16.7	14.6
^{95}Nb	9.4	16.7	16.7	13.5	11.9
^{132}I	4.2	7.7	8.1	7.1	6.9
^{134}Cs	6.3	7.7	7.1	5.3	5.3

RESULTS & DISCUSSION

Table 1 gives the effective dose (E_1) as given by ICRP-67 and the estimated value of ^{95}Zr, ^{95}Nb, ^{132}I and ^{134}Cs. Table 2 gives the %age change in effective dose estimates for Indian population as compared to the effective dose values for ICRP population. In case of ^{95}Zr and ^{95}Nb, an increase of 9-26% in effective dose values is found as the maximum contribution comes from colon whose DTF is computed considering its mass proportional to body weight. However, in case of ^{132}I and ^{134}Cs, the increase in E values are less (4-8%). In case of ^{132}, the increase in E values is less as the maximum contribution to comes from thyroid, whose weight in Indians is considered to be the same as that of ICRP counterpart. However, the dose coefficients for ^{134}Cs is nearly same in all organs.The effective dose estimates for Indian adult and childern of various age groups are higher than their ICRP counterpart as the organ masses in Indians are smaller as compared to ICRP.

In conclusion, it may be said that the revised effective dose estimates for Indian adult and child of various age groups were marginally higher as compared to the corresponding values for their ICRP counterpart for the four radionuclides considered.

INTRODUCTION

The world-wide radiation protection concerns that followed the Chernobyl accident created an increased need for basic data to assess internal doses to members of the public in each country. Therefore, the Reference Asian Man Programme was proposed by Japan and initiated as a part of the IAEA Regional Cooperative Agreement Project for Strengthening Radiation Protection Infrastructure to coincide with the revision of Reference Man data by ICRP Committee 2 (1, 2, 3).

The first priority was given to compilation of data on physique, and mass of internal organs where possible, for populations throughout the Asian region. Data on daily consumption of foods and nutrients were also emphasized since they are important components of the ingestion pathway for uptake of radionuclides by humans. Pulmonary function and water balance parameters were considered important in relation to the inhalation pathway and water contamination (4). The programme was also endorsed by ICRP.

MATERIALS AND METHODS

Physical measurements

Data on the body height and weight, sitting height, head and neck circumference, and circumference, width and depth of the chest were compiled or measured in 9 countries. Age ranges assigned were the newborn, 1, 5, 10, 15 and 20-50y (2, 4) which apply to all types of data in the CRP. The source of data was recent national statistics (e. g. school health statistics, national nutrition survey, etc.), relevant scientific papers or specific measureent programme. The sample size ranged from 865 to 1.01×10^6.

Organ mass measurements

Masses of the brain, heart, kidney, liver, lung, pancreas, pituitary gland, spleen, testis, thymus and thyroid gland in the male, and the above and the breast and ovary in the female were studied in 7 countries, 4 of which also compiled data on relative weights of individual organs to the body weight. The m ain partof the potocol was as follows: autopsy should be carried out by qualified medical doctors within 24 h after sudden deaths and with exclusion of data showing any pathological changes which affect normal weights of internal organs. Data were obtained from a medical examiner's office, forensic departments, medical colleges and hospitals. The number of cases ranged from 155 to some more than 20, 000.

Nutritional data

The daily dietary intake of categorized foods (cereals, pulses, potatoes, vegetables, fats and oils, fish and shellfish, meats, milk and milk products, etc.) and principal nutrients (carbohydrate, protein, fat or lipid, energy) were studied in 8 countries using national statistics and special programs of limited scales. Determination of elements for intake study was left to each country due to available resources and manpower.

Physiological parameters

The vital capacity, total lung capacity, minute volume and 8-hr working volume were studied in 4 countries, for different age groups and three activity levels, mostly in hospital personnel and university students. Other data were extracted from routine medical examination files or from executive check-ups. For water balance, measurement was carried out on the 24-hr intake and elimination of water in the urine, sweat, breath and faeces, in healthy volunteer subjects also in 4 countries.

RESULTS AND DISCUSSION

Physical measurements

Some of the compiled data on physical measurement, e. g. body height, weight and sitting heiht are shown in Table 1. Mean and population-weighted mean, range and rounded mid-point for height and weight in the adult male and female were also obtained. Most participants agreed that the range mid-points would

Table 1. National means of body height, weight and sitting height of the adult (20-50y)

		BAN	CHI	IND	JPN	KOR	PKS	PHI	VIE	Midpoint *
Male	Height (cm)	163. 9	169. 2	163. 4	167. 8	166. 8	170. 6	163. 4	163. 8	167. 0
	Weight (kg)	57. 8	58. 3	51. 5	63. 6	63. 8	63. 9	56. 6	51. 8	57. 7
	Sitting ht. (cm)	85. 7	91. 8	85. 8	89. 4	90. 1	-	86. 0	86. 2	88. 8
Female	Height (cm)	154. 9	158. 2	151. 0	155. 0	154. 9	157. 5	151. 3	154. 0	154. 62
	Weight (cm)	49. 9	51. 1	44. 2	52. 3	54. 5	52. 6	49. 2	46. 8	49. 4
	Sitting ht. (cm)	80. 6	86. 2	80. 0	84. 1	83. 9	-	80. 3	81. 2	83. 1

*) Including Indonesia.

represent most reasonable compromise if a single value is to be used in practical aspects. These results on heights and weights were compared with those of revised ICRP Reference Man, 170cm and 73kg for the male and 163cm and 60kg for the female. In revised Tanaka Model, these are 170cm and 60kg, and 160 cm and 51kg in the adult male and female, respectively.

For intra-regional variation, the data might be grouped in the two: (a) China, Japan, Korea and Pakistan, and (b) Bangladesh, India, Philippines and Vietnam. For instance, the average body height is 5cm higher in the former group (168. 6cm) than the latter (163. 6cm). The lower mean height and weight from developing countries are attributable to a large proportion of the populations having various degrees of undernutrition. Secular trends in the body height and weight were noticed for Japan, China, Korea during the last decades. Assuming secular trends of 1-1. 5cm in 10 years for height during the period from 1985 to 2005, possible reference values would be 169-170cm for the adult male, and 157-158cm for the female.

Organ mass measurements

Mean and S. D. s of organ masses in the adult were calculated to compare the results with values of the ICRP Reference Man and Tanaka Model and some of the data are shown in Table 2. Accuracy of measurement can be adversely affected by several factors (presence of blood, remaining extraneous tissues, delay in post-mortem measurement, etc.). The brain mass in the male had a mean of 1361 g with a small variation (RSD 5. 7%) as the testis, 33. 6g (RSD 5. 4%); the liver and lung showed a mean (RSD), 1429g (17. 8 %) and 976g(20. 1%), respectively. Mass of the thyroid gland widely varied from 16. 8 to 35. 5g and from 16. 8 to 36. 0g for the male and female, respectively, which may presumably be associated with variation in natural iodine intakes.

Table 2. Reported means of mass of the brain, liver and thyroid gland in the adult (20-50y), g

		CHI	IND	IDN	JPN	KOR	PHI	VIE	Reference Man	Tanaka Model
Male	Brain	1433	1236	1345	1442	-	1387	1321	1400	1470
	Liver	1357	1135	1156	1599	1864	1472	1418	1800	1600
	Thyroid	27.4	19	16.8	18.8	-	22	35.5	20	19
Female	Brain	1317	1140	1203	1309	-	1321	1284	1200	1320
	Liver	1272	1051	1115	1345	1611	1361	1319	1400	1368
	Thyroid	26.6	-	17.8	16.8	-	30	36	17	17

In the male, ten organs showed comparable or smaller masses than those for ICRP Reference Man while the pancreas and thyroid weights were larger than the Reference Man's. In the female, the mean mass -es ofeight organs were smaller than or comparable to Reference Woman's while larger for the brain, heart, pancreas, thyroid and adrenal gland. Influences of general nutritional conditions on masses of organs were also shown in the systematic study for normal Japanese (5).

Mean fractional masses reported for many organs by Japan, India and China may indicate a little lrger contribution of such organs to the total body weight in Asian populations than in Westerners.

Nutritional data

Daily consumption of cereal varied from 171 to 520g as compared with 207g for Reference Man. That for meat, milk and milk products, was 12-172 and 9-147g, respectively (5 countries) in contrast to 228g and 508g, respectively in Western European and North American countries. Fat or lipid is much less consumed in the diet (15.8-56.2g against 120g in the Western diet). The levels of calcium intake reported were approximately one half of that for Reference Man. Information on intake of 9 other elements was also obtained.

Physiological parameters

Total lung capacity ranged 4.43-5.76 liters (range mid-point 5.10) and 3.28-4.40 (3.84) liters in the male and female, respectively; mid-point of minute volume being 6.6 and 5.1 l/min in 5 countries. These are approx. 85-91% of the corresponding ICRP values. Water intake ranged from 3.31-4.53 (mid-point 3.53) l/d in the male and 2.14-3.60 (2.87) l/d in the female among 4 countries as compared with 3.00 and 2.10 l/d of Reference Man and Woman. Measurement of water balance was made difficult due to multitude of mechanisms for elimination. The particular values and pathways are dependent on ambient and environmental conditions. This is important in the tropical conditions that are prevalent in many Asian countries.

CONCLUSION

A great amount of data on physical measurements was accumulated in this research programme along with essential information on the organ masses in Asian populations was obtained, that are useful for internal dosimetry. Data on consumption offood groups, principal nutrients and some elements was provided, suggesting typical Asian dietary habits. Some information on pulmonary function and water balance was also obtained. The results of the CRP also contributed to revision of ICRP Reference Man.

However, due to limited physiological and metabolic data, intake of elements of importance in radiation protection, representative of each populations, particularly need to be studied further.

ABSTRACT (See instructions overleaf)

A significantly large contribution of the organically bound tritium (OBT) to the total absorbed dose in human body after tritium intake has been emphasized by many authors. In the present research, an animal experiment using mice was performed to find possible correlation between the tritium level in the blood and that averaged for the total body after intake of OBT. A mixture solution of five tritiated amino-acids was administered to male DDY mice and the tritium level in the blood, urine, total body, spleen, liver , brain, kidney and testis was determined after various periods. It was found that there is a strong correlation between the tritium level in the blood and the body-averaged tritium concentration. The accumulated dose that is estimated on the basis of the blood tritium level gave a conservative estimation for the body-average accumulated dose. The dose commitment estimated from the tritium level in the urine gave an estimated dose for 55 days periods which is about 60 percent of the body-averaged dose.

ELECTRON PROBE X-RAY MICROANALYSIS OF INHALED (UO_2, PuO_2) MIXED OXYDES IN ALVEOLAR MACROPHAGES OBSERVED *IN TOTO*

Philippe Massiot, P. Fristch, H. LeNaour, G. Rateau, C. Lizon and I. L'hullier

CEA/DSV/DRR/SRCA, Laboratoire de RadioToxicologie, BP 12, 91680 Bruyères-le-Châtel France

INTRODUCTION

Microanalysis has been mainly used to characterize chemical composition of uranium compounds retained *in vivo* (1) but, to our knowledge, similar experimental approach on other actinides has not yet been performed. However, some results are available on native (UO_2, PuO_2) mixed oxyde powders containing 18 % Pu which corresponded to a solid solution of $(U, Pu)O_{1,96}$ (2). We have previously shown that chemical composition of mineral particles phagocytosed by alveolar macrophages can be performed on entire cells by using transmission electron microscopy and energy dispersive X-ray microanalysis (EDX) (3). The aim of this work was to study the chemical composition of inhaled particules in alveolar macrophages observed *in toto* after exposure of rats to (UO_2, PuO_2) mixed oxyde aerosols containing 5.3 % Pu.

MATERIAL AND METHODS

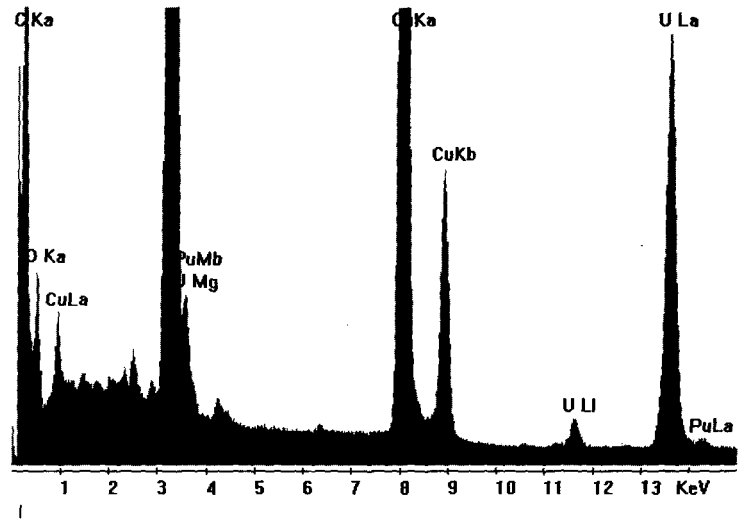
Male Sprague-Dawley rats were exposed at 3 months of age to (UO_2, PuO_2) mixed oxydes aerosols as previously described (4). Animals were killed during the first week after exposure under pentobarbital anesthesia (40 mg/kg). Lungs were lavaged by repeated instillations of 5 ml NaCl 0.9 % until a total volume of 20 ml had been collected. Cells from 0,4 ml of the lavage fluid were put on collodium coated slides using a cytospin. They were fixed during 30 minutes in 70% ethanol and the collodium film was put on 300 mesh copper grids which were coated with carbon.

Entire cells were observed with a CM200 Philips electron microscope at 200 kV with the scanning transmission mode. Microanalysis was performed using EDAX silicon detector with the super Utw window which allowed us to detect any element with atomic number down to that of beryllium. Most of the EDX analysis were performed at a 300.000 magnification using a spot size of 14 nm.

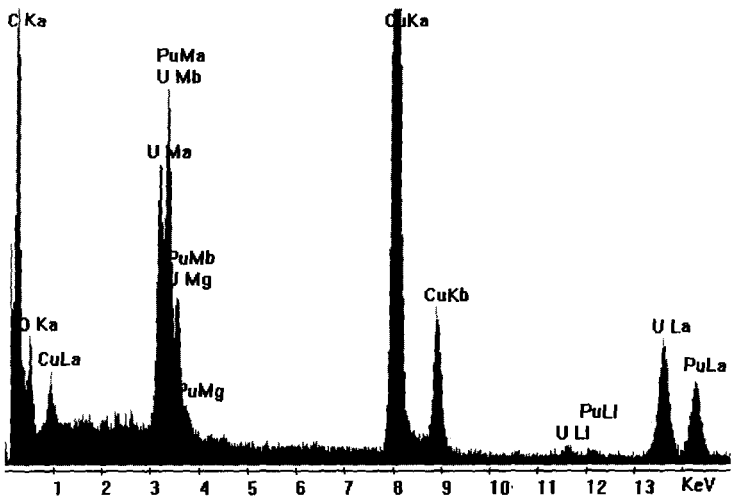
RESULTS

Preliminary EDX analysis were performed on either uranyl hydroxyde particles directly deposited on coated grids or on unexposed alveolar macrophages. The spectra obtained for particles have shown specific rays of U without any Pu-ray whereas, no specific U or Pu-ray was observed in control alveolar macrophages.

After exposure to (UO_2, PuO_2) mixed oxydes, most of the particles had a diameter less than 0.3 µm and were clearly identified at magnifications down to 5000 with high-angle annular dark-field observation. This was due to the discrimination according to the atomic number of the elements using this "dark field" observation mode which provided more contrasted images than usual "bright field" observation mode.



1A



1B

Figure 1: example of EDX spectra obtained on two different (UO_2,PuO_2) particles

Figure 1 shows spectra observed on two different (UO_2, PuO_2) mixed oxyde particles. Only energies up to 15 keV are shown in which specific Mα, Mβ, Mγ and Lα rays of actinides are encountered. In this energy range, specific Kα and Kβ Cu-rays are also observed and correspond to the background due to the chemical composition of the grid. Both actinide specific rays can be observed but the U-Mβ and the Pu-Mα, and the U-Mγ and the Pu-Mβ are superposed. The Lα-ray intensity values of Pu and U allowed to estimate the actual relative concentration of these actinides within the particle. In Figure 1A, the U/U+Pu ratio is about 0.95 which corresponds to the expected composition of the mixed oxyde studied. However, for some particles, a quite different ratio was measured as for example in Figure 1B, with a ratio at about 0.6. This phenomenon could be observed according to the particle analysed and even according to the site analysed within the same particle.

Spectra up to 2 keV, including usual organic elements were not very different if they were performed in the alveolar macrophage on or out of the particle and contained the specific rays for C, O, N, S, P... which were due to the presence of the biological matrix.

DISCUSSION

These preliminary results demonstrate that EDX is a useful tool to characterize the chemical composition of inhaled particles containing actinides especially (UO_2, PuO_2) mixed oxydes. Because the measurements are performed on alveolar macrophage observed *in toto,* quantitative results are easily obtained for experimental purposes in rodents but could also be obtained in primates. Moreover, this analysis is potentialy possible on humans after pulmonary lavage without any technical modification. However, these measurements need very specialized and costly equipment and are very time consuming.

Because particles are within a biological matrix, the experimental procedure used did not allow us to determine the actual chemical composition of the particle including O and other element which could be part of the particle once it has been phagocytosed such as phosphorus for example. Further studies are in progress in order to extract phagocytosed particles for determination of their actual chemical composition

These preliminary results obtained with mixed (UO_2, PuO_2) oxydes i.e. apparent heterogeneous distribution of Pu, are difficult to explain. Other experiments are needed including mapping of actinides and autoradiography which are in progress. Thus, once these complementary methods will be available, our experimental approach might be usefull both to characterize experimentally, the behaviour of any inhaled actinide oxyde or mixed oxyde and to analyse human samples.

THE AUGER ELECTRON EFFECT IN RADIATION DOSIMETRY - A REVIEW

Lars Persson, Swedish Radiation Protection Institute,
S-17116 Stockholm, Sweden

ABSTRACT

Radionuclides that emit Auger electrons are widely used in nuclear medicine and biomedical research. The Auger emitting radionuclides give off a cascade of low energy electrons, the total energy of which is deposited within some nanometers; the local dose is therefore very high. If the radionuclide is part of a chemical compund which forms a DNA base analogue or which preferentially enters the cell nucleus, the biological effects of the Auger electrons to the DNA or the nucleus can be as severe as from high-LET alpha particles. Neither the recommendations of the International Commission on Radiological Protection (ICRP) in Publication No. 60, nor the International Basic Safety Standards for Protection against Ionizing Radiation and for the Safety of Radiation Sources provide any guidance on calculating the equivalent dose for these radionuclides. For the radiation weighting factor of electrons (value 1) they recommend excluding the Auger electrons emitted from nuclei bound to DNA. However, recently a Task Group of the American Association of Physicists in Medicine (AAPM) has proposed that the component of dose from the Auger electrons for radionuclides bound to DNA be given a preliminary radiation weighting factor of of 10 for deterministic effects and 20 for stochastic effects. The dose equivalent calculated with these weighting factors must be modulated by experimentally determined subcellular distributions.

INTRODUCTION

Radionuclides that emit a high proportion of Auger electrons are widely used in nuclear medicine (e.g. ^{99m}Tc, ^{123}I, ^{201}Tl) and biomedical research (e.g. ^{51}Cr, ^{125}I). Natural radioactive isotopes exist with Auger electron emissions (e.g. ^{40}K). In nuclear weapon debris exists inter alia the isotope ^{55}Fe and in the nuclear energy cycle the isotope ^{65}Zn. The dosimetry of Auger electrons and other low energy radiations has been discussed in ICRU Report 32 (1). Recent reviews of the Auger electron effect are found in two articles are by Persson (2,3).

ICRP discussed the Auger electron effect in its Publication No. 60 (4). On page 6, paragraph 26 they state: "Auger electrons emitted from nuclei bound to DNA present a special problem because it is not realistic to average the absorbed dose over the whole mass on DNA as would be required by the present definition of equivalent dose. The effects of Auger electrons have to be assessed using the techniques of microdosimetry". In the International Basic Safety Standards for Protection against Ionizing Radiation and for the Safety of Radiation Sources (5), it is stated that Auger electrons emitted from nuclei to DNA are excluded from the radiation weighting factor of value 1 for electrons of all energies with the remark that special microdosimetric considerations apply.

MEDICAL APPLICATIONS

There appears to be two important issues for Auger electron emitters in medicine. At the root of both is that characteristic of the Auger electron decay: the highly localized irradiation of the surrounding volume. Considerable exposure is delivered to the part of a cell or a macromolecule which is in the vicinity of the decaying nuclide. This on the one hand brings about a problem in risk estimation for nuclear medicine and on the other hand promises of a selective attack on cancer cells: "molecular surgery".

The following isotopes (normally bonded in a chemical compound) are of special interest in nuclear medicine as Auger electron emitters: ^{51}Cr, ^{55}Fe, ^{67}Ga, ^{75}Se, ^{77}Br, ^{80m}Br, ^{99m}Tc, ^{110}In, ^{111}In, ^{114m}In, ^{123}I, ^{125}I, ^{145}Sm, ^{193m}Pt, ^{195m}Pt, and ^{201}Tl. Some of these radionuclides may also have a role in cancer treatment.

EXPERIMENTS WITH LIVING CELLS

Rao et al. (6) have studied the radiotoxicity of ^{125}I-iododeoxyuridine (IUdR) by the determination of the survival of spermatogonial cells of mice. Narra et al. (7) studied the same issue by investigating the survival of pre-implantation mouse embryos. Iododeoxyuridine is a thymidine analogue and incorporates into the DNA of proliferating cells. ^{125}I incorporated into DNA was as effective as densely ionizing 5.3 MeV α-particles from

^{210}Po in reducing the sperm head population in mice. The embryo survival curves show that the dose at 37% survival is only about 0.15 Gy for ^{125}IUdR, whereas for 662 keV gamma rays from ^{137}Cs, it is 1.75 Gy. These results are consistent with the observations in mouse testis and cultured cells and point to the need for assessing the radiation risk from incorporated Auger electron emitting radionuclides based on their sub-cellular distribution. Also ^{125}I-labelled DNA binding agents other than ^{125}IUdR have been shown to cause severe damage to the DNA molecule, as discussed by Ludwikow et al. (8).

EQUIVALENT DOSE FOR AUGER ELECTRON EMITTERS

Howell et al. (9) stated: "Depending on the subcellular distribution of the radionuclide, the biological effects caused by tissue-incorporated Auger emitters can be as severe as those from high-LET alpha-particles. However, the recently adopted recommendations of the International Commission on Radiological Protection (4) provide no guidance with regard to calculating the equivalent dose for these radionuclides. The present work, using spermatogenesis in mouse testis as the experimental model, shows that the lethality of the prolific Auger emitter ^{125}I is linearly dependent on the fraction of the radioactivity in the organ that is bound to DNA. This suggests that the equivalent dose for Auger emitters may have a similar linear dependence. Accordingly, a formalism for calculating the equivalent dose for Auger emitters is advanced within the ICRP framework".

The equivalent dose in an organ or tissue T is defined as $H_T = w_R \cdot D_{T,R}$, where w_R is the radiation weighing factor, and $D_{T,R}$ is the absorbed dose in the tissue from radiation R. For a mixed radiation field, such as those generated by many radionuclides including Auger emitters,

$$H_T = \sum_R w_R \cdot D_{T,R} . \qquad (1)$$

Howell et al. (9) propose that the equivalent dose specifically for the Auger electrons may be expressed as:

$$H_{T,R(Auger)} = (1 + f_o(w_{R(Auger)} - 1)) \sum_{R(Auger)} D_{T,R} . \qquad (2)$$

where f_o is the fraction of the radioactivity in the organ bound to DNA. This equation limits appropriately at $f_o = 0$ and $f_o = 1$. Although this equation is fundamentally sound, separation of the biological effects of the Auger electrons from those of other radiations emitted by the radionuclide is not possible experimentally because the observed RBE values are for the composite spectrum of emissions. Therefore, it is difficult to assign a value to w_{Auger} that corresponds directly to measured RBE values.

In Report no. 3 of American Association of Physicists in Medicine - AAPM - Nuclear Medicine Task Group no. 6 methods of Auger electron dosimetry at the DNA, cellular, multicellular, and organ level are discussed (10). This Task Group recommends a preliminary value of 10 be used for $w_{R(Auger)}$ in equation (2) to obtain the deterministic equivalent dose H_T for prediction of therapeutic outcome and a value of 20 for stochastic effects. The dose equivalent calculated with these radiation factors must be modulated by experimentally determined subcellular distributions. It should be noted that equation (2) is based on experiments where ^{125}I is covalently bound to DNA in the cell nucleus. When the Auger emitter is localized in the nucleus but not covalently bound to DNA, somewhat lower RBE values may be expected. The equivalent dose from the Auger electrons may then be a factor of 2 lower.

Calculations of equivalent dose for Auger electron emitting radionuclides distribution in humans organs have recently been performed (11). These calculations show an increase in the mean equivalent dose for Auger electron emitters when a significant fraction of the organ activity localizes in the DNA.

CONCLUSIONS

The AAPM Task Group (10) recommends use of radiation weighting factors for cellular and organ dosimetry in conjunction with equivalent dose formalism that takes the subcellular distribution distribution of the Auger emitter into account. Based on the currently available radiobiological data which show that the effects caused by the Auger emitters are similar to those of incorporated alpha emitters, a preliminary radiation weighting factor of 10 is recommended for deterministic effects (i.e., cell survival) and a value of 20 is recommended for stochastic effects (i.e., risk assessment for cancer induction). The dose equivalent calculated with these weighting factors must be modulated by experimentally determined subcellular distributions.

There are good reasons to consider the Auger electron effect not only in medical radiation protection of patients but also in the context of annual limits of intake for workers and the public. It may also be prudent to review the current equivalent dose estimates for radiopharmaceuticals labeled with Auger electrons.

Further experimental and theoretical, radiobiological research in the field is advocated by the author. Inter alia studies of survival rates, chromosome aberrations, micronuclei formations, and cell tranformations, performing animal carcinogenic experiments and mathematical modeling are important tools for a deeper understanding of the subcellular structures and also for the processes involved in the interaction of radiation with biological materia. The scientific basis for radiation protection, especially against the Auger emitting isotopes, will then also improve.

SIMPLIFIED EXCRETION FUNCTIONS FOR RECENT RECYCLING BIOKINETIC MODELS

A Khursheed and T P Fell
National Radiological Protection Board, Oxfordshire, United Kingdom

Abstract

Recent trends in biokinetic model development have seen the replacement of a simple, schematic one-way transfer of materials between compartments with more realistic and complex linkages, including "recycling". In its Publications 67 and 69, ICRP proposes the use of such models for Am, Np, Pu, Ba, Ra, Sr, Pb, Fe, Th, U and I. These models have been developed primarily with a view to providing time-dependent organ retention data which may be used as the basis for calculations of effective dose. However, these new models may also be of value in predicting faecal and urinary excretion rates, particularly if models are adapted for non-standard subjects such as children. In this paper simplified functions for organ retention and instantaneous excretion rates are obtained from the above models, and the latter are compared with excretion functions given in ICRP Publication 54[1]. The potential for using future biokinetic models to predict urinary and faecal excretion rates is discussed.

1 Background

The physiologically-based biokinetic models recommended in recent ICRP Publications have the potential for becoming useful tools in bioassay assessments. In most cases, excretion data are fed into the models at a development stage, since such data are relatively abundant. Models therefore carry within them bioassay information obtained from experiment, in addition to physiological information embedded within their formulation. It is possible to adapt the models for non-standard subjects when good physiological data is available. For example, bioassay data is not generally available for children, but copious physiological data does exist, allowing biokinetic models to be adapted for children.

The biokinetic models of ICRP consist of compartments which represent tissue groups of interest, linked by first order kinetics. Calculating retention and excretion from the simple, Bateman[2] type models of ICRP Publication 30[3] is straightforward, as general analytical solutions may be obtained. For models of the type represented by the recent recycling models of ICRP Publications 67[4] and 69[5] however, general solutions are not available and alternative methods are used. In this paper, an exact, eigenvalue method is used, which obtains organ retention functions in the form of the sum of decaying exponentials. These expressions, typically containing as many terms as there are compartments in the models, are reduced to shorter, approximate expressions by a least squares function minimisation procedure[6].

Exact curves of urinary and faecal excretion are obtained from the models of ICRP Publications 67 and 69 for injection of unit quantities of Am, Np, Pu, Ba, Ra, Sr, Pb, I, Fe, Th and U. Simplified excretion function are published elsewhere[7].

2 Results and Discussion

The models may be placed in two main categories; generic actinides, including Am, Np, Pu and Th, and generic alkaline earths, including Ba, Ra, Sr, Pb and U. The models for the remaining elements are treated individually. Plots of the excretion curves show that the functions can depart markedly from those of ICRP Publication 54. These differences are discussed briefly for a few representative elements below.

2.1 Generic actinide models

Urinary excretion rates predicted by the biokinetic models of ICRP Publication 67 for plutonium and americium are on the whole higher than the rates given by ICRP Publication 54, with the difference being particularly marked at times remote from the intake (see figure 1) e.g. for plutonium the difference approaches an order of magnitude at 10,000 days. The Pu data of the earlier report was obtained from experiments with humans by Langham[8] and later animal experiments reported by Durbin[9]. Good recent human volunteer data has become available however[10], and this has been incorporated in the Publication 67 biokinetic model. The rates predicted by the model

are therefore closer to the recent data than those of Publication 54. Faecal excretion rates predicted by the biokinetic models are also characterised by higher rates at times remote from intake (approximately t > 10years), though they do dip noticeably below those of Publication 54 in the range 1 - 100 days. These data, too, are consistent with recent experiments with humans.

2.2 Alkaline Earth models

The elements for which the generic alkaline earth biokinetic model is applied (Sr, Ra, Ba, Pb and U) generally follow the biochemical pathways of calcium in the body. A good deal of human and animal excretion data are available for all of these elements and much of these have been incorporated in the formulation of the models. To take an example, the excretion curves given by the model for strontium are generally similar to those in ICRP Publication 54, but are on the whole smoother (see figure 2). Differences of up to a factor of 3 occur at particular times. Simplified excretion functions given for strontium are so close to the exact functions as to be indistinguishable on a plot.

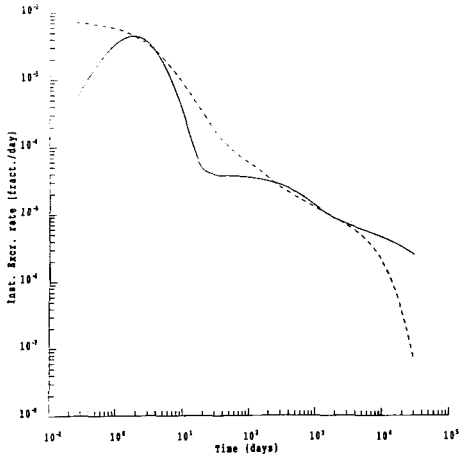

Figure 1 Faecal excretion rate of Pu: ICRP Publication 67 model (solid line) against Publication 54

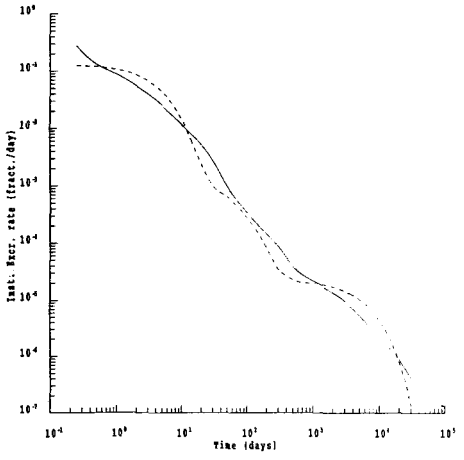

Figure 2 Urinary excretion rate of Sr: ICRP Publication 67 model (solid line) against Publication 54

3 Revised estimates of doses

Upon measuring levels of a radionuclide in urine or faeces at a particular time, a common procedure is to estimate the excretion rates and then use the function/curve for time dependent excretion rates to estimate the size of the original intake of the radionuclide. The latter is then used in conjunction with a dose coefficient to obtain an estimate of the effective dose likely to result from the intake.

From the viewpoint of a user of the excretion functions given in NRPB-M564[7] an important question would seem to be: "Where the new excretion rates differ substantially from the rates of Publication 54, will there also be a substantial differences in doses estimated from bioassay ?". Effective doses are calculated for an observed faecal excretion rate of 200 Bq/day 10 days after an intake of Pu-239 and a urinary excretion rate of 200 Bq/day 30 days after intake of Sr-90 using the excretion curves of both ICRP Publication 54 and the Publication 69 model. The results, given in table 1, demonstrate that the differences in the excretion rates predicted by Publications 54 and 67 are translated to differences in estimations of effective dose. As a general rule, effective dose varies with excretion rate.

Table 1 Effective doses for Pu-239 and Sr-90 following typical bioassay analysis

	Estimated intake Publication 54	Estimated intake Publication 67	Effective dose Publication 30	Effective dose Publication 67
Pu-239	2.22×10^5 Bq	1×10^6 Bq	1.22×10^2 Sv	4.93×10^2 Sv
Sr-90	2×10^5 Bq	6.67×10^4 Bq	17.6×10^{-3} Sv	5.85×10^{-3} Sv

Note that when this procedure for working back to doses is adopted it is necessary to use the appropriate dosimetric model for a particular excretion function. In the example given above, the urinary excretion rates for uranium given in ICRP Publication 54 were obtained from the biokinetic model presented in Publication 30. This same model should therefore be used to estimate the intake and effective dose.

4 Conclusions

Instantaneous excretion rates are obtained for the biokinetic recycling models of ICRP Publications 67 and 69 and are expressed as simple exponential functions. These rates are based on models which have in most cases been adjusted against recent human excretion information and can differ substantially from the rates given in ICRP Publication 54, which were largely obtained from the biokinetic models of Publication 30. It is expected that bioassay analyses utilising the new excretion rate functions will lead to estimations of effective dose which can be substantially different from those that would be obtained from the existing ICRP Publication 54 excretion rates. It is expected that in future more emphasis will be placed on the use of biokinetic models for predicting excretion rates.

ABSTRACT
Specification conditions are suggested here for guiding the work in order to obtain compounds appropriated to in vivo chelation of uranium. The first step will consist in speciation studies of the contaminant in the biological field to determine its biokinetics and the kind of interactions it makes with the biological components. In the second step, structural and modelisation studies will help to determine a potential chelate. The latest step is to ensure that the complex remains stable at physiological pH and to test the decorporating compound in vivo.

INTRODUCTION

Internal contamination with actinides induces radiological toxicity and the current approach to reduce the radiation dose resulting from accidentally-deposited radionuclides is to use a decorporation therapy in order to accelerate excretion and to reduce their binding to target organs.
At the present time, the therapy proposed after uranium contamination is still an infusion with 250 ml of sodium bicarbonate (1.4 %) (1). However, because of the incomplete effectiveness of bicarbonate treatment, the development of more effective substances remains an important aspect of radioprotection. Despite the interesting results already obtained, the decorporation therapy remains not completely satisfactory for some compounds like uranium or caesium, or uneffective for a compound such as neptunium. For these elements, studies are still in progress in order to find a molecule able to chelate them *in vivo* and to enhance their excretion out of the body. Concerning uranium, a lot of work has been done using different compounds like phosphonates or host molecules, but it was not really successful. Some interesting results have been obtained with 3,4,3-LIHOPO but present limitations for further work are due to the fact that this compound is hard to synthetize.
This work emphasizes uranium decorporation and it suggests a methodology for guiding the search for compounds appropriate for *in vivo* chelation.

SPECIATION STUDIES

The speciation studies will concern more specifically the interactions between the radionuclide and the biological components, at the cellular and blood levels and several studies will be necessary such as the *in vivo* speciation of the radionuclide in the main target organs (plasma, kidney and skeleton), and study of mechanisms which govern the uranium chelation.
On one hand, the determination of the chemical form of the complexes between uranium and blood components involves the development of specific analytic tools. The efficiency of capillary electrophoresis is currently tested to determine the chemical form of uranium at the blood level. On the other hand, the determination of the binding to biological ligands mechanisms in order to substitute a chelating agent will allow to optimise the choice of this agent as well as the therapeutic treatment. This work will mainly be done using cell culture models, in order to identify and localise the accepting sites of the radionuclide. Complementary *in vitro* studies devoted to determine the complexation kinetics will be performed.
The determination of the metabolism and pharmacokinetic of the complex is an important point in order to assess whether or not the chelating treatment do not increase the tissue concentration of the radionuclide in some organs other than the target ones. The injection of the complex will allow to determine its *in vivo* stability and biokinetics.

STRUCTURE OF POTENTIAL LIGANDS:

Chemical requirements
Several theoretical studies have already been conducted in order to propose a strategy allowing to find new interesting ligands for decorporation purpose. For some compounds like plutonium, the ratio of the ion charge versus the ionic radius is a value which has been considered to be important (2). Topologic analysis, taking into account the branching of the compounds (Wiener indice) have shown that this factor can also contribute to the decorporation properties (3).

The analysis of this different strategies allowed to propose some specifications adapted to uranium decorporation. According to the chemical properties of the uranyl ion some chemical requirements are of first importance: the diameter of the cavity which the ligand makes has to be sized between 4.7 and 5.2 Angström to complex the uranyl ion. Concerning the complexation type, uranyl ion forms planar equatorial hexacoordination with the ligating atoms. This means that it can form complexes particularly with one hexadentate ligand or two tridentate ligands. For statistical considerations, one hexadentate ligand is preferable considering that it has more chances to complexes with uranium in the body than two tridentates.
Due to its hard acid character, the uranyl ion forms complexes preferentially with hard bases. For that reason, the best binding groups are those containing oxygen.
The complexation constant between the uranyl ion and the ligand has to be high and the ligand has to be very uranium selective, compared to other metals present as traces in the body.

Biolological requirements
Some biological requirements have to be taken into account: after incorporation in the body, the uranyl ion is mainly excreted through the urinary way. The compound complex formed with the ligand has, for this reason, to be hydrosoluble. Moreover, the size of the compound must be appropriate for an easy elimination of the complex. The complex must remain stable at pH values ranging from 5 to 7; this will avoid the dissociation of the complex at blood pH and in the kidneys, leading to the binding of uranium to the membrane phospholipids of the of tubular cells which results in nephrotoxic effect. Moreover, the pK_a of the complexing groups have to be lower than 5 in order to allow the complexation at physiological pH 5 (including in the kidneys). Obviously, the compound has to be non toxic at the effective concentration.

COMPUTER SIMULATION
In addition to the chemical structure studies, we try to collate our experimental results with theoratical calculations using the HYPERCHEM (4) computer model. It could help to screen the potential ligands for uranium faster than physico-chemical studies do. HYPERCHEM allows to calculate the lowest energy levels between differents ligands and a specific metal. We are currently introducing in the model the specific values for uranium force fields, calculated from uranium carbonate and uranium nitrate.
For uranium carbonate, the total energy of the complex was found to be 610.6 $kcal.mol^{-1}$. This value includes different terms mainly due to electrostatic, van der Waals and covalent interactions. For uranium nitrate, the total energy was found to be 523.5 $kcal.mol^{-1}$. These first results have shown that the force field of the uranyl ion determined with the carbonates remains valid with the nitrates. Further tests are needed before using them to screen complexing compounds.

SYNTHESIS OF TRIPODE COMPOUNDS
All this considerations lead us to choose a family of tripode molecules. The theoretical complex which can be formed with the uranyl ion are shown Fig.1,2,3,4.

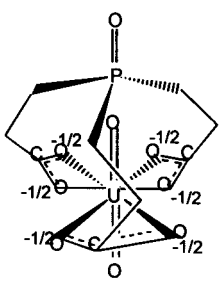

Fig.1: Complex 1/1 with phosphorylated tripode

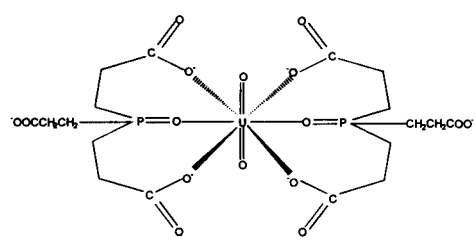

Fig.2: complex 1/2 with phosphorylated tripode

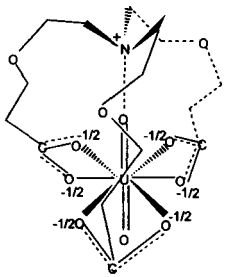

Fig.3 : Complex with nitrogenated tripode; G=COOH

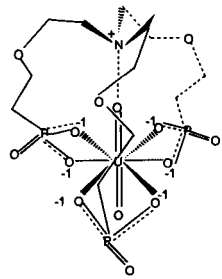

Fig.4: Complex with nitrogenated tripode; G=PO_3H_2

The tris(2-carboxy ethyl)phosphine oxide (R_3PO) has been synthetized (5). The stoechiometry of the complex R_3PO/UO_2^{2+} has been determined by conductimetry. The results confirmed that the formation of the complexes 1/1 and 2/1 is possible as shown in Fig.1 and 2.

The efficiency of this compound for uranium decorporation has been unsuccessfully tested *in vivo*. This lack of efficiency is probably due to the length of the molecule, which could be too short, and to the nature of the complexing groups, which are not completely ionisided at physiological pH.

We are currently synthetizing a new molecule, belonging to the same family, longer than R_3PO and with a pKa lower than 5, in order to allow the ionisation of the 3 groups in the blood and in the kidneys.

CONCLUSION

Methodologic aspects for selecting molecules appropriate for uranium decorporation treatment have been considered in this work. It includes several steps:

(1) speciation of uranium in the target organs: intra- or extracellular localisation, pH, affinity constants with biological ligands, etc., in order to provide basic information for the synthesis of new chelators,

(2) theoretical study of radionuclide and potential ligands structures,

(3) modelling studies consisting in theoretical and computer simulation studies,

(4) syntheses of new chelating compounds

(5) assessment of the physico-chemical properties of uranium/ligand complex: stability constant, pK, stability versus pH, hydrosolubility...

(6) first screening of the compound efficiency based on cell culture model,

(7) animal studies to optimize the removal of uranium.

The same process could be, later on, used for decorporation studies concerning other radionuclides.

I INTRODUCTION

Radiotoxicological monitoring of workers exposed to non-transferable forms of uranium requires six-monthly examinations. These examinations are prescribed according to the kind of product manipulated and to the industrial risk attached to the workplace. The range of examinations that are useful for this kind of monitoring includes whole body counting examinations, urine analyses and in-line faecal sampling:

- ⇨ whole body examinations, which are fundamental to monitoring, provide a lung retention value. However, the detection limit of lung examinations is not low enough for chronic operational monitoring;
- ⇨ urine examinations are extremely sensitive to alpha activity (1mBq per isotope) but the fraction detected in the urine after incorporation by inhalation is very small;
- ⇨ in-line 24-hour faecal sampling allows avoiding any workplace exclusion;

Before 1989, faecal examinations were not prescribed systematically but only in case of incident. In 1989, after being informed of particular modifications in two workrooms, the occupational medical doctors decided to settle systematic faecal monitoring in addition to the existing radiotoxicological examinations (lung retention examinations and urine analyses). The authors intend to present their experience acquired over a six year period in the field of interpreting systematic faecal examinations after chronic inhalation of the different uranium compounds. They also present results of a study carried out to determine normal uranium concentrations in the faeces of a non-exposed population, the uranium content in drinking waters and the consequences on faecal excretion. Establishing the isotopic content of uranium in the faeces makes it possible to determine practical investigation levels for occupational monitoring.

Even if faecal sampling may be critically perceived by the personnel, the authors' experience highlights the value of this kind of analysis which allows to track down the industrial reality of the exposure. Internal dosimetry calculations cannot, however, be carried out, because the physical parameters of the inhaled aerosols are not always known.

II MATERIALS AND METHODS

The sampling of the faeces takes place over a period of 24 hours. It is prescribed without any prior exclusion. The notifications are sent out at the same time as the notifications for the lung retention examinations and the 24-hours urine analyses.

Measurement of uranium in the faeces : analytical method

The samples are reduced to ashes using a heating programme. They are then mineralised by an acid solution. The uranium is extracted and specifically eluted. Once the uranium present has been electrically deposited, alpha spectrometry is carried out.

Measurement of uranium in drinking water : analytical method

The samples come from the drinking fountains of the company restaurant and from bottles of water sold in the self-service cafeteria. The uranium present is extracted and specifically eluted. After electrodeposition, the eluate is analysed by alpha spectrometry. A weight measurement is also carried out on the eluate.

III RESULTS

Table 1: Uranium content in drinking water bottles sold by the company restaurant

Water samples	Uranium weight	Uranium activity	^{234}U	^{235}U	^{238}U	^{234}U / ^{238}U ratio	activity / weight ratio
	$\mu g.l^{-1}$	$mBq.l^{-1}$	$mBq.l^{-1}$	$mBq.l^{-1}$	$mBq.l^{-1}$		$mBq.\mu g^{-1}$
1	2.8	72	35	2	35	1	26
2	2.9	64	36	< 1	28	1.3	22
3	3.7	246	211	5	30	7	67
4	81	3800	2600	46	1154	2.3	47
5	0.3	15	11	< 1	4	2.8	50
6	0.5	12	8	< 1	4	2	24
7	0.1	2	1	< 1	1	1.0	20
8	< 0.1	< 1	< 1	< 1	< 1	om	om
9	4.9	115	54	15	46	1.2	24
10	1.4	49	30	< 1	19	1.6	35

om = out of matter

The results presented in table 1 show the importance of knowing the water intake (and, more generally, the food intake) of the workers being monitored. The variation of the isotopic composition is apparently due to the depth of the water capture source.

Table 2 : Yearly time series of faecal uranium content

Year	1989	1990	1991	1992	1993	1994	1995	general
Faecal content mBq/24h	350	325	942	325	300	218	200	390

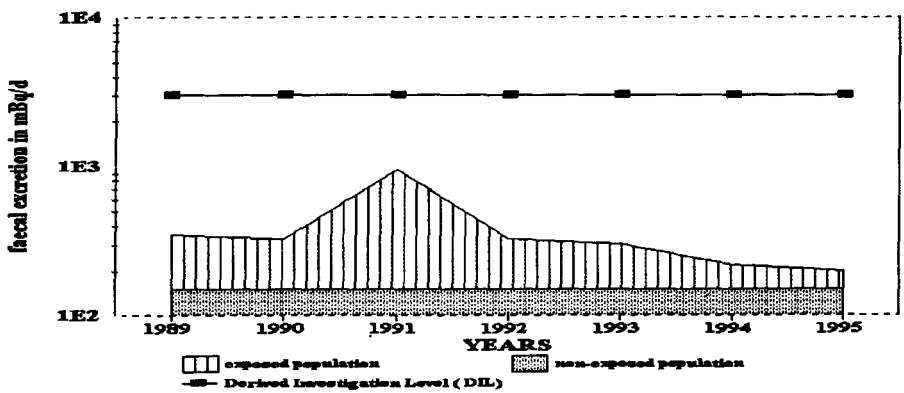

Figure 1 : faecal excretion variation as a function of the year

The table 1 and the figure 1 reveal an increase of total alpha activity in 1991. This evolution was sudden and significant. Since 1992, we observed a distinct decrease of the faecal uranium content. This is due to the information campaigns carried out by occupational medical doctors and the employers who were able to take corrective and preventive radioprotection actions in the workrooms and at individual workplaces.

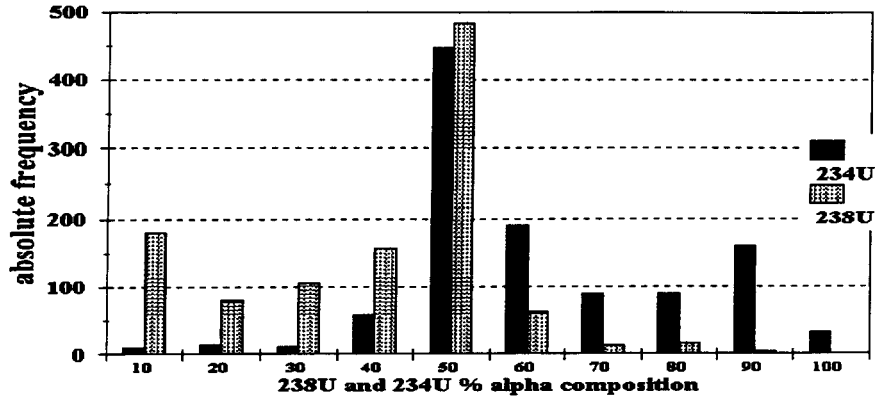

Figure 2 : Histogramms showing the values of faecal isotopic compositions

The figure 2 shows the various isotopic alpha compositions of the faecal samples. The most frequent alpha determinations are around the natural composition of uranium (50% ^{234}U and 50% ^{238}U). All the other isotopic compositions correspond to different workplaces. This informations indicate the origins of the intakes.

IV CONCLUSIONS AND PERSPECTIVES

The analyses prescribed after a contamination incident (urine and faecal measurements and whole body examinations) allow the importance of the incident to be quantified. They also make it possible to estimate the value of the incorporation according to the various International Commission for Radiological Prevention (ICRP) models.
The incorporation mode taken into account in systematic monitoring is chronic uranium inhalation. Given that the results of lung and urine analysis are always negative, the measurements of 24-hour non-exclusive faecal samples make it possible to track the evolution of an exposure to non-transferable compounds of uranium. The study carried out allows to determine normal values in the faeces for a non-exposed population on the one hand and the uranium content in the food supply, in particular in drinking water, on the other. In this way, it allows practical action levels to be established, leading to improved occupational monitoring.

The authors recommend the use of the values given below:

- ⇨ daily food intake value = 150 - 200 mBq
- ⇨ average value calculated for 1300 systematic examinations (over six years) = 390 mBq/24h
- ⇨ value higher than 1 Bq/24h: 24-hour faecal examination check

As well as the information concerning total 24-hour activity, the doctors have information on the isotopic composition of the uranium present in the faeces. This information means that the origin of the exposure can be ascertained so that specific tests may be ordered at the workplaces.
Because the whole body examinations and a 24-hour urine analysis were carried out at the same time as the faecal examinations, this study also makes it possible to satisfactorily quantify the occupational risk attached to a given workplace. However, it does not justify internal dosimetry calculations because the physical parameters of the inhaled aerosols (particularly, the granulometry) are not always known and because the sampling was done without preliminary exclusion.

The authors' experience highlights the usefulness of this type of radiotoxicological monitoring for occupational medical doctors who are able to track the radiological risk of personnel exposed to non-transferable uranium compounds in a manner that reflects industrial reality as closely as possible.

OPTIMIZATION OF MEASURING GEOMETRY OF THE SEIBERSDORF WHOLE-BODY COUNTER

ABSTRACT

Whole-Body Counters are very useful for measuring incorporated radioactive isotopes that emit gamma rays. One of the main problems in whole body counting is the measuring geometry. The whole - body counter at the Research Center Seibersdorf is working in scan position and has two high purity germanium detectors. One of these detectors is located under the bed. Because of the constant vertical distance from the back of the measured object (human) and this detector, the geometry is the same for all measured humans. The second detector is located above the bed. The aim of the vertical position of this detector should be to keep the same distance from the chest for all humans. This distance is very important for the efficiency of the measuring system. We found that the best distance is 12 cm from the chest. If the chest thickness is known the obtimized distance can be fixed very quickly, because the upper detector can be adjusted vertically by a ruler. The main problem now is that different humans have different body sizes. For quick measurements we tried to calculate the vertical thickness of the chest (when the body lies on the bed) depending on weight and height of the measured person. We measured people at the Research Centre Seibersdorf and found a linear correlation between the chest thickness and the weight per height (kg/dm). With this new optimized geometry the efficiency calibration of the whole body counter was done.

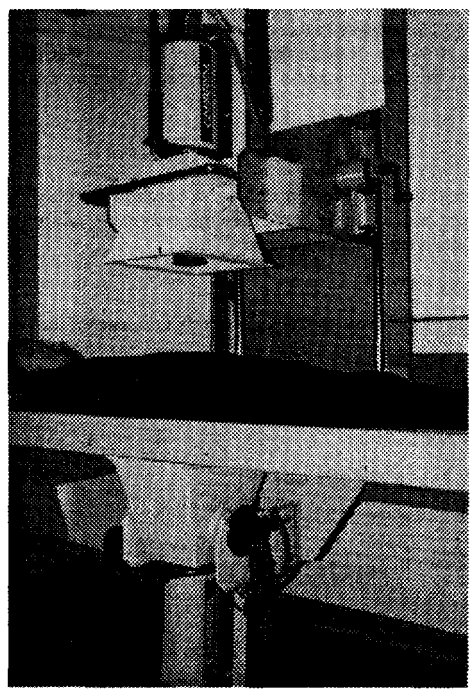

Fig. 1: HPGe-Whole-Body Counter Seibersdorf

INTRODUCTION

The Seibersdorf Whole-Body Counter (Fig. 1) has two coaxial hyper pure Germanium detectors (30% rel. efficiency each) in scan-geometry, i.e. that the person is lying on a bed and both detectors are moving from the head to the legs of the person. Because of the measuring room dimensions the maximum scanning length is 174 cm. One detector is located under the bed (p-type, Al-entrance window). Its distance to the bed is fixed but it can be changed indirectly by adjusting the height of the bed which is possible in 2 cm steps. We set the distance from the Al-entrance window to the upper bed surface to 7 cm. Generally, this distance is the same for all routine measurements. The upper detector (n-type, Be-entrance window) can be adjusted vertically. Its position depends on the chest thickness of the person to be measured. This position of the upper detector effects the efficiency very much. Both detectors are shielded with 2 cm to 4 cm thick lead. This shielding surrounds the whole detector crystal except towards the person. The open area has a dimension of 22 x 30 cm. The walls of the measuring room consist of 30 cm thick low activity concrete, 1 cm thick steel in the walls and ceiling and 7 cm thick steel in the floor. The entrance is built as a labyrinth.

For quantitative measurements with a Whole-Body Counter you need the efficiency (1,2) of the measurement. So it has to be always the aim to improve the efficiency of the system. Because of the $1/r^2$ - law and the attenuation in the body, the geometry of the object to be measured is very important for efficiency reasons. Also in wholebody counting this geometry (distance: body surface - detector) should be the same for all measured persons. But here we have the problem that the bodysizes (i.e. the body thickness) are not the same for different persons. In our case the distance from the lower detector to the upper bed surface (i.e. to the back of the measured person) is always the same. The upper detector can be changed in height. Its position should be arranged so that the pulse rates at this detector are the same as that of the lower detector in a wide range of energies. On the other hand physical damage of the person should be prevented. In our case there was a third point to be looked at. For a later calibration for localisation of pointsources in the body the count rates of the upper and lower detector should be equal when the pointsource is located in the middle of the chest. Because of the different attenuation (bed) and the different detector types the distance from the chest to the upper detector is not the same as from the lower detector to the back of the person. To get this optimized distance of the upper detector five measurements in different heights of the upper detector with the same phantom were done. We used 1 litre bottles with homogeneous distributed ^{166m}Ho solution. With these measurements we found an energy dependent position of the upper detector to get equal count rates. So we decided to use a distance of 12 cm because in this case we get equal count rates for middle energy region (about 800 keV) for both detectors. Now this distance (chest - upper detector) was fixed. For quick measurements the only value unknown now was the chest thickness when the person lies on the bed. That value we had to figure out.

MEASUREMENTS

In routine whole body counting we need to know the height and the weight of the person. We tried to calculate the chest thickness out of these data. We measured 41 adult people at the Research Centre Seibersdorf. The measurements were done as follows:

- people were lying on the bed
- the highest point of the chest was taken for measurements of the body thickness

Statistical data of measured people:

- age between 20 and 65 years
- height between 156 cm and 197 cm
- weight between 52 kg and 112 kg
- 38 male and 3 female

RESULTS

We found that the chest thickness varied between 21 cm and 30 cm. To get a correlation between the chest thickness and the height and weight, we used the weight per height (relative thickness in [kg/dm]) as parameter. The relationship is shown in Fig. 2. All datapoints are meanvalues of the weight per height at a given chest thickness. The error bars are the standard deviation. No error bar means, only one person was available. We derived the linear regression of the mean values. The values of the line variable are shown below.

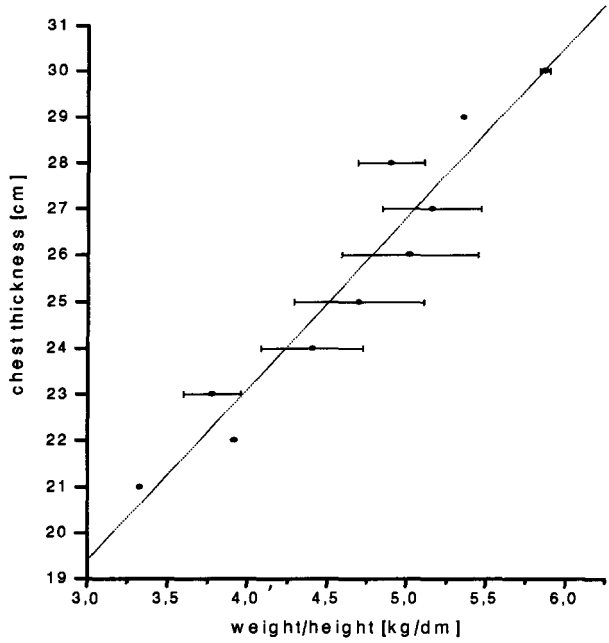

Fig. 2 Relationship between chest thickness and weight per height

Line data:

$$y = a + b \cdot x$$

a=8,2783

b=3,70758

y...chest thickness [cm] when the person lies on the bed

x...weight per height [kg/dm]

CONCLUSION

With this linear regression it is possible to calculate the chest thickness of a person with the personal data weight and height. The accuracy of the derived value is ±2 cm. It follows, that the uncertainty of the efficiency for homogeneous distributed activity in the body in the region of 800 keV is ±15% in worst case. With that uncertainty this method is useful for our routine whole body counting. For higher accuracy it will be necessary to measure the chest thickness of each person before scanning. We found no significant difference between male and female.

ABSTRACT (See instructions overleaf)
When determining the quantity of a particular radionuclide contained in an environmental sample, errors arise due to differences in geometry and specific construction of the standard versus the sample. The difference is particularly acute when the isotope of concern is a low energy beta emitter.

Environmental samples are assayed against commercially available standards of various constructions including anodized, electroplated, polymeric membrane, and filter paper. In order to cover a large range of beta energies C-14, Tc-99, Cs-137, and Sr-90 are investigated. Differences in assay results are discussed in terms of beta spectra and average beta energies. Substantial discrepancies are demonstrated when when improper standards are used for low energy beta assays.

NEUTRON MEASUREMENTS BY IN-SITU GAMMA-RAY SPECTROMETRY USING CADMIUM CONVERTERS

Matjaž Korun, Rafael Martinčič, Bogdan Pucelj

J. Stefan Institute, Ljubljana, Slovenia

Abstract. Ambient fast neutron fluxes were measured with a neutron-gamma ray converter consisting of an aqueous solution of cadmium nitrate. The gamma rays were detected by a portable gamma-ray spectrometer. For fission neutrons with an asymptotic energy spectrum fair agreement between the flux density measured with the cadmium converter and converters containing boron was achieved. Also for the natural neutron background agreement between the measured and predicted flux density was established.

INTRODUCTION

The presence of neutrons is reflected in gamma-ray spectra in peaks belonging to neutron capture and inelastic scattering on materials in the vicinity of the sensitive volume of the detector. These peaks are usually present in low-level background measurements and contribute to the background [1]. In in-situ measurements neutron-induced peaks cannot be observed in the spectra because of the high background. However, the sensitivity of the measurements to neutron induced radiation can be enhanced by surrounding the sensitive volume of the detector by a neutron-gamma ray converter. Such converters are most effective at thermal neutron energies because of the high cross sections for neutron reactions. The best materials boron and cadmium [2]. ^{11}B has a high cross section for the n,α reaction. After α particle emission the residual nucleus is formed in its first excited state with a probability of 0.94 and emits deexcitation gamma rays at 477 keV which are Doppler broadened. In case of a cadmium absorber neutrons are captured by the isotope ^{113}Cd. If the converter is mixed with a moderating material, the measurements are also sensitive to fast neutrons. This offers the opportunity to measure thermal and fast neutron fluxes separately.

Ambient neutron fluxes were measured on-site in a nuclear power plant using boron converters [2]. Also the natural cosmic-ray induced neutron background at an altitude of 300 m was measured [3]. However, measurements to determine the natural background with a relative uncertainty of some tens of percent last approximately one day. To improve the sensitivity of the measurements, boron in the converter was exchanged by cadmium. From the point of view of sensitivity, boron exhibits several disadvantages as compared to cadmium:

- Its line is Doppler broadened to about 14 keV;
- The energy of the gamma ray, characteristic of absorption of neutrons in boron, is the same as that belonging to the decay of cosmic-ray produced ^{7}Be and
- The Compton edge of gamma rays belonging to the decay of ^{137}Cs induces an uneven background at the energy of 477 keV.

All these effects contribute to the uncertainty of the peak area and the sensitivity. Therefore, cadmium converters are more suitable for measurements of small neutron fluxes. The line at 558 keV from the capture of neutrons on ^{113}Cd is not interfered by lines from naturally occurring radionuclei and is not Doppler broadened.

METHODS AND MEASUREMENTS

The measurements were performed with a 25% semiconductor detector and a cadmium converter with a volume of approximately 2 litres. The converter thickness was 5 cm at the front of the detector and 4 cm at the side of the detector. The converter was prepared as an aqueous solution of cadmium nitrate. The amount of cadmium dissolved in the converter is about 255 g. The count rate in the 558 keV line is given by:

$$n(558) = b(558)\,[\eta_T(558)\,\Phi_T + \eta_F(558)\,P_F\,\Phi_F] \quad .$$

Here $b(558)$ denotes the probability for the emission of gamma rays of energy 558 keV which is 0.73, $\eta_T(558)$ the probability for the detection of gamma rays with the energy of 558 keV from capture of thermal neutrons, $\eta_F(558)$ the probability for the detection of gamma rays from capture of fast neutrons, P_F the probability for thermalization of fast neutrons and Φ and Φ the fluxes of thermal and fast neutrons through the converter surface. Since the average free path of thermal neutrons in the converter is about 1.7 cm, thermal neutrons entering the converter through the surface are absorbed far from the detector sensitive area. Therefore, the probability for the registration of the corresponding gamma rays in the detector is small. On the other hand, since the diffusion length of fast neutrons during moderation is larger than the thickness of the converter [4], the source of gamma rays from fast neutrons is homogeneous. Neglecting the contribution of thermal neutrons, the flux density of fast neutrons is expressed as:

$$\Phi_F = \frac{n(558)}{b(558)\,\eta(558)\,P_F S} \quad ,$$

where S denotes the cross section of the converter.

The response of the converter-spectrometer system to neutrons was determined from the response of the same spectrometer to neutrons using two borated paraffin converters. The first had the same geometry as the cadmium converter, and for the second the thermalization probability was calculated with the ANISN code for asymptotic fission neutron spectrum [2]. The ratio of count rates in the 477 keV line in the measurement with the two converters is:

$$\frac{n_1(477)}{n_2(477)} = \frac{\eta_1(477)}{\eta_2(477)}\,\frac{P_{F1}}{P_{F2}}\,\frac{S_1}{S_2} \quad .$$

Since $S=S_1$ and assuming $P_F=P_{F1}$, because the converters are of equal dimensions, the flux density can be expressed as:

$$\Phi_F = \frac{n(558)}{b(558)\;\eta_2(447)\,\dfrac{\eta(558)}{\eta_1(477)}\,\dfrac{n_1(477)}{n_2(477)}\,P_{F2}\,S_2} \quad .$$

The efficiency of the second converter $\eta_2(477)$ was calculated from the measurement of an internal soil standard in the same geometry [2] and found to be 1.70 (1 ± 0.03). The efficiencies $\eta(558)$ and $\eta_1(477)$ refer to the same geometry. Their ratio was determined from the measurement of another internal standard in the geometry of the cadmium converter to be 0.88 (1 ± 0.02). This value was used for the calculation of the neutron flux density, and therefore the differences in the self-absorption of the cadmium converter, the borated paraffin converter and the internal standard were neglected. Near the reactor building the ratio of the count rates in the 477 keV line from the two borated paraffin converters was measured as 1.20 (1 ± 0.05). The probability for the thermalization of fast neutrons, calculated by the ANISN code, and the cross section of the corresponding converter are 0.42 (1 ± 0.02) and 104 cm^2 respectively [2]. Finally, the relation between the count rate in the 558 keV line and the flux density of fast neutrons is:

$$\Phi_F = \frac{n(558)}{0.57(1 \pm 0.08)\;cm^2} \quad .$$

To test the response of the spectrometer to small neutron fluxes measurements were performed in the vicinity of a nuclear power reactor at two distances from the reactor building. The measurements lasted approximately 50 and 500 minutes respectively. The flux densities of fast neutrons at the two locations were found to be 0.068 (1 ± 0.17) cm^{-2} s^{-1} and 0.006 (1 ± 0.5) cm^{-2} s^{-1}, respectively.

To test the reliability of the neutron flux measurements with the cadmium converter a measurement was performed at a location where the thermal and fast neutron fluxes had also been measured using boron converters [2]. The measurements gave 0.13 (1 ± 0.08) cm^{-2} s^{-1} and 0.86 (1 ± 0.06) cm^{-2} s^{-1} respectively. The measurement with the cadmium converter gave a slightly lower value of 0.76 (1 ± 0.09) cm^{-2} s^{-1} for the flux of fast neutrons.

DISCUSSION

It should be noted that in an asymptotic fission spectrum, as well as in the spectrum of naturally occurring neutrons, the flux density of thermal neutrons is much smaller than the flux density of fast neutrons [2,5]. Only in this case can the contribution of thermal neutrons to the 558 keV line be neglected. The results show fair agreement between the fast neutron flux density measured by boron converters, where the thermal neutron flux is accounted for, and the flux density measured with the cadmium converter.

The time required to measure the natural neutron background flux is about ten hours. This time may be shortened by using a larger semiconductor detector and by shielding the spectrometer against background gamma-ray radiation.

CONCLUSION

It was shown that a high-resolution gamma-ray spectrometer can be converted to a neutron flux meter by using a suitable cadmium converter. A converter containing neutron moderating and absorbing materials, in the present case water and cadmium, is sensitive to fast neutrons. It should be noted that for a quantitative relation between the neutron flux and the count rate in the 558 keV line the neutron spectrum must be supposed. The agreement between the flux measured with the cadmium and boron converters near the reactor building, as well as the agreement between the natural neutron background and the flux measured further away reflects the fact that the spectra of fast neutrons far from a fission source and of natural neutrons are similar [2,6].

ON THE DISTINCTION OF SMALL EXTRA DOSES FROM THE NATURAL BACKGROUND

DESIGN AND TESTING OF A SENSITIVE TL-DOSEMETER

D. Samsom and A.J.J. Bos

Interfaculty Reactor Institute, Delft University of Technology, Mekelweg 15, NL 2629 JB, Delft, Netherlands

INTRODUCTION

An important issue in environmental dosimetry is the detection of artificial doses added to the environmental dose by installations, working with ionising radiation (e.g. hospitals, reactors, in this article called a 'facility'). Dutch legislation sets a limit for the extra radiation dose rate added to the environment by a facility to a maximum of 40 μSv/a (1). Straightforward environmental dosimetry isn't able to distinguish such a small artificial dose from the fluctuating natural background within a reasonable measuring time.
A special method and dosimetry system, SEAD (Sensitive Extra Ambient Dosemeter) (2) which takes into account fluctuations in natural background and is sensitive enough to detect an extra dose rate of 40 μSv/a is presented in this study.

FLUCTUATIONS IN NATURAL BACKGROUND

Natural background radiation is build of three components: cosmic radiation, terrestrial radiation and radiation due to airborne and deposited radioactivity (radon and progeny). Terrestrial radiation varies in the Netherlands from 105 μSv/a to 683 μSv/a (3). Temporal fluctuations in airborne radioactivity and cosmic radiation occur on an daily basis and depend on rainfall, temperature, air-pressure and windvelocity; short risings due to rainfall can be up to 80 nSv/h compared to an average of 70 nSv/h. Typical temporal fluctuations are shown in figure 1. Due to temproal fluctuations weekly ambient doses can differ more than 2 μSv. Translated to a dose per year, this gives a difference of 100 μSv.

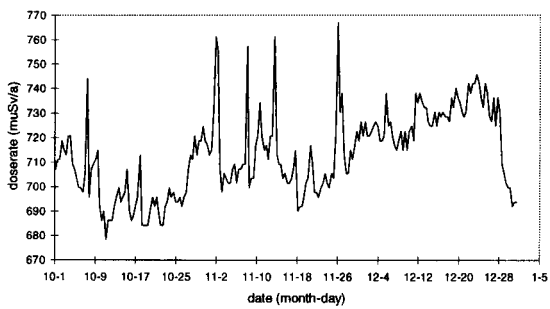

Figure 1: Fluctuations of the natural background based on 10-hour measurement periods at Delft. Dose rates are converted into yearly doses.

CUSTOMARY METHODS TO DISTINGUISH ARTIFICIAL DOSES FROM NATURAL BACKGROUND

There are a few different methods in use to detect an artificial dose added to the environment by a facility, all with the purpose to estimate the natural background and subtract this estimation from the measured dose rate around the facility, leaving an estimation of the artificial added dose rate.

The first way to estimate the natural dose rate is by measuring the dose rate at a place where there's no influence of the facility on the background radiation. Because the terrestrial component of the natural background differs strongly form place to place, this method is unlikely to produce an unbiased estimation of the 'natural background around the facility'. The second method is only usable in the case of facilities where the source(s) of ionising radiation can be switched off. In this case the background can be estimated by a measurement at a time the facility doesn't contribute to the natural background. Figure 1 shows clearly that it's rather unlikely that also this method provides an unbiased estimation within a practical measuring period (2 weeks). A reasonable improvement, but only for facilities where the sources can be switched off, can be made by combining these two methods. Two different measurements at the facility can be corrected for temporal fluctuations by measurements on a reference location (outside the influence of the facility). A last method estimates the fluctuations in natural background by mathematical modelling. This estimation needs a lot of precise meteorological data on air-pressure, rainfall, temperature at a high spatial resolution and is particularly difficult in the case of rainfall (wash-out of radon-progeny).

A NEW METHOD FOR MEASURING THE EXTRA ARTIFICIAL DOSE

Considering the disadvantages of the customary methods a different method is introduced. This method doesn't give an estimation of the natural background but uses the angle dependence of the incoming radiation and is based on the application of a radiation shield. By placing two detectors on both sides of a *radiation-shield*, one side faced to the facility and one to the opposite side, it's possible to measure a natural component (*not* natural background) and a natural component + artificial component in the same time and on the same place. In this way temporal and spatial fluctuations are taken into account and the difference between the two detectors provides a unbiased estimation of the extra dose added to the environment by the facility

DETECTOR DESCRIPTION

The detector SEAD (figure 2) is composed of two dosemeters of ten TL- samples each. The TL-material is LiF: Mg, Cu, P (GR200A), which is very sensitive to photons and has some other outstanding properties for ambient dosimetry (like low-fading-rate and low hygroscopicity). Using ten samples in each dosemeter improves the statistics of the experiment and thus lowers the lowest artificial dose which can be discriminated from the dose due to natural background. The samples are shielded with 5 mm PTFE .The shielding materials consist of 10 cm thick lead, which is enough to shield 6 MeV gamma-radiation for 98,7%. The lead is specially selected for its low specific activity (old) and is covered with 4 mm Copper to provide for as less signal as possible due to the lead-shielding. The cover of the detector is made of 1,5 mm Aluminium which transmits more than 80% of 30 keV photon-radiation and isn't a impediment for higher energies. The cover protects the dosemeters against extreme weather conditions.

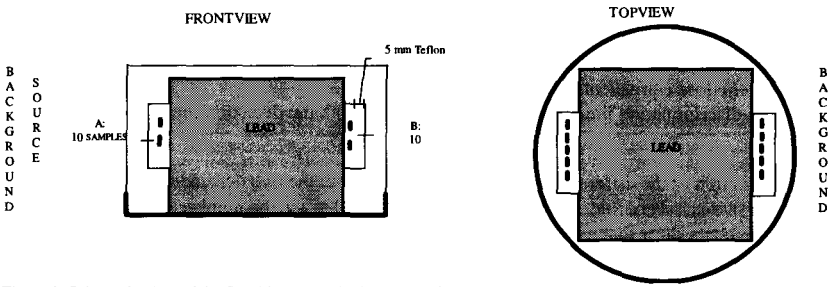

Figure 2: Schematic view of the Sensitive Extra Ambient Dosedetector

PERFORMANCE

Annealing and read-out The TL-material GR200A has an excellent performance, but only when specific and highly reproducable annealing and read-out procedures are applied. It's shown that an annealing temperature 240 °C for 10 minutes followed by fast cooling (>150 K/min) gives a good sensitivity. The *read-out procedure* consists of a plateau on 150°C for 5 seconds, followed by a heating-rate of 3 K/s to 240°C and a second plateau at 240 °C for 13 seconds. The integrating limits for TL-light are from 155°C to *the end* of the second platform. In this way the, non-stable peak 2 (peak temp ≈120 °C) is left out of the integration and peak 4 (peak temp 220 °C) is included as much as possible.

Uniformity and reproducibility To gain a batch of GR200A-samples with a great uniformity a selection of these 40 samples is made out of 100 'new' samples with a manufacturer-guarantee of max. 5% deviation. The standard deviation of the readings of 40 samples after equal irradiation with 10 mR is 0.8%. The standard deviation of 6 readings of each sample after 6 equal irradiations with 60 μGy is less than 2%.

Fading Three groups of 4 samples were placed outdoors for 14 days. One group was irradiated with 3,65 mR before the storage and one group was irradiated after the 14 days with 4,35 mR. After accounting for the different doses and the environmental dose in 14 days (measured with the third group) a fading of (2 ± 4) % (1 st.dev. of the mean) was calculated.

Zero-dose. The zero-dose of all samples was measured by reading them directly after annealing. Most of the readings of the zero-dose didn't exceed the minimum detectable value (determined by the variance in reader-background). The samples which did have a detectable zero-dose were left out of the selection.

Length of field-cycle. The length of the field cycle was determined by irradiating a group of 6 samples which different (low) doses. It was proven that the relative standard-deviation of the mean of 6 readings remained constant when the samples were exposed to 4 mR or more. This can be explained by writing the relative standard deviation σ_N as a function of the total counts n and standard deviation of the reader-background σ_B.(4)

$$\frac{\langle \sigma_N^2 \rangle}{N^2} = b + \frac{1}{n} + 2\frac{\sigma^2_B}{n^2} \qquad (1)$$

where b is a constant. In the case of GR200A and the used reader (modified Harshaw 2000) b>0.001, σ_B=10 and n > 4000 counts for a dose of 4 mR, leaving b, a constant, as the only significant contribution to the relative standard deviation. A dose of 4 mR is equal to the environmental background in 14 days. Fig. 4 shows the relative standard deviation of a TL-measurement as a function of the measurement time in a natural background.

Hygroscopicity. After 14 days storage the difference of the mean between 5 samples placed in a closed can, filled with water and five samples placed in a dry environment was non-significant (0 ± 2)%.

Energy response The relation of measured counts and irradiated dose (mR) is plotted in fig. 3. The defined dependence between ambient dose equivalent (cSv) and exposure (R) as given by ICRU (5) is plotted in fig. 3.

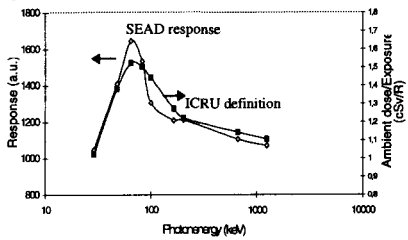

fig 3: TL-response of SEAD and ICRU definition

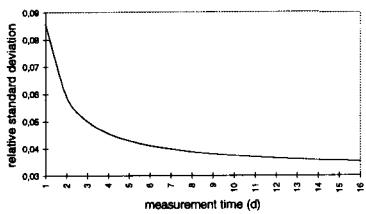

fig 4: Relative standard deviation as a function of measuring time

From fig 3 it's clear that the combinaton of lead, 1,5 mm Al and the 5 mm PTFE gives an excellent agreement with the ICRU definition of ambient dose equivalent.

Discrimination limit The discrimination limit, O_D, (not to be confused with the detection limit) is defined by

$$O_D = t_{\alpha/2}(n+m-2)S_d \qquad (2)$$

Where S_d is the standard deviation of the difference of the mean readings from the two dosemeters and $t_{\alpha/2}$ is the Student-t critical value for a two-sided confindence interval of 1-α and n and m are the number of samples in dosemeter A and B. Measurements show that n=m=10 is sufficient to reach the desired discrimination limit.

Field measurements Results of 4 measurements with SEAD are shown in table 1, two of them at one place at the site boundary of a research reactor and three at different places at the site boundary of a hospital in which radiation facilities are operated.

Table 1: Resluts of measurements with SEAD.

	Reactor	Reactor	Hospital 1	Hospital 2
Extra artificial dose (mSv/a)	0.032	0.037	-0.017	-0.032
'Background' (mSv/a)	0.73	0.68	0.86	0.87
Discrimination limit (95%) (mSv/a)	0.030	0.021	0.033	0.029

DISCUSSION AND CONCLUSION

SEAD is capable of distinguishing an artificial dose rate of 40 μSv/a from the natural background in a measuring time of 14 days. The performance tests show that SEAD shows excellent stability, in particular because of the use of (well-selected) GR200A-samples. Table 1 shows, however, that in absence of any artificial radiation source a difference in natural dose rate can be up to 32 μSv/a (hospital 2). This difference isn't a result of diffence in soil-type (both dosemeters are virtually on the same spot) but is due to diffences in surrounding elements (buildings, trees etc.) on both sides of the detector. This difference can only be established precisely when measurements around a facility can be performed with 'the source switched off'. In other cases the artificial dose rate as established by SEAD must be considered as best estimate, because it eliminates by far more biasing factors than methods used up to now.

PLASTIC SCINTILLATOR WATER MONITOR RESPONSE TO ^{32}P

INTRODUCTION

Water monitors equipped with a plastic scintillator are widely used to measure the radioactive concentrations of β-emitters in liquid waste. Plastic monitors are highly sensitive to high energy β-emitters like ^{32}P, but they are insensitive to low energy β-emitters like ^{3}H, ^{14}C. This is a result of the detector's surface being covered by a thin protective layer. A computerized plastic scintillator water monitor system was devised for high energy β-emitters at our facility. The response to ^{32}P was investigated so that optimum conditions for operating the monitor could be achieved.

MATERIALS AND METHODS

Fig.1 shows a schematic diagram of the sistem that is composed of a personal computer, plastic scintillator detector, controler and pipe lines. A computerized sequence for operating the monitor, background (BG) measurements, waste liquid sampling, sample measurements, and detector cleaning, was programmed. Signals of the detector were fed to a multichannel scaler(MCS) to analyze the time variations of the count rate.

^{32}P solution of 0.04-0.4Bq $\cdot$ cm^{-3} prepared in a radioactive liquid waste storage tank of100m^3 was used to measure the detector response, which was also analyzed by using a short cut circuit connected to a 20 ℓ polyethylene tank containing ^{32}P solution of 5Bq $\cdot$ cm^{-3}. The activity in the water sampled near the detector was measured by a liquid scintillation counter(LSC), and was compared with those values measurd by the water monitor, MCS, and a multichannel analyzer(MCA) . This was done to confirm and/or adjust the different methods giving the same values as LSC.

RESULTS AND DISCUSSION

Figure 2 represents an example of time variation of count rates measured at a dwell time of10sec/Channel. by MCS. The counting efficiency was 5.1 $\pm$0.1%. The time to replace BG water with waste

liquid was about 6 min. and a cleaning time was about 1min. This difference is due to the the dissimilarity of both pipe line lengths. Some measurements showed that the count rates after cleaning was a little higher than that of BG, because of the ^{32}P in the residual waste liquid in the pipe near the detector after the first cleaning. This means that contamination occasionally remains on the detector's surface after cleaning contingent on the pipe arrangement. The detector was dismantled and the surface was completely decontaminated by wiping it with soft tissue paper. Second cleaning also completely washed out any residual waste liquid. The detector was then free of any contamination.

Replace times, cleaning times, and repeat times should be experimentaly confirmed for each monitoring system, since each system differs in pipe line arrangement as well as length.

ABSTRACT (See instructions overleaf)
When determining the quantity of a particular radionuclide contained in an environmental sample, errors arise due to differences in geometry and specific construction of the standard versus the sample. The difference is particularly acute when the isotope of concern is a low energy beta emitter.

Environmental samples are assayed against commercially available standards of various constructions including anodized, electroplated, polymeric membrane, and filter paper. In order to cover a large range of beta energies C-14, Tc-99, Cs-137, and Sr-90 are investigated. Differences in assay results are discussed in terms of beta spectra and average beta energies. Substantial discrepancies are demonstrated when when improper standards are used for low energy beta assays.

NEUTRON MEASUREMENTS BY IN-SITU GAMMA-RAY SPECTROMETRY USING CADMIUM CONVERTERS

Matjaž Korun, Rafael Martinčič, Bogdan Pucelj

J. Stefan Institute, Ljubljana, Slovenia

Abstract. Ambient fast neutron fluxes were measured with a neutron-gamma ray converter consisting of an aqueous solution of cadmium nitrate. The gamma rays were detected by a portable gamma-ray spectrometer. For fission neutrons with an asymptotic energy spectrum fair agreement between the flux density measured with the cadmium converter and converters containing boron was achieved. Also for the natural neutron background agreement between the measured and predicted flux density was established.

INTRODUCTION

The presence of neutrons is reflected in gamma-ray spectra in peaks belonging to neutron capture and inelastic scattering on materials in the vicinity of the sensitive volume of the detector. These peaks are usually present in low-level background measurements and contribute to the background [1]. In in-situ measurements neutron-induced peaks cannot be observed in the spectra because of the high background. However, the sensitivity of the measurements to neutron induced radiation can be enhanced by surrounding the sensitive volume of the detector by a neutron-gamma ray converter. Such converters are most effective at thermal neutron energies because of the high cross sections for neutron reactions. The best materials boron and cadmium [2]. ^{11}B has a high cross section for the n,α reaction. After α particle emission the residual nucleus is formed in its first excited state with a probability of 0.94 and emits deexcitation gamma rays at 477 keV which are Doppler broadened. In case of a cadmium absorber neutrons are captured by the isotope ^{113}Cd. If the converter is mixed with a moderating material, the measurements are also sensitive to fast neutrons. This offers the opportunity to measure thermal and fast neutron fluxes separately.

Ambient neutron fluxes were measured on-site in a nuclear power plant using boron converters [2]. Also the natural cosmic-ray induced neutron background at an altitude of 300 m was measured [3]. However, measurements to determine the natural background with a relative uncertainty of some tens of percent last approximately one day. To improve the sensitivity of the measurements, boron in the converter was exchanged by cadmium. From the point of view of sensitivity, boron exhibits several disadvantages as compared to cadmium:

- Its line is Doppler broadened to about 14 keV;
- The energy of the gamma ray, characteristic of absorption of neutrons in boron, is the same as that belonging to the decay of cosmic-ray produced ^{7}Be and
- The Compton edge of gamma rays belonging to the decay of ^{137}Cs induces an uneven background at the energy of 477 keV.

All these effects contribute to the uncertainty of the peak area and the sensitivity. Therefore, cadmium converters are more suitable for measurements of small neutron fluxes. The line at 558 keV from the capture of neutrons on ^{113}Cd is not interfered by lines from naturally occurring radionuclei and is not Doppler broadened.

METHODS AND MEASUREMENTS

The measurements were performed with a 25% semiconductor detector and a cadmium converter with a volume of approximately 2 litres. The converter thickness was 5 cm at the front of the detector and 4 cm at the side of the detector. The converter was prepared as an aqueous solution of cadmium nitrate. The amount of cadmium dissolved in the converter is about 255 g. The count rate in the 558 keV line is given by:

$$n(558) = b(558)\,[\eta_T(558)\,\Phi_T + \eta_F(558)\,P_F\,\Phi_F] \quad .$$

Here $b(558)$ denotes the probability for the emission of gamma rays of energy 558 keV which is 0.73, $\eta_T(558)$ the probability for the detection of gamma rays with the energy of 558 keV from capture of thermal neutrons, $\eta_F(558)$ the probability for the detection of gamma rays from capture of fast neutrons, P_F the probability for thermalization of fast neutrons and Φ and Φ the fluxes of thermal and fast neutrons through the converter surface. Since the average free path of thermal neutrons in the converter is about 1.7 cm, thermal neutrons entering the converter through the surface are absorbed far from the detector sensitive area. Therefore, the probability for the registration of the corresponding gamma rays in the detector is small. On the other hand, since the diffusion length of fast neutrons during moderation is larger than the thickness of the converter [4], the source of gamma rays from fast neutrons is homogeneous. Neglecting the contribution of thermal neutrons, the flux density of fast neutrons is expressed as:

$$\Phi_F = \frac{n(558)}{b(558)\,\eta(558)\,P_F S} \quad ,$$

where S denotes the cross section of the converter.

The response of the converter-spectrometer system to neutrons was determined from the response of the same spectrometer to neutrons using two borated paraffin converters. The first had the same geometry as the cadmium converter, and for the second the thermalization probability was calculated with the ANISN code for asymptotic fission neutron spectrum [2]. The ratio of count rates in the 477 keV line in the measurement with the two converters is:

$$\frac{n_1(477)}{n_2(477)} = \frac{\eta_1(477)}{\eta_2(477)}\,\frac{P_{F1}}{P_{F2}}\,\frac{S_1}{S_2} \quad .$$

Since $S=S_1$ and assuming $P_F=P_{F1}$, because the converters are of equal dimensions, the flux density can be expressed as:

$$\Phi_F = \frac{n(558)}{b(558)\;\eta_2(447)\,\dfrac{\eta(558)}{\eta_1(477)}\,\dfrac{n_1(477)}{n_2(477)}\,P_{F2}\,S_2} \quad .$$

The efficiency of the second converter $\eta_2(477)$ was calculated from the measurement of an internal soil standard in the same geometry [2] and found to be 1.70 (1 ± 0.03). The efficiencies $\eta(558)$ and $\eta_1(477)$ refer to the same geometry. Their ratio was determined from the measurement of another internal standard in the geometry of the cadmium converter to be 0.88 (1 ± 0.02). This value was used for the calculation of the neutron flux density, and therefore the differences in the self-absorption of the cadmium converter, the borated paraffin converter and the internal standard were neglected. Near the reactor building the ratio of the count rates in the 477 keV line from the two borated paraffin converters was measured as 1.20 (1 ± 0.05). The probability for the thermalization of fast neutrons, calculated by the ANISN code, and the cross section of the corresponding converter are 0.42 (1 ± 0.02) and 104 cm^2 respectively [2]. Finally, the relation between the count rate in the 558 keV line and the flux density of fast neutrons is:

$$\Phi_F = \frac{n(558)}{0.57(1 \pm 0.08)\;cm^2} \quad .$$

To test the response of the spectrometer to small neutron fluxes measurements were performed in the vicinity of a nuclear power reactor at two distances from the reactor building. The measurements lasted approximately 50 and 500 minutes respectively. The flux densities of fast neutrons at the two locations were found to be 0.068 (1 ± 0.17) cm^{-2} s^{-1} and 0.006 (1 ± 0.5) cm^{-2} s^{-1}, respectively.

To test the reliability of the neutron flux measurements with the cadmium converter a measurement was performed at a location where the thermal and fast neutron fluxes had also been measured using boron converters [2]. The measurements gave 0.13 (1 ± 0.08) cm^{-2} s^{-1} and 0.86 (1 ± 0.06) cm^{-2} s^{-1} respectively. The measurement with the cadmium converter gave a slightly lower value of 0.76 (1 ± 0.09) cm^{-2} s^{-1} for the flux of fast neutrons.

DISCUSSION

It should be noted that in an asymptotic fission spectrum, as well as in the spectrum of naturally occurring neutrons, the flux density of thermal neutrons is much smaller than the flux density of fast neutrons [2,5]. Only in this case can the contribution of thermal neutrons to the 558 keV line be neglected. The results show fair agreement between the fast neutron flux density measured by boron converters, where the thermal neutron flux is accounted for, and the flux density measured with the cadmium converter.

The time required to measure the natural neutron background flux is about ten hours. This time may be shortened by using a larger semiconductor detector and by shielding the spectrometer against background gamma-ray radiation.

CONCLUSION

It was shown that a high-resolution gamma-ray spectrometer can be converted to a neutron flux meter by using a suitable cadmium converter. A converter containing neutron moderating and absorbing materials, in the present case water and cadmium, is sensitive to fast neutrons. It should be noted that for a quantitative relation between the neutron flux and the count rate in the 558 keV line the neutron spectrum must be supposed. The agreement between the flux measured with the cadmium and boron converters near the reactor building, as well as the agreement between the natural neutron background and the flux measured further away reflects the fact that the spectra of fast neutrons far from a fission source and of natural neutrons are similar [2,6].

ON THE DISTINCTION OF SMALL EXTRA DOSES FROM THE NATURAL BACKGROUND

DESIGN AND TESTING OF A SENSITIVE TL-DOSEMETER

D. Samsom and A.J.J. Bos

Interfaculty Reactor Institute, Delft University of Technology, Mekelweg 15, NL 2629 JB, Delft, Netherlands

INTRODUCTION

An important issue in environmental dosimetry is the detection of artificial doses added to the environmental dose by installations, working with ionising radiation (e.g. hospitals, reactors, in this article called a 'facility'). Dutch legislation sets a limit for the extra radiation dose rate added to the environment by a facility to a maximum of 40 μSv/a (1). Straightforward environmental dosimetry isn't able to distinguish such a small artificial dose from the fluctuating natural background within a reasonable measuring time.
A special method and dosimetry system, SEAD (Sensitive Extra Ambient Dosemeter) (2) which takes into account fluctuations in natural background and is sensitive enough to detect an extra dose rate of 40 μSv/a is presented in this study.

FLUCTUATIONS IN NATURAL BACKGROUND

Natural background radiation is build of three components: cosmic radiation, terrestrial radiation and radiation due to airborne and deposited radioactivity (radon and progeny). Terrestrial radiation varies in the Netherlands from 105 μSv/a to 683 μSv/a (3). Temporal fluctuations in airborne radioactivity and cosmic radiation occur on an daily basis and depend on rainfall, temperature, air-pressure and windvelocity; short risings due to rainfall can be up to 80 nSv/h compared to an average of 70 nSv/h. Typical temporal fluctuations are shown in figure 1. Due to temproal fluctuations weekly ambient doses can differ more than 2 μSv. Translated to a dose per year, this gives a difference of 100 μSv.

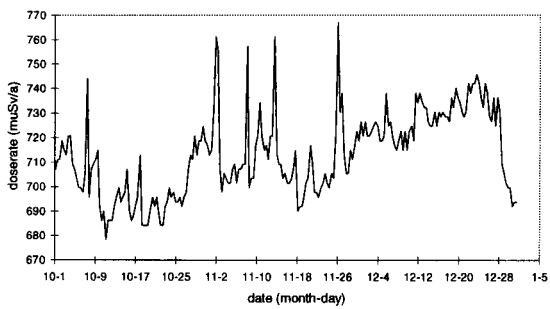

Figure 1: Fluctuations of the natural background based on 10-hour measurement periods at Delft. Dose rates are converted into yearly doses.

CUSTOMARY METHODS TO DISTINGUISH ARTIFICIAL DOSES FROM NATURAL BACKGROUND

There are a few different methods in use to detect an artificial dose added to the environment by a facility, all with the purpose to estimate the natural background and subtract this estimation from the measured dose rate around the facility, leaving an estimation of the artificial added dose rate.

The first way to estimate the natural dose rate is by measuring the dose rate at a place where there's no influence of the facility on the background radiation. Because the terrestrial component of the natural background differs strongly form place to place, this method is unlikely to produce an unbiased estimation of the 'natural background around the facility'. The second method is only usable in the case of facilities where the source(s) of ionising radiation can be switched off. In this case the background can be estimated by a measurement at a time the facility doesn't contribute to the natural background. Figure 1 shows clearly that it's rather unlikely that also this method provides an unbiased estimation within a practical measuring period (2 weeks). A reasonable improvement, but only for facilities where the sources can be switched off, can be made by combining these two methods. Two different measurements at the facility can be corrected for temporal fluctuations by measurements on a reference location (outside the influence of the facility). A last method estimates the fluctuations in natural background by mathematical modelling. This estimation needs a lot of precise meteorological data on air-pressure, rainfall, temperature at a high spatial resolution and is particularly difficult in the case of rainfall (wash-out of radon-progeny).

A NEW METHOD FOR MEASURING THE EXTRA ARTIFICIAL DOSE

Considering the disadvantages of the customary methods a different method is introduced. This method doesn't give an estimation of the natural background but uses the angle dependence of the incoming radiation and is based on the application of a radiation shield. By placing two detectors on both sides of a *radiation-shield*, one side faced to the facility and one to the opposite side, it's possible to measure a natural component (*not* natural background) and a natural component + artificial component in the same time and on the same place. In this way temporal and spatial fluctuations are taken into account and the difference between the two detectors provides a unbiased estimation of the extra dose added to the environment by the facility

DETECTOR DESCRIPTION

The detector SEAD (figure 2) is composed of two dosemeters of ten TL- samples each. The TL-material is LiF: Mg, Cu, P (GR200A), which is very sensitive to photons and has some other outstanding properties for ambient dosimetry (like low-fading-rate and low hygroscopicity). Using ten samples in each dosemeter improves the statistics of the experiment and thus lowers the lowest artificial dose which can be discriminated from the dose due to natural background. The samples are shielded with 5 mm PTFE .The shielding materials consist of 10 cm thick lead, which is enough to shield 6 MeV gamma-radiation for 98,7%. The lead is specially selected for its low specific activity (old) and is covered with 4 mm Copper to provide for as less signal as possible due to the lead-shielding. The cover of the detector is made of 1,5 mm Aluminium which transmits more than 80% of 30 keV photon-radiation and isn't a impediment for higher energies. The cover protects the dosemeters against extreme weather conditions.

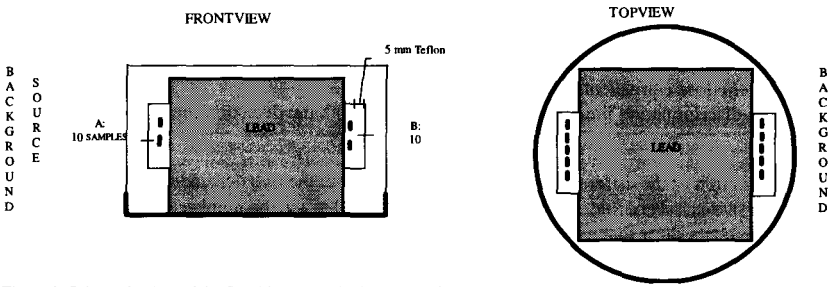

Figure 2: Schematic view of the Sensitive Extra Ambient Dosedetector

PERFORMANCE

Annealing and read-out The TL-material GR200A has an excellent performance, but only when specific and highly reproducable annealing and read-out procedures are applied. It's shown that an annealing temperature 240 °C for 10 minutes followed by fast cooling (>150 K/min) gives a good sensitivity. The *read-out procedure* consists of a plateau on 150°C for 5 seconds, followed by a heating-rate of 3 K/s to 240°C and a second plateau at 240 °C for 13 seconds. The integrating limits for TL-light are from 155°C to *the end* of the second platform. In this way the, non-stable peak 2 (peak temp ≈120 °C) is left out of the integration and peak 4 (peak temp 220 °C) is included as much as possible.

Uniformity and reproducibility To gain a batch of GR200A-samples with a great uniformity a selection of these 40 samples is made out of 100 'new' samples with a manufacturer-guarantee of max. 5% deviation. The standard deviation of the readings of 40 samples after equal irradiation with 10 mR is 0.8%. The standard deviation of 6 readings of each sample after 6 equal irradiations with 60 μGy is less than 2%.

Fading Three groups of 4 samples were placed outdoors for 14 days. One group was irradiated with 3,65 mR before the storage and one group was irradiated after the 14 days with 4,35 mR. After accounting for the different doses and the environmental dose in 14 days (measured with the third group) a fading of (2 ± 4) % (1 st.dev. of the mean) was calculated.

Zero-dose. The zero-dose of all samples was measured by reading them directly after annealing. Most of the readings of the zero-dose didn't exceed the minimum detectable value (determined by the variance in reader-background). The samples which did have a detectable zero-dose were left out of the selection.

Length of field-cycle. The length of the field cycle was determined by irradiating a group of 6 samples which different (low) doses. It was proven that the relative standard-deviation of the mean of 6 readings remained constant when the samples were exposed to 4 mR or more. This can be explained by writing the relative standard deviation σ_N as a function of the total counts n and standard deviation of the reader-background σ_B.(4)

$$\frac{\langle \sigma_N^2 \rangle}{N^2} = b + \frac{1}{n} + 2\frac{\sigma^2_B}{n^2} \qquad (1)$$

where b is a constant. In the case of GR200A and the used reader (modified Harshaw 2000) b>0.001, σ_B=10 and n > 4000 counts for a dose of 4 mR, leaving b, a constant, as the only significant contribution to the relative standard deviation. A dose of 4 mR is equal to the environmental background in 14 days. Fig. 4 shows the relative standard deviation of a TL-measurement as a function of the measurement time in a natural background.

Hygroscopicity. After 14 days storage the difference of the mean between 5 samples placed in a closed can, filled with water and five samples placed in a dry environment was non-significant (0 ± 2)%.

Energy response The relation of measured counts and irradiated dose (mR) is plotted in fig. 3. The defined dependence between ambient dose equivalent (cSv) and exposure (R) as given by ICRU (5) is plotted in fig. 3.

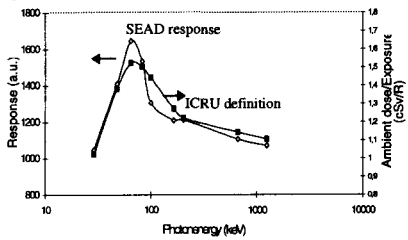

fig 3: TL-response of SEAD and ICRU definition

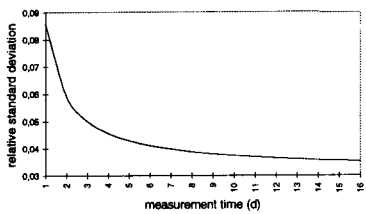

fig 4: Relative standard deviation as a function of measuring time

From fig 3 it's clear that the combinaton of lead, 1,5 mm Al and the 5 mm PTFE gives an excellent agreement with the ICRU definition of ambient dose equivalent.

Discrimination limit The discrimination limit, O_D, (not to be confused with the detection limit) is defined by

$$O_D = t_{\alpha/2}(n+m-2)S_d \qquad (2)$$

Where S_d is the standard deviation of the difference of the mean readings from the two dosemeters and $t_{\alpha/2}$ is the Student-t critical value for a two-sided confindence interval of 1-α and n and m are the number of samples in dosemeter A and B. Measurements show that n=m=10 is sufficient to reach the desired discrimination limit.

Field measurements Results of 4 measurements with SEAD are shown in table 1, two of them at one place at the site boundary of a research reactor and three at different places at the site boundary of a hospital in which radiation facilities are operated.

Table 1: Resluts of measurements with SEAD.

	Reactor	Reactor	Hospital 1	Hospital 2
Extra artificial dose (mSv/a)	0.032	0.037	-0.017	-0.032
'Background' (mSv/a)	0.73	0.68	0.86	0.87
Discrimination limit (95%) (mSv/a)	0.030	0.021	0.033	0.029

DISCUSSION AND CONCLUSION

SEAD is capable of distinguishing an artificial dose rate of 40 μSv/a from the natural background in a measuring time of 14 days. The performance tests show that SEAD shows excellent stability, in particular because of the use of (well-selected) GR200A-samples. Table 1 shows, however, that in absence of any artificial radiation source a difference in natural dose rate can be up to 32 μSv/a (hospital 2). This difference isn't a result of diffence in soil-type (both dosemeters are virtually on the same spot) but is due to diffences in surrounding elements (buildings, trees etc.) on both sides of the detector. This difference can only be established precisely when measurements around a facility can be performed with 'the source switched off'. In other cases the artificial dose rate as established by SEAD must be considered as best estimate, because it eliminates by far more biasing factors than methods used up to now.

INTRODUCTION

Water monitors equipped with a plastic scintillator are widely used to measure the radioactive concentrations of β-emitters in liquid waste. Plastic monitors are highly sensitive to high energy β-emitters like ^{32}P, but they are insensitive to low energy β-emitters like ^{3}H, ^{14}C. This is a result of the detector's surface being covered by a thin protective layer. A computerized plastic scintillator water monitor system was devised for high energy β-emitters at our facility. The response to ^{32}P was investigated so that optimum conditions for operating the monitor could be achieved.

MATERIALS AND METHODS

Fig.1 shows a schematic diagram of the sistem that is composed of a personal computer, plastic scintillator detector, controler and pipe lines. A computerized sequence for operating the monitor, background (BG) measurements, waste liquid sampling, sample measurements, and detector cleaning, was programmed. Signals of the detector were fed to a multichannel scaler(MCS) to analyze the time variations of the count rate.

^{32}P solution of 0.04-0.4Bq $\cdot$ cm^{-3} prepared in a radioactive liquid waste storage tank of100m^3 was used to measure the detector response, which was also analyzed by using a short cut circuit connected to a 20 ℓ polyethylene tank containing ^{32}P solution of 5Bq $\cdot$ cm^{-3}. The activity in the water sampled near the detector was measured by a liquid scintillation counter(LSC), and was compared with those values measurd by the water monitor, MCS, and a multichannel analyzer(MCA) . This was done to confirm and/or adjust the different methods giving the same values as LSC.

RESULTS AND DISCUSSION

Figure 2 represents an example of time variation of count rates measured at a dwell time of10sec/Channel. by MCS. The counting efficiency was 5.1 $\pm$0.1%. The time to replace BG water with waste

liquid was about 6 min. and a cleaning time was about 1min. This difference is due to the the dissimilarity of both pipe line lengths. Some measurements showed that the count rates after cleaning was a little higher than that of BG, because of the ^{32}P in the residual waste liquid in the pipe near the detector after the first cleaning. This means that contamination occasionally remains on the detector's surface after cleaning contingent on the pipe arrangement. The detector was dismantled and the surface was completely decontaminated by wiping it with soft tissue paper. Second cleaning also completely washed out any residual waste liquid. The detector was then free of any contamination.

Replace times, cleaning times, and repeat times should be experimentaly confirmed for each monitoring system, since each system differs in pipe line arrangement as well as length.

SEPARATION OF THE INDUSTRIAL AND THE NATURAL COMPONENTS OF THE AMBIENT BACKGROUND BY A STATISTICAL METHOD

Lidia Purghel and Nicolae Valcov

Institute of Atomic Physics, P.O.Box MG-6, Bucharest, Romania

INTRODUCTION

The continuously increasing number of industrial facilities involving nuclear tehniques, such as nuclear power stations, gamma irradiators, particle accelerators a.s.o., lead to new requirements concerning the control of the ambient background. By considering the ambient background as being composed by two components - the natural background and the industrial component - it is of great practical interest to measure separately this two components of different origins. As concerns the industrial component of the ambient background, it is represented mostly by the penetrating gamma-ray field, the other radiation fields being, more or less rapidly, absorbed after emission.

In this way the problem considered by us was to separate the natural background from the gamma -ray field of industrial origin (the usual method of subtracting the natural background from the mixed natural background + gamma-ray field is connected very often with some difficulties, as the unknown industrial gamma-ray field can not be canceled for the natural background measurement). For this purpose we decided to use the statistical discrimination method based on the ionization chamber as radiation detector.

PRINCIPLE OF METHOD

As it has been recently shown (1), the ratio between the variance and the mean value of the current of the ionization chamber, placed in a radiation field, $k = \sigma^2/\bar{I}$, depends on the radiation field type, through the mean value and the distribution function of the energy, lost by the ionizing particles in the chamber volume. Besides, for a given radiation field, the statistical factor k does not depend on the strength of the field, i.e. on the ionization current value. As a consequence, a new method of statistical discrimination of components in a binary mixed radiation field has been proposed (2). By following to the statistical discrimination method, for the case of the superposition of an industrial gamma-ray field (leading to an ionization current mean value $\bar{I}_\gamma$) and a natural background field (leading to an ionization current mean value $\bar{I}_B$), by measuring the total ionization current mean value $\bar{I}$ and its variance σ^2, the two components of the ionization current may be deduced from the following relationships:

$$\bar{I}_\gamma = \bar{I}\,(k_B - k)\,/\,(k_B - k_\gamma) \qquad (1)$$

and:

$$\bar{I}_B = \bar{I}\,(k - k_\gamma)\,/\,(k_B - k_\gamma) \qquad (2)$$

where k, k_γ and k_B represent the statistical factors for the mixed field, the gamma-ray field and the natural background field. As it has been also shown in (2), the range of use and the precision of the method are depending on the ratio k_B/k_γ between the statistical factors of the superposed fields.

In this way our first step in using the statistical discrimination method was represented by the measurement of the statistical factors k_γ and k_B. For this purpose we used a 10 l - atmospheric pressure air filled ionization chamber, biased at 400 V. The integration time constant of the electrometric scheme has been equal to 2 s. The variance and the mean value of the ionization current, corresponding to a given radiation field, were obtained by processing series of 300 readings.

We obtained for the natural background:

$\bar{I}_B = 9.5 \times 10^{-15}$ A $\qquad \sigma_B = 4.0 \times 10^{-15}$ A $\qquad k_B = 1.7 \times 10^{-15}$ A

By using a 370 MBq activity ^{60}Co gamma source, mounted at 10 cm from the ionization chamber wall, we obtained:

$\bar{I}_\gamma = 2.5 \times 10^{-10}$ A $\qquad \sigma_\gamma = 2.18 \times 10^{-13}$ A $\qquad k_\gamma = 1.9 \times 10^{-16}$ A

By looking at the measured values of the statistical factors, we have to emphasize the following points:

- the ionization current mean value corresponding to the gamma source is much higher than the natural background ionization current mean value and we shall consider to have in this case a practically pure gamma-ray radiation field.

- we don't know how pure is the natural background radiation field and the obtained ratio $k_B/k_\gamma = 9$ has to be considered as a lower limit of this ratio.

- at the same time the ratio value of about ten is proving the validity of the statistical discrimination method for this mixed field.

- the higher value of the statistical factor for the natural background radiation field could be qualitatively explained by the presence of ionizing particles of much higher stopping power than the secondary electrons produced by the gamma-ray atomic interactions; such ionizing particles could be, for instance, the μ -mesons or other cosmic rays components.

STATISTICAL UNCERTAINTIES

The relationships (1) and (2) are limited in use by the statistical uncertainties of determining the $\bar{I}_\gamma$ and $\bar{I}_B$ values. In order to deduce this statistical uncertainties, we have to estimate the experimental statistical errors associated with I and σ^2 and then to use the propagation error formulae. Let's emphasize the double role played by σ in this calculation, being at the same time an error (or a part of it) for the $\bar{I}$ value and a measured quantity with its own error. As concerns the statistical error on the σ value this one depends only on the number of readings (3) (for instance, the statistical error at a 95% confidence level is of about 10%, for 300 readings, and is varying as $n^{-0.5}$, where n represents the number of readings).

The statistical relative uncertainties of the statistical discrimination method, at a 95% confidence level obtained, in such a way, are the following:

$$\varepsilon_\gamma = \left(\frac{4k(1+\beta_\gamma)}{\bar{I}\,\sigma^2 n^2} + \frac{2.25\beta_\gamma}{n} \right)^{1/2} \qquad (3)$$

$$\varepsilon_B = \left(\frac{4k(1+\beta_B)}{\bar{I}\,\sigma^2 n^2} + \frac{2.25\beta_B}{n} \right)^{1/2} \qquad (4)$$

where:

$\beta_\gamma = k^2 / (k_B - k)^2$

$\beta_B = k^2 / (k - k_\gamma)^2$

n = number of readings

σ = integration time constant

In order to have a better understanding of the relationships (3) and (4), in figure 1 the dependences of ε_γ and ε_B on the gamma-ray absorbed dose rate in air for a given natural background absorbed dose rate in air equal to 10μrad/h (0.1 μGy/h), in the case of a 10 l ionization chamber with a τ = 30 ms integration time constant and n = 1000 readings, are shown.

From the practical point of view, we are highly interested, in a few absorbed dose rates. First of all the gamma - ray absorbed dose rate representing the detection limit, corresponding to a 100% statistical uncertainty, is equal to 0.02 μGy/h. The gamma - ray absorbed dose rate of 0.1 μGy/h, equal to the assumed natural background absorbed dose rate, may be measured with an acceptable statistical uncertainty of less than 20%. The gamma -ray absorbed dose rate of 0.5 μGy/h corresponding to a total absorbed dose rate in air of 0.6 μGy/h corresponding to the admissible dose rate for population (5 mSv per year), may be measured, with a statistical uncertainty of about 5%, while the statistical uncertainty for the assumed 0.1 μGy/h natural background absorbed dose rate measurement does not exceed 12%.

CONCLUSIONS. The conclusions are the following:

1) The statistical discrimination method provides for a simultaneous measurement of the natural background and of the industrial gamma-rays absorbed dose rates in good conditions.

2) For a 10 l - atmospheric pressure air-filled ionization chamber and 1 min total measuring time, the estimated gamma-ray detection threshold may be as low as 0.02 μGy/h, by assuming a 0,1 μGy/h absorbed dose rate in air for the natural background (see fig. 1).

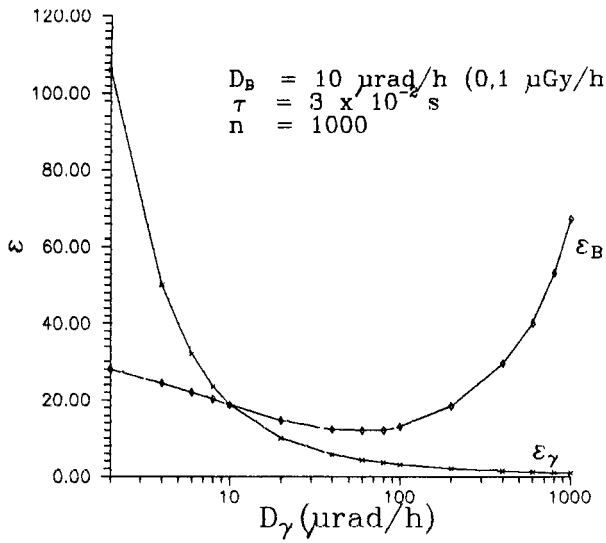

Fig. 1 - Statistical uncertainty of the method (example)

The results were checked by using a functional model with the block scheme shown in fig. 2. The agreement with the calculations was good.

IC	ionization chamber
EA	electrometric amplifier
S	sampling circuit
ADC	analog - to - digital convertor
P	microprocessor
DAC	digital - to - analog convertor
D	display

Fig. 2 - Block scheme of the functional model

3) The proposed statistical discrimination method leads to lower statistical uncertainties than those corresponding to the usual method, based on the subtraction of the natural background. For the same experimental conditions as those used in fig. 1, the method of natural background subtraction would lead to a 0.04 μGy/h for the gamma - ray detection threshold and to a statistical uncertainty of measurement for the 0.1 μGy/h gamma - ray absorbed dose rate in air equal to 47% (instead of 19%, given by the statistical discrimination method).

HIGH SENSITIVITY DOSIMETRYCAL SYSTEM FOR ENVIRONMENTAL, NATURAL RADIOACTIVITY SURVEY

Ana Stochioiu, Caliopia Turcus, Cornelia Craciun, Dorina Pop

Institute for Physical and Nuclear Engineering,
Bucharest, Romania

The high sensitivity dosimetrycal system is destined for measuring of the absorbed dose in air which is produced of the X and gamma radiations within the interval 30 keV - 3 MeV.

This system consists in a dosimetrycal box which has a cylindrical form with the next dimensions: $\phi = 50$ mm, h = 10 mm, which contains five thermoluminescent detectors type $CaSO_4$:Dy.

The detectors are tablets with dimensions: ϕ = 10 mm and h = 0.8 mm.

The raw materials used for obtaining the thermoluminophor powder are the pure substances: $CaSO_4$ u.p.; H_2SO_4 e.g. and spectral Dy_2O_3.

The tablets are obtained pressing the thermoluminophor powder and teflon mixture. In this way the thermoluminophore substance is uniformly included in a teflone matrix.

$CaSO_4$:Dy thermoluminescent detectors (TLD), are obtained in our laboratory by the controlled dopping of the $CaSO_4$ crystal with the activant dysprosiu.

The original technology allows obtaining of the thermoluminescent crystals with high sensitivity leaving from very pure substances.

The measurement of the absorbed dose is based on the principle of the thermoluminescence, consisting in the occurence of excited states in the $CaSO_4$:Dy crystal during irradiation; when heating, thip crystal, following a pre-established thermal cycle, returns to its background state by emitting a fluorescence hight whose intensity in proportional with the absorbed dose [1]. We use for reading of the detectors a Victoreen 2800 equipment.

The dosimetric system is exposed to the environmental irradiation for a minimum period of 30 days and is placed at a standard height, 1 m from the soil.

The main dosimetric characteristics of the system are in accordance with the requirements of the International Standards [2].

They are presented in the following:

- the absorbed dose measuring interval has between (10^{-5} - 10^{-1}) Gy; linearity value R is defined by the ratio between to measured dose (D) and the conventionaly true dose EIR = D/E:

a) whitin the interval (10^{-5} - 10^{-4}) Gy, $0.5 \leq R \leq 1.5$;

b) whitin the interval (10^{-4} - 10^{-1}) Gy, $0.75 \leq R \leq 1.25$;

- the homogenity of the lot detectors from dosimeters is $\varepsilon \leq 30$ %; one lot has 50 detectors;

- the reproductibility of the irradiation during 10 complete cycles: irradiation, reading of the information, regeneration of the detectors for absorbed doses of 5.10^{-5} Gy and 2.10^{-4} Gy is defined by a standard deviation, $\sigma \leq \pm 7.5$ %;

- the dependence of the response with the radiations energy on the whole energetic interval is given by a permissible value of R, $R \leq 2$.

The high sensitivity dosimetrycal system can be used in environmental for measuring absorbed dose in air, he is not influenced by climatic factors.

We hope as with our dosimeter systems to participate to compare international.

BETA TIME-SPECTROMETRY WITH MULTICHANNEL SCALING – A PORTABLE LOW LEVEL MONITOR FOR NATURAL AND ARTIFICIAL RADIONUCLIDES IN AIR, WATER AND SOLIDS

Henning von Philipsborn[1], and Christoph Hoffmann[2]
[1]University of Regensburg, D-93040 Regensburg
[2]Münchener Apparatebau GmbH, Mehlbeerenstr. 2, D-82024 Taufkirchen

Abstract: **The portable beta-/gamma-sensitive Low Level Monitor LLM 500 is equipped with hardware and software for automated repeated measurements of large-area samples (diskettes), up to 100 times for gate times between 1-100 min. Data stored and released to a printer or a PC yield a spectrum of activity vs time. The value of such time-spectra to discriminate natural and man-made radionuclides simply by their half-life, is evident. Three examples discriminating fresh and old radon, radon and thoron decay products, and radon decay products from filtration of snow water are illustrated and explained.**

INTRODUCTION

There is a need to discriminate natural and man-made radionuclides because of their different values both for radiation protection and for the public. In addition, such nuclide-specific measurements should be accurate, reliable, low-cost, and quick and the instrument should be easy to handle and the procedure easy to understand for laymen. There are two nuclide-specific properties which may be used to discriminate natural and man-made radionuclides: the energy of their gamma and alpha radiation, and half-life. New germanium and silicon detectors have made gamma- and alpha energy-spectrometry to be beautiful swans for the purpose stated and have left old time-spectrometry to be an ugly duckling. All natural and man-made radionuclides which need to be identified for practical purposes in public, such as the radon and thoron decay products Pb-214, Bi-214, Pb-212, and Bi-212, and reactor-made I-131, Cs-137 and Sr-90 have clearly different half-lives of minutes, hours, days and years and may thus be discriminated by time-spectrometry or in modern terms "multichannel scaling". In addition, the radionuclides listed are all beta emitters and are most likely to be deposited on large solid surfaces or collected from air or water on large-area filters. For such samples large-area, beta-sensitive, sealed proportional detectors of low cost and high sensitivity are a better choice than any alpha or gamma detector. Proportional detectors are well known from commercial hand-held contamination monitors and may be used for the purposes stated if endowed with appropriate hardware and software. Surprisingly, the Living Level Monitor LLM 500 of Münchener Apparatebau (1, 2) is the first and portable (7 kg, 28 cm x 29 cm x 19 cm) Low Level Monitor with automated time-spectrometry. Its main features and some practical results of three years experiences are reported in the following. The LLM 500 means a renaissance of beta time-spectrometry. Such decay curves to distinguish radon and thoron were first used by E. Rutherford, J. Elster and H. Geitel, and H. A. Bumstead in 1901 - 1904.

MATERIALS AND METHODS

The instrument LLM 500 contains a sealed proportional detector with a 7 mg/cm² aluminum window, argon-methane gas filling and an active area of 11 x 11 cm². The detector is very sensitive for beta and much less for gamma radiation. Its unshielded background rate is ~150 cpm at 70 nGy/h. The detector is connected to a pulse counter and to hardware electronics with software. The instrument has a front panel with a 4 x 4 array of numbered or symbolized buttons as keyboard, a PC-type opening for the measuring diskette, and a four-line, 20 digits each LC display, as well as data memory and output via a RS 232 interface. The LLM 500 is designed to accept samples in 135 x 200 x 2 mm³ diskettes. There are three types of diskettes. Type one is made of two pieces of cardboard each 1 mm thick, with an opening of 10 cm diameter, a glass fibre filter MN 85/90 (Macherey-Nagel, D-52348 Düren) in between and glued together. The diskette fits a patented holder attached to a Staplex high volume sampler with a flow rate of 800 L/min. With such diskettes, grab samples of air are drawn for subsequent measurement in the LLM 500, calibrated in Bq/m³ as equilibrium equivalent radon concentration EER (potential alpha energy concentration). Type two diskettes are made of PVC with an opening of 11.1 cm diameter. They are closed on one side with a 12 x 12 cm

piece of transparent adhesive tape cut from rolls of tape used to protect books. Thus a plate is formed to accept smear tests or filters of 11 cm diameter from water filtration. Such diskettes are also used for thin solid or powder samples between two tapes. Type three diskettes are plates made of white polystyrene and charged by friction to collect electrically charged radon decay products in air, called Philion Plates, described elsewhere (3, 4). All three types of diskettes fit in the slit of the LLM 500 like hand to glove.

After insertion the sample comes to rest under the proportional detector and above a 0.1 mm thick tungsten plate. Tungsten by virtue of its high atomic number is a good beta reflector and increases the counting efficiency for thin samples by about 20 %. The activity calibration factor k and the instrument efficiency e are defined in conformity with SI units by virtue of the dimensional analysis [k] = [Bq/cps] = [1] and [e] = [1/k] = [%]. As described elsewhere (1), k has been determined and confirmed by several different methods to be 3.0 ± 0.3 Bq/cps for two beta/gamma emitters such as the radon decay products in EER [Bq/m³]. The high efficiency of >30% for radon decay products (EER) means a high resolution both of activity (2 Bq) and time (less than 5 min). Proper functioning of the LLM 500 may be checked any time with a test diskette containing 1.9 g KCl with 30 Bq K-40 at k = 6.0 Bq/cps. The software and the simple keyboard of the LLM 500 allow to choose the gate time between 1 and 100 min and the number of repetitions between 1 and 100 or free running either for measurement of the background or of the sample , after subtraction of one background. The calibration factor may be changed between 0.1 and 9.9 and the volume or the weight of the sample is entered via the keyboard for calculation of activity concentrations. All data are stored and may be released either to a printer in columns or to a PC to be plotted as log of net count rates or activity concentrations vs time from which half-lives are extracted.

RESULTS AND DISCUSSION

The discriminating power of beta time-spectrometry is demonstrated by 3 practical examples simply drawn from air and snow water.

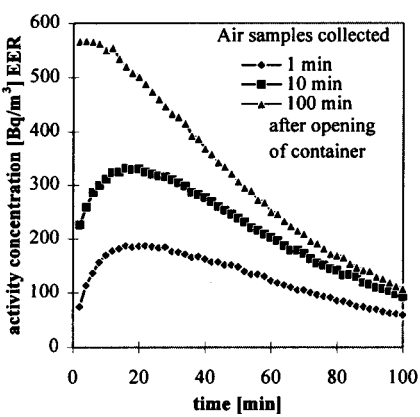

Fig. 1. Activity concentration on filter vs time after collecting sample. Note the difference between "fresh" radon (curve of 1 min after opening the container with uranium minerals) and old radon.

A problem often encountered is to locate a source of fresh radon, such as the entrance of radon from the soil or a water system into a room. Fresh radon has a low factor F of radioactive equilibrium, i.e. contains a larger than normal fraction of Po-218 (half-life 3 min) relative to Pb-214 (27 min) and Bi-214 (20 min). Such an atmosphere is conveniently created in a laboratory by opening an air-tight container with uranium minerals. 1 m³ of air was collected with a Staplex sampler within 75 s. Three samples were taken 1 min, 10 min, and 100 min after opening the container in a room of 100 m³. The glass fibre filters of 10 cm diameter held in cardboard diskettes were evaluated in two LLM 500. The time-spectra of total beta activity are quite different for the 3 samples. In fig 1, spectrum 1 shows a sharp rise of measured activity on the filter within the first 10 min. The large fraction of the alpha emitter Po-218 contributes only after its decay while the measurement is going on. Sample 3, collected 100 min after opening the container shows a normal decay curve for a normal factor of equilibrium of F ~ 0.6. The initial plateau for about 10 min is very practical. No correction to account for time of sampling, transfer and first measurement is necessary, as long as the total time does not exceed 10 min. Spectrum 2 is in between spectra 1 and 3. To obtain information on F, 10 points at 1 or 2 min intervals are quite sufficient.

Thoron (Rn-220) and its daughter Po-216 are both alpha emitters, with short half-lives of 55 s and 0.15 s resp. Their decay products Pb-212 and Bi-212 are beta/gamma emitters with convenient half-lives of 10.6 h and 1 h. Because of its short half-life, Rn-220 was believed not to leave the matrix of its mother Ra-224, such as building materials containing sand, frequently with monazite $CePO_4$, with some Th replacing Ce.

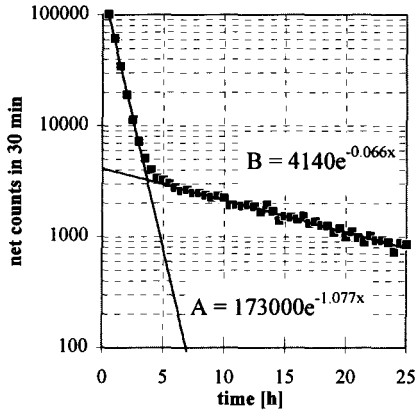

Fig. 2. Decay of a sample of 24 m³ of air, containing radon and thoron decay products. 20 x 30 x 24 = 14400 counts are equivalent to 1 Bq/m³. Note the two branches for radon and thoron decay products.

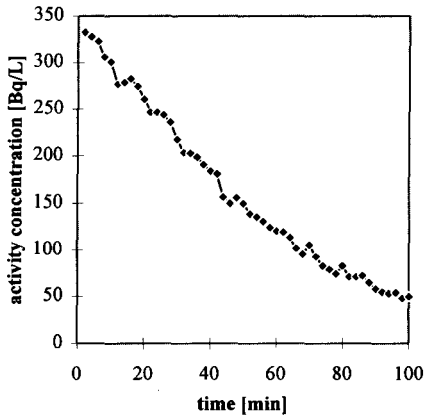

Fig. 3 Decay of a sample of radon decay products from 170 mL of melted snow, collected by simple filtration on a glass fibre filter. Half-life 40 min.

With beta time-spectrometry the presence of thoron decay products was demonstrated in normal room air. 24 m³ were collected on a glass fibre filter within 30 min as described before. 50 measurements automatically repeated at 30 min intervals were made with the LLM 500. Its calibration factor k = 3 Bq/cps means 20 cpm are equivalent to 1 Bq, or 20 x 30 x 24 = 14400 counts in 30 min for 24 m³ are equivalent to 1 Bq/m³. Background count was 4774 counts in 30 min, first net count was 101230. Fig. 2 shows the semilogarithmic plot of count rate vs time, yielding two equations: For radon decay products A = 173000 exp(-1.077 x) giving an activity of 12 Bq/m³ and a half-life of 38 min. Note this value is smaller than the value of 52 min taken from spectrum 3 in fig. 1, where Po-218 still contributes because of the short sampling and measuring time. For thoron decay products B = 4140 exp(-0.066 x) giving a nominal activity of 0.3 Bq/m³ and a half-life of 10.5 h.

Glass fibre filters were found to be very efficient (> 95 %) and reproducible for rapid filtration of radon decay products in water. This was unexpected and may be the reason why it was not tried before. No reference was found in the literature on ten different methods for measuring radon or radon decay products in water. Equilibrium (after 3 h) may always be assumed to exist in water. For water filtration we use the same filters as for air sampling, type MN 85/90, 90 g/cm², 0.40 mm thick, 0.5 µm retention (information from the manufacturer). With a filter of 11 cm diameter in a cylindrical Büchner funnel, filtration without a water jet pump takes only 5 min for 1 L. Wet filters are dried in 1 min on a 300 °C hot stage and measured on a plate-type diskette in the LLM 500. Neutral or alkaline state is good, acidic is poor for retention. The surface of glass fibre filters may act similar to the surface of glass electrodes (Nernst' potential) to provide negative ionic bonding to cations. For fig. 3 fresh snow was melted to 170 mL of water, showing a concentration of 330 Bq/L from snow-out of radon decay products. The decay curve in fig. 3 is for illustration, for a measurement the first value of 1 or 2 min is sufficient. In fresh rain concentrations up to 100 Bq/L radon were found. The detection limit is 1-2 Bq/L, found in any drinking water, for which a US EPA limit is 11 Bq/L.

CONCLUSIONS

Ten years after Chernobyl the hope is expressed, that the instrument described may not be required in the future to discriminate natural and reactor-made airborne radionuclides and that its use be reserved to research, teaching and services in natural environmental radiation.

ABSTRACT (See instructions overleaf)

A completely portable and self-contained environmental dosimetry system, based on proven hot-gas TLD technology and enhanced with hyper-sensitive TL material, neural network dose computation, and requiring only electrical power for operation is presented and performance testing is discussed. The dosimeter is composed of a symmetric holder containing proper filtration to measure $Hp^*(10)$, $Hp^*(0.07)$ and discriminate low, intermediate and high energy environmental radiation. The TLD material is newly developed LiF:Mg,Cu,P mounted on Kapton® or sandwiched between Teflon® sheets. The new TLD material is tissue equivalent and is shown to be well suited for enviromnmental dosimetry with higher sensitivity, more uniform response with respect to energy, and negligible fade. The TLD Workstation is equipped with an Air Supply Unit and provides portable field readout capability. The workstation is composed of a TLD reader, associated application software system, and a personal computer. The workstation software provides instrument control, data acquisition and storage, QC monitoring, and dose calculation algorithm. A new aspect of QC monitoring is the glow curve analyzer, which provides automatic screening to identify abnormal glow curves. The recently developed neural network-based algorithm computes the desired dose quantities more accurately than a simple dosimeter reading or a decision tree dose algorithm. This environmental dosimetry system was designed to comply with the current ICRP requirements and the proposed ANSI requirements.

THE DETERMINATION AND OPTIMIZATION OF MULTIPLE MEASUREMENTS FOR ACTIVITY CALCULATIONS

Brian G. Scott[1]

[1] MS K487 Los Alamos National Laboratory, Los Alamos, NM 87545

ABSTRACT

The calculation of the radioactive contents of a waste container is often performed by a dose rate per activity ratio. This ratio is determined for a selected detector location, gamma energy and activity distribution. If the spatial distribution of the activity is unknown, however, the resulting calculated assessment of the activity from a single detector may contain a high degree of uncertainty. In addition, the optimal location of the measurements becomes a function of the background radiation, the amount of activity present and the desired statistical confidence of the result. If a set of N measurements is considered an N vector response, the incorporation of multiple detector measurements can reduce the uncertainty of the calculated assessment. The multiple detector calculations are performed by applying dimensional measurement space and a unit response set to the problem of assessing and optimizing multiple independent detector measurements of various waste containers. The associated errors of multiple measurements are calculated for various detector placement configurations. The calculations indicate that multiple detector measurements and optimal placement of the measurements combined with appropriate mathematical techniques significantly reduce the assessment uncertainties due to lack of knowledge of the spatial distribution of activity.

INTRODUCTION

A number of methodologies have been utilized to reduce the uncertainty in the assessment of unknown spatial distributions of activity. Rotation of the source container, segmenting the measurement volume seen by a detector and linear combinations of detector responses have been demonstrated as methods in reducing the assessment uncertainty for such configurations as a point source and a small cylinder source within a waste container (1).

The use of a detector response space for multiple measurements has been previously introduced to the problem of measuring the largest uncertainty that a detector system will generate when assessing randomly distributed radioactive material (2,3,4,5,6). The mathematical framework is independent of the container volume and the type of detector present. In this paper, detector response space is applied to the problem of interpreting detector responses in the presence of randomly distributed radioactive material. The resulting method, the ray-method, can be utilized to assess the amounts of radioactivity that could result in the given detector response (7).

FUNDAMENTAL CONCEPTS

When accounting for the detector responses which are the result of random or unknown spatial distributions of activity, the use of sets becomes a convenient terminology. A number of definitions have been utilized which aid in describing the set of detector responses that result from the distribution of a fixed amount of activity (2). If f_n is the nth detector response from a unit amount of radioactivity then the set of N detector response functions can be represented as

$$f(x,y,z) = (f_1(x,y,z), f_2(x,y,z), \ldots f_N(x,y,z)). \qquad (1)$$

The set of detector responses from all possible locations of a single unit point source of

radioactive material is called the point source response set. If (X,Y,Z) represents the set all possible positions that the activity may be located, the point source response set is defined as

$$F=\{f: f=f(x,y,z) \text{ for all } (x,y,z)\in(\mathbf{X},\mathbf{Y},\mathbf{Z})\}. \quad (2)$$

Let $r(x_0y_0z_0)$ represent the density of the radioactive material at point $(x_0y_0z_0)$. The integrated response to a source density distribution $r(x,y,z)$ is

$$c=\int_V r(x,y,z)\,f(x,y,z)\,dxdydz. \quad (3)$$

The set of all detector responses from any spatial distribution of one unit of radioactive material is called the complete response set. The complete response set can be represented as

$$C=\{c: c=\int_V r(x,y,z)\,f(x,y,z)\,dV \text{ for all } \int_V r(x,y,z)\,dV=1\}. \quad (4)$$

The complete response set has been shown to be the smallest convex set (i.e. the convex hull) that contains the point source response set (2). This property of convexity allows the complete response set to be constructed from the point source response set and the set of all distributions of activity to be defined in terms of point distributions of activity.

METHODOLOGY

A given N detector response, $(h_1,h_2,...,h_N)$, resulting from some unknown amount of activity creates a line passing through the origin with slopes

$$s_1=\frac{h_2}{h_1},\ s_2=\frac{h_3}{h_1},\ \ldots,\ s_{N-1}=\frac{h_N}{h_1}. \quad (5)$$

Detector responses on the above line are the result of different amounts of activity with the same distribution. The intersection of this line with the complete response set C, forms a line segment which represents different distributions of a unit amount of activity that result in detector responses which satisfy equation (5). The respective distances from the origin of the endpoints of this line segment are the maximum and minimum distances from the origin that result in the above detector response proportions from one unit of activity. Two ratios are computed by dividing the respective distance from the origin of each of these endpoints into the distance from the origin to the given detector response h. The resulting ratios give the maximum and minimum activity that could result from the point $(h_1,h_2,...,h_N)$. The assessment equation is

$$\min_{g\in C}\sqrt{\left(\frac{h_1^2+h_2^2+\ldots+h_N^2}{g_1^2+g_2^2+\ldots+g_N^2}\right)} \le A \le \max_{k\in C}\sqrt{\left(\frac{h_1^2+h_2^2+\ldots+h_N^2}{k_1^2+k_2^2+\ldots+k_N^2}\right)} \quad (6)$$

where the points are subject to the constraints

$$f_2=s_1f_1,\ f_3=s_2f_1,\ \ldots,\ f_N=s_{n-1}f_1 \text{ for all } f\in C \text{ and all } (x,y,z)\in(\mathbf{X},\mathbf{Y},\mathbf{Z}). \quad (7)$$

APPLICATION

The above methodology was applied to a waste container problem. The necessary calculations were simplified by several assumptions. The radiation detectors are limited to two and are considered point detectors. Only the unscattered flux is taken into account. Self-attenuation and the attenuation coefficient outside the source container are considered negligible. The detector responses are proportional to the amount of radioactive material present for identical distributions of activity. The background levels of radiation are ignored. Statistical uncertainty of a detector response is considered negligible.

DISCUSSION

Calculations of the above application demonstrate that the addition of a second detector measurement can decrease the calculated uncertainty by approximately 30-fold. The application relied on the assumption that the activity is proportional to detector response. The assessment of nonproportional response sets (i.e. self-shielding) can be performed by generating successive sets of incremented activity and searching for amounts of activity for which overlap of the detector responses ceases (5). In some cases, a self attenuation function for limited distributions can be calculated which may give a functional relationship between the detector responses and the activity (8).

Although the above application relied on point source formulations, the utilization of standard shielding codes to construct the complete response set from the generated point source response set and subsequently to solve the interpretation of the given detector responses should pose few difficulties for calculations not involving self-shielding.

CONCLUSION

The application of response sets to the problem of multiple detector measurements allows the analyst and designer to calculate the actual and maximum calculated activity uncertainty due to spatial uncertainty of the activity distribution. With this information detector systems can be optimized to minimize the maximum uncertainty and measurements can be exploited to a full extent.

INTRODUCTION

Liquid scintillation counting is one of the most used techniques for the measurements of tritium contamination [1]. Until few years ago a problem related to this kind of measurement was the potential toxicity of the liquid cocktails used to produce the required scintillation. Some new products that guarantee an almost negligible impact on the environment and that are no longer toxic for the operators are now available.

Some of this new scintillation cocktail are suitable to be used for tritium measurement. Due to the great benefit from the health point of view of these new materials a test of their scintillation performance has been done at the ENEA centers to select the product having the best characteristics for tritium measurement.

THE COCKTAILS

Three new generation cocktails (biodegradable) were used in our test together with an old toxic (xylene based) scintillation liquid widely utilised in the past. Some characteristics of the examined cocktails are given in table 1, where the new products are indicated with the generic names SAFE 1, SAFE 2 and SAFE 3.

Table 1 - Cocktails characteristics

Cocktail	Applications	General composition	Flash point (°C)
SAFE 1 *low toxicity*	Low level counting, high sample acceptance	___	> 130
SAFE 2 *low toxicity*	High counting efficiency	Di-isopropyl-naphthalene (DIN)	148
SAFE 3 *low toxicity*	Low level counting	DIPN	150
OLD *toxic*	Large variety of application	Xylene	___

The four cocktails are appropriate for low level counting when large amount aqueous samples are needed.

INSTRUMENTS, METHODS AND SAMPLES

A Wallac 1220 Quantulus counter was used for all the measurements. The counter includes lead shielding, cooling system, liquid scintillation guard counter and pulse analyzer, to reduce the background level.

The Zinsser 900 vials (teflon coated) that were used for the counting process.

The preparation of the samples in the case of the cocktails SAFE 1, SAFE 3 and OLD was carried out adding 10 ml of scintillation liquid to 10 ml of tritiated or bidistillated water, for the SAFE 2 cocktail 9 ml of water and 11 ml of cocktail were used.

The percentage of the scintillation liquid used in the sample solutions was always that suggested by the cocktail manufacturer.

The counting time for all the measurements was 120 minutes. Two independent energy windows were fixed for each sample; the larger one (the same for all the cocktails) was choosen to contain all the tritium energy spectrum and the other was selected to maximize the figure of merit for the specifically used cocktail.

THE TEST PARAMETERS

The parameters considered to compare the cocktail performances were the efficiency and the Minimum Detectable Activity (MDA). The former was determined measuring a standard tritium source. The uncertainty on the efficiency determination can be calculated taking into account the following components. A first source of error is the uncentainty in the tritium quantity used in the sample. The tritium source used in our test is an organic substance soluble into water prepared by the Amersham International and distributed by Wallac. The uncertainty in the activity of this standard source is about 7.9 %. Other statistical errors have to be taken into account for the samples preparation depending on the specific cocktail and counter. In table 2 the total error (combined standard uncertainty) for each cocktail is reported [2].

Table 2 - Statistical error in efficiency evaluation

Cocktail	Type B uncertainty (%)	Type A uncertainty (%)	Combined standard uncertainty (%)
SAFE 1	7.9	5.9	9.8
SAFE 2	7.9	5.5	9.6
SAFE 3	7.9	5.7	9.7
OLD	7.9	7.6	10.9

The MDA has been evaluated with the following formula [2,3]:

$$MDA = \frac{4.66 \cdot Sb}{\varepsilon \cdot V \cdot 60} \quad [Bq/l]$$

where:
S_b is the estimation of the standard deviation (cpm)
ε is the efficiency
V is the volume of the sample (l)

Table 3 - Cocktail performances

Cocktail	Window (channels)	Background ± σ (cpm)	MDA (Bq/l)	Efficiency (%)	FM	FMV^2
SAFE 1	20-270	2.23±0.13	6.2	16.4	120	12000
	20-120	0.63±0.08	4.5	12.8	255	25500
SAFE 2	20-270	2.48±0.13	6.3	18.0	130	10530
	20-130	0.70±0.08	4.4	15.1	325	26325
SAFE 3	20-270	2.51±0.14	6.0	18.1	130	13000
	20-130	0.76±0.10	4.9	15.1	296	29600
OLD	20-270	3.06±0.23	11.2	16.2	85	8500
	20-119	0.85±0.10	5.7	13.3	207	20700

RESULTS AND CONCLUSIONS

The results of the measurements were elaborated and the relevant parameters are presented in table 3.

Fig. 1 shows a graphic presentation of the efficiency and MDA for the various scintillation liquid tested. The conclusion that can be drawn from our results is that the three SAFE cocktails used show a similar behaviour and have better characteristics than the OLD cocktail

A SIMPLE CALIBRATION METHOD FOR THERMOLUMINESCENCE DETECTORS USED IN ENVIRONMENTAL MEASUREMENTS

L. P. Pashchenko
Research Institute of Industrial and Marine Medicine,
67, Y. Gagarin Prospect, St. Petersburg 196143, Russia

INTRODUCTION

Recently, it has been proposed a calibration method for potassium halide thermoluminescence (TL) detectors (1). The procedure is based on the irradiation of potassium halide TL detector due to β particles, emitted by natural radioactive nuclide ^{40}K contained in the crystal itself as well as in a coat made of crystalline KCl salt surrounding the detector during a period of the calibration exposure time. The aim of this paper is to extend the proposed method to TL detectors manufactured from other materials. This is especially important for high sensitivity TL detectors used in environmental investigation, since the doses involved in the proposed method are comparable to the doses usually measured in environment.

GENERAL CONSIDERATION

To illustrate the method let us at first consider TL detector manufactured from KCl (for example, KCl:Eu) embedded into a coat of KCl crystalline salt as depicted in Fig. 1.

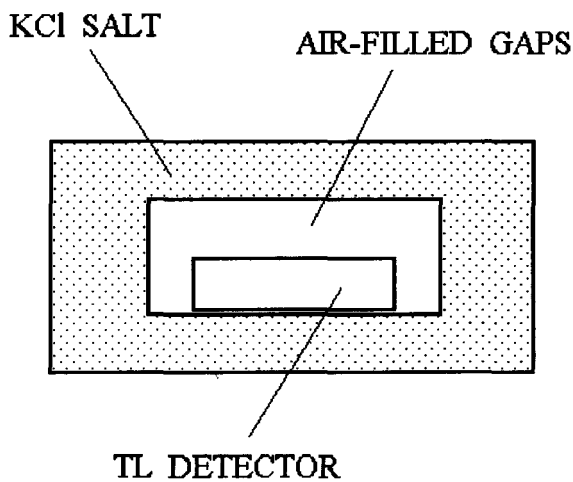

Figure 1. Schematic diagram for detector calibration exposure

If the thickness of the KCl coat is much larger than the range of the most energetic β particles, emitted by ^{40}K, and if the air filled gaps between detector and the inner surface of KCl coat are small enough, according to the cavity theory (2) the absorbed energy in the detector is equal to the energy produced per unit mass of KCl. Thus, the absorbed in the detector dose D is given by

$$D = C\,E\,t$$

where C is the activity of ^{40}K per unit mass of KCl, E is the average β ray energy per disintegration, and t is the time of exposure. Substitution of the values of C and E (3) in this expression gives the absorbed dose in the detector

$$D = 4.9\,t,\ \mu Gy,$$

where t must be expressed in hours. Therefore the exposure rate in potassium halide thermoluminescence detector embedded into a crystalline coat is 4.9 μGy/h and if the exposure time is equal 1 - 2 days, the absorbed dose must be equal to 100 - 200 μGy (10 - 20 mrad), i.e. the value, comparable to quarter dose usually measured in environment. Thus the calibration method is useful for detectors applied in environmental investigations. Unfortunately the fading of the KCl:Eu detectors according to recent investigation (4) is large, and because of that these detectors are not promising in environmental measurements. More perspective are LiF or Al_2O_3 detectors which show high sensitivity and low fading, adequate for environmental dosimetry.

RESULTS OF MEASUREMENTS AND ACCURACY OF THE METHOD

It is clear, that for LiF or Al_2O_3 detectors embedded into a KCl coat the exposure rate must be less (compared to potassium halide detectors) for lack of the self-irradiation effect. In order to determine the exposure rate for LiF and Al_2O_3 detectors we have made a comparison of TL signals, obtained from these detectors after theirs exposure in KCl coat, and TL signals, obtained after the detectors irradiation by using ^{137}Cs γ-ray source of well-known activity. The irradiation was made in condition of the existing of the electron equilibrium. In experiments were used detectors LiF:(Ti, Mg) and anion-defective α-Al_2O_3 :C single crystals, commercially grown in Russia as DTG-4 and TLD-500K, respectively. The size of the crystals were 5 mm diameter and 1 mm thickness. The crystalline KCl coat salt used for irradiation was with wall thickness around 1 g cm^{-2}. From the results of the comparison it was found that exposure rate in TL detectors LiF and Al_2O_3 embedded into a cavity in KCl crystalline block is 2.09 μGy/h and 1.73 μGy/h, respectively. These values of the exposure rates may be used for detectors calibration.

As was shown in (1), the main sources of errors in the proposed calibration method are: the impurities of the KCl salt which may change the content of ^{40}K per unit mass of salt as compared to that of pure KCl salt, the energy lost by the β particles because of the existing air-filled clearances between the surface of the detector and that of the cavity in the KCl salt, the ^{40}K γ radiation which may give a small contribution to the absorbed detector dose, variations of the natural radiation background during the exposure time, the statistical variation of the number of β particles which were absorbed by the detector during the

exposure time. In (1) was also shown that the total uncertainty of the absorbed detector dose due to all these sources of errors under certain conditions does not extend the common error of 1.5% - 2.0% of traditional calibration methods practiced in specially equipped metrological laboratories (5).

CONCLUSION

In conclusion, we have developed a very simple and highly accurate calibration procedure for LiF and Al_2O_3 detectors based on application crystalline KCl salt block as a source of β radiation due to the natural content of the radionuclide ^{40}K. The method does not require artificial radiation sources or precision equipment and may be carried out in any laboratory. The proposed procedure may be used in environmental investigation, since the doses involved in the method are comparable to the doses usually measured in environmental dosimetry.

APPLICATION OF REAL TIME SPECTRUM MEASUREMENT TO RADIATION MONITORS

K. Matsuno,[1] M. Watanabe,[1] and T. Sakamaki[2]

[1]Fuji Electric Techno Engineering Co.,LTD., Tokyo, Japan
[2]Fuji Electric Co.,LTD., Tokyo, Japan

ABSTRACT

A multichannel analyzer (MCA) and two realtime spectrum monitoring methods have been developed for use in radiation monitors. The new MCA was designed to be installed at a local site as a component of a radiation monitor. The MCA repeats spectrum measurement at short intervals (Δt) and, after each measurement, transmits a spectrum datum to the operation console. The authors applied two methods to process Δt spectrum counts for each channel for longer time interval.

One method of processing counts is the "running average (RA) method". The other method is the "exponential smoothing (ES) method", which simulates RC rate meters by subtracting a fraction corresponding to the accumulated counts. Relative standard deviations for each channel can be made the same by selecting an appropriate value. The response with the "ES" method is initially faster than that with the "RA" method, but the "RA" method allows a full response to be reached at a predictable time.

INTRODUCTION

In order to measure various radionuclides contained in typical radioisotope facilities, gamma spectrometry is necessary. The detectors of radiation monitors are installed at a local site, separately from a control room.

Radiation monitors must be able to operate continuously and respond quickly to changes in radiation levels. The MCA conventionally used in labolatory analysis is not designed to measure varying radiation continuously or as quickly as radiation monitors need. The conventional MCA is also expensive.

For these reasons, spectrum measurement has not been applied to radiation monitors. Only the count rates of the total spectrum have been measured until now.

We have developed a relatively inexpensive MCA and data reduction methods with a real time response to be used in radiation monitors.

REAL TIME SPECTRUM MEASUREMENT

Table 1 shows the specifications of the MCA.

The MCA contains an amplifier, a high voltage power supply, a temperature sensor and an optical interface for data transmission to the console. Detector bias voltage, amplifier gain and Δt are adjustable at the personal computer in the console.

Table 1. Specifications of the MCA.

Bias voltage supply	600 - 1,200 V
Amplifier gain	1.1 V/pc $\times$1,2,3
ADC conversion gain	512 ch
Counts per channel	$2^{16}-1$
Integral non-linearity	$\pm$ 0.5 %
Differential non-linearity	$\pm$ 2 %
Operating condition	0-45 ℃, 95 %RH

A specturm measurement is repeated at short intervals (Δt) in the MCA and, after each measurement, spectrum data are transmitted to the operation console via an optical fiber cable. The personal computer in the operation console processes Δt spectrum counts for each channel for longer time interval.

We applied two computing methods. Both methods have been utilized in digital count rate meters. One method is the "running average (RA) method". Each Δt spectrum datum transmitted from the preamplifier is stored in a rotating 10 stage memory stack. The most recent datum replaces the oldest cyclically. The total of all the counts for the same channel in the memory stack is updated each time a datum is replaced. Thus the spectrum is refreshed every Δt measurement. The counting time of the spectrum is $10 \times \Delta t$. Because the spectrum of the "RA" method is simply the mean value in $10 \times \Delta t$ interval, its response is delayed with fast radiation changes.

The other method is the "exponential smoothing (ES) method", which responds exponentially to radiation changes. It simulates the response of analogue RC rate meters by subtracting a fraction corresponding to the accumulated counts.

$$N_i = R_i^{-1} [N_{in} + (R_i - 1) N_{i(n-1)}], \quad (1)$$

$$\tau_i = (R_i - 0.5) \Delta t, \quad (2)$$

$$P = [2 \tau_i N_{i(n-1)}]^{-1/2} \times 100, \quad (3)$$

where

N_i = Counts of i-channel after refreshment;
R_i = Exponential smoothing coefficient;
N_{in} = Counts of i-channel transmitted;
$N_{i(n-1)}$ = Counts of i-channel before refreshment;
τ_i = Time constant of i-channel; and
P = Relative standard deviation which is common to whole channel.

The exponential smoothing coefficient R_i is derived from equations, (1),(2) and (3).

$$R_i = [2 N_{i(n-1)} \Delta t]^{-1} (100/P)^2 + 0.5 . \quad (4)$$

This method has been used in digital count rate meters. Although digital count rate meters have only one channel, there are i number of channels with spectrum monitoring. By setting the values of Δt and P beforehand, R_i is calculated with $N_{i(n-1)}$. Then, the count numbers of each channel are exponentially smoothed. The time constant for each channel changes according to the count for each channel. As the results, relative standard deviations of whole channel have the same value in the range of τ_i from 1 to 10 min. The range is limited from the the point of actual application to radiation monitors.

THE RESULTS OF MEASUREMENT

In the background radiation field, we put two radiation sources, ^{137}Cs and ^{60}Co, whose radiation intensities are less than 3.7 MBq, near to a 2"ϕ NaI(Tl) scintillator. After the spectrum reached equilibrium, we picked up both sources.

Figure 1 shows changes in the spectrum measured with the "RA" method with Δt=1 min. Figure 2 shows changes in the gross counts of the ^{137}Cs peak area.

The counts increase, then decrease according to the same ratio step.

Figure 3 shows changes in the spectrum measured with "ES" method when the relative standard deviation is set to 5 %. Figure 4 shows changes in the gross counts of the ^{137}Cs peak area when the standard deviation is set to 5%, 10% and 20%. It is recognized that each time constant varies according to standard deviations.

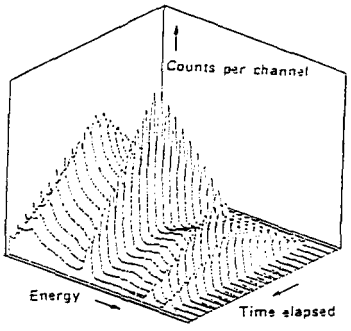

Figure 1. Changes in spectrum with running averaging.

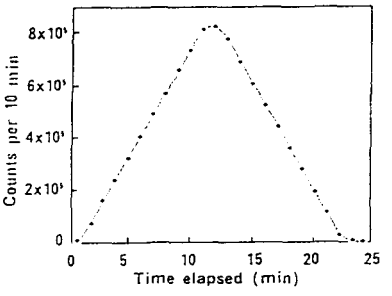

Figure 2. Changes in gross counts of ^{137}Cs with running averaging.

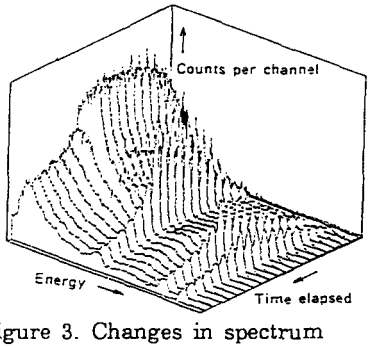

Figure 3. Changes in spectrum with exponential smoothing.

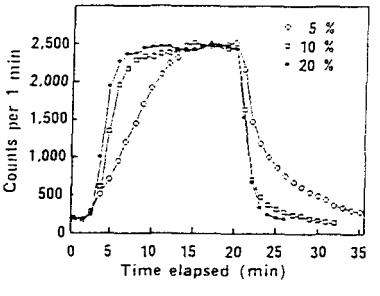

Figure 4. Changes in gross counts of ^{137}Cs with exponential smoothing.

APPLICATION TO RADIATION MONITORS

Real time spectrum measurement is applicable to area monitors, liquid effluent monitors and gaseous effluent monitors. NaI(Tl) scintillators are suitable for such radiation monitors. In liquid and gaseous effluent monitors, specific energy regions are set to determine the radioactive concentration of each radionuclide, which will be released from a radioisotope facility. The dose equivalent rate of an area monitor is calculated from the measured spectrum and energy weighting factors. Such an area monitor is more sensitive than one with an ionization chamber.

In routine radiation monitoring, only calculated radioactive concentrations and dose equivalent rates are stored in the personal computer. When those values exceed the preset levels, the spectrum at that time is also stored automatically.

SUMMARY

We have developed an MCA and two real time spectrum monitoring methods for use in radiation monitors. The "running average method" cannot keep up with radiation changes, but shows a precise spectrum. The "exponential smoothing method" has a fast response because of an automatically variable time constant.

The latter method is preferable for area monitors and gaseous effluent monitors.

MEASUREMENT OF THE AVERAGE PATH OF GAMMA-RAYS IN THE SAMPLE

Matjaž Korun[1], Rafael Martinčič[1], Beno Rola[2]

[1]J. Stefan Institute, Ljubljana Slovenia
[2]Department of Physics, University of Ljubljana, Ljubljana, Slovenia

Abstract. It is shown that the valley-to-peak ratio in gamma-ray spectra bears information about the average path of gamma rays, thansversed in the sample. The measurements of the intrinsic valley-to-peak ratio, due to the response of the detector to gamma rays are presented. The average path in homogeneous sample, estimated from the valley-to peak ration is compared to the path, calculated from the derivative of the efficiency on the attenuation coefficient.

INTRODUCTION

In gamma-ray spectrometry the activity of gamma-ray emitting nuclides can be evaluated if the probability for the registration of gamma rays in the full energy peaks is known. This probability depends on the characteristics of the detector, the sample and their geometry. For homogeneous samples it can be measured by measuring calibrated sources [1], which resemble the samples in all characteristics. Therefore it is convenient to have a method to justify the supposition about the homogeneity of unknown samples. Hence, methods are sought to determine the inhomogeneity from the measured spectrum itself.

An indication for the presence of inhomogeneity can be obtained from the comparison of the measured average path of detected gamma rays in the sample with the calculated one under the supposition that the sample is homogeneous. When gamma rays pass the material they may by scattered for small angles. The corresponding energy loss is small and they register in the energy interval between the Compton continuum and the full energy peak. However, in this energy interval counts are present even if there is no material between the source and the detector, because of scattering on insensitive layers of the detector and since gamma rays may lose any amount of energy in the sensitive area before escaping. Therefore only the increase of the number of counts in the interval over its intrinsic value bears the information about the thickness of the transversed layer [2]. This information can be then used to assess the distribution of the emitter within the sample or to calculate self-absorption corrections.

METHOD

The relation between the number of gamma rays emitted from the vicinity of the point $\vec{r}$ which are registered in the "valley" between the Compton continuum and the full energy peak and the average path transversed in materials between the sample and the detector has two terms. The first describes the number of counts of the bare detector and the second the increase due to the scattering in the transversed material:

$$dN_v(\vec{r}) = K(\vec{r})\, dN_p(\vec{r}) + \eta'(\vec{r})\, P_1(\mu_a,\vec{r})\, dN(\vec{r}) \quad .$$

Here $dN_v(\vec{r})$ denotes the number of gamma rays emitted in the vicinity of the point $\vec{r}$ and registered in the valley, $dN_p(\vec{r})$ the number of counts registered in the peak, $K(\vec{r})$ the ratio of the number of counts in the valley and the number of counts in the peak for a source placed at the point $\vec{r}$ and in the absence of material between the source and the detector, $P_1(\mu_a,\vec{r})$ the probability for single scattering of gamma rays to the energy interval of the valley, $\eta'(\vec{r})$ the probability for detection of scattered rays with full energy and $dN(\vec{r})$ the number of rays, emitted from the point $\vec{r}$. The constant $K(\vec{r})$ represents an intrinsic property of the detector and must be measured in a similar way as the total-to-peak or peak-to-Compton ratios. The probability for single scattering is given by [2]:

$$P_1(\mu_a,\vec{r}) = K_1\,\mu_a\,\bar{d}(\vec{r})\,e^{-\mu_a\bar{d}(\vec{r})}\,P_\Omega(\vec{r}) \quad ,$$

where K_1 denotes the fraction of the total number of interacted rays, which are scattered into the energy interval of the valley, μ_a the total interaction coefficient, $\bar{d}(\vec{r})$ the average path of gamma rays through the material and $P_\Omega(\vec{r})$ the probability for transversing the space occupied by the scattering material. K_1 is given by the ratio of the integral of the Klein-Nishina cross section over the interval of angles, defined by the energy interval spawning the valley region, and the total interaction cross section. The number of gamma rays detected in the valley region is:

$$dN_v(\vec{r}) = K(\vec{r})\,dN_p(\vec{r}) + K_1'\,\mu_a\bar{d}(\vec{r})\,dN_p(\vec{r}) \quad ,$$

where we have used the relation $dN_p(\vec{r}) = \eta(\vec{r})dN$ and $K_1' = K_1\eta'(\vec{r})e^{-\mu\bar{d}}P_\Omega(\vec{r})/\eta(\vec{r}) = K_1\eta'(\vec{r})P_\Omega(\vec{r})/\eta_o(\vec{r})$. In the last expression $\eta_0(\vec{r})$ denotes the efficiency in the absence of the absorbing medium. It can be shown [3], that the dependencies on $\vec{r}$ in the expression on K_1' partially cancel out. The rest can be accommodated to the average path $\bar{d}(\vec{r})$ by its redefinition, so that the valley-to-peak ratio for a volume sample is obtained by integration of the previous equation over the sample volume and division by N_p:

$$\frac{N_v}{N_p} = \frac{\int_{V_s} K(\vec{r})\,dN_p(\vec{r})}{N_p} + K_1'\,\mu_a\,\frac{\int_{V_s}\bar{d}(\vec{r})\,dN_p(\vec{r})}{N_p} \quad .$$

Since the last factor in the last term represents just the average path in the sample of the scattered and detected rays, it can be expressed as:

$$\bar{d} = \frac{\dfrac{N_v}{N_p} - \dfrac{\int_{V_s} K(\vec{r})\,dN_p(\vec{r})}{N_p}}{K_1'\,\mu_a} \quad .$$

MEASUREMENTS

The valley-to-peak ratio of the detector $K(\vec{r})$ has been measured for a p-type detector of 35% relative efficiency at energies of 320, 661, 835 and 1115 keV on a grid of points within 5 cm in the radial direction and 4 cm in the axial direction from the centre of detector cap with the interval of 1 cm. In order to avoid the contribution of counts from the low-energy tail of the full energy peak the upper limit of the valley region was set to 25 keV below the energy of the gamma rays. The energy interval of the valley region is presented in Fig. 1. The measured energy dependence of $K(\vec{r})$ in the detector axis on the detector surface is presented in Fig 2.

The constant K_1' was measured with a parallel beam of rays, scattered on a layer of material of known thickness. To measure the average path of gamma rays in the sample four sources with aqueous solution of the ^{137}Cs isotope were measured. They were of cylindrical shape with dimensions of Φ60x10, Φ60x36, Φ90x16 and Φ90x39 mm. The comparison between the average path in the sample of the detected rays, calculated from the derivation of the volume-source efficiency on the absorption

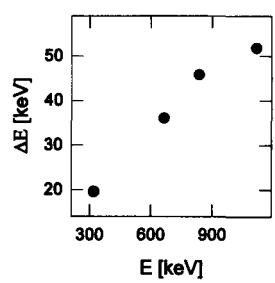

Figure 1. The energy dependence of the valley region.

coefficient [4], and the average path in the sample of scattered and detected rays is presented in Table 1. It may be observed that the path of scattered and detected rays is larger. This is due to the scattering angle, which permits the detection of rays which would not pass the sensitive volume of the detector.

DISCUSSION AND CONCLUSION

The valley-to-peak method was developed for use in in-situ gamma-ray spectrometry, to measure the average depth of the radionuclides deposited in surface layers of the soil. It has been shown that also in laboratory conditions it yields useful results. In laboratory conditions the difference between the paths of scattered and unscattered rays becomes measurable. This difference, since is due to the scattering angle, falls off with increasing energy of gamma rays. The comparison between both average paths offers the opportunity to check the supposition about the homogeneity of the sample on one hand and presents an independent check for the accuracy of the calculation of the influence of self-attenuation on the efficiency on the other. It should be noted also, that in laboratory conditions the spatial dependence $K(\vec{r})$ which reflects the variation of the detector response on the position of the source must be taken into account. Consequently, in measurement of volume samples the integration in Eq. (1) has to be carried out, in order to obtain unbiased results.

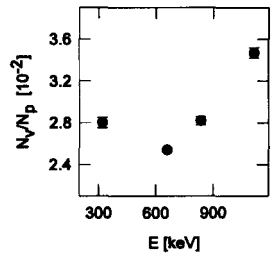

Figure 2. The energy dependence of the valley-to-peak ratio for a point source located on the detector surface on its axis.

ABSTRACT (See instructions overleaf)

Today, the knowledge of the radioactivity level in a given environment is one of the essential questions that seems concerned all citizens. In the Université de Franche Comté, to reply for the different investigations in situ that we have been asking by institutional and academic institutions, industrial person or simple citizen, we have developed or adapted different techniques. The whole of these instruments is autonomous and portable. They localised in a specially mobile laboratory to realise measures rapidly. The available measure instruments are : - a proportional counter, specially developed to measure the radon concentration directly in every atmosphere, soil and aquatic point, - an alpha spectrometer of terrain using a silicon detector adapted to perform alpha emitter measurements on all surfaces and with the possibility to analyse the alpha emitters fixed on aerosols and collected by a filtering membrane, - a portable gamma spectrometer (8192 channel) using NaI (Tl) detector for monitoring gamma ray emission s from natural (potassium, uranium, thorium,...) or artificial (caesium, ...) radionuclides and - a device to analyse the concentration in ozone that is proportional to the rate of ionisation produced on the site of measure. All devices connected to a portable micro-computer that centralises the results and gives the cartography of the radioactivity level for the studied environment.
Different fieldwork's have shown the quality and the efficiency of implementation systems.

THE BGO ALPHA-BETA-GAMMA SCINTILLATION SPECTROMETER*

Yehoshua Kalish

Medical Physics Department, Beilinson Medical Center,
Petah-Tiqva, Israel

Introduction

The NaI(Tl) alpha-beta-gamma (ALBEGA) scintillation spectrometer was invented by Kalish in 1972 [1,2]. It was introduced at an international conference in March 1973 [3] and further described at other conferences [4-10]. The first manual NaI(Tl) ALBEGA spectrometer was developed and constructed by Kalish in cooperation with Beta Research & Development Co. (Israel) during 1972-1974 and a prototype of an automatic version was displayed by Kalish and Beta Research & Development at the 5th International Conference on Medical Physics in August 1979 in Jerusalem.

The core of the NaI(Tl) ALBEGA scintillation spectrometer comprises a cylindrical NaI(Tl) crystal coupled to two photomultiplier tubes. At the center of the crystal, perpendicular to its major axis, is a cylindrical cavity covered with quartz. When a sample containing a beta- or alpha- emitting isotope is to be measured, it is dissolved in a liquid scintillator, and the vial containing the radioactive liquid scintillator is loaded into the cavity. The light emitted from the liquid scintillator when a beta or alpha particle interacts with it is piped through the NaI(Tl) crystal to the two photomultiplier tubes. Only when the pulses from both tubes coincide and only when the pulses are fast, as determined by a pulse-shape analyzer, is the signal stored in a multi-channel analyzer. The NaI(Tl) crystal serves not only as a light pipe but also as an anti-coincidence shield for reducing background counting rate. When a gamma, or cosmic, ray interacts with both the liquid scintillator and the NaI(Tl) crystal, the "false" pulse is not counted; such background pulses are rejected by the pulse-shape analyzer. The light emitted from the liquid scintillator and the NaI(Tl) crystal reaches the same photomultiplier tubes. However, the shape of a pulse originating in the organic liquid scintillator differs from that originating in the inorganic NaI(Tl) crystal: whereas the decay constant of a light pulse from the liquid scintillator is about 2 ns, the decay constant of a light pulse from the NaI(Tl) crystal is about 230 ns. By using a pulse-shape analyzer it is possible to ascertain the origin of the pulse.

When a gamma emitter is to be measured the NaI(Tl) crystal acts as a conventional gamma scintillation detector.

The BGO ALBEGA Spectrometer

The NaI(Tl) ALBEGA scintillation spectrometer is a universal spectrometer with which any kind of radioactive isotope can be measured. However, it is unsuitable for the measurement of samples containing low activities of tritium. With conventional liquid scintillation spectrometers the background in the tritium window is about 20 counts per minute (cpm), whereas with a NaI(Tl) ALBEGA scintillation spectrometer it is over 100 cpm [6]. This is a rather serious disadvantage as tritium is widely used, inter alia, in biological laboratories, being the only radioactive tracer of

hydrogen. Noakes and Spaulding [11], who experimented with a similar NaI(Tl) ALBEGA spectrometer, also got high background in the tritium window and could not explain its origin. Kalish suggested that the high background was caused by afterglow from the NaI(Tl) crystal and that the best way to solve the problem was to use BGO crystals instead [12-15]. While the afterglow from a NaI(Tl) crystal 3 ms after irradiation is 0.5-5%, the afterglow from a BGO crystal 3 ms after irradiation is only 0.005% [16]. In 1992, Kalish convinced R. J. Valenta (Packard Instrument Co.) to test the performance of an ALBEGA scintillation spectrometer using a BGO crystal. It was found that the BGO crystal did indeed solve the problem of high background in the tritium window extremely well. The figure of merit values for C-14 and tritium - as compared with those obtained with a conventional liquid scintillation spectrometer - showed dramatic improvement, from 1595 to 6300 (295%) for C-14, and from 544 to 1030 (89%) for tritium. In the measurement of a C-14 3.5 ml benzene sample in a 7 ml glass vial with the BGO ALBEGA system the background is very low, only 0.227 cpm and the figure of merit is 18,624.

Kalish now suggests a way to render the BGO ALBEGA spectrometer suitable for ultralow-level counting of radioisotopes that coincidently emit beta-gamma (e.g., I-129), beta-gamma-gamma (e.g. Co-60 and positron emitters), alpha-gamma (e.g., U-235), or alpha-gamma-gamma rays (e.g., Am-241). With this procedure, a sample containing a radioisotope that simultaneously emits a beta particle and a gamma photon is dissolved in a liquid scintillator. The beta particle interacts with the liquid scintillator and the gamma photon interacts with the BGO crystal. Each of the output pulses of the photomultiplier tubes is comprised of two components: a fast one, caused by the interaction with the liquid scintillator; and a slow one, caused by the interaction with the BGO. By analyzing the shape of the pulse with a suitable pulse-shape analyzer, the sizes of the fast and slow components may be determined. Only when these components are of the right size, is a pulse recorded. This, in a way, is a beta-gamma coincidence measurement. The probability for a background event to interact with both the liquid scintillator and the BGO such that the energy absorbed in the liquid scintillator would be within the right beta window and simultaneously the energy absorbed in the BGO would be within the right gamma window is expected to be very low. The same procedure may be used with alpha-gamma emitters. With a positron emitter, for example, the pulse output of each photomultiplier tube is resolved into its fast and slow components. The two fast components are added, and only when this summed pulse is within the beta window and is in triple coincidence with 0.51 MeV slow-component pulses from gamma interactions with the BGO, is a signal recorded. Again, the probability of such triple coincidence as a result of a background interaction is extremely low. Background levels with these procedures are expected to be less than 1 count per day.

Summary

The BGO ALBEGA spectrometer can measure samples of alpha-beta- and gamma-emitting radioisotopes. Gamma-emitting samples can be measured with or without a liquid scintillator. The figure of merit values for tritium and C-14 are superior to those of conventional liquid scintillation spectrometers. The author expects that BGO ALBEGA spectrometers will in future replace conventional gamma and liquid scintillation spectrometers.

NEW THREE-COUNT TECHNIQUE FOR SHORT-LIVED RADON DECAY PRODUCTS IN AIR

Deyuan Tian[1] and Zhizhao Lu[2]

[1]Lab. of Industrial Hygiene, Ministry of Public Health, Beijing 100088
[2]Suzhou Medical College, Suzhou 215007, Jiangsu, People's Republic of China

ABSTRACT

Up to the present, radon and its short-lived decay products in air are usually monitored by means of α detection. But radon progenies, including RaB (^{214}Pb) and RaC (^{214}Bi) which are β and γ emitters, contribute about 90 % to the equilibrium equivalent radon concentration (EECRn). Therefore, this paper introduces a new three-count technique by a β detector in the light of radioactive decay law and its boundary conditions during sampling and counting times to solve the Bateman equation. β (even low level β) instruments have been fairly popularized domestically and internationally. It can be used not only as an instrument for radon and its daughters in air, but also as a monitor for β airborne activity in the environment. This new method taps further the latent power of the present instrument and realizes various uses for a unit.

Keywords : radon, three-count technique, equilibrium equivalent radon concentration (EECRn), thoron

INTRODUCTION

It is well known that natural radon and its short-lived decay products in airborne state may cause serious radiation harm to human health such as inducing lung cancer to those who were exposed to them for a long period. Therefore, detailed studies for how to monitor them were conducted. Today, along with the improvements in science and technology, the monitoring procedures for radon progenies have made an encouraging progress. Tsivoglou et al.[1] proposed the Tsivoglou method (a three-point method) for monitoring radon daughters in air on the basis of the count-ratemeter in 1950s. Thomas[2] then improved the three-count technique (or modified Tsivoglou method) on the foundation of the scaler in 1970s. In addition, there are some rapid methods for monitoring the radon progenies in air[3], which are all by means of α-particle detection. However, β and γ rays are emitted in the decay process of radon daughters and reports concerning the detection method of them were not seen so far.

PRINCIPLE

Radon and its short-lived decay products emit α, β and γ rays during the decay process. Their main decay diagram is shown in Fig. 1. Radon (^{222}Rn) decays to form ^{218}Po (RaA), ^{214}Pb (RaB), ^{214}Bi (RaC), ^{214}Po (RaC'), ^{210}Pb(RaD), etc., consecutively. The former four decay products are called radon short-lived daughters because their half-lives are less than 30 min. RaD and the subsequent nuclides have much longer half-lives, for instance 22.3 y for RaD. They are quite stable as compared with the former ones. For this reason, it can be regarded as if RaD and the latter are not to decay, and the multi-progeny decay for radon and its daughters may be simplified to a four-progeny decay. On the other hand, the half-life of nuclide RaC' is very short, only 164 μs. The radioactivity equilibrium between RaC and RaC' appears right away. It can be said that RaC is simultaneously emits one β- and one α-particles and decays immediately to RaD, not through RaC'. Hence, the four-progeny decay is further simplified to a three-progeny decay.

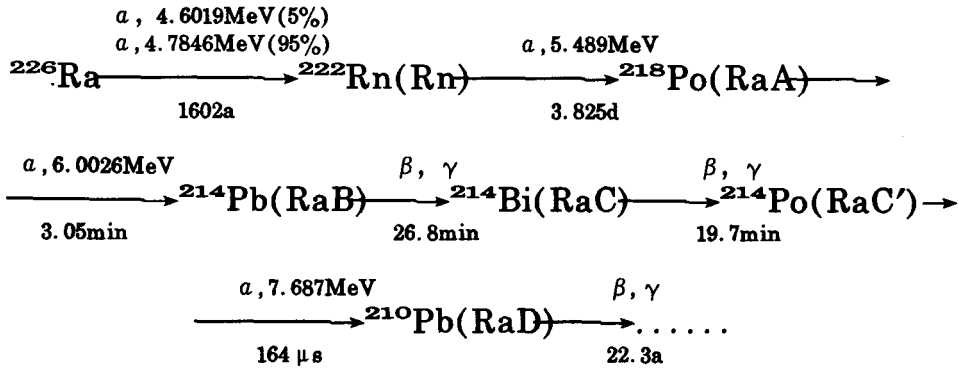

Fig. 1 Main decay diagram of radon and its short-lived decay products

Radon short-lived progenies emit two α-particles in all. For this reason, radon daughter monitoring in air is almost by means of α-particle detection because of its high α-energy and α-pulse signal amplitude, very low background, and the simple structure and easy manufacture of α-detector. On the other hand, the equilibrium equivalent radon concentration (EECRn) is given by:[4]

$$EECRn = 0.105\ C_{RaA} + 0.516\ C_{RaB} + 0.379\ C_{RaC}\ Bq/m^3 \quad (1)$$

where C_{RaA}, C_{RaB} and C_{RaC} are the concentrations of radon progenies, RaA, RaB and RaC, respectively. If the three radon daughter concentrations in air are known, EECRn can be obtained immediately from Eq. (1), and their dose to the public can be evaluated. The RaC′ concentration, $C_{RaC'}$, does not contribute to EECRn as seen from Eq. (1).

Two radon progenies, RaB and RaC, which contribute about 90 % to EECRn are not α-emitter, but are both β and γ emitters. Hence, it is unsuitable to say that α-particle counting for detecting RaA and RaC′ is the best choice because radiation doses are caused mainly by α-radiation. On the contrary, β or γ counting is an optimal selection.

Based on the radioactive decay law and relevant boundary conditions during sampling and counting periods, the Bateman equations were solved and got integral gross β counting which includes three unknowns hiddenly, namely the RaA, RaB and RaC concentrations in air. That is a ternary first-order equation. It is well known that only a set of three simultaneous equations can be solved to get a sole answer when there are three unknowns in it. For this reason, three equations with three observed values are required. Three activity measurements on the filter (i.e., three countings) are to be conducted in the experiment for three different time intervals after the end of sampling. Hence, this method is called the three-count technique. A set of simultaneous linear equations obtained from three countings was set up and solved by the inverse matrix method. The formulas for radon progeny concentration in the air to be measured by the gross β coun-ting method are derived via a computer. According to the UNSCEAR definition[5], the formula of Potential Alpha Energy Concentration (PAEC) is led in. The formula coefficients are a series of complicated exponential operations which are functions of sampling and counting times. A computer program was written to calculate all coefficients rapidly so long as each time parameter inputs are given. These coefficients are simplified constants and do not need to be computed every time for a certain procedure with fixed time parameters.

However, it is possible not to start and/or stop the countings on time in actual situations for a variety of reasons. The data will become invalid at the moment. It is well known that the radon and its daughter concentrations in air change with time and place. Reappeared them is impossible yet even though they are determined again. Therefore,

the above-mentioned program is onlined to realize the automatic measurements. Output data from various procedures can be typed out immediately in the light of both relative parameters and measured gross β countings.

RESULTS AND DISCUSSION

To compare conveniently with the Thomas three-count technique[2], the same procedures as his were used , i.e., 5 min sampling time and 2~5, 6~20 and 21~30 min countings after the end of sampling to obtain the three gross β countings, N_1, N_2 and N_3, respectively. If the total β counting efficiency G (including the instrument and filter efficiencies, self-absorption and backscattering corrections on the filter, etc.), sample flow rate V L/min and background counting rate N_o cpm (counts per minute) are known, the formulas for the radon progeny concentrations, PAEC and EECRn are:

$$C_{RaA} = (-60.9933N_1 + 29.6053N_2 - 27.9909N_3 + 20.4233N_o) / GV \ Bq/m^3 \quad (2)$$

$$C_{RaB} = (+8.50301N_1 - 4.71163N_2 + 5.32176N_3 - 7.44207N_o) / GV \ Bq/m^3 \quad (3)$$

$$C_{RaC} = (-3.08556N_1 + 2.90511N_2 - 3.84836N_3 + 3.22043N_o) / GV \ Bq/m^3 \quad (4)$$

$$PAEC = (-175.253N_1 + 97.9325N_2 - 90.9556N_3 - 26.6961N_o) / GV \ 10^{-10} \ J/m^3 \quad (5)$$

$$EECRn = (-3.18617N_1 + 1.77840N_2 - 1.65155N_3 - .475117N_o) / GV \ Bq/m^3 \quad (6)$$

Generally, the flow rate V, efficiency G and background rate N_o are determined previously, and their errors can be managed to be reduced as much as possible or neglected. Statistical counting errors can not be decreased and are dominant in the environmental level. The resultant concentration uncertainties are shown below according to the error resultant rule when only statistics are considered:

$$S_{RaA} = \sqrt{3720.19N_1 + 876.476N_2 + 783.490N_3 + 268734N_o} / GV \ Bq/m^3 \quad (7)$$

$$S_{RaB} = \sqrt{72.3011N_1 + 22.1994N_2 + 28.3211N_3 + 7295.81N_o} / GV \ Bq/m^3 \quad (8)$$

$$S_{RaC} = \sqrt{9.52067N_1 + 8.43965N_2 + 14.8099N_3 + 2939.46N_o} / GV \ Bq/m^3 \quad (9)$$

$$S_{PAEC} = \sqrt{30713.5N_1 + 9590.78N_2 + 8272.93N_3 + 2826321N_o} / GV \ 10^{-10} \ J/m^3 \quad (10)$$

$$S_{EECRn} = \sqrt{10.1517N_1 + 3.16270N_2 + 2.72761N_3 + 932.190N_o} / GV \ Bq/m^3 \quad (11)$$

where S_{RaA}, S_{RaB}, S_{RaC}, S_{PAEC} and S_{EECRn} are the resultant uncertainties for the RaA, RaB and RaC concentrations, PAEC and EECRn in the air, respectively.

The experiments showed that the results of this new three-count technique agree well with that of the Thomas' method.

SUMMARY

Almost all monitors and dosimeters commercially available now for radon and its progenies in the air employ generally the method of detecting α-particle. Their efficiencies are low and detector areas are small normally although the method is good. It means these instruments are well suited for integrated or continuous long time measurements, but not for the rapid and sensitive grab ones at low levels in the environment. This paper develops for the first time a new three-count technique by gross β countings to determine the radon daughters in the air. The formula for calculating EECRn is led firstly in so as to realize the combination monitoring of radon and its progenies. This sdudy fully utilizes the high efficiency and large area of the β detector, and is a new pioneering work in radon and its daughter monitoring in the air. The new method taps further the latent power of these β instruments and realizes the various uses for a unit.

INTRODUCTION

The passive environmental gamma-radiation dosimetry is mainly based on TL (thermoluminescent) dosimetry. This method offers considerable advantages due to its high precision, low cost, wide range, etc. (1). At the same time its application involves uncertainty caused by the dose collected during the transport from the point of annealing to the place of exposure and back to the place of evaluation. Should an accident occur read-out is delayed due to the need to transport to a laboratory equipped with a TLD reader.

A portable reader capable of reading out the TL dosimeter at the place of exposure (in situ TLD reader) eliminates the disadvantages mentioned above. A microprocessor based portable TLD reader was developed (2) by us for monitoring environmental gamma-radiation doses.

Using a portable reader for in situ evaluation there are several disadvantages as well. The method requires the transport of the reader instead of dosimeters. The portable reader should be battery operated with low power consumption. Due to this requirement the temperature stabilization of the reader requests different solution as in laboratory type devices.

The lowest power consumption can be achieved by bulb type dosimeters. The bulbs have high reproducibility due to constant heat contact. Construction of bulbs makes use of usual temperature regulation system practically impossible. Lack of temperature stabilization of the light detection system and the heating plate leads to some difficulty in use of portable, battery operated readers.

Both investment and running costs of environmental monitoring are different for laboratory and in situ readout systems.

Comparison of recently developed in situ and traditional laboratory evaluation methods of environmental TL dosimeters is given in recent paper. The comparison was made in the same conditions. The most characteristic - for environmental monitoring - numerical TL data (dose range, reproducibility, fading, self dose etc.) are given for manufactured by us $CaSO_4$:Dy bulbs (portable reader) and very advantageous, high sensitive Al_2O_3:C dosimeters (3) (laboratory evaluation).

PORTABLE TLD SYSTEM

At the beginning of the 80's the KFKI laboratory produced a great number of portable, battery operated TLD readers (named Pille - "Butterfly") (4). These devices used $CaSO_4$ bulb dosimeters and the evaluation technique was based on analogue timing circuits and analogue to digital conversion of the photomultiplier current with a read-out precision of 1 μGy. The measured values were displayed and manually recorded. The version with an external power supply was used for space dosimetry as an onboard TLD reader (5).

Based on a microprocessor an up-to-date version of the battery operated portable reader was developed in 1994-95 at the Atomic Energy Research Institute. The new system consists of a set of TL bulb dosimeters with built-in memory chips and the microprocessor based reader with main characteristics as follows:

- The $CaSO_4$:Dy bulb dosimeter is the same as the earlier one (5).
- The TLD bulb has a common case with the memory chip containing the identification number of the bulb. The heating supply and the high voltage supply are controlled via digital-analogue converters by the microprocessor thereby providing a possibility to program the time dependence both of the heating current and of the high voltage.
- The light output of the bulb dosimeter is measured by a photomultiplier, a wide range I/U converter, and a digital voltmeter. (The range of the light detecting system exceeds 8 orders of magnitude.) The built in, stabilized LED light source controls the light sensitivity of the reader in each measuring cycle.
- The four digit alphanumeric LED display indicates the measured dose in exponential form, the possible error codes and the menu/submenu points of the setup. The removable memory card can store up to 4000 measured data sets (dose, identification number, date and time, and digital glow curve).
- The mass of the battery operated version of the reader is about 2.2 kg, its dimensions are 190 x 155 x 70 mm. The rechargeable battery (9.6 V) provides capacity for about 200 read-outs. The reader also works from a 12 V or 24 V car battery in buffer mode.

The environmental temperature influences both the position and the area of the glow curve. Using the built in digital thermometer this effect can be taken into account.

The gamma-radiation energy dependence is relatively small due to 0.7 mm thick Sn filter to cut the well known oversensitivity of $CaSO_4$ below 200 keV. The angular dependence is significant only in case of irradiation along the axis of the bulb. The decreased response in environmental exposure in comparison with standard calibration can be taken into account using a correction factor.

The self irradiation of the bulb dosimeters is caused by glass envelope. For our case (glass with low potassium content) it was found equal to 5 ± 2 nGy/h.

Fading of the $CaSO_4$:Dy at usual environmental temperatures is negligible.

Environmental doses can be measured using in situ read-out of the dosimeters. The wide measuring range of the system (3 μGy - 10 Gy) provides the possibility to measure dose values from natural background up to very large accidental doses. The measuring error (σ) of individually calibrated dosimeters does not exceed $\pm 2.5\%$ above 50 μGy (typical monthly environment dose rate) at room temperatures. Having a temperature range from -10°C to +40°C for the reader the temperature dependence after corrections is below $\pm 2\%$. It means that the overall uncertainty (σ) is below $\pm 5\%$.

LABORATORY EVALUATION USING AL_2O_3 DOSIMETERS

Measurements on high sensitive Al_2O_3:C single crystal dosimeters (diam. 5 x 0.9 mm) were carried out on Harshaw 2000 AB TLD reader at the heating rate of 10°C/s. The dosimeters were linearly heated up to 300°C, the dosimetry peak (190°C) was integrated within the interval of 120°C to 250°C.

All measured data were calculated as the average of 5 dosimeters reading. During irradiation and handling the dosimeters were kept in dark polyethylene foil to exclude undesirable light exposure (6).

Self dose measurements and room temperature fading investigations were performed at a low background place, in an iron shield, having 20 cm thick walls. The dose rate within the shield was 20 nGy/h measured with high pressure ionization chamber.

For TL measurements the dosimeters were exposed using a calibrated ^{90}Sr-^{90}Y source.

One of the important parameters of the Al_2O_3:C is its 40 times higher TL sensitivity compared with common TLD-100 dosimeter.

The batch inhomogeneity (σ) of 20 pieces of dosimeters does not exceed 15% and the reproducibility of a single dosimeter on the basis of repeated (5 times) irradiation (1.75 mGy) and evaluation was found within 5 %.

The lowest detectable dose is 100 nGy.

Self dose effect on the dose responses of dosimeters could not be demonstrated by measurements of five months.

With storing the dosimeters in the iron shield place at room temperature for four weeks the fading was negligible.

Results obtained suggest that the Al_2O_3:C dosimeters are promising for environmental monitoring due to their high sensitivity, good reproducibility, low fading and easy handling.

COMPARISON OF LABORATORY AND IN SITU EVALUATION

Main characteristics of laboratory and in situ evaluation are given for Al_2O_3:C and $CaSO_4$:Dy bulb dosimeters are given in table.

Characteristics	Laboratory evaluation (Al_2O_3 dosimeter)	In situ evaluation ($CaSO_4$:Dy bulb)
Minimum detectable dose (3σ of the background), μGy	0.1	1
Reproducibility	$\pm$5%	$\pm$2.5%
Self dose, nGy/h	negligible	5$\pm$2
Environmental temperature effect	negligible	$\pm$2% with correction
Transport dose effect	may be significant	excluded
Time delay of read-out	significant	short
Investment cost, reader, USD	from 20 000	about 10 000
Investment cost, dosimeter, USD	3-5/piece	30-50/piece
Cost of readout/piece	low	medium
Recommended field of application	wide (national) scale monitoring	local scale monitoring around nuclear installations

NEUTRON SPECTROMETRY FOR PROTECTION DOSIMETRY AT VERY LOW LEVELS

A.G. Bardell and D.J. Thomas

National Physical Laboratory, Teddington, Middx, TW11 0LW, UK.

INTRODUCTION

Dose limits for exposure of members of the public are significantly lower than those for designated radiation workers. The new ICRP 60 (1) recommendation for critical groups of the general public is an effective dose limit of 1 mSv per year which requires a measurement capability at levels down to about 100 nSv h^{-1}. Radiation protection dosimetry for neutrons at these levels is problematical, nevertheless, operators of nuclear sites are still required to demonstrate acceptably low radiation levels in areas accessible to the public.

In addition to the known poor dose equivalent response of available dosemeters, there is an added problem at low levels of inadequate sensitivity. Personal dosemeters are certainly not sufficiently sensitive, and the sensitivity of area survey instruments is such that they can only be used in integral mode. Even then, the statistical uncertainties are likely to be large. One further problem concerns the quantity measured. Survey instruments are designed to measure the operational quantity ambient dose equivalent, H*(10), which always tends to be an overestimate of the present limiting quantity effective dose equivalent (2). If in any situation exposure is near the limit, an estimate of H*(10) may not be sufficient to prove conclusively that levels are less than the statutory limit, and a direct estimate of effective dose equivalent may need to be made.

The only way of estimating effective dose equivalent is via an absolute spectral measurement. From such a spectrum any relevant dosimetric quantity can be estimated via tabulated fluence to dose equivalent conversion factors. (Certain quantities also require information about the angular dependence of the field - see later text). Spectrometry at such low neutron fluence levels is difficult, however, there is one instrument available which can perform the required measurements, and this is a well characterised Bonner sphere (BS) set.

MEASUREMENT SITES

The general public are very rarely exposed to neutrons, other than those from cosmic rays, however, neutron levels can occasionally be detected in the vicinity of nuclear power plants. The measurements described in this paper were performed at various points at distances around a reactor building which ranged from about 61 m to nearly 200 m from the building. All the measurements were performed out of doors although rudimentary temporary shelters were available for most of the sites and for the electronics which was centrally situated at a position of up to 100 m from the various measurement positions. At the site furthest from the reactor not even these facilities were available and measurements were made in the open air with the electronics located in a small van and powered by a portable generator.

SPECTROMETRY SYSTEM

The BS spectrometry set used for the present measurements consisted of eight spheres of high density polyethylene of diameters 3", 3½, 4", 5", 6", 8", 10", and 12"[†]. The central counter was a spherical ^{3}He proportional counter of diameter 32 mm (type SP9 manufactured by Centronic Ltd). In addition to using the eight spheres, measurements were also made with the thermal neutron counter, both bare and under a 1 mm thick cadmium cover, to provide a direct determination of the thermal neutron component of the field.

The derivation of a neutron energy spectrum from a set of Bonner sphere measurements is possible because of the different degree of moderation in each of the spheres. Each 'sphere plus thermal counter' combination has a different sensitivity to the various parts of the neutron energy spectrum. Small spheres are most sensitive to the low-energy part of the spectrum, whereas large spheres are most sensitive to higher energy neutrons. Provided the response functions, i.e. the response as a function of neutron energy, of all the spheres are known, the neutron spectrum can be unfolded from the count rates of the spheres.

[†] Bonner spheres are conventionally made to exact inch sizes, and the diameter in inches remains the accepted 'label' for each sphere.

Considerable effort has gone into the characterisation of the NPL BS set. The determination of the response functions for the spheres involved a series of measurements, with monoenergetic neutrons from 70 keV to 14.7 MeV (3,4), and also with thermal neutrons (5). These measurements are all traceable to national standards. In addition, two sets of calculations, one with the discrete ordinates transport code ANISN, and one with the Monte Carlo transport code MCNP, have been used. These data have all been combined to provide an optimised set of response functions.

Neutron spectra are unfolded from measured sphere count rates using the least-squares program STAY'SL. The difficulties of Bonner sphere unfolding have been much discussed in the literature (see for example reference 6). The problem is mathematically under-determined, however, STAY'SL has produced good results in spectrometry comparisons (7), and in unfolding code comparisons (6).

MEASUREMENTS

To measure the spectra, all spheres of the set were placed in turn at the measurement sites, and the count rates recorded for an appropriate length of time. The aim was always to count for long enough to obtain better than 1% statistical accuracy in the count rate; and this was achieved for the majority of spheres with the exception of the furthest distance from the reactor where the statistical uncertainties were higher, and no measurement was possible with the 12" sphere.

Because of the large distance from the source of neutrons the measurements were sensitive to changes in air scatter and attenuation caused by changes in atmospheric conditions such as temperature, and pressure. For this reason a monitor, consisting of a 5" BS, was positioned at a distance of about 150 m from the reactor and readings were corrected by the ratio of the mean monitor count rate over the total measurement period to the monitor count rate over the period of a particular sphere measurement. (The measurements covered a period of five days). Although the corrections were not large, the maximum being 3.8%, they were necessary because of the high sensitivity of BS unfolding to the ratios of the sphere count rates.

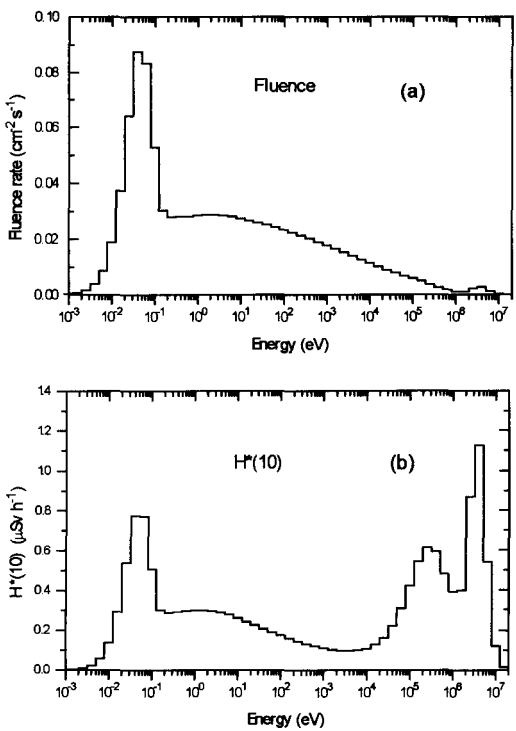

Figure 1. Average of the six measurement sites (a) fluence spectrum, (b) ambient dose equivalent spectrum.

RESULTS

Measurements were performed of the spectra at six sites at several distances in the range from 61 m to 191 m from the reactor building. The spectra at all sites were very similar, and an average of the six measurements, normalized to unit fluence rate, is shown in Figure 1 along with the corresponding ambient dose equivalent spectrum. (conversion factors were obtained from Wagner et al. (8)). The fluence is predominantly in the low and intermediate energy region with a substantial thermal peak, an intermediate energy distribution which decreases with increasing neutron energy, and a small component of fast neutron with energy greater than 1 MeV. When converted to H*(10), as shown in Figure 1 (b), the importance of the contribution from the small high energy component becomes apparent.

Values for effective dose equivalent for the six sites were calculated and these ranged from about 155 nSv h^{-1} to 16 nSv h^{-1}. These were for A-P irradiation of an individual. For all other angular dependencies of the fluence the effective dose equivalent is less and so these values can be considered as upper limits for the limiting quantity.

DISCUSSION

The present set of measurements were performed around a nuclear reactor, mainly within the site boundary where access was not possible for the general public. They did, however, include measurements outside the site boundary fence. These proved that measurements can be made with this type of BS system at extremely low levels well below the statutory limit for critical groups of the general public.

For the types of low energy spectrum seen, the quantity H*(10) over-estimated the limiting quantity effective dose equivalent by about a factor of about two for the assumption of A-P irradiation. Many area survey instruments overestimate H*(10) because of they over-read for intermediate energy neutrons. The net effect is thus an even greater overestimation of the effective dose equivalent. For the Harwell neutron dose equivalent monitor type 0949 the overestimation of H*(10) was approximately a factor of two resulting in a overall overestimation of the limiting quantity by a factor of about four. The Studsvik 2202D instrument did not significantly over-respond for H*(10) indicating that overestimation by this instrument in the intermediate energy region is compensated by under-reading in other regions. The spectrometry measurements give direct calibration factors for these instruments allowing them to be used with greater confidence in this particular environment in future.

The new limiting quantity recommended in ICRP 60, effective dose, was on average a factor of 2.3 higher than effective dose equivalent for these fields giving an even greater significance to the problems of the low sensitivity of neutron dosimetric instruments.

BACKGROUND RADIATION SPECTRUM AND ITS INFLUENCE ON LOW LEVEL ACTIVITY MEASUREMENTS IN THE ENVIRONMENTAL SAMPLES

D.Popovic,[1] D.Todorovic,[2] G.Djuric,[1] and A.Radoičic[1]

[1]Department of Physics and Radiology, Faculty of Veterinary Medicine, 11000 Beograd, Yugoslavia
[2]Institute of Nuclear Sciences Vinca, Beograd, Yugoslavia

ABSTRACT

The paper discusses the variations in the background gamma radiation spectrum as an important parameter in low level activity measurements. The background radiation spectrum has been recored from 1993 to 1995 on two HPGe detectors under equival environmental conditions but placed in differently constructed Pb cages. The results indicate that when one estimates low level activities of natural radionuclides in the environmental samples, background radiation can be a significant source of error, due to unadequate shielding or long counting time intervals. Special attention should be paid to the seasonal variations of the lines of Bi-214 and Pb-214, while errors due to intensity variations in K-40, U-235 and Th-232 lines in the spectrum are within the total eror of the method. Errors in intensity estimations in low and high energy range of the background spectrum should not be neglected , too.

INTRODUCTION

Background radiation spectrum is one of the basic Quality Assurance and Quality Control parameters in the evaluation of natural and man made radionuclides' activities in the environmental samples, especially when estimating low level activities of natural radionuclides. Intensity and stability of the spectrum are due to the technical characteristics of the detector itself, materials and design of the shielding, environmental conditions (ventilation ecc), construction of "low level chamber",ecc (1,2). Regular control of background radiation can point to the possible contamination of the detector or the environment (3). Some of the lines in the background spectrum can interfere with some of the lines in fission radionuclides spectrum or other complex spectra making the evaluation of the activities less reliable (4).

MATERIALS AND METHOD

Background gamma radiation spectrum has been recorded from 1993-1995 on two HPGe vertical detectors D1 and D2, relative

efficiency 23% and 20% respectively, both placed in a ground floor laboratory, with ventilation. Both detectors have Pb shieldings (10 cm) with layers of Cu (3mm) and Fe (10 mm D1, 6mm D2) on the inner wall of the cages (45cmx45cmx45cm). The cages differ in construction: the upper surface of D2 cage is covered with additional Pb movable plates, so there is no free space between Pb bricks. Detectors are used for radioactivity measurements in the environmental samples (soil, grass, food, building materials) in different geometries (standard Marinelli beakers, plastic bottles, planshettes).

Background has been recorded monthly and the means of count rates (imp/1000s) over the counting interval (250.000-400.000s) have been calculated. Energy calibration was performed with a standard set of point sources (COFFRET d'etalon gamma ECGS-2,Saclay with Ba-133,Co-57,60 & Cs-137).

RESULTS AND DISCUSSION

The results of the background radiation recordings on D1 and D2 detectors have been presented in Table 1. The data present the means ($\bar{X}$) of monthly counts rates (imp/1000s) for the three years and the coefficients of variation CV(%) for the 1993-1995 period (T) and for each year (93,94,95).

Table 1. Mean count rates $\bar{X}$(imp/1000s) and variations CV(%) in the background radiation spectrum for detectors D1 and D2 from 1993 to 1995

		Detector D1					Detector D2				
Radio-nuclide	E(KeV)	$\bar{X}$	CV(%) 93	94	95	T	$\bar{X}$	CV(%) 93	94	95	T
Th-234	63.3	5.2	4	11	4	3	1.9	11	11	5	8
PbX	74.8+77.1	11.5	47	29	52	6	6.3	22	42	58	16
PbX	89.7	18.2	10	10	16	3	8.7	7	17	19	7
U-235	185.7	8.2	19	24	19	11	3.6	8	7	16	8
Pb-212 +214	238.6 +241.5	8.6	28	14	36	5	6.4	9	24	26	9
Pb-214	295.2	11.6	49	48	57	7	7.1	24	52	60	16
Pb-214	351.9	18.9	51	30	54	10	11.5	25	52	61	18
anih.	511.0	15.0	4	9	3	1	10.9	2	4	1	4
Tl-208	583.1	1.1	17	22	24	11	0.8	22	20	8	6
Bi-214	609.3	14.2	47	29	54	10	8.7	27	48	59	19
Cs-137	661.6	1.5	12	10	10	3	2.7	32	18	5	12
Ac-228	911.1	0.6	24	24	31	17	0.5	17	20	20	2
Bi-214	1120.3	2.5	27	28	81	17	1.7	27	54	56	13
Co-60	1173.2	1.8	4	12	12	15	0.4	16	21	20	22
Bi-214	1238.1	1.2	35	36	55	13	0.7	30	46	44	19
Co-60	1332.5	1.6	12	17	8	14	0.4	27	17	22	22
K-40	1460.8	1.9	8	6	10	5	1.4	10	11	4	4
Bi-214	1764.5	2.3	23	27	51	13	1.4	25	44	54	16

The mean background peak rates counts recorded on D1 are generally higher than those recorded on D2 with better shielding construction (on the average the means of D1 are 1.5 time higher than the means of D2 and for energies up to 200 keV twice as high). Co-60 lines in both spectra are due to the amounts of Co in the shielding material, the shilding of D2 being much less contaminated. The presence of Cs-137 in the background spectra is due to the Chernobyl nuclear plant accident in 1986. However, higher peak counts on 661.6 keV of D2 point to the contamination of the detector while used for environmental samples activity measurements.

As for natural radionuclides, special attention should be paid to the unstable lines of Bi-214 and Pb-214 as their high seasonal variations within a year (due to variations of radon concentrations in air) could be a significant source of error when estimating low level activities of natural radionuclides in the environmental samples. Long counting time intervals (up to 400.000 s) can cause an additional error in activity estimation as some variations of the background radiation could occur in the interval. Averiging the background count rates over long counting time intervals can be another source of error, too. On the other hand, the lines of K-40, U-235 and Th-234 are relatively stable and their variations are within the total error of the method.

Relatively low variations (T<20%) over three years period for both detectors confirm the stability of the systems and of the environmental and measuring conditions.

Higher variations for lower values of the mean peak counts can be asigned to the errors in intensity estimation.

(China Institute for Radiation Protection)
(P.O. Box 120, Taiyuan, Shanxi, China, O30006)

1. Introduction

During the period 1985~1994, our laboratory participated in a series of international intercomparison activities of radioactivity measurements sponsored respectively by WHO IRC, IAEA AQCS and IAEA MEL, with 20 samples measured in total. This paper describes the intercomparison activities concerned during past decade, methods of analysis and measurement, and measurement results. Some problems involved in measurements was discussed.

2. Samples

Among these 20 interncomparison samples, there were 12 samples from WHO IRC and 8 from IAEA. WHO IRC samples were liquid milk (No. 42L300), liquid effluent (No. 43E300), aquatic plant (No. 45V300), dry may blossom (No. 48V300), ground water (No. 56P300), mineral water spring (No. 49SH300), river sediment (No. 55SR300), white mine (No. 57VI300), pasteurized milk (No. 58L300), mineral water spring (No. 60SH300), liquid effluent (No. 59E300) and water (No. 61E300), which were required to analyses ^{3}H, ^{90}Sr, ^{58}Co, ^{60}Co, ^{134}Cs, ^{137}Cs, ^{106}Ru, ^{124}Sb, ^{110}m Ag, ^{226}Ra, ^{210}Po, ^{40}K, U and Th respectively. IAEA samples were Russian soil (IAEA-375), Russian grass (IAEA-373), Irish sea cockl flesh (IAEA-134), Irish Sea sediment (IAEA-135), Baltic Sea sediment (IAEA-300), Arabian Sea sediment (IAEA-315), black soil (IAEA-326) and Podssolic soil (IAEA-327), which were required to analyse transuranium elements, γ emitters and β emitters and to be given analysis of trace elements.

3. Analytical methods

Analytical methods used in the laboratory for measurement intercomparisons are shown in Table 1. Ge(Li) and HPGe gamma spectrometer were used for measurements of gamma rays emitting nuclides. Sample containers were employed according to the magnitude and shape of samples, including the original containers containing sample, 600 ml Marinelli Beaker, and ϕ 75 mm polyethylene container, about 25, 50 75 mm high respectively. For analyses of U, Th and K, chemical analytical methods were used in addition to Ge gamma spectrometer. To determine ^{134}Cs and ^{137}Cs in samples, direct measurement was firstly made by Ge gamma spectrometer and then so did again after radiological separation.

4. Reference sources and samples

Reference sources were from different laboratories in different countries as shown in Table 2. Standard point sources and reference point sources, containing ^{241}Am, ^{57}Co, ^{60}Co, ^{133}Ba, ^{203}Hg, ^{137}Cs, ^{54}Mn, ^{22}Na, ^{88}Y and ^{152}Eu, were purchased from China Institute of Atomic Energy, Britain Amersham Corporation and China National Institute of Metrology respectively. Standard solution and reference solution were from China Institute of Atomic Energy, WHO IRC and Amersham. Standard U, Th, U-Ra ore powder were received from Beijing Institute of Uranium Mine Geology.

Table 1. Analytical methods used in the laboratory for intercomparison

Nuclids	Methods
Gamma emitters	Ge(Li) or HPGe gamma spectrometer
^{3}H	Liquid sinctilation counter
U, Th	HPGe gamma spectrometer
U	Laser fluorescence or photospectrometry
Th	N-235 extractration photospectrometry, choromotography
^{226}Ra	HPGe spectrometer, radon emanation measurement
^{90}Sr	HDEHP choromotography or cation ion exchange chomoto-graphy, and beta measurement
$^{234}U, ^{235}U, ^{238}U$	Alpha spectrum analysis after evaporation and depletion
^{210}Po	Alpha measurement after evaporation and depletion
$^{134}Cs, ^{137}Cs$	Ge gamma spectrum meausrement after HPGe gamma reasurement or radiochemical analysis.

Table 2. Reference sources an samples

Type	Nuclide	Provided by
Point source	^{241}Am, ^{57}Co, ^{60}Co, ^{133}Ba, ^{208}Hg, ^{137}Cs, ^{54}Mn, ^{22}Na, ^{88}Y,	China Institute of Atomic Energy
Point source	^{241}Am, ^{57}Co, ^{60}Co, ^{133}Ba, ^{208}Hg, ^{137}Cs, ^{54}Mn, ^{22}Na, ^{88}Y,	Amersham, Britain
Point source	^{152}Eu	China National Institute of Metrology
Solution	^{60}Co, ^{137}Cs, ^{152}Eu, ^{241}Am	China Institute of Atomic Energy
Solution	^{58}Co, ^{137}CS, ^{60}Co, ^{226}Ra, U	WHO IRC
Solution	^{90}Sr, ^{137}Cs	Amersham, Britain
Ore powder	U, Th, U-Ra	Beijing Institute of Uranium Mine Geology
Soil	U, Th, Ra, K	China Institute of Radiation Protection
Spike sample (powder)	U, Th, Ra, K	China Institute for Radiation Protection
Spike sample (solution)	^{60}Co, ^{137}Cs, ^{152}Eu	China Institute for Radiation Protection
Spike sample (powder)	^{60}Co, ^{137}Cs, ^{152}Eu	China Institute for Radiation Protection

Radioactive point source is a basis of transferring national or international laboratory standard radioactivity quantity value, which transfers standard quantity value to reference materials or reference samples[1]. The first step for out laboratory transfers radioactivity quantity value is to check standard solution and reference solution. Measurement is made using Ge gamma spectrometer that was calibrated with standard and reference point sources to ensure system to have the capability of transferring standard quantity value.

In measurement intercomparison, radioactive standard solution and reference solution from various national laboratories are directly used as calibration standards of radiochemical analysis and ^{3}H measurements. Soil reference samples prepared by our laboratory were taken

from natural soils in Hengyang, Hunan Province, in which natural radioactive nuclide contents were determined by laboratories of the China Institute of Radiation Protection and the National Environmental Protection Agency. Additionally, our laboratory prepared soil spike samples and solution spike samples, which be directly used for measurement of gamma spectra. In measurements of solution sample, sediment samples and soil samples, ore powder separately containing U, Th, R-Ra and spike samples containing ^{137}Cs and ^{152}Eu were used.

5 Results

During these intercomparisons, the laboratory received 9 summary reports, 6 from WHO IRC and 3 from IAEA. Results shown a deviration within 10% of our reported value from WHO IRC reference values, with a few in exceed of 10%. There also were some data that shown no deviration from the WHO IRC value. Examples are ^{90}Sr and Ca in No. 42L300 milk in 1985, ^{235}U in No. 49SH300 mineral srping water in 1988, and U in No. 60SH300 milk in 1993. During the intercomparions of IAEA samples, the laboratory reported the analytical results of gamma secpectrometry, which were within the acceptable range. But no data were given for gamma emitting nuclides with low content in sample. Analyses of transuranium nuclides were not done.

6. Discussion

In the WHO IRC sponsored intercomparison, IRC presented reference values. Data from various laboratories were for quality assessment on the basis of a comparison with reference value. IAEA AQCS and MEL organized intercomparison haven't presented reference value, but taking median or total average as recommended value or informative value. So IAEA organized mesurement intercomparison, in fact, was the measurements for determining value, which raised higher requirements to those laboratories participating in intercomparison. In particular, reference sources or reference samples used for calibration must be national or international standards or tracable to national or internatinal standards. Careful analyses of measurement errors and correction factors will result in acqusition of reliable data which may be used as recommended or reference values.

INTRODUCTION

In nuclear energy related facilities, contamination by transuranic nuclide must constantly be monitored.

As an example of the monitoring methods, thin electrodeposited sources prepared after the chemical separation processes, give high sensitivity in α spectrometry by Si detectors or gridded ionization chambers; thus, often used for α contamination analysis of environmental samples.

Because of the complicated source preparation processes, this method can hardly be recommended for analyzing many samples in a short period of time. For the cases of large area contamination, such as nuclear accidents, simple and rapid analysis is a prime importance.

As a simple α detection method, so-called gross counting technique by ZnS scintillation counters, is well known. But this method does not give α energy information at all and is insufficient to identify the nuclide. Consequently, α background by natural nuclide cannot be subtracted from the measured gross counts. And further, it is impossible to find the effective discrimination level for α particle counting; therefore, α counting efficiency for thick samples can only be determined by the actual measurement for the identical sample configuration and for the identical nuclide.

The purpose of this work is to develop a new α spectrometry method for thick samples.

Experimental results and mathematical analysis have confirmed that qualitative analysis of α nuclide in thick samples is feasible. And problems related to the analysis are also discussed in this report.

EXPERIMENTAL METHODS

Si Detectors

Si detectors used for experiments are Surface Barrier Detectors (SBD)-(1),fabricated from p-Si wafers. The vacuum evaporated Al face is the sensitive side for α particle injection. With the Al face up, fine powdered samples were directly mounted on the electrode, so that the Al layer thickness is 50 $\mu g/cm^2$ which is thicker than usual detectors. Particles which contain a small amount of acid or alkali, such as ion exchange resins, often result leakage current increase. To prevent the degradation of detector characteristics, outer edges of the electrodes are covered by Epoxy Resin as shown in Fig.1.

Measurements

^{210}Po of 6 Bq/mg was adhered to fine Ni powder of several grain sizes. The powder was directly mounted on the Al electrode of an SBD and the α spectrum was measured. Also measured in the same manner with another SBD, was the powder of low grade uranium ore. Another way of thick alpha sample spectroscopy is :a) filling

a sample dish, b)making the powder surface flat, c)placing an SBD close to the sample, and d)measuring the α spectrum. However, if soil samples were measured by this method, Rn and Tn daughters stick to the electrode and their contamination give problems to the spectrum analysis(3).
It was confirmed that the powder samples adhered to Al electrodes could be removed almost completely by soft brushing and/or methanol cleansing.
α energy spectrum measured at the surface of an infinitely thick sample (thicker than α ranges), in which α emitters distribute uniformly and α particle straggling is negligible, is given by the following formula(3);

$$dn(E)/dE = 0.25 \cdot S \cdot D/(dE/dx)_E \qquad [1]$$

where $dn(E)/dE$ [keV^{-1}] : differential detector counts
S [cm^2] : detector sensitive area
D [Bq/mg] : specific α activity in the sample, and
$(dE/dx)_E$ [$kev \cdot mg^{-1} \cdot cm^2$] : stopping power of the medium at E

EXPERIMENTAL RESULTS AND DISCUSSION

Fig.2 shows two groups of different spectra : 1)the measured α spectra of ^{210}Po adhered to three different grain sizes of indefinitely thick Ni powder samples, and 2)the α spectrum calculated by formula [1] with Ziegler's Stopping Power Data. In case the grain size is sufficiently smaller compared to α range the measured spectrum agrees well with the calculated results. While grain size of the powder increases, alpha spectra peaking at the high energy edges tends to be significant.This tendency was unexceptionally observed in other metal powders. This peaking phenomena can be explained as followings: if grain size increases, the portion of α particles which does not penetrate grain medium or go through short path to SBD, increase. Because all the α emitters are adhered on the surface of grains comparative to or larger than the α particle ranges. If noticeable peaking is observed with a sample, it means α emitters are not distributed uniformly in it ,and qualitative analysis by formula [1] can not be applied. It means some process has to be made. As shown in Fig.3 in the case of uranium ore, this can be easily solved by grinding the sample into fine powder in an agate mortar. Peaking is, however, advantageous to identify α nuclide. This is especially true for the identification of artificial α emitters, because they are, in most cases, attached on the surface of sand or ion exchange resin grains.
Total α counting rate for infinitely thick samples, as calculated by integrating formula [1], is shown in Fig.4. Since the medium is SiO_2, this result can be applied for soil samples as a good approximation.

CONCLUSION

(1)Without making any chemical separation process, α spectrometry can be made by using a Si detector and infinitely thick samples.
(2)Qualitative analysis for each nuclide can be made, if sample components are identified, by grinding samples into fine powder.
(3)Edge peaking in an alpha spectrum can effectively used for the nuclide identification.

AN IMPROVED METHOD OF IN-SITU MEASUREMENT OF ^{137}Cs CONCENTRATION IN SOIL TEN YEARS AFTER CHERNOBYL.

M. Fülöp and P. Ragan
Institute of Preventive and Clinical Medicine
Limbová 14, 83301 Bratislava, Slovakia

Introduction

This contribution is aimed to the possibility of improving the in-situ gamma spectrometry to be independent on a priori knowledge about a depth distribution of ^{137}Cs in soil and sufficiently sensitive for the measurement of the post-Chernobyl ^{137}Cs at present, as well. The depth distribution of ^{137}Cs averaged over a large area of soil is obtained by unfolding of the detector responses to primary and in soil forward scattered photons. The proposed method employs detector with and without collimator.

Methods

The detector response N(i) to ith characteristic of gamma ray field above ground with radionuclide distributed homogeneously in horizontal direction is described by integral equation :

$$N(i) = \int \sigma(i,\zeta)\, A(\zeta)\, d\zeta \qquad i=1,2,...,n \qquad (1)$$

where $\sigma(i,\zeta)$ [$Bq^{-1}.m^2$] - detector response in gamma field of plane source of unit activity-per-area located at the depth ζ, $A(\zeta)d\zeta$ [$Bq.m^{-2}$] - unknown activity of the plane source to be determined by unfolding, ζ [$kg.m^{-2}$] - depth in the soil in units mass-per-area.

The responses of collimated and uncollimated detector $\sigma(i,\zeta)$ to primary 0.662 MeV and to 0.62-0.655 MeV photons scattered in the soil are considered in the proposed method. The detector responses are obtained by calculations in combination with experimental calibration.

Calculational procedures

The detector response $\sigma(i,\zeta)$ to ith characteristic of gamma field with flux $\phi(i,\zeta,\theta,E)$ per-unit-activity of plane source at the depth ζ in the soil can be described as follows:

$$\sigma(i,\zeta) = \iint \phi(i,\zeta,\theta,E).R(i,\theta,E)d\theta.dE \qquad (2)$$

where R(i,θ,E) - detector response in peak of total absorption for a parallel photon beam of energy E impinging at angle θ to the detector axis.

The Equation (2) can be simplified by assumption that the dependences R(i,θ,E) are in the energy range of photons from 0.62 up to 0.662 MeV constant:

$$\sigma(i,\zeta) = \int \Phi(i,\zeta,\theta).R(i,\theta)d\theta \qquad (3)$$

where $\Phi(i,\zeta,\theta)\, d\theta$ - photon flux at angle θ integrated over energy, R(i,θ) - angular dependence of detector response for a parallel photon beam of energy 0.662 MeV.

The photon flux Φ has been calculated by our Monte Carlo code SOILSC. Homogeneous and isotropic plane source of thickness 0.5 $g.cm^{-2}$ was simulated up to 85 $g.cm^{-2}$ of depths in the soil, starting with the plane source on the ground. The plane source radii were chosen 100 m to represent an infinitive plane soil contamination with radionuclide ^{137}Cs.

Experimental procedures

A portable N-type high purity germanium HPGe detector with relative efficiency of 12,5% and resolution of 1,7 keV for 1,33 MeV gamma rays has been used. The detector was supported by a tripod and the front of the detector was at the height 100 cm above the ground. The orientation of the detector is facing downward.

A cylinder-shaped collimator has been used to modify the angle distribution of photons impinging to the detector surface. The collimator is made from lead cylinder with the outer/inner diameter 19/10 cm and height 10 cm laying on aluminium cylinder with the outer/inner diameter 30/10 cm and height 2 cm. The bottom of aluminium disk was located at height of 100 cm above the ground.

The experimental calibrations were aimed to determine the responses $R(i,\theta)$ (in Equation 3) of collimated and uncollimated detector in the energy region 0.62-0.655 MeV and in peak of total absorption of the 0.662 MeV photons, as well, and to asses the background in the energy region 0.62-0.655 MeV due to photons from the natural sources.

Application to post-Chernobyl ^{137}Cs

The photon spectra were recorded over lawns in Southern Slovakia. In-situ gamma spectrometry was performed with and without collimation of the detector, which was located above the centre of the area used for soil sampling.

Figure 1 shows the pulse height distribution measured by the unshielded detector at the location No.2 in the energy interval 0.55 - 1.0 MeV. Exponential approximation of the spectrum in the interval 0.67 - 1.0 MeV, bold line in the figure, is used for assessment of background for 0.62-0.655 MeV photons scattered in the soil.

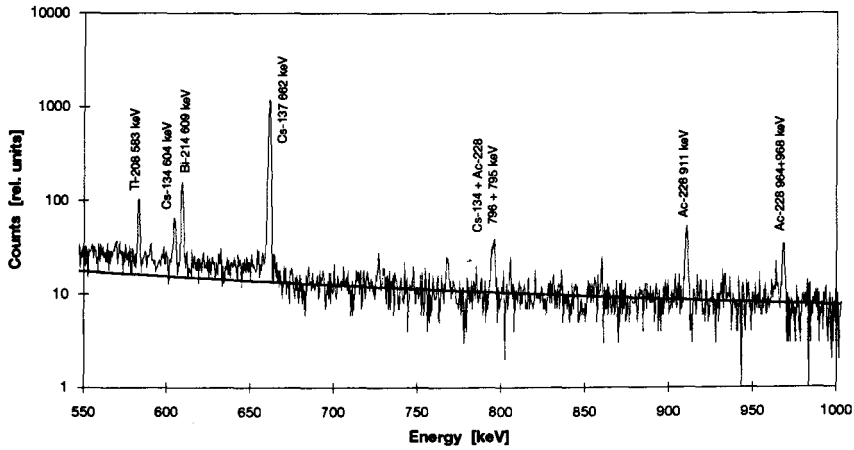

Figure 1. The pulse height distribution measured by the HPGe detector at the location No.2.

Figure 2 shows depth distributions of the ^{137}Cs activity in soil measured in surrounding of Bratislava, the places were in distance 20 km. The results obtained by presented method are compared to results by soil sampling. The relative standard deviation of the ^{137}Cs activity in soil samples were <10% for each depth of soil.

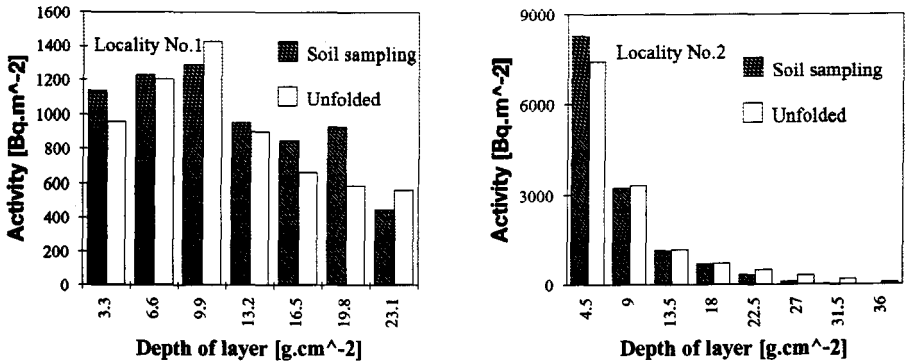

Figure 2. Distributions of the ^{137}Cs activity in soil profile of lawn in the locality No.1 and 2 determined by presented method and by soil sampling, as well.

The downward transport of ^{137}Cs have occurred to a peak concentration that lies below the surface of lawns. The differences between presented method and soil sampling of the distributions in Figure 2 are within 20%, except of distributions at the deeper depths where resolution of unfolding method is worse.

The ^{137}Cs activity-per-mass and/or activity-per-area in soil determined by presented method of deconvolution, by sampling method and by standard in-situ spectrometry using the exponential depth distribution in the soil (1), that has been determined by exponential least squares fit of results of soil sampling, are given in Table 1.

Table 1. ^{137}Cs activities in soil of lawns in Southern Slovakia determined by various methods.

No. of	Presented method		Soil sampling		Standard method	
locality	[kBq.m^{-2}]	[Bq.kg^{-1}]	[kBq.m^{-2}]	[Bq.kg^{-1}]	[kBq.m^{-2}]	[Bq.kg^{-1}]
1	6.3±1.6	274±68	6.8±0.7	258±26	-	307
2	13.2±3.5	-	13.8±1.5	-	12.5	-
3	1.2±0.5	39±16	1.1±0.2	36±7	-	33

Conclusion

In the presented method a fairly accurate concentration estimate for the top layer of the soil, down to a depth of about 30 g cm^{-2}, is obtained. The analysis of the spectra collected with the detector, used in this study indicates that ^{137}Cs concentration in soil, in time of 10 years after the Chernobyl accident, would be measurable using a middle HPGe detector (about 30% of relative efficiency) and a counting time of the order 1 hour or less. Even with smaller detectors, ^{137}Cs concentrations of 5 kBq m^{-2} are measurable and the depth distribution of ^{137}Cs of activities above 10 kBq m^{-2} in soil can be estimated by presented method when counting time of the order 3 hours is used.

DETERMINATION BY IN SITU GAMMA SPECTROMETRY OF OUTDOOR AND INDOOR DOSE RATES IN POPULATED AREAS OF GREECE DUE TO NATURAL AND ARTIFICIAL SOURCES OF RADIATION

A. Clouvas, M. Antonopoulos-Domis and S. Xanthos

Department of Electrical and Computer Engineering,
Aristotle University of Thessaloniki
GR.-54006 Thessaloniki Greece

INTRODUCTION

Knowledge of radiation levels in buildings is important in the assessment of population exposure (1). This is because most individual spend the majority of their time indoors exposed to the radiation from the radionuclides (mainly Ra-226, Th-232, their decay products and K-40) in walls, floors and ceilings. The rest of their time is spent outdoors on roads or near buildings, which exposes them to radiation from materials used for construction. In situ gamma spectrometry is a powerful tool to study indoor and outdoor dose rates. In the present work we report 300 indoor and outdoor in situ γ-spectrometry measurements performed in the two most populated towns of Greece: in Athens, the capital of Greece and in Thessaloniki, the second town of Greece.

EXPERIMENTAL PROCEDURE

The portable Ge detector used for the in situ measurements is a high purity Ge coaxial cylinder 44 mm in diameter and 41 mm in length with a relative efficiency of 10%. The spectrum is collected in a portable multichannel analyzer that also provides high voltage and pre-amp. to the detector. The first analysis of the spectra can be performed in a portable computer (notebook) connected to the multichannel analyzer with the use of a home-made software. The measurements are performed with a downward tripod-mounted facing detector at 1m above soil surface for a counting period of 2000s.

The calibration procedure in field spectrometry consist of not simply identifying the γ emitters present at a site but mainly to convert the measured count rates for each γ emitter to some meaningful quantity such as dose rate or radionuclide concentration. The procedure used in this work is the one proposed by Beck et al. (2) and Helfer and Miller (3). We have shown (4) that the field geometry factors derived from the calibration procedure can be applied to indoor geometry at least in the case of masonry structure which is typical in the most of the buildings and houses in Greece.

The γ emitters present in a typical measured spectrum are the various nuclides of the Uranium and Thorium series, the K-40 and Cs-137 mainly from the Chernobyl accident. In the calibration procedure used an equilibrium is assumed along the various nuclides in the U and Th series, so that the measurement of any one spectral line yields concentration values for the entire series, although averaging several spectral lines will give a more precise value. For the U-series we used the lines of 0.352 MeV (Pb-214) and 0.609 MeV (Bi-214) and for the Th-series the lines of 0.583 MeV (Tl-208) and 0.911 MeV (Ac-228). Disequilibrium in the U series due to exhalation of Rn-222 from the soil surface or the building materials can cause a percentage error in the U series exposure rate, however according to Beck et al (2) this error is smaller than 15%. The absolute error in the absorbed dose rate in air from U-series, Th series, K-40 and Cs-137 is of the order of 20% mainly due to the accuracy of the semiempirical calibration factors used for the calibration of our Ge detector for the indoor and outdoor in situ measurements.

RESULTS AND DISCUSSION

In Thessaloniki and surroundings we have performed 143 indoor measurements, 19 outdoor measurements on roads and pavements, 37 outdoor measurements over soil. The mean value of the indoor dose rate in air is $\dot{D} = 70 \pm 15$ nGy/h with a relative contribution of 23%, 34%, 42% and 0.7% due to Uranium series, Thorium series, K-40 and Cs-137 respectively (Table 1).

For the houses and buildings constructed before 1986 the actual indoor Cs-137 gamma radiation is only due to the presence of Cs-137 from the Chernobyl accident in the nearby outdoor environment. The radiocesium contamination in Thessaloniki is mainly due to the Chernobyl accident, since the contribution from the nuclear weapons fallout can be neglected (5), (6). For the houses and buildings constructed after 1986 the actual indoor Cs-137 gamma radiation is due not only to the presence of Cs-137 from the Chernobyl accident in the nearby outdoor environment but also to the possible presence of radiocesium in the building

materials. In Figure 1 is shown the indoor dose rate in air due to Cs-137 as a function of the construction year of the house or building. It is impressively shown a pronounce peak for the year 1986 where the Chernobyl accident occurred. This fact indicates that for houses and buildings that were under construction in 1986, the Cs-137 act also as an indoor source term, however with small contribution to the total dose rate.

THESSALONIKI

Table 1. Absorbed dose rate in air (nGy/h)

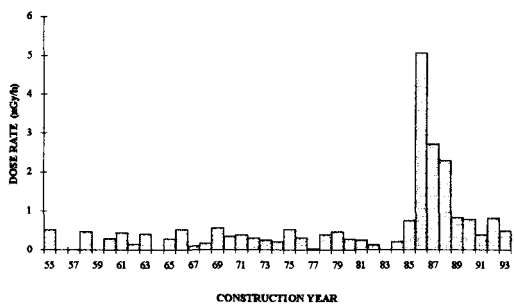

Figure 1. Indoor dose rate due to Cs-137 as a function of the construction year

The fact that for the houses and buildings constructed before 1986 the actual indoor Cs-137 gamma radiation is only due to the presence of Cs-137 in the nearby outdoor environment, gave the opportunity to measure in real conditions the attenuation of the gamma radiation by the building materials. For such buildings the dose rate due to Cs-137 was determined outdoor, in the vicinity of the building, as well as inside the building. These values gave dose attenuations, due to the shielding of the buildings, between 75% and 100%. In Figure 2 is presented the distribution function F(x) of the dose attenuation for these houses and buildings.

The mean value of the outdoor dose rate in air deduced from in-situ outdoor measurements on roads and pavements is $\dot{D} = 33 \pm 20$ nGy/h with a relative contribution of 26%, 26%, 40%, 8% due to Uranium series, Thorium series, K-40 and Cs-137 respectively. It can be seen that the contribution of Cs-137 is one order of magnitude higher than the one deduced from the indoor measurements and that the total outdoor dose rate $\dot{D}$ is smaller compared with the indoor dose rate. The higher value of the indoor dose rate compared with the outdoor dose rate can be easily explained from the fact that for the indoor environment we have a 4π source geometry compared to the 2π source geometry of the outdoor environment. As the number of country-wide indoor surveys is relatively small compared to those conducted outdoors, the indoor to outdoor ratio has been commonly used for the estimation of the average indoor absorbed dose rate in air from the outdoor values.

The mean value of the outdoor dose rate in air deduced from 37 in situ outdoor measurements on soil is $\dot{D} = 52 \pm 16$ nGy/h with a relative contribution of 17%, 32%, 36% and 15% due to Uranium series, Thorium series, K-40 and Cs-137 respectively. The Cs-137 contribution to the dose rate $\dot{D}$ is not any more negligible (15%) and is comparable to the contribution of the Uranium series (17%). The Cs-137 contribution to the outdoor dose rate over soil is two times higher than the one measured on roads and pavements. The influence of building, road and other materials used in urban areas affect significantly the external dose rate. Therefore estimation of dose rates based on measurements of soil samples do not apply, in general, to urban areas.

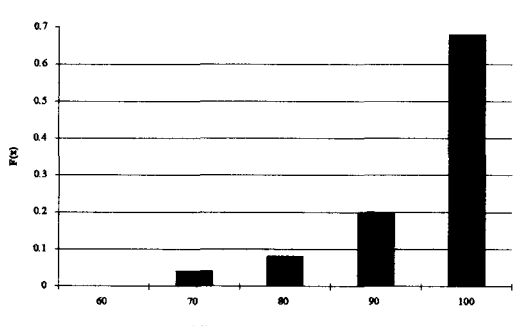

Figure 2. Distribution function of dose rate attenuation between indoor and outdoor measurement in the same place (26 measurements

From the above results, and taking

into account that 80% of people's time is spent indoors, a mean annual equivalent dose of 0.4 mSv for the γ-dose radiation can be deduced, for Thessaloniki.

In Athens and surroundings we have performed about 100 in situ measurements. The mean dose rate in air and the relative contribution of the Uranium series, Thorium series, K-40 and Cs-137 for the 79 indoor measurements, 8 outdoor measurements on roads and pavements, 12 outdoor measurements on soil are presented in Table 1. The presented mean indoor and outdoor dose rates are smaller by a factor of about 2.5 compared with the corresponding values in Thessaloniki. For all measurements the highest contribution to the D dose rate is due to K-40. The Cs-137 contribution to the indoor and outdoor dose rate in Athens is one order of magnitude smaller compared with the value obtained in Thessaloniki. This is explained from the fact that the Cs-137 deposition in Thessaloniki (~20 kBq/m^2) due to the Chernobyl accident was considerably higher than the deposition in Athens (~2 kBq/m^2).

	Indoor average absorbed dose rate in air nGy/h	Outdoor average absorbed dose rate in air nGy/h	indoors to outdoors ratio
Austria	71	43	1.65
Norway	95	73	1.6
Germany	70	94	1.36
Poland	-	87	1.2
Sweden	96	-	-
France	99	81	1.11
world populated weight average	80	57	1.4
Athens	24.5	18.8	1.3
Thessaloniki	70	52	1.64

Table 2. Comparative mean indoor-outdoor dose rates.

From the indoor and outdoor dose rates a mean annual equivalent dose of 0.14 mSv for the γ-dose radiation in Athens, assuming that 80% of people's time is spent indoors.

In table 2 the mean indoor-outdoor dose rates for Athens and Thessaloniki are compared with National averages from different countries and with the world populated weighted average (1).

CONCLUSIONS

The main conclusions of the present work are:

- First results of 212 indoor and 86 outdoor in-situ gamma dose measurements at the two most populated towns of Greece were presented. The mean absorbed dose rate in air and the relative contribution to the dose rate of the Uranium series, Thorium series, K-40 and Cs-137 were determined. From these results a mean annual equivalent dose of 0.14 mSv and 0.4 mSv for the γ-radiation could be deduced for the population of Athens and Thessaloniki respectively.
- The enhancement of the outdoor exposure rate due to radiocesium deposition from the Chernobyl accident is less than 15% for parks and gardens and less than 8% for roads and pavements.
- Estimation of dose rates based on measurements of soil samples do not apply, generally, to urban areas.
- For houses and buildings under construction in 1986, the year of the Chernobyl accident, radiocesium acts also as indoor source term however with small contribution to the total dose rate.
- The attenuation of the outdoor radiation (661.6 keV) observed, due to the shielding of the houses, was at least 75% up to 100%.
- The mean indoor-outdoor dose rates in Athens and Thessaloniki are smaller than the world indoor-outdoor population average and National averages of European countries.

ABSTRACT (See instructions overleaf)

The airborne gamma-ray scintillation spectrometry enables to detect photons, emitted by natural radioelements (K, U, Th) as well as man-made contaminants, dispersed in the soil surface layer. Proper mathematical processing of experimental spectrometric data is needed to calculate superficial / specific activities of individual radionuclides and air kerma rates in the reference level 1 meter above ground. On-line processing is desired for mapping this values over the scanned region of interest.

The new data processing method for ENMOS airborne gamma-ray scintillation spectrometry system (produced by PICODAS Group Inc.) was developed. Using the Monte Carlo method, the spectrometer responses for natural radioelements, selected artificial contaminants (including depth distribution models) and set of flight altitudes were calculated. Two basic spectrometer respose matrixes for energy interval up to 3 MeV and mostly used altitudes were prepared. Different methods for the spectra decomposition to contributions of individual radionuclides were tested and impact of the statistical and systematic errors was analysed. Main advantages of this method are: 1) no experimental calibration and corrections of the energy dependence are necessary, 2) calculation of responses can be provided for any experimental arrangement.

The method can be effectively applied for the airborne gamma-ray spectrometry data interpretation in environmental monitoring, operational or accidental monitoring / mapping of the radioactive contamination and for geological mapping. Some examples of monitoring results are also presented.

AEROGAMMA-SPECTROMETRIC MONITORING OF THE EARTH SURFACE

V.I.Fominykh (State Research Center, D.I.Mendeleyev Institute for Metrology, VNIIM)

V.S.Danilov, V.V.Filimonov (A.A.Logachyov Institute, VIRG-Rudgeophisika)

The basic task of radioecological monitoring is in receiving a reliable information about radiation conditions, and,first of all, their changes for estimation of radiation safety in the location of people's residence and activities. The aerogamma-spectrometric (AGS) method is the only one to provide for a reliable and efficient information about radiation conditions on large territories. This method has been successfuly applied in Russia since 1963, originally being used to solve problems in geology. In the course of the AGS method improvement in Russia, a special attention was paid to increasing the sensitivity and ensuring the stability of equipment parameters, as well as to the metrological assurance of AGS measurements as a whole.

A high sensitivity is ensured by using a set of identical detecting units (their number is limited only by the possibilities of an aircraft), while stability of parameters is provided by an effective system of energy scale stabilization. As the experience shows, when using an aerogamma-spectrometer with 22 NaJ(Tl) crystals, 200 mm in diameter and 100 mm in height, without any adjustment, during 3 - 5 months, the ambient temperature changing from -5° to $+50^{\circ}C$, the energy scale for each crystal and the whole detecting unit is not changed by more than 0.5 % from the initial value.

When advanced equipment is available, methodical and metrological support of the work plays the most important role for receiving a reliable information in AGS monitoring. Aerogamma-spectrometers have the same measurement assurance as energy spectrometers. A high quality of the final result is achieved by using a set of measurement techniques. Natural testing grounds certified in the rank of State standard materials of the Russian Federation, are used as a refernce standard. Several of such testing grounds have been already certified for the content of thorium, uranium and potassium in rocks and the radiocesium in the upper soil layer. Small-volume (up to 10 l) working sources are used to adjust and control the stability of equipment parameters.

Measurement results are reduced to the Earth surface level taking into account the distortions of the energy spectrum of rock gamma-radiation by the atmosphere and the differencies in passing of rock gamma-radiations and technogenic radionuclides through the atmosphere. Preliminary results have been obtained on accounting for the local landscape peculiarities and the nature of penetration of radionuclides in the soil.

The AGS technology (VIRG-Rudgeophisika) as a whole (equipment, methodical and metrological support, application packages, etc.) has made a good showing to solve both various geological and radioecological problems. Specifically, this technology was widely and successfully used for mapping of the radioactive contamination of the territory after the accident at the Chernobyl atomic power station. A high reliability of the AGS results is proved by earth sampling.

ABSTRACT (See instructions overleaf)

ENVIRONMENTAL GAMMA DOSE RATE MONITORING STATIONS: DISCUSSION ON DOSE QUANTITIES, SITE LOCATION AND CALIBRATION SCHEMES

Volker Genrich, Genitron Instruments, D-60488 Frankfurt (Germany)

In view of decreasing tolerance levels for ionizing radiation, there is a great effort all over the world to advance environmental monitoring equipment close to its physical and technological limits. The author proposes a new concept for high precision monitoring of environmental gamma dose rate, together with decision schemes for the "efficient" operation of these devices.

- ☐ Which of the dose quantities (as preferred in different countries today) is most appropriate: exposure (USA), air kerma (F), photon dose equivalent (D) or ambient dose equivalent (potential future standard) ?
- ☐ Where exactly is an appropriate site for the placement of an environmental gamma dose rate probe? Which "structures" in the vicinity of the probe should be avoided?
- ☐ How can environmental measurement systems be calibrated in-situ? What about the cosmic components of natural background radiation? Which methods for automatic quality assurance can be provided?

AN ORIGINAL METHOD TO MEASURE THE NATURAL RADIOACTIVITY IN THE OUTDOOR ENVIRONMENT BY MEANS OF A MOBILE LABORATORY.

ABSTRACT

The Nuclear Protection and Safety Institute has developed a special tool, a mobile laboratory, to perform measurement of natural radioactivity (gamma radiation and radon activity in the air) in the outdoor environment. With this mobile laboratory, it is possible to study the temporal and the spatial variations of the natural radioactivity. For that, measurements are made either by stopping the mobile laboratory at one point, or while the vehicle is moving. This last configuration allows to obtain cartographies of gamma radiation and radon level, that can be correlated with the geological characteristics of the site under study. This methodology can be applied to study the impact of radium-rich by-products storage site in the outdoor environment. It can provide very rapidly information useful for the site operator, the local authorities and the population.

Measurements made in France with this mobile laboratory show significant various areas as a function of the geological parameters. For example, the gamma dose rate is comprised between 60 and 300 $nGy.h^{-1}$ and the radon activity between 5 and 100 $Bq.m^{-3}$ and even higher.

INTRODUCTION

In the open air, the activity of radon gas depend locally on the exhalation rate and on the conditions of atmospheric diffusion. We can observe temporal and spatial variation in the range of a few $Bq.m^{-3}$ to several hundred $Bq.m^{-3}$ (1-2).
In fact, depending on the thermal structure of the atmosphere, with the presence or absence of temperature inversion, and on others meteorological parameters, the observed concentrations vary at a given site by a factor from 10 to 100.
Radon concentration also depends on the geological and pedological characteristics of the studied site (for example granitic or sedimentary area and parameters of the soil such as porosity, humidity, permeability, ...).So, we observe spatial changes in radon concentration due to the type of soils and not to the variation of meteorological parameters.

DESCRIPTION OF THE MOBILE LABORATORY

To perform measurement of natural radioactivity (gamma radiation and radon activity in the air) our Institute has developed a mobile laboratory. The vehicle is a diesel powered, cross-country four-wheel drive. The inside is fitted out with racks. These are equipped with silentblocs, selected according to the weight of the instruments, to eliminate low frequencies emitted by the vehicle engine or present in road noise. The measuring equipment is modular to accommodate the various tasks the mobile laboratory may be assigned.

It is equipped with the following:

- an electrical power generation system which provides 24 hours of measurement autonomy,
- a navigation system,
- a data acquisition and processing unit,
- ionisation chambers, for continuous measurement of the gamma dose rate, at approximately 2 m off the ground, and of the radon activity concentration. The air samples are taken at approximately 1.5 m off the ground.

The mobile laboratory is used to measure the temporal and/or spatial evolution of a pollutant on times scales ranging from a few minutes to several hours, and distance scales ranging from a hundred metres to tens of kilometres. Several measurement procedures have thus been developed.

Measurements are made as follow:

- at fixed stations, at several points of the site, over periods of several hours to several days and under various conditions of atmospheric diffusion. This reveals variations according to time of the day which are related, for example, to temperature changes at night;

- along various points of paths determined according to the site's characteristics (i.e. road infrastructure, housing, orography, etc.) and according to weather conditions under various conditions of atmospheric diffusion. This reveals spatial variations;

- at semi-fixed stations : the mobile laboratory is immobilised for 4 to 5 minutes at a point of known co-ordinates (x, y and z) then moved by a few hundred metres (in accordance with the orography) to carry out new measurements.

RESULTS

Figure 1 shows the results of cartographies made in east of France. These itineraries cross trough a granitic area (top of the map) and a sedimentary area (bottom of the map). Accordingly we find more radon in the north than in the south. The same phenomena is observed for the gamma dose rate. During the night the radon activity reached 200 $Bq.m^{-3}$ in the north for some points. For a same point of measurements, we observe that the radon concentration is increased by a factor of 2 between night and day.

This methodology can be applied:

- within the framework of studies on radon in buildings, to identify the radon-prone areas. Thus, some mitigation technics can be applied to reduce radon at home;.
- to study the impact of radium-rich by-products storage site in the outdoor environment. It can provide very rapidly information useful for the site operator, the local authorities and the population (3);
- to study the radiological regional background.

MOBILE LABORATORY FOR MEASURING RADIOACTIVITY IN THE ENVIRONMENT

Y. TESTINI
Department of Safety, Radiation Protection and the Environment
EDF/DEPT, SAINT-DENIS (FRANCE)

The emergency contingency plans of nuclear power stations provide for the measurement of radioactivity in the environment and, particularly, using mobile laboratory vehicles.
The originality of these vehicles is that they have been specially designed for nuclear power plants. EDF was able to achieve this design thanks to the standardisation of it nuclear power plants. This system is designed to enable non specialist technician to make reliable measurements easily.
The use of these vehicles is an integral part of the fixed environmental monitoring system of each nuclear power plant and includes the task of taking measurements in the field in order to corroborate the impact of radioactive releases into the environment in comparison with theoretical forecast calculations.

These vehicles are equipped mainly with the following:
- A radiation meter, which monitors activity continuously and the data from which is processed by a PC.
- A gamma spectrometer with a NaI probe for the specific measurement of Iodine and Cesium.
- Automatic beacons: these are truly portable environmental monitoring stations. They are used to gather aerosols and rain water and are fitted with a built-in radiation meter to measure exposure levels.
- A 220V electrical power unit supplied by a converter, which is supplied by a battery capable of operating for 48 hours.

All data collected are processed by the on-board measurement system. The data acquisition and processing system is designed to limit operator interventions to the minimum:
- Input data are processed automatically.
- Data and results are saved automatically without the intervention of the operator.

In continuous operating mode, the value of the dose rate is calculated every 10 seconds using data from detectors mounted on the side of the vehicle. The results are displayed in the form of a histogram and data are saved to the hard disk periodically.

The operator can «mark» certain points on the curve by assigning comments to them.
The gamma spectrometry measurements are taken automatically. Energy calibration is performed on power up and the system includes an automatic spectrum stabilisation function.
In order to start data acquisition, the operator installs the sample and selects the appropriate geometry.
The results are displayed on the screen and are saved to the hard disk on completion of the acquisition phase.

The parameters of the automatic beacons can be set. Sampling can be triggered either according to dose rate or according to time setting.
The measurement of exposure levels is continuous.
The sampling device consists of two identical pumping circuits, each of which is fitted with a removable cell which contains a filter with 1 or 2 active charcoal filter cartridges.
Rain water samples are also taken by a device consisting of two bottles.
Once the system is connected to the computer, data are downloaded to the computer automatically.

In addition, various items of sampling equipment are installed in the vehicle. The samples thus collected by them are subjected to gamma spectrometry analysis later in the various laboratories of the power plant.

ENVIRONMENTAL RADIOACTIVITY MONITORING IN LATVIA

J.Berzins[1], J.Alksnis[1], V.Bute[2], I.Upitis, I.Ljulko[3], T.Vasiljeva[3]

1 Nuclear Research Center Latvian Academy of Sciences
2 Environment Data Center Ministry of Environment
3 Hidrometeorological Agency Ministry of Transport

The first measurements of radioactivity in Latvia were performed in 1967. During the following 20 years the network of the radioactivity control were organized for all regions of Latvia. Until 1991 in Latvia the sample collection were solely performed, whereas the measurements were done in Obninsk (Russia). At present only a small research reactor with the thermal power of 5000 kW and the depository of radioactive waste are located in Latvia. The nearest nuclear power stations are situated in Ignalina (Lithuania), St.Petersbourg, Finnland and Sweden. A power of our reactor is small, therefore the increasing of radiation background can be caused only from the neighbour nuclear power stations or transport of radioactive materials.

After Chernobyl reactor accident a great attention from different organizations was paid to the control of radiation situation in Latvia. In this connection the determination of radionuclide concentration in environmental and food samples were organized in the Laboratory of nuclear spectroscopy at Nuclear Research Center of Academy of Sciences of Latvia till 1986 (1,2).

At present there are several organizations and paralel systems which ensure the control of the radioactivity in our republic.The first control system was organized in the Latvian Hidrometeorological agency. Now the system for the continuous measurements and processing of the data is developed.

At present the 46 stations for measurement of gamma radiation (approximately one in 1390 km^2) are established in Latvia. The largest density of such stations is found inside of the 100 km zone around the Ignalina nuclear power station..

The control program consists of registration of gamma radiation dosis rate from 46 stations, measurement of total beta activity of aerosols from the surface layer of the atmosphere and the precipitations and determination of the radionuclide concentration in various samples.

Since 1992 the concentration of natural and artificiel radionuclides in the aerosols, water, precipitation and sediments were measured in the Nuclear Research Centre of the Latvian Academy of Science using the methods of low background gamma spectroscopy and radiochemistry.

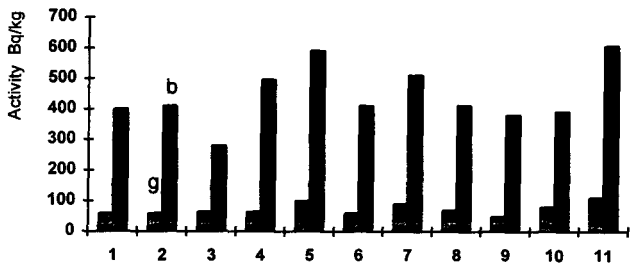
All data obtained from the network are transmitted to the several state institutions and are used for the international programs MORS and HELCOM. The information is obtained from the telecommunication network and forwarded by the direct telephon line BALTMET Riga-Norrkoping. Every day the infomation of gamma dosis rate is transmitted to Sweden.

The measurements of total beta activity of aerosols and precipitations from the reactor control zone were performed by the group of dosimetry of our nuclear reactor. These measurements were performed since 1967.

During the last years a new control system were organized in the Environmental Data Center at Ministry of Environment. In order to measure the gamma radiation the

automatic system was developed in the Environmental Data Center in cooperation with the Swedish Institute of Radiation Protection. Since December 1993 eight Rados radiation detector RD-02 were instaled in Daugavpils, Salaspils, Salacgriva, Talsi, Liepaja, Madona, Rezekne and Ventspils. This system has two signal levels consisting of a warning level at 0.2 μSv/h and an alarm level at 0.5 μSv/h. In order to evaluate the concentration of radionuclides the spectrometrical analysis of aerosol, soil and precipitation samples is forseen in a case of the first signal level. Similar systems are instaled inside of other Baltic states allowing to perform the data exchange. This year these data will be sent to IAEA, too. In order to colect the samples of plants and soils for spectrometrical analysis the control area are organized near the four cotrol stations located at Daugavpils, Salaspils, Ventspils and Liepaja. The results of measurements show that the total gamma activity of the soil samplesnear Daugavpils corresponds to 82-120 Bq/kg. The 1.Fig. shows the total beta and gamma activity near Liepaja.

Fig.1. The total gamma and beta activity of soils from Liepaja district



Number of sample
g-gamma b-beta

1. Bernati	5. Siksni	9. Ziemupe
2. Jurmalciems	6. Barta	10. Grini
3. Nica	7. Dubeni	11. Durbe
4. Rucava-Pape	8. Akmenrags	

The following conclusions can be proposed from the measurements obtained during the last four years.

1.The mean values of exposure gamma radiation dosis rate per year were ranged from 9 to 13 μR/h, the minimum was at 6 μR/h (Liepaja) and the maximum at 19 μR/h (Kuldiga, Madona, Kraslava). The mean value of 7 μR/h was obtained from the automatic gamma stations within the last 5 months in 1994.

2.The mean monthly values of the total beta activity during the last four years decrises slowly from $8.8.10^{-5}$ to $6.3.10^{-5}$ Bq/m^3. Newertheless, we can see an insignificant increase of the total beta activity in the summer months.

3.The mean monthly values of radioactive pollution in 1993 in the precipitation vary from 0.5 Bq/m^2 in Ventspils to 2.5 Bq/m^2 in Daugavpils.

4.The concentration of radionuclides in aerosols and precipitation were determined in the Laboratory of nuclear reactions of Nuclear Research Center with the methods of gamma spectroscopy. Only ^{7}Be, ^{40}K and ^{137}Cs were detected in the samples of aerosols and ^{40}K and ^{137}Cs in precipitations. The mean concentration of ^{137}Cs in aerosols was $0.07.10^{-5}$ Bq/m^3 and 0.7 Bq/m^2 in precipitations in 1993. The highest ^{137}Cs concentration in aerosols (three times above the mean concentration) was observed in May and September of 1993. Such concentration would be connected with the air mass movement from Byelorussia during the forest fire and can be caused from Chernobyl accident.
5.The water samples were taken from the four biggest rivers of our republik, the Gulf of Riga and the Baltic Sea. The concentrations of ^{90}Sr and ^{137}Cs were determined. The mean concentration of ^{90}Sr observed for the rivers, the Gulf of Riga and sea water was 25, 46 and 21 Bq/m^3, respectively. The concentration of ^{137}Cs was smaller than 0.03 Bq/l.
6.The concentration of ^{137}Cs is 2.7 Bq/kg in the river sediments, nevertheless, the value of 41Bq/kg in the Gulf of Riga and 97 Bq/kg in the Baltic Sea were measured. These values are practically the same as in 1992.

Fig. 2. Concentration of radionuclides in aerosols of Riga in 1994

A REGULATORY PROGRAMME TO ASSESS LICENSEES' ARRANGEMENTS FOR MONITORING THE PUBLIC IMPACT OF DIRECT RADIATION FROM CIVIL NUCLEAR SITES IN THE UK

C E Temple

Nuclear Safety Division, Health and Safety Executive, St Peter's House, Stanley Precinct, Bootle, Merseyside L20 3LZ, United Kingdom

ABSTRACT

Civil nuclear sites in the UK are licensed by HM Nuclear Installations Inspectorate (NII) which forms part of the Nuclear Safety Division of the Health and Safety Executive. Licence conditions include a requirement for site operators to have an adequate safety case for any operation that may affect safety. NII expects these safety cases to include arrangements that ensure that doses received by members of the public from direct radiation from nuclear sites are acceptably low. In 1993 NII decided that there would be advantages in supplementing existing techniques for assuring itself of the adequacy of the licensees' arrangements by making independent measurements of direct neutron and gamma radiation dose-rates near the perimeter fences of nuclear sites. A five-year programme was established covering all civil licensed nuclear sites in the UK.

This paper presents the measurement protocol adopted and discusses some early results from this monitoring programme. Technical aspects of the interpretation of measured air kerma rates in terms of operational dose quantities are outlined. Appropriate conversion factors are applied, and 'occupancy' data considered, in order to assess the effective doses likely to be received by the most exposed members of the public. These are considered in the light of the current UK statutory public dose limit, the ICRP-recommended limit of 1 mSv per year and other factors, including the basic safety limits and objectives established in NII's published Safety Assessment Principles (SAPs) for Nuclear Power Plants.

INTRODUCTION

The regulatory background to this work has been described by Bacon et al[1] in 1994. The purpose of this work has been to increase NII's confidence in the adequacy of licensee's arrangements for ensuring that direct radiation doses to the public from site operations are acceptably low. In order to achieve this, we have ourselves assessed licensees' arrangements and independently measured gamma dose rates at site perimeter fences. At selected sites we have also arranged for independent measurements of neutron dose rate to be carried out by the National Radiological Protection Board (NRPB), and for surveys of local public occupancy to be performed by the Ministry of Agriculture, Fisheries and Food (MAFF), in each case under contract to NII.

PROTOCOL

Gamma dose rates were measured using Mini Instruments Type 6.80 environmental gamma dose rate monitors. We subtracted background count rates due to instrument noise and cosmic radiation and applied a calibration factor to obtain measurements in terms of the quantity air kerma, Ka, relative to ^{226}Ra. Air kerma rates due to terrestrial background radiation were assessed (by reference to published data[2] and to our own limited background measurements) to obtain an estimate of the air kerma rate from direct gamma radiation from the site. Energy-dependent conversion factors were then applied to interpret measured air kerma rates in terms of the quantities ambient dose equivalent ($H^*(10)$) and effective dose equivalent (H_E). Our contractors, NRPB, measured neutron dose rates at specified locations near the perimeter fences of relevant sites using a Studsvik 2202D dose rate meter calibrated in terms of $H^*(10)$ with respect to ^{241}Am/Be. The response of this instrument is dependent on neutron energy and a knowledge of the neutron energy spectrum is therefore required in interpreting measurements. The highest neutron dose rates encountered in our monitoring programme have been associated with Magnox power stations. We consider that the neutron energy spectra near these stations are such that the Studsvik instrument provides a reasonably accurate response in terms of effective dose equivalent.

Occupancy surveys carried out by MAFF, under contract to NII, have sought to identify those members of the public who comprise the critical group for direct radiation from the sites, evaluate the annual period of exposure to elevated dose rate fields from the site and consider any shielding effect of building construction materials. This work, which has sometimes involved the measurement of gamma dose rates inside and outside occupied buildings, has enabled us to intepret the results of our dose rate measurements in terms of public impact.

n: Neutron Monitoring (NRPB) *c*: Occupancy Survey (MAFF)

UK PUBLIC DOSE CRITERIA

The statutory dose limit for members of the public in the UK is specified in the Ionising Radiations Regulations 1985 (IRR 85)[3] at 5 mSv per year (in terms of the quantity effective dose equivalent, H_E). More recent guidance from ICRP[4] has recommended a principal dose limit to members of the public of 1 mSv in any single year (in terms of the quantity effective dose, E). NRPB[5] has endorsed this view but has gone further to say that a dose constraint of 0.3 mSv from a single source should be a realistic target for most UK nuclear sites. The ICRP advice is also reflected in NII's Safety Assessment Principles for Nuclear Plants[6] (SAPs). Principle 14 sets a Basic Safety Limit (BSL) of 1 mSv per year and a Basic Safety Objective (BSO) of 0.02 mSv per year for doses to the public. These values are related to risk figures published by HSE in the Tolerability of Risk from Nuclear Power Stations paper[7]. NII expect licensees to have an adequate safety case to show that this BSL is not exceeded and that doses in excess of the BSO are kept as low as reasonably practicable (ALARP).

CASE STUDIES

It is our policy to make our findings available to members of the public via local liaison committee meetings. At most sites we have found that no member of the public receives more than 0.1 mSv per year from direct radiation. However, higher dose rates were found at the three sites which are discussed below.

Nuclear Electric plc, Dungeness Nuclear Power Station (gamma, neutron monitoring and occupancy survey)

This site features relatively high gamma and neutron dose rates at the eastern perimeter within 100 m of two inhabited cottages. These aspects have previously attracted licensee and regulatory attention as part of NII's assessment of the licensee's long term safety review for the Magnox power station at Dungeness "A"[8]. Our independent gamma and neutron dose rate measurements results were broadly consistent with those reported by the licensee. Our findings provided confidence in the licensee's assessment at that time, based on comprehensive measurements and conservative assumptions regarding occupancy and reactor operating conditions, that the most exposed occupant of these cottages might receive an effective dose equivalent of approximately 0.83 mSv y^{-1}. The licensee has since arranged for neutron dose rates to be reassessed following the installation of additional polythene shielding on the roof of one of the reactor buildings. This work has shown that neutron dose rates at the cottages have been significantly reduced. We now believe that the most exposed member of the public is unlikely to receive an effective dose equivalent greater than 0.53 mSv y^{-1}. Considering the licensee's neutron energy spectrum data in the light of the revised radiation weighting factors for neutrons, as recommended by ICRP, we have estimated that this corresponds to an effective dose, E, of approximately 0.64 mSv y^{-1} (0.44 gamma, 0.20 neutron). Our work at Dungeness has highlighted a number of interesting aspects. For example, the gamma energy spectrum at Dungeness "A" is dominated by a component of energy ~ 6.3 MeV (from decay of N^{16} in the external ductwork of the reactor). We therefore needed to allow for the over-response of our instruments to this component and to apply modified factors in converting from Ka to H*(10) and H_E. We found that there was virtually no significant terrestrial gamma dose rate above the shingle surrounding the Dungeness site and that gamma dose rates measured in some buildings near the site were higher than those measured immediately outside. We consider that the elevated dose rates are probably attributable to natural radioactivity in the building construction materials.

Amersham International plc, Amersham Laboratories (gamma monitoring only)

As at Dungeness, occupied buildings are located very close to part of the perimeter fence of the Amersham site. The results of our gamma dose rate measurements were broadly consistent with those reported by the licensee (there being no neutron component). As a result of our work, the licensee has completed an assessment of the dose to the public using revised occupancy data and is making further improvements to shielding. We are currently examining the licensee's assessment that no member of the public is likely to receive an effective dose equivalent exceeding 0.2 mSv y^{-1} from direct radiation from the site.

British Nuclear Fuels plc, Chapelcross Nuclear Power Station (gamma, neutron monitoring and occupancy survey)

As with the previous two case studies, occupied buildings are located very close to the nuclear site. The radiation field features gamma and neutron contributions, including a high-energy gamma component of ~ 6.3 MeV. NII's independent assessment has broadly confirmed the licensee's safety case. This shows that the most exposed members of the public are residents of a nearby farm who might receive an effective dose equivalent of up to 0.12 mSv y^{-1} (0.10 gamma, 0.02 neutron). Key features of this work were the identification of the appropriate terrestrial background, the inclusion of a neutron component, and assessment of additional members of the public. The licensee is currently carrying out further investigations, which will include neutron energy spectrum determination, at this site.

SUMMARY

We have found that licensees have employed a variety of approaches and technical methods in seeking to ensure that doses received by members of the public from direct radiation from nuclear sites are acceptably low. Our independent assessment has, in some cases, prompted licensees to review and refine their arrangements for assessing the impact of direct radiation from their sites and to seek means of reducing off-site dose rates, in accordance with the ALARP principle. We have found that members of the public living close to nuclear sites have received effective dose equivalents (and effective doses) significantly less than 1 mSv per year as a result of direct radiation from the site. This work has provided useful supplementary information in support of discussions on ALARP. Nothing has emerged which has reduced our confidence in the adequacy of the licensees' arrangements for meeting public dose limits. No significant deficiencies, requiring regulatory enforcement, have been identified.

The views expressed in this paper are those of the author and do not necessarily represent those of HSE.
The author wishes to acknowledge the assistance of his colleagues Mr I F Robinson, Mr J S Griffiths, Dr D N Simister and Miss E A McCullough, and the co-operation of the licensees, in the course of this work.

ENVIRONMENTAL MEASUREMENTS AROUND

FRENCH NUCLEAR POWER PLANTS

A. LE CORRE, T.BOURCIER

Department of Safety, Radiation Protection and the Environment
EDF/DEPT
SAINT-DENIS (FRANCE)

Electricité de France generates 75 % of its electricity in nuclear power plants with pressurized water reactors (PWR). Theses plants comprise 34 units of 900 MW and 20 units of 1300 MW, the first of which was connected to the grid in 1977, and the last in 1993. Three other units of 1400 MW are under construction.

The environmental measurements are performed in two complementary ways :

1. Routine regulatory monitoring carried out by the operator according to a programme and procedures drawn up by the Ionizing Radiation Protection Office (OPRI), which is the State monitoring authority in France. The OPRI checks the results against those obtained with its own samples.

   Around each power plant, the following are monitored :

   - Ambient γ-radiation (continuously) at 8 points around the site within a radius of 5 km ;
   - Aerosols in the air (once per day) at 4 points within a radius of 1 km ;
   - Rainwater and groundwater (monthly) ;
   - Surface waters (whenever there is a liquid radioactive discharge) ;
   - Milk and vegetables (monthly) at 2 points in the area close to the site.

   The plant has an off-site laboratory, two specially-adapted vehicles and e team of three chemists.

   These measurements are quite separate from those conducted on radioactive wastes.

2. Annual and ten-yearly radioecological measurement campaigns around the sites in order to improve scientific knowledge of the environmental impact of the plants.

   A ten-yearly campaign consists of "radioecological photographs" which are compared with the "initial zero point". About 40 samples are taken and various analyses performed (total β, α and γ spectra, strontium, carbon-14, free and organic tritium). The choice of samples and the places where they are taken depend on the zero point and the special features of the region. Items sampled include drinking water, irrigation water, ground moss, vegetables, fruit, field crops, field soil, humic gley soil, meadow grass, milk, sewage sludge, wine, sediments, water or marine plants, fish or shellfish.

The annual campaigns around each site enable a picture to be built up of the radiation situation in time and space from γ-spectrometry measurements on 27 samples selected as being the most suitable indicators (sediments, bryophytes, fish, moss, fruit, drinking water, milk, wine, soil).

The programm involves around 600 samples and 800 measurements per year and is conducted, at our request, by the Institute for Radiation Protection and Nuclear Safety (IPSN) which has established the methodology for the sampling and measurements and has the capacity to ensure the continuity indispensable for this type of measurement..

The results of all these measurements are published and communicated to the public through the most appropriate media.

AN ASSESSMENT OF THE RADIOLOGICAL SIGNIFICANCE OF CONSUMING WILD FOODS COLLECTED NEAR THE SELLAFIELD NUCLEAR FUEL REPROCESSING PLANT.

MJ Fulker,[1] DRP Leonard,[2] K McKay,[1] C John[1] & D Jackson[1]

[1]*Westlakes Research Institute, Moor Row, Cumbria, CA24 3LN UK*
[2]*MAFF Food Science, 17, Smith Square, London SW1P 3JR UK*

1. Dose estimates and modelling of food pathway

Extensive monitoring of conventional agricultural produce in the vicinity of the BNFL Sellafield plant is undertaken, by both the operator and the Ministry of Agriculture, Fisheries and Food, to determine levels of radioactivity and doses[(2)] arising to the consumer. Monitoring is also undertaken[(3)], albeit less extensively, for market garden and domestic produce. By contrast, few data exist with respect to levels of radioactivity in 'wild foods' (e.g. hedgerow fruits, field mushrooms etc.) or associated consumption habits. It has been postulated that such foodstuffs could contribute an appreciable radiation exposure dose to groups of high level consumers, potentially including members of the existing identified critical group for local agricultural produce. This paper assess the actual radiological significance of wild foods collected near Sellafield.

2. The Habit Survey

A previous survey of the consumption of locally produced foods had provided useful information for the assessment of doses from food produced close to the Sellafield nuclear plant[(1)]. In the current project, the habit survey had the main objective of identifying wild foods which could contribute to the ingestion dose. The survey was carried out during the spring and summer of 1994 by CN Research (Carlisle, UK). A total of 72 households were surveyed, and data collected for 181 individuals; comprising 3 infants (taken to be up to 2 years old), 21 children and 157 adults. Information was obtained on a total of 49 foods, including 9 species of fungi, 11 herbs, 16 fruits, 12 types of game, as well as nuts and honey; collected from areas near to Sellafield.

Table 1 Consumption Rate Data for some Key Foods

Food	Number of Consumers	Consumption rate (kg/year)			
		Mean	Max	Ratio max/mean	97.5th percentile
Venison	23	8.16	134.4	16.5	72.3
Blackberry	129	1.45	10.24	7.06	9.72
Honey	49	1.29	6.72	5.21	6.27
Elderberry	6	2.59	6.7	2.59	6.35
Pheasant	72	1.44	7.17	5.00	5.08
Fungi	64	0.57	4.98	8.74	2.06
Mallard	29	1.27	5.82	4.58	5.82
Nuts	30	0.49	2.56	5.22	2.56
Goose	10	1.08	2.69	2.49	2.59
Rabbit	7	0.86	1.34	1.59	1.34

In many cases, the maximum consumption rate of a food was much greater than the average value for all consumers of that food. In the most extreme case the maximum consumption rate for venison, by a game keeper, was 134 kg per year: 16.5 times the average value of 8 kg per year for all 23 consumers. This difference between the extreme rate and the average is, for wild foods, greater than for most conventional agricultural products, and requires special attention in the assessment of radiation doses from the consumption of wild foods.

In this survey, the consumption of wild fungi, although including a variety of species, was fairly low, being naturally limited by availability. The consumers of all wild foods were mainly adults, with generally insignificant consumption by infants and children.

3. Measurements of radioactivity in wild foods and consumption doses arising.

The information collected in the habit survey was used as a guide in the collection of samples of fruit, nuts, wild game (such as venison, rabbits, pheasant, duck and goose), as well as honey and fungi. Samples were measured for gamma emitters, actinides (plutonium and americium) and, on selected samples, ^{14}C and ^{129}I.

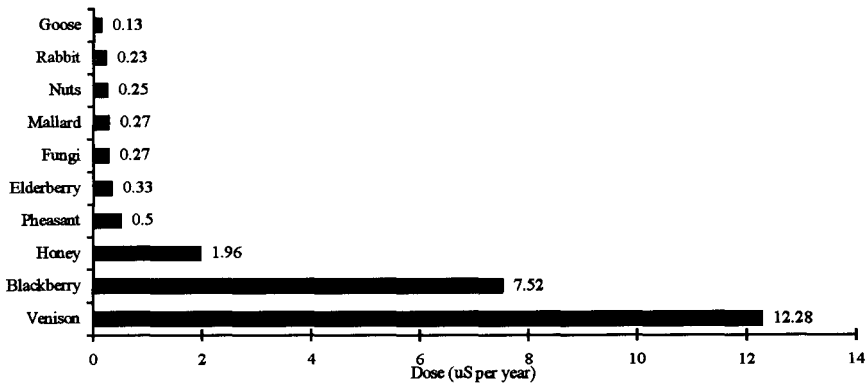
The dominant gamma emitter was ^{137}Cs; the highest concentrations being found in some samples of honey. Pollen analysis identified these honey samples as containing significant proportions of honey derived from heather. In West Cumbria heather grows on upland organic soils which received significant deposition from the Chernobyl accident in 1986. Table 2 compares two samples of honey from the area close to Sellafield.

Table 2 Comparison of caesium content and primary pollen source of upland and lowland honey from West Cumbria

	Upland honey	Lowland honey
^{137}Cs (Bq/kg)	254	21
Pollen Species:		
Calluna (heather)	71%	
Trifolium (clover)	9.2%	48%
rowan, hawthorn and cherry		20%

Figure 1 shows the contributions to the dose from wild foods consumed at the 97.5 percentile rates, assuming maximum measured radionuclide concentrations for each food, demonstrating the relative importance of blackberries and venison. In this assessment the upland honey samples were omitted, in order to avoid the inclusion of contributions from Chernobyl deposition through the heather-honey pathway.

Figure 1 Contributions to dose from different wild foods for the 97.5th percentile consumption rates



The dose from wild food can be compared to the critical group dose from locally produced agricultural products (e.g. milk, vegetables and meat); where the highest such dose was 24-54 μSv/year (Committed Effective Dose) to an infant in 1994, of which 7-36 μSv/year is from milk[(2)]. For an adult, more relevant for comparison to this project, the dose from local agricultural products is calculated to be 10-24 μSv/year committed effective dose (CED) of which 3-9 μSv/year is from milk.

The contribution to ingestion dose by individual radionuclides present in the wild foods is presented in Table 3. It can be seen that the dominant nuclide overall is ^{137}Cs, which may derive in this locality from Sellafield emissions, the Chernobyl accident and/or weapons test fallout.

Table 2: Committed effective dose based on 97.5th percentile consumption by an adult

	Effective dose (μSv/y)						Total	Collective dose*
Food	^{14}C	^{129}I	^{134}Cs	^{137}Cs	^{239}Pu	^{241}Am		μmanSv/y
Venison	0.00	0.00	0.45	11.82	0.00	0.00	12.28	282
Blackberry	0.57	0.49	0.22	5.99	0.11	0.24	7.62	983
Honey	0.08	0.00	0.12	1.67	0.10	0.003	1.96	96
Elderberry	0.00	0.31	0.00	0.02	0.01	0.00	0.33	2
Pheasant	0.03	0.17	0.00	0.30	0.00	0.00	0.50	35.8
Fungi	0.00	0.00	0.01	0.27	0.00	0.00	0.27	18
Mallard	0.00	0.00	0.00	0.27	0.00	0.00	0.27	8
Nuts	0.00	0.00	0.00	0.25	0.00	0.00	0.25	8
Goose	0.00	0.003	0.00	0.13	0.00	0.00	0.14	1
Rabbit	0.00	0.00	0.01	0.22	0.00	0.00	0.23	2
Consumption dose by isotope (μSv/y)	**0.68**	**0.97**	**0.81**	**20.9**	**0.21**	**0.24**	**23.8**	
%	**2.88**	**4.08**	**3.38**	**87.79**	**0.89**	**1.10**	**100**	

** Collective dose is calculated only for the consumer group for each foodstuff: i.e. the 23 consumers of venison each receive just over 12 μSv per year, or collectively 282 μSv per year. This is a very narrow definition of collective dose, used only to illustrate the relative importance of each of the foodstuffs analysed.*

Considering both collective and individual dose, venison and blackberries dominate the consumption pathway, contributing 282 and 983 μmanSv per year respectively to the group of consuming individuals. Blacberries are of particular importance in calculating collective dose, because of their ubiquitous distribution and consumption.

4. Conclusions

The project has highlighted the importance of blackberries, which are easy to collect and are consumed by large numbers of people. Game (e.g. pheasant) is also important because of the concentrations of radiocaesium in game reared close to Sellafield and fed on locally grown grain. Venison is an example of unusual consumption patterns by a very small number of individuals. The radioactivity in honey was very variable, with some samples containing radiocaesium from Chernobyl through the soil-heather-honey pathway, whilst other samples contained very little anthropogenic derived radioactivity.

Overall, the extreme doses from wild foods are comparable with doses to the critical group for consumption of conventional agricultural produce from close to the Sellafield site, but the 97.5th percentile of the individual effective doses from wild foods are generally lower. All doses are well below applicable dose limits, even when the doses are assessed additively.

This study was funded by the Ministry of Agriculture, Fisheries and Food (Food Science Division). The authors are grateful to David Weir of English Heritage, London, for the pollen analysis of honey samples.

THE KGE COMPUTER SYSTEM

P. SAGOT - Y. TESTINI
Department of Safety, Radiation Protection and the Environment
EDF/DEPT, SAINT-DENIS (FRANCE)

A computer system has been developed to assist crisis management teams of the Command and Control Centres (PCC) of PWR power plants in evaluating releases and the radiological impact of such releases on the environment in the event of an accident.

This industrial application, known as GEEE (Gestion de Effluents Et de l'Environnement - Waste and Environmental Management) is supported by the KGE system, in accordance with encoding of the basic systems of nuclear power plants.

Each EDF Nuclear power plant (CNPE) is equipped with the KGE computer system.

This computerised tool is also installed in the technical control room of the national crisis centre.
Environmental specialists can link up with the KGE computer of the plant in which the accident has occurred and that of a neighbouring site or sites.
Certain parameters relating to all sites can also be consulted under normal conditions.

The evaluation of the radiological impacts on the environment is made on the basis of the condition of the installation in three stages, both in terms of diagnostic evaluations and prognoses.
These three stages are as follows:
* evaluation of the source; that is, the level of activity released into the environment for each major group of radionuclides (rare gases, iodines and cesiums)
* evaluation of the transportation and dispersion of this level of activity into the environment
* calculation of doses for the various forms of transport at various distances from the release source.

In order to monitor releases in real time (diagnostics), the KGE computerised system is connected to:
* the computer and data processing system (KIT) of the unit which provides thermo-hydraulic measurements and various activity measurements from the plant radiation monitoring system (KRT)
* to the environmental monitoring system (KRS) which provides data on wind speed and direction, the level of precipitations and the atmospheric stability index.
* to the radioactivity measurement and monitoring station at 1 and 5 km from the plant (RSN radiation meter beacons).

Therefore, the evaluation of the source is obtained through continuous radioactivity measurements from the plant radiation monitoring system (KRT) (beta total gas) and the ventilation rate from the nuclear auxiliary building ventilation system (DVN). Evaluation of the transport of waste is obtained through the continuous acquisition of meteorological measurements for the site from the environmental monitoring system. The evaluation of the dispersion of waste into the environment is obtained through the use of a "burst" diffusion model, which takes into account the weather variables at the time of the release.

In order to forecast the consequences (prognosis), the evaluation of the source is obtained using predetermined values based on the type of accident, the transport evaluation is obtained using average weather data supplied by the inter-regional division of the French weather service. The evaluation of the dispersion of activity into the environment is obtained using a monogram model from the IPSN.

The dose conversion factors set out in ICRP 29 are used for calculate the full organism dose, the thyroid dose equivalent and the dose rate, whether for the prognosis or diagnostic evaluation.

The application enables the results of the evaluation of the impact of gas releases (environmental message , impact map for the entire organism or thyroid, etc.).

The level of precision achieved for the areas affected by the release enable the targeting of activity measurements in the field on the one hand and the establishment of priorities for the implementation of measures to protect the population (confinement, evacuation) on the other.

The Automatic Radiation Monitoring Distributed System SRM-256C

Stetsenko G.N., Rastsvetalov Ya.N., Yanovich A.A.

Institute for High Energy Physics, 142284 Protvino, Russian Federation

The Controlled and Supervised Areas (CSA) of UNK proton accelerator builded in Protvino (IHEP, Russia), borrows the significant area (more than 15 sq. km.) [1]. Submitted in work [2] results of accounts show, that by major factors, influencing to a radioecological conditions in region at the expense of work UNK are: 1) the output of pulsing radiation on day-time surface; 2) the radionuclides receipts with drinking water; 3) the pollution of radioactive air from system of ventilation. At normal mode of UNK operation the equivalent dose rates on day-time surface of pulsing radiation will changes in limits from 0.5 mcSv/hours near overmines buildings up to 0.1 mcSv / hour on the CSA border [2]. The average equivalent dose rates per year due to internal irradiation at use (intakes) of drinking water will not exceed 5 - 50 mcSv/years [2]. The Maximum equivalent dose rates on day-time surface, caused by pollution of radioactive air does not exceed 0.01 ... 0.03 mcSv/hour in limits of CSA, and the average equivalent dose per year caused by internal irradiation does not exceed 0.05 mcSv / years [2]. At emergency-free operation the maximum degree of the UNK influence in limits of CSA is estimated in terms of average equivalent dose per year at levels, not exceeding 0.05 ... 0.10 mSv/year [2]. For maintenance of integral environmental monitoring of total external radiation levels in limits of CSA network of passive monitor stations [3] will be developed.The UNK influence on radioecological condition of environment , according to resulted estimations, will insignificant and can be determined only by long measurements, as before UNK start , and during its operation. One of differential monitoring components [4] of environment in UNK region will be The Automatic Monitoring Distributed System (SRM-256C). Its based on network of Sensors, recording radiation parameters of the environment, connected through Input/Transmitting Stations (IOS) via the communication line (the switched telephone communications or the non-switchable cable communications of radial organization) with managing computer (IBM PC/AT compatible).The IOS executes reception, accumulation of the information from sensors and transmission of data in Communication Line (CL) on inquiry from managing computer. The data are received by managing computer through specialized modem. The program shell of SRI-256Å routes cyclic inquiry of IOS , reception and decoding of the information from them, executes the control of reliability of distributed sensors , archiving of the received information in specialized database, mathematical processing and graphic representation of data with binding on the controlled area , recall and notification under given telephone number list in case of dose rate limits exceed. The first developed variant of IOS (IOS1) consists of following main functional units: power supply unit (PSU); unit of the interface with communication line (ICLU); the timer unit (TU); the RAM unit (RAMU) (RAM with capacity 4 Kbytes); unit of address logic formation (ALFU); the unit of counters (CU); unit of the reliability control of detectors (RCDU); the unit of the universal shifting register (USRU). The IOS1 permits to accept, to store and to transfer data in line on inquiry from two detectors (are used modified industrial detector BDMG-08R for gamma - radiation

detecting (the measuring range of equivalent dose rate are 0.1 mcSv/hour ... 100 mcSvhour) and the DPN neutron detector (the measuring range of equivalent dose rate are 2.5 mcSv/hour ... 25 mSv/hour .) for registration of neutron radiation [3]. The signals from sensors are recounted with CU and through installed timing interval are recorded in higher word (with address W:2047) of RAMU. ALFU and TU controls the work of USRU and organize arithmetic shift of whole data file in RAMU to lower addresses. The changeable range of a timing cycle of record in unit the RAMU makes Tc = 1 minute ... 4 hours, thus minimum data storage time (without loss) makes (1 mines o 2048) 2048 minutes. With detecting of an asynchronous inquiry in CL by ICLU a cycle of sensors reliability testing (the testing radioactive Sr/Y sources deliverance are organized to a sensitive volume of detectors) is initiated, and then ALFU and RCDU give out in consec utive CL data file from RAMU and results of detectors diagnostics . The data are broadcasted to CL with installed rates of transfer: in telephone line - up to 2048 baud; to coaxial cables - up to 9600 baud. Taking into account experience of IOS1 operation the second variant (IOS2) was developed. Basis of IOS2 is the one-crystal microprocessor 80Å31AI of clone Intel MCS-51 (USA). The software of IOS2 is realized with TASM for MSDOS (Speech Technology Inc.) cross-tools.The IOS2 carries out all functions of IOS1, however the IOS2 use less of chips and is simple in set-up. The amount of served sensors may reached 8. The updating of functional opportunities for IOS2 is reduced to reprogramming of ROM (capacity of 4 Kbytes) The specialized modem is developed for ISA system bus (AT-bus) of IBM PC/AT - compatible computer. The modem cyclically recalls the IOS, accepts data, together with has an opportunity to give out the speech information on telephone lines. The software of system ÅDI-256Å is realized in environment of programming shell Borland C ++ and permits to serve up to 256 of IOS.

CENTRALIZATION OF ENVIRONMENT MONITORING MEASUREMENTS

Y. TESTINI
Department of Safety, Radiation Protection and the Environment
EDF/DEPT, SAINT-DENIS (FRANCE)

According to French legislation, the operators of nuclear installations are required to install a certain number of monitoring devices to ensure that such installations have no radioecological impact on the natural environment and the surrounding population.
For this, the most recent nuclear power plant, that is the CHOOZ power plant, which belongs to the N4 series, has been equipped with a new system which centralizes the measurement data from sensors installed in the environment around the installation.
This system gathers radiation meter, meteorological and physico-chemical data measured in the environment together with a certain number of parameters related to the nuclear units themselves, such as power and continuous stack release activity measurements.

All these data are then centralized and exploited using a supervision mode which performs the surveillance, statistical, maintenance and communications functions.

The surveillance function enables the operator to display data concerning the environment around the power plant under the form of different screens for each measurement field:

- Radiation meter,
- Meteorological analysis,
- River monitoring,
- SODAR measurements.

Data are displayed under various forms, either under the form of a map showing the location of sensors in particular or under the form of tables of graphs.
The colour of the name of each sensor changes according to its status.
All maps show an indicator, which shows the direction and strength of the wind as well as atmospheric stability.
In the event of a pre-set value being exceeded and since the parameters of each sensor can be modified, a local signal is transmitted automatically to the control room of the power plant, where an alarm is generated.
Any screen can be printed out at any time.
In addition, each screen displays a band, which indicates the actual status of the network and maintenance operations on the system, in real time.

The statistic function is used for the management and storage of data as well as to print out graphs and tables showing particularly interesting points.

The CPU also transmits data to the various users on site and transmits data to the various organisations concerned; such as the national crisis centres or the national meteorological service.

The system can also act as a server and transfer certain processed data to other applications; such as the computerised waste release management system.

This system has been in service in the CHOOZ power plant since the summer of 1995.

ENVIRONMENTAL STRAY RADIATION MONITORING AT THE NSRL

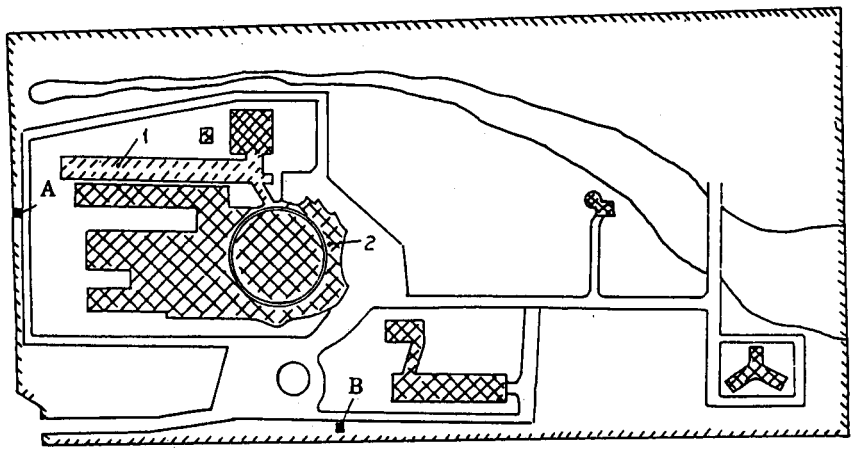
THE NSRL AND ITS ENVIRONMENTAL RADIATION FIELD

The first dedicated synchrotron radiation light source in China is fixed in the National Synchrotron Radiation Laboratory (NSRL). A 200 MeV electron linac and an 800 MeV storage ring are its main equipment. The linac works as the injector and the ring provides VUV synchrotron light for various kinds of optical experiments. Fig.1 is the sketch map of the NSRL.



1. Tunnel 2. SR Hall A. E.M. Station A B. E.M. Station B

Fig.1

The environmental radiation field around it is distinctive and its variation is related closely with the operation states of the synchrotron radiation machine. Its displays are as follows:

1. It is a mixed field. Not only bremsstrahlung but also neutron exists in it. Both of them have wide spectrum. These two components distribute quite differently. The former is directive while the latter is isotropic.
2. It is a prompt field with small duty factor(1×10^{-7}). The high instantaneous value and low average of the radiation dose are the most distinctive differences compared with the steady field.
3. Since the linac is in an underground tunnel covered with three-meter thick soil, no observable radiation dose caused by it can be recorded during the environmental monitoring. The additional environmental stray dose mainly comes from the injection of the storage ring. It skips every time the electrons from linac are injected into the ring. As mentioned above, although the peaks can be observed clearly on the curve recorded, the accumulated dose is limited.

It is necessary to monitor, record and analyze such a characteristic radiation field. To avoid the shortcomings of the discontinuous monitoring and TLD method, an intelligent environmental monitoring system has been set up for this radiation field.

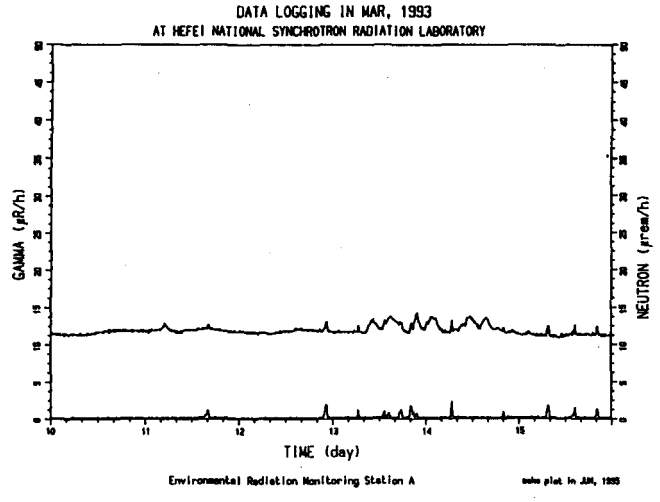
ENVIRONMENTAL RADIATION MONITORING

The intelligent environmental radiation monitoring system includes environmental monitoring stations, control computer and several peripheral devices. In Fig. 1, the points marked A and B are the locations of two environmental monitoring stations. Station A is at the west border of the NSRL area where is close to the linac. Station B is near the south border where is about 104 meters far from the injection point and exactly towards the injection direction. There are detectors and data acquisition device in every station. The gamma detector is a 8.5 liter volume pressurized ionization chamber filled with argon. Its sensitivity is $1.03\times10^{-4}A/(C\cdot kg^{-1}\cdot h^{-1})$. The neutron detector is a BF_3 tube in polythene moderator. Its sensitivity is $(17.0\pm0.3cps)/(n\cdot cm^{-2}\cdot s^{-1})$. The data acquisition device is a microprocessing unit with M146805E CPU. It can work well with rechargeable batteries when power supply fails. The environmental radiation data can be stored in its RAM and transferred to the control computer's disk once a week. In past years, the plenty of data provided scientific basis for us to analyze the field's characteristics and make tables or charts. The software for special research purpose is programmed during the work, such as the program for calculating additional dose or injection time.

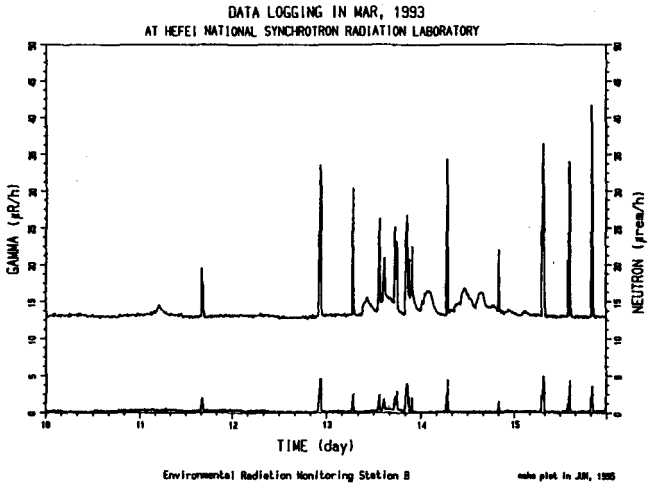
THE ANALYSIS FOR THE NSRL ENVIRONMENTAL STRAY RADIATION FIELD

By the environmental radiation monitoring system, we have gotten a series of monitoring results that reflect the field's characteristic and stray radiation level correctly. At the same time, some interesting things attract us very much and make us to think deeper about certain phenomenon. For instance, we have new idea about the relationship between rain and gamma natural background. Fig.2 includes two charts plotted by the system. They are gamma and neutron environmental radiation dose rate curves in the same six days. Here is the explanation:

1. The chart marked (a) is from monitoring station A and (b) is from station B. In every chart, the upper curve represents gamma dose rate and the lower one represents neutron. Their relative values are shown in the left and right of the chart respectively. The X axis is the date.
2. The increase of gamma dose rate is caused by the bremsstrahlung. Compare chart (a) with chart (b), we can see clearly that the gamma radiation level recorded by station B is much higher than that by station A during the injection period of the ring. This is because of the different location of these two stations. A is at the side of the injection direction while B is toward it. Strong directive is shown here. In the meantime, the neutron dose rate is isotropic. The difference is only because of the different distance between the stations and injection point.
3. On the gamma curve, all the peaks that no responses on the neutron curve are caused by the rain. It seems that the heavier the rain is, the higher the peak rises. The radiation level falls to background as soon as the rain stops. We do not think this phenomenon accords perfectly with the traditional theory about the background increase caused by the rain. So a further research is going on.
4. Neutron radiation level is not affected by rain. Its total dose equivalent is much less than that produced by gamma. It increases only during the injection period. So we can take it as a symbol to recognize if the gamma increase is caused by the rain.
5. From the charts we can see the additional dose is limited. Sometimes the gamma increase caused by rain is higher than that by machine operation. The natural background dose is about 1000 μSv per year, the recorded increase dose caused by the machine operation is usually much lower than 50 μSv even if at the station B.



(a)



(b)

Fig.2

CONCLUSION

We began to cumulate natural background data in 1987. Since then, the environmental radiation monitoring system has worked well for eight years. It helps us and other researchers a lot in many aspects. It is not only a guarantee for the radiation safety, but also a useful tool in the scientific research. The data acquisition device and processing software are improving so that we can study the field in a better way.

THE ARTIFICIAL RADIOACTIVITY IN BECHET-DABULENI AREA, FIVE YEARS OF SURVEY

Elisabeta Dobrescu, C.Milu, R.Gheorghe, F.Lida, D.Gruia

Institute of Hygiene, Public Health, Health Services and Management, Bucharest, Romania

INTRODUCTION

The Bechet-Dabuleni area is placed in the southern part of Romania, in the Danube zone, near the Nuclear Power Plant from Kozlodui (Bulgaria). Here there is a very important agricultural area, with small and also big farms where for irrigation the Danube water is used.

The purpose of the study was the long term surveillance of the artificial radioactivity for the main foodstuffs. It has been investigated the radioactive content of the following foodstuffs from this area : vegetables (potatoes, carrots, onion, etc.), fruits (apples, pears, apricots, peaches) and cereals (wheat, barley). It has also been determinated the radioactive content of the irrigating water from the Danube River.

MATERIAL AND METHOD

Global beta-measurements were performed in order to obtain initial data on the contamination level of the samples. The determination of the Cs-137 and Sr-90 content from the water samples was done by coprecipitation from 50 l water followed by the chemical separation. Cs-137 was concentrated on APM and measured with a beta counter as Cs-hexacloroplatinate and Sr-90 was precipitated as carbonate and after the separation was measured as yttrium oxalate after the radioactive equilibrium.

The beta-measurements were done with a low level anticoincidence beta counter with 14% counting eficiency for Sr-90+Y-90 standard source. For the determination of the specific Cs-137 content from vegetables were used the ashes obtained in a thermoregulating furnace at the temperature of 450°C. The measurements were performed using a multichannel analyser system (4096 channels) type Canberra 40, with a high resolution Ge(Li) detector and with a multichannel analyser system (1024 channels) with a NaI(Tl) detector. The calibration of the equipment was made using internal standards, volume standards from IFA-Magurele and using also the intercomparison samples from activities organized by IAEA-Vienna.

RESULTS

The data obtained during 1989-1993 are synthesized in this study. The results pointed out the low levels of the artificial radioactivity in this area in comparison with the rest of Romania. The values for the radioactive content in the irrigating Danube water are presented in the figure 1.

The Cs-137 content was in the range 0.0013-0.0045 Bq/l and the Sr-90 content in the range 0.0066-0.0121 Bq/l, for the whole period.

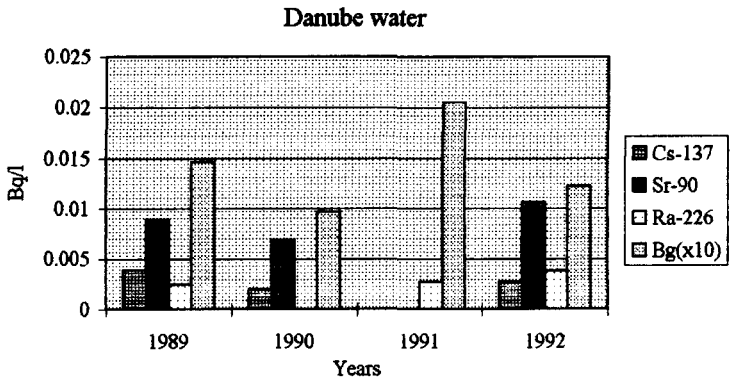


Figure 1. The radioactive content in the Danube water during 1989-1992.
Bg - global beta

In general the radioactive content for fresh vegetables was in the range 0.2-0.6 Bq/kg in Cs-137 and in the range 0.05-1.1 Bq/kg in Sr-90. Particularly Cs-137 had the maximum value (0.6 Bq/kg) in potatoes and minimum value (0.2 Bq/kg) for rest of vegetables (bean,onion,fruits, etc.). For Sr-90 high values were in bean and carrots and low values in potatoes.

The results obtained for vegetables are presented in the figure 2.

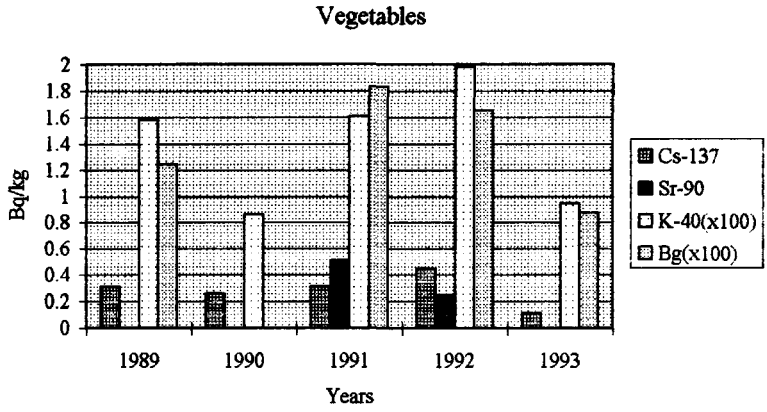

Figure 2. The radioactive content in vegetables.
Bg - global beta

The data obtained for fruits and cereals were frequently near the detection limit.

CONCLUSIONS

The artificial radioactivity content in the foodstuffs analysed from the investigated area (Bechet-Dabuleni) was at a low level and it has had an unsignificant variation in time.

ON-LINE LOW CONCENTRATION STACK ACTIVITY RELEASE MONITORING SYSTEM FOR NUCLEAR REACTORS

P.V.Bhatnagar , S.P.Chaganty , R.K.Jakati , K.R.Gopalakrishnan

Electronics Division , Bhabha Atomic Research Centre,Bombay 400 085 , India

INTRODUCTION

Monitoring of radioactive effluents at Nuclear Installations is extensively reported, detailing aims & designs of Health-Safety Program[1].The references[2,3] describe techniques of Nuclear Data Processing with computer[4] based On-Line monitors.Using these as guidelines and with state-of-the-art technology,a monitoring system is successfully implemented which provides greater functionality,reliability,operator-acceptance and meets the stringent requirements of Health-Physicist & Regulatory Board.Although sophisticated techniques of Nuclear Data Processing & Analysis are used in laboratory instruments,porting these to field instruments calls for special expertise.

SYSTEM CONFIGURATION AND HARDWARE FEATURES

The system consists of main channel and hot standby channel.Each channel comprises of one Air Particulate Beta monitor,one Iodine-131 monitor and one Gross Gamma (mainly Ar^{41}) activity monitor as shown in fig 1. Activity released is measured through detector assemblies consisting of photomultiplier tube and scintillator (plastic for Beta Particulate monitor, NaI(Tl) for Iodine-131 & Gross Gamma monitor) and are shielded by lead rings. Beta and Iodine-131 activity is accumulated on easy to remove and replace filter paper[a] and charcoal cartridge[b] respectively,whereas two litres of chamber surrounding the detector assembly is used for Gross Gamma activity monitor.The direction of flow and position of filter is carefully selected to improve detection sensitivity. The hardware is identical in three monitors. Iodine-131 monitor functions as 128 channnel,16 bit wide Multichannel Analyser performing energy-spectrum processing, while only gross counting is performed in other two monitors.The design of microcomputer is based on popular,8 bit microprocessor with standard VME back plane (single height,six layer,five slots) and plug in EURO boards facilitating ease of testing, and maintenance.A hand held terminal provides user friendly man-machine interface for setting up the important system parameters. Liquid Crystal Display essentially displays the integral release,release rate of the activity in Engineering units.Pulse height spectrum is continuously displayed on CRO, in XY mode,enabling easy calibration and precise marking of Iodine-131 window. Comprehensive report of activity released is made available through printer and the system also annunciates alarms in case the integral release,release rate exceed the set alarm limits. Logarithmic analogue output is provided for remote logging.

SYSTEM SOFTWARE DESIGN FEATURES

System software is designed and developed adopting modular approach for ease of testing and modification. It offers adequate degree of freedom for incorporating advanced statistical & analytical techniques to improve the performance of the system. Integral release and Release rates are computed on the basis of gross counts obtained within a set period of time in Beta Particulate and Gross Gamma monitors, while in Iodine-131 monitor,net peak area under the Iodine-131 peak is used. Intrinsic interference due to the background is minimised in Iodine-131 monitor by incorporating spectrum analysis technique,wherein Trapezoidal Compton background area is determined employing End Point Averaging Technique (EPAT) .Software critically balances the contradictory requirements of fast response time and acceptably good statistical stability along with accurate determination of lower detectable limit of 10^{-11} µCi / ml by automatic selection of optimum acquisition time interval.Additional feature of the software common to all the three monitors is the sliding averaging technique used for providing stable display information of activity release with acceptable time constant and update time. System software also supports interfacing of the monitors to IBM compatible PC,where energy spectrum can be analysed by powerful spectrum analysis techniqes for radioactive isotopes other than Iodine-131.

NET PEAK AREA COMPUTATION

From figure 2, Total peak area and its standard deviation using simple Total Peak Area (TPA) method[5] are computed as

$$\text{Total Peak Area (TPA)} = \sum_{i=K1}^{i=K2} C_i - \{ [(K2 - K1 + 1) / 2] * [C_{K1} + C_{K2}] \} \qquad (1)$$

$$\sigma TPA = \left\{ \sum_{i=K1}^{i=K2} C_i + [(K2 - K1 + 1) / 2]^2 * [C_{K1} + C_{K2}] \right\}^{1/2} \quad (2)$$

Net peak area and its standard deviation using EPAT[3] are computed as

$$\text{Net Peak Area (NPA)} = \sum_{i=K1}^{i=K2} C_i - \{ [(K2 - K1 + 1) / 2] * [(B1 / N1) + (B2 / N2)] \} \quad (3)$$

$$\sigma NPA = \left\{ \sum_{i=K1}^{i=K2} C_i + [(K2 - K1 + 1) / 2]^2 * [(B1 / N1^2) + (B2 / N2^2)] \right\}^{1/2} \quad (4)$$

Where C_i is the counts of i^{th} channel

K1, K2 are cursor locations at left and right valley point of Iodine-131 peak, respectively

$\sum_{i=K1}^{i=K2} C_i$ is the Gross Area (GA) under the Iodine-131 peak

$[(K2 - K1 + 1) / 2] * [C_{K1} + C_{K2}]$ is the Trapezoidal Compton background Area (TA)

$[(K2 - K1 + 1) / 2] * [(B1 / N1) + (B2 / N2)]$ is TA using EPAT

B1 is the sum of counts over N1 channels including K1 and B2 is the sum of counts over N2 channels including K2. As seen from equations (2) and (4) EPAT gives considerable improvement in standard deviation than simple TPA method. An improvement of 22 % in standrad deviation was observed in the actual system by keeping N1 = 2 and N2 = 4 while the maximum difference in the value of net peak area, computed by two methods, was 6% only, which is acceptable. As EPAT and TPA methods assume linear background under the Iodine-131 peak, it may introduce error due to non linearity of compton background caused by presence of high energy isotopes. This error may be reduced by using Step Pedestal[4] or Quadratic Baseline interploation method for estimating the compton background under such conditions.

AUTOMATIC SELECTION OF OPTIMUM ACQUISITION TIME INTERVAL

Criteria[6] used for selecting new acquistion time interval aims at maintaining the Fractional Standard Deviation (FSD) constant throughout the monitoring range of the system. New acqusition time interval is estimated as : Let PA1 be the current peak area obtained after subtracting Trapezoidal Compton background Area (TA1) from Gross Area (GA1) under the Iodine-131 peak with acquisition time interval of T1. Let T2 be the optimum acquisition time interval for achieving the desired FSD_d, then peak area PA2 and its Variance will be as follows :

$PA2 = GA2 - TA2$ and $\sigma^2 PA2 = GA2 + [(K2 - K1 + 1) / 2]^2 * [(B1' / N1^2) + (B2' / N2^2)]$

But $GA2 = (T2 / T1) * GA1$, $B1' = (T2 / T1) * B1$, $B2' = (T2 / T1) * B2$ & $PA2 = (T2 / T1) * (GA1 - TA1)$

$\therefore \sigma^2 PA2 = \{ T2 / T1 \} * \{ GA1 + [(K2 - K1 + 1) / 2]^2 * [(B1 / N1^2) + (B2 / N2^2)] \}$

And $\sigma^2 PA2 / PA2^2 = (FSD_d)^2 = (T1 / T2) * (FSD_o)^2$ Where $(FSD_o)^2 = \sigma^2 PA1 / PA1^2$

i.e $(FSD_o)^2 = \{ GA1 + [(K2 - K1 + 1) / 2]^2 * [(B1 / N1^2) + (B2 / N2^2)] \} / \{ GA1 - TA1 \}^2$

$$\text{OR} \quad T2 = (FSD_o / FSD_d)^2 * T1 \quad (5)$$

Equation (5) gives the optimum acquisition time interval for the FSD desired. Figure 3 shows the estimated absolute fluctuations in computed activity release through stack as a function of activity accumulated on charcoal filter, for fixed FSD of 1 % and variable acquisition time interval as predicted by equation (5). The graph indicates that though response time improves with increase in accumulated activity , the absolute statistical fluctuations in estimated integral release also increase, thereby worsening the minimum detectable limit. Thus in the adopted fixed filter scheme, either for loaded or fresh filter paper / charcoal cartridge, sufficiently large counting times are required. Based on these findings, system was tested with various large counting time intervals, results of which are plotted in figure 3. The results clearly point out that counting time of 60 minutes as the optimum fixed counting time resulting in acceptable statistical performance for measuring low concentration release rates (50μCi / day or 10^{-11}μCi / ml). Large counting time is also necessary for applying decay correction.

SYSTEM CALIBRATION

Iodine-131 deposited on the charcoal layer closest to the detector, makes maximum contribution to the counts accumulated, while contribution due to subsequent layers of charcoal goes on reducing. Since effective depth of

charcoal for accumulating Iodine-131 is estimated to be 5 mm, a calibrated Iodine-131 source on filter paper was moved away from detector surface by 5 mm in steps of 1 mm and the average efficiency computed was found to be 10.32 %. Another important parameter is the effect of interference due to Gamma background.This was estimated by placing a Co^{60} source of 47 nCi (corresponding to $Argon^{41}$ release rate of 700 Ci / day) along with 3.75 nCi of Iodine-131 source and error due to interfering background was observed to be of the order of 20 %.System minimum detectable limit was determined using Iodine-131 source of 40 pCi under the clean background conditions with acquisition time interval of 60 minutes and it was found to be 60 µCi / day. Similar calibration of Air Particulate Beta monitor was performed using $Strontium^{90}$ & other Beta sources,deposited on filter paper,giving an average efiiciency of 20 %.The detector sensitivity of Gross Gamma monitor was determined by measuring the countrate from chamber filled with calibrated Ar^{41} sample and was found to be 1cps / pCi / ml.

CONCLUSION

Low concentration stack activity releases of 50 µCi / day were measured with the system installed at nuclear power plants in India.For composite Beta-Gamma detection using phoswich detector and simultaneous processing of multiple peaks,the eight bit microprocessor design can be easily upgraded to advanced 16 / 32 bit processor design.A networking configuration using network controller board on the same VME back plane can be provided.

ABSTRACT (See instructions overleaf)

This paper presents the environmental monitoring in Qinshan Nuclear Power Plant, the first one in mainland China.

According to the ALARA principle of the ICRP, the environmental monitoring program is optimised during the operation of NPP. Using estimated dose equivalent received by the public with mathematical model and results of environmental monitoring, the quality of environment around Qinshan NPP is evaluated. Continuous effort is made to mitigate the environmental impact due to the operation of NPP.

ENVIRONMENTAL RADIOACTIVITY SURVEILLANCE OF THE ROMANIAN CANDU REACTOR OF CERNAVODA; NORMAL OPERATION AND ACCIDENT SCENARIOS

[2] Cernavoda Environmental Radioactivity Station, Cernavoda

INTRODUCTION

On behalf of the Ministry of Waters, Forests and Environmental Protection and according to the Romanian legislation, the environmental radioactivity surveillance in the Cernavoda area is performed by the Environmental Radioactivity Laboratory (ERL) of the Institute for Environmental Research and Engineering.

ERL is the scientific supervisor of the National Environmental Radioactivity Surveillance Network (NERSN). NERSN comprises 46 manned stations located in Romania's major cities. These stations perform gamma dose rate and global beta measurements. Routine global beta measurements are performed upon air, atmospheric deposition, water, soil and vegetation samples. Four of these stations also perform gamma spectroscopy on environmental samples.

Cernavoda Environmental Radioactivity Station is part of NERSN. Beside the standard gamma dose rate and global beta measurements equipment common to NERSN stations, Cernavoda Station is equipped with HPGe gamma spectrometer, Tritium (H-3) in air monitor, Iodine monitor, noble gases monitor and liquid scintillation analyzer. Global beta and gamma spectrometric measurements were performed in the Cernavoda area by ERL and Cernavoda Station starting with the 80's **(Figure 1, 2)**

In the framework of emergency planning and intervention ERL is the coordinator of the dose assessment group, one of the various groups acting as part of the Central Commission for Nuclear Accident (CCANCOC).

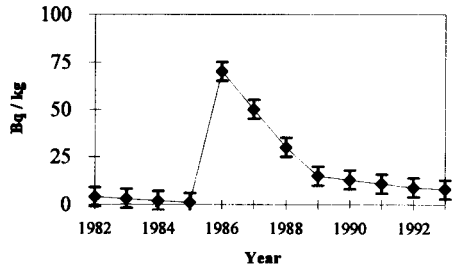

Figure 2. Cs-137 in surface soil at Cernavoda.

ENVIRONMENTAL RADIOACTIVITY SURVEILLANCE PROGRAM

The first unit (operational later in 1996) of the Cernavoda Nuclear Power Plant (CNPP) is powered by a CANDU 600 reactor. The town of Cernavoda (22043 people of which 8125 children) is 2 km away from the site of the reactor. Except of the flat, 20 km wide, island of the Danube to the West , the terrain around the CNPP is rough with hills up to 70 m. The first unit will have the liquid discharge in to the Danube - Black Sea navigation channel.

Gaseous effluents

Normal operation source term is: $3.4\ 10^{14}$ MeV Bq / year Noble gases, $9.4\ 10^{7}$ Bq / year Iodine, $9.4\ 10^{8}$ Bq / year Particulates, $5.7\ 10^{12}$ Bq / year C-14 and $3.5\ 10^{14}$ Bq / year H-3. The stack is 50.3 m height and

2.34 m in diameter. In between 3.9 m^3/s in winter time and 11 m^3/s in summer time is evacuated from the stack at 40– C. Particle size is a mean 0.3 – m with a maximum 1.0 – m.

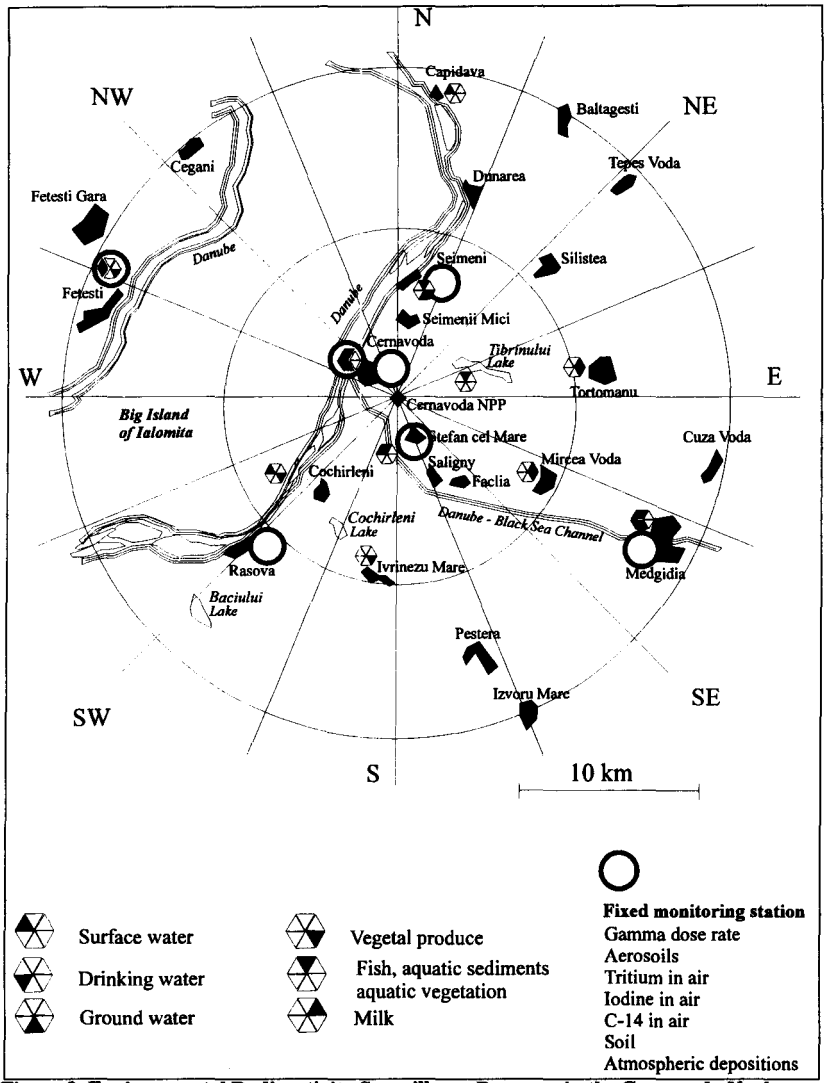

Figure 3. Environmental Radioactivity Surveillance Program in the Cernavoda Nuclear Power Plant Area.

Liquid discharge

Medium global activity of liquid discharge in the Danube - Black Sea navigation channel is 7.7 10^6 Bq/m^3 half of which consists of I-131. Tritium (H-3) will constantly be discharged at the rate of 1.23 10^{10} Bq/m^3. Other nuclides such as Co-60, Mo-99, Ce-144, Cr-51, Cs-134, Cs-137, will be discharged at rates representing 3 to 15% of the total global activity.

Location of the monitoring stations

Population distribution in the area and food habits, wind pattern and meteorological conditions, source term data were employed to establish the type, frequency and location of monitoring measurements to be performed in the environmental radioactivity surveillance program. Calculations using *CAP 88 PC* code (USA EPA Office of Radiation Programs) point the relevant wind sectors affected by continuous emission occurring in normal

operation of CNPP. Last, practical reasons such as security and access have also been considered in positioning the fixed off-site monitoring stations. In the fixed monitoring stations gamma dose rates are measured by RADOS intelligent detectors and radio transmitted to the central computer of Cernavoda Environmental Radioactivity Station. Gamma spectroscopy and global beta measurements are weekly performed upon atmospheric aerosoils, soil and atmospheric depositions samples. In the sampling points presented in **Figure 3**, milk samples, surface, drinking and ground water are weekly sampled and subjected to gamma and liquid scintillation analyses while fish, aquatic sediments and aquatic vegetation, vegetal produce are sampled and analyzed quarterly or according to the season.

External exposure and inhalation is a critical pathway for the people in the town of Cernavoda. Water from the Danube - Black Sea navigation channel is used for irrigation and drinking purposes so water ingestion is a critical pathway for people in Constanta (250 000 inhabitants). In order to control these two pathways emphasis is given to monitor H-3 concentration in air at Cernavoda (Berthold Tritium in air monitor) and H-3 concentration in the Danube - Black Sea navigation channel (H-3 content of water samples from the channel to be determined by means of liquid scintillation spectroscopy).

ACCIDENT SCENARIOS

In case of emergencies CNPP applies detailed procedures. Notification of competent authorities is common to all the procedures. These notifications contain source term, site meteorological conditions and projected doses for the population which may be affected if the releases would be done at various moments of time and in the given meteorological conditions. The computer code *Cernavoda Emergency Response Projection* (*CERP*) developed by CNPP mainly considers small or large loose of cooling (*LOCA*) accident type with or without maintaining the intervention capability of the emergency cooling systems. *CERP* also considers various situations of the reactor containment. According to *CERP* a small *LOCA* accident with intact containment (a release time of one hour starting the moment the accident is produced) will have a released activity of 7.5 10^{10} Bq Iodines (I-131) and 2.3 10^{12} Bq noble gases (Xe-133). A large *LOCA* accident with failure of emergency cooling systems and intact containment (a release time of one hour starting the moment the accident is produced) will have a released activity of 4.7 10^{14} Bq Iodines (I-131) and 1.6 10^{16} Bq noble gases (Xe-133).

Using these information provided to CCANCOC by CNPP, ERL performs first evaluation of population dose. Field dosimetry is employed and, with confirmed wind pattern the source term is modified and dose evaluation is again performed. *PC COSYMA* and modified *RASCAL* computer codes are used by ERL for accident consequences assessment. While *COSYMA* code may best provide countermeasures and long term effects, simple Gaussian models are best suited for the initial stages of the emergency response. There is an accepted agreement (*i.e.* same order of magnitude for thyroid dose) in between the computer codes used by CNPP and the computer codes used by ERL in accident consequences assessment.

CONCLUSIONS

For more than one decade the Environmental Radioactivity Laboratory (ERL) has been performing environmental radioactivity measurements in the Cernavoda area. This constitutes a reference base line for environmental radioactivity surveillance of the future to be operational CANDU 600 reactor of Cernavoda Nuclear Power Plant (CNPP).

An environmental radioactivity surveillance program has been designed and will be implemented before the commissioning of the CNPP.

Emergency preparedness for CNPP is developed in the legal national framework and ERL plays a key role here as coordinator of the dose assessment and monitoring group. There is an accepted agreement in between the computer codes used by CNPP and the computer codes used by ERL in accident consequences assessment.

EMERGENCY PLANNING FOR THE ROMANIAN CANDU REACTOR OF CERNAVODA; THE ENVIRONMENTAL APPROACH

Adriana Baciu, F. Baciu, M. Georgescu,

Environmental Radioactivity Laboratory, Institute for Environmental Research and Engineering, PO BOX 11-2, RO 72400, Bucharest, Romania

INTRODUCTION

Cernavoda Nuclear Power Plant (CNPP) emergency exercise "AXIOPOLIS" was carried out in August 1995. Environmental Radioactivity Laboratory (ERL) of the Institute of Environmental Research and Engineering is responsible for the dose calculations and monitoring of the radioactivity in the environment following an off- site event at CNPP. The response actions were performed at local and national level by various Civil Protection structures coordinated by the Central Commission for Nuclear Accident (CCANCOC). CCANCOC is scientifically advised by groups of experts such as the dose assessment and radioactivity monitoring group where ERL plays a key role.

SCENARIO OVERVIEW

The scenario was designed by CNPP Emergency Planning Section. It is considered that the reactor has been operated at full power for about 10 months and the pre-equilibrium core conditions allow for maximum fission product released to containment. Reactor safety systems are poised and no maintenance is underway. Tritium levels in the reactor building are higher than normal and pressure heat transfer pump alarms for very high vibrations.

Vibrations cause a damage in the heat transfer balance piping which separates. A large loss of coolant (large LOCA) accident takes place. Shut down systems 1 and 2 trip. Containment is sealed. Emergency cooling systems fires. Dousing commence as a result of the containment pressure rise.

Scenario accident is built to test various emergency procedures both on-site and off-site. There is a contaminated casualty in the plant and the rescue and medical teams have to deal accordingly. The Main Control Room licensed staff demonstrated their ability to correctly evaluate the radiation incident, the emergency condition of the plant and the amount of radioactivity in the containment. Emergency Operation Center and the Command Unit were activated by the Shift Supervisor in a timely manner. For the off-site response of the authorities up to the phase of sheltering some area residents, the accident source term as given by *CERP* (*Cernavoda Emergency Response Projection*) code had to be modified.

INTERVENTION LEVELS AND CALCULATIONS

Intervention levels for sheltering as recommended by the regulatory body (National Commission for Nuclear Activities) are of in between 3 to 30 mSv for whole body and/or 30 to 300 mSv for thyroid, lung, skin where these values represent the external plus the committed dose through intake during the first 24 hours. The source term provided by CNPP and the given dispersion conditions did not led to calculated values within the above ranges. However for the need to check the response of local authorities sheltering was recommended and simulated in the town of Cernavoda. Calculations were performed by ERL representatives in CCANCOC using *PC COSYMA*, *RASCAL* and Gaussian dispersion models. **Figure 1** presents a *RASCAL* evaluation in the conservative condition of fast (10 minutes) release.

COMMUNICATIONS AND FIELD DATA

Communications from CNPP to CCANCOC were performed via facsimile and telex lines. Source term, meteorological site conditions and *CERP* projected doses, as given by CNPP, are presented as "fill in", previously prepared, forms. Field radiation monitoring is performed by teams of Cernavoda Environmental Radioactivity Station (CERS) and of Constanta County Civil Defense. The teams run a previous established route taking gamma dose rate readings in several locations focused on the centerline of the radioactive plume. The teams send the information to CERS by radio. CERS sends the information by public telephone to ERL. Environmental sampling is performed by the survey teams at request from ERL and gamma spectroscopy is performed on location at CERS in Cernavoda.

Cernavoda Environmental Radioactivity Station (CERS) plays an important role in the off-site response. When activated by Constanta County Civil Defense or ERL, the station switches on emergency program. Atmospheric aerosoils are sampled for 10 minutes, three times per hour and inspected for global beta activity. Frequent readings of the gamma dose rate meters are performed. The Iodine monitor and the Noble Gases

monitor are powered. Gamma spectroscopy is performed upon air, atmospheric depositions, soil samples collected by the field teams. All the above data are sent to ERL.

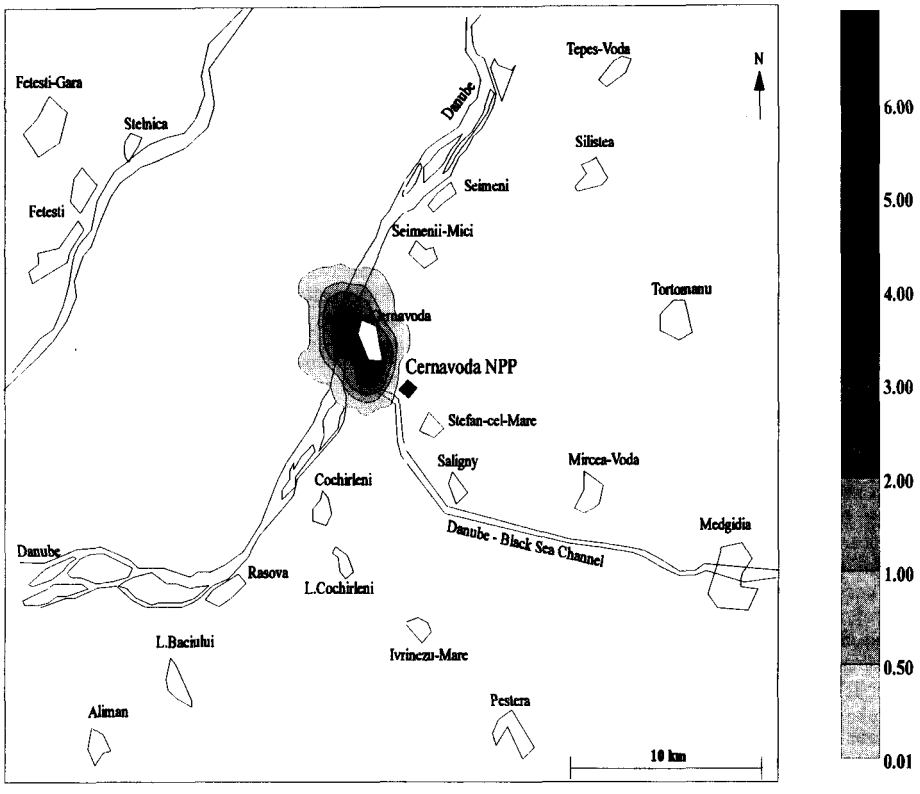

Figure 1.
Thyroide dose (mSv) 10 minutes after the start of the stack level emission.
Source term: I-131: 50 TBq, Xe-133: 200 TBq, release time: 10 minutes.
Meteorological data: 8 m/s wind blowing from SE toward NW , stability class D.

CONCLUSIONS

"AXIOPOLIS" 1995 tested emergency procedures both on-site and off-site CNPP. The capacity of the NERSN stations and field teams to carry out the emergency environmental radioactivity survey was tested. Dose predictions were performed by ERL within CCANCOC and as a back up, at the laboratory location. Countermeasures were issued by the dose assessment group coordinated by ERL within CCANCOC.

While radioactivity measurement equipment of NERSN stations (Ministry of Waters, Forests and Environmental Protection) generally complies with the requirements, there is a need for more consistent meteorological field data in the area. Communications is to be improved at all levels as reliability of public telephone lines is always low. The exercise has to be prepared and attended to each year as it was proved that only the players who practiced the procedures before, could give a satisfactory response.

MAJOR SCIENTIFIC TOPIC NUMBER ..4.. (see page 7)

ABSTRACT (See instructions overleaf)

Liquid scintillation Tritium measurements were performed by the Environmental Radioactivity Laboratory in the Cernavoda area starting with 1994. The sampling points were upstream and downstream Cernavoda on the Danube and downstream Cernavoda on the Danube - Black Sea navigation channel where the nuclear power plant discharge will take place. Measurements will continue after the commissioning of the Cernavoda nuclear power plant in the second half of 1995.

Danube and Danube - Black Sea navigation channel water are used as irrigation and drinking water sources. Based on liquid scintillation measurements and aquatic dispersion modeling, the paper presents dose values and dose predictions for the Tritiated water consumption in the influence area of the Romanian CANDU reactor of Cernavoda.

Radioactive liquid discharges in relation with the phosphogypsum industry in European Countries

I - The phosphated fertilizers industry

Phosphate contained in phosphated rocks being not directly assimilated by vegetal plants, a chemical treatment is needed to produce phosphate fertilizers. Most often, the ore is reacted with sulfuric acid to produce phosphoric acid. The by-product of the reaction is a calcium sulfate (phosphogypsum) which is separated by precipitation. Typically, the production of 1 tonne of phosphoric acid needs the extraction of 3 tonnes of ore and creates 4 to 5 tonnes of phosphogypsum. Most of the uranium contained in the raw material is associated to the phosphoric acid and the main part of radium remain in the phosphogypsum. In the average, phosphogypsum contains 14 % of the ^{238}U contained in the ore, 30 % of the ^{232}Th and 80 % of the ^{226}Ra.
If compatible with economical constraints, phosphogypsum is used in building materials or back-fill and road-base materials, but, most often, it is discharged to sea or disposed on tailing piles. Globally, 14 % of phosphogypsum produced is used, 58 % is stored on tailing piles and 28 % is discharged to sea.
The annual world production of phosphate ore turns around 130 Mtonnes. Ore importations by european countries has been divided by a factor 2 between 1980 and 1994 balanced by phosphoric acid importation. It was about 8 Mtonnes in 1994 (about one half from Morocco) [1]. It is obvious that the phosphoric acid and phosphogypsum productions have the same evolution. Producers expect that this trend will continue in the future (a 10 % decrease in the european countries phosphated fertilizer production is expected between 1993 and 1997).

II - The radioactive ore content

Natural radionuclides concentration in ore depends on its origin: minerals extracted from sedimentary soils have the highest uranium content (1,500 $Bq.kg^{-1}$ is a typical value). This kind of soil produces about 80 % of the world production. When extracted from volcanic areas, its uranium content is about 70 $Bq.kg^{-1}$. Table 1 gives natural radionuclides content for the main producing countries.

Table 1 : Natural radionuclides concentrations for different ores ($Bq.kg^{-1}$) according to Baetsle [2]

	^{238}U	^{226}Ra	^{232}Th	^{40}K
Morocco	1,500 - 1,700	1,500 - 1,700	20 - 30	10 - 200
United-States				
Florida	1,500 - 1,900	1,600 - 2,100	16 - 59	
Idaho	1,850	1,800	30	
Wyoming	2,300	2,300	10	
Togo	1300	1,200	110	<100
Tunisia	590	520	92	
Israel	1,500 - 1,700			
Jordan	1,300 - 1,850			
former USSR	44 - 90	30 - 70	78	

Nevertheless, some ores have higher concentrations: the content of ores extracted from South Carolina and from Tanzania is about 5,000 $Bq.kg^{-1}$ for ^{238}U and ^{226}Ra. At the opposite Chilian ore is particularly poor in natural radionuclides: 40 $Bq.kg^{-1}$ for ^{238}U and ^{226}Ra, 30 $Bq.kg^{-1}$ for ^{232}Th. The ^{232}Th concentrations also vary, from 10 $Bq.kg^{-1}$ (Wyoming, USA) to 110 $Bq.kg^{-1}$ (Togo). The 30 $Bq.kg^{-1}$ value is representative of concentrations in Moroccan ore.

Globally, we can conclude that concentrations in phosphogypsum are around 210 Bq.kg^{-1} for ^{238}U, 1200 Bq.kg^{-1} for ^{226}Ra and 10 Bq.kg^{-1} for ^{232}Th, so that a plant having a 300,000 t.y^{-1} capacity produces each year residus containing 10 GBq of ^{238}U, 300 GBq of ^{226}Ra and 1 GBq of ^{232}Th.

III - Discharges from european countries and environmental concentrations

In 1984, the industry of the european countries produced 17 Mt phosphogypsum, about 7 Mt of which was dumped. According to the mean concentrations, the annual discharge was 8.4 TBq for ^{226}Ra, 1.5 TBq for ^{238}U, 0.07 TBq for ^{232}Th. The decrease of the production by itself leads to an annual discharge about two times lower in 1993. In fact the waste management has been changed so that the decrease of dumping is now much higher. Globally, the european countries discharges in 1993 were 2,1 TBq for ^{226}Ra, 0.5 TBq for ^{238}U, 2.2 TBq for ^{210}Po. Phosphogypsum discharges in european waters are mainly due to industrial practices in the UK, in France (these two countries have ceased the water dumping in 1992) and in The Netherlands.

III.1 - France

About 3 Mt has been dumped in the Seine estuary, but the corresponding radiation exposures have not been estimated [3]. Several measurement campaigns were carried out along the Channel coast, showing ^{210}Po concentrations in the range 130 - 770 Bq.kg$^{-1}_{dry}$ in mussels, 0.2 - 2.7 Bq.m^{-3} in filtered water, 20 - 130 Bq.kg^{-1} in suspended matters and 10 - 120 Bq.kg$^{-1}_{dry}$ in sediments. The highest concentrations are observed in the Mont Saint Michel bay. The ^{210}Pb concentrations in sediments are in the same order of magnitude as the ^{210}Po ones. They are much lower in mussels (maximum: 17 Bq.kg$^{-1}_{dry}$).

III.2 - United Kingdom

From 1954 to 1992, the Whitehaven (Cumbria) phosphoric acid production plant dumped phosphogypsum in the Solway Firth. Since 1993, operations have been limited to the purification of imported phosphoric acid and an effluent processing plant is operating. The evolution of annual discharges is given in table 2.

Table 2 : Evolution of the mean annual discharge (TBq.y^{-1}) from UK

	^{238}U or ^{234}U	^{234}Th	^{230}Th	^{226}Ra	^{210}Pb	^{210}Po
from 1972 to 1992	0.42	0.60	0.31	0.57	0.36	0.36
1993	0.13	0.13	0.026	0.0011	0.01	0.0027

The ^{226}Ra global inventory in the area under control decreases exponentially (half-life: 70 days) from 1.46 GBq in 1992 to 0.06 GBq in December 1993 [4]. The ^{210}Po concentration in marine products strongly varies with marine species: it is about 260 Bq.kg^{-1} in winkles and 70 Bq.kg^{-1} in lobsters. These concentrations decrease with distance from the source point by about a factor 10 within 30 km. The ^{210}Pb concentration in the Eastern Irish Sea sediments varies from 5 to 14 kBq.m^{-2}, the mean deposition rate has been estimated by McCartney et al. about 200 Bq.m^{-2}.y^{-1}.

Before 1992, annual dose received by critical group (high consumption of marine products caught in the Saltom bay) due to phosphogypsum discharges was 0.27 mSv for adults and 0.38 mSv for children. Since 1993, it is estimated to be 0.05 mSv.y^{-1} (the natural background is around 0.3 mSv.y^{-1}) [5].

III.3 - The Netherlands

Three ore processing plants are still operating in The Netherlands, dumping the phosphogypsum produced in the Rhine estuary. Up to 1993, the annual ^{210}Po and ^{226}Ra discharges (about 2 Mt) were about 1 TBq [6] [7]. Since 1993, a 20 % reduction has been observed, due to a change of the ore origin.

Discharges are responsible for a 100 Bq.kg^{-1} increase in the edible part of mussels and shrimps in a 50 - 100 km radius around the pipe. Table 3 gives water and sediment concentrations along the North Sea coast, and the total sediment activity in a 2,500 km^2 area and a 5 cm deep layer [8]:

Table 3 : Natural radionuclides concentrations in water and sediments in the North Sea, along the Dutch coast

	Water concent. (Bq.m^{-3})	Sediment concent. (Bq.kg^{-1})	Global activity in sediments (TBq)
^{226}Ra	1.5	20	3.5
^{210}Pb	1.0	20	3.5
^{210}Po	1.0	20	3.5
^{231}Pa	0.001	1	0.17

According to the radiological half-life, Van der Heijde et al. consider that the equilibrium concentration for ^{210}Pb and ^{210}Po will be about 15 TBq after several decades with discharges (assumed to be constant). Locally much higher concentration have been measured [9] (see table 4) :

Table 4 : Natural radionuclides concentrations as a function of distance from the source

	water concentration ($Bq.m^{-3}$)			concentration in suspended matter ($Bq.m^{-3}$)		
	^{210}Po	^{210}Pb	^{226}Ra	^{210}Po	^{210}Pb	^{226}Ra
North Sea (30 km outside)	0.7	0.8	5.3	86	119	
Nieuwe Waterweg	3.3	10	19	478	444	300
Schelde estuary	6.1	6.2	68	258	218	145

For these three radionuclides, concentrations in Nieuwe Waterweg sediments are usually above 150 $Bq.kg^{-1}$ as far as 5 km from the pipe. Concentrations of 800 $Bq.kg^{-1}$ for ^{210}Po, 1000 $Bq.kg^{-1}$ for ^{210}Pb and 600 $Bq.kg^{-1}$ for ^{226}Ra are measured in harbours. The ^{210}Po concentration in mussels is in the range 20 - 50 $Bq.kg^{-1}$ (2 to 3 times higher than in non-affected areas). There is no significant increase of the ^{226}Ra in fishes, molluscs and shell-fishes.

Effective dose received by the Dutch population due to consumption of marine products caught in the concerned area is about 20 $\mu Sv.y^{-1}$ and can reach 200 - 300 $\mu Sv.y^{-1}$ for the critical group, mainly (90 %) due to ^{210}Po [9]. Phosphogypsum discharges contribute for about 50 % of this dose. Annual collective dose for the Dutch population due to marine products consumption is 170 man.Sv, phosphogypsum discharges contributing for less than 1 %.

Conclusion

Since 1980, phosphogypsum discharges in North European waters are considerably decreasing. Natural radionuclides concentrations are significantly enhanced 30 km around the pipe. Effective dose received by people consuming marine products near operating plants are usually 20 $\mu Sv.y^{-1}$, but it can be 10 times higher for some people. This dose is mainly due to ^{210}Po.

CHANGES IN LIQUID RADIOACTIVE WASTE DISCHARGES FROM SELLAFIELD TO THE IRISH SEA: MONITORING OF THE ENVIRONMENTAL CONSEQUENCES AND RADIOLOGICAL IMPLICATIONS

G J Hunt, B D Smith and D J Swift

Ministry of Agriculture, Fisheries and Food, Fisheries Laboratory
Lowestoft NR33 0HT, United Kingdom

INTRODUCTION

In January 1994, British Nuclear Fuels plc (BNFL) were granted revised authorisations for disposal of radioactive wastes from their Sellafield site in Cumbria, UK, including the discharge of liquid effluent to the Irish Sea. The revisions took account of a continuing Government commitment to review authorisations regularly, as well as of new Sellafield plants and changes to existing operations. The new plants of prime importance were the Thermal Oxide Reprocessing Plant (THORP) for the reprocessing of oxide fuels, and the Enhanced Actinide Removal Plant (EARP) for improved treatment mainly of waste streams from the older, Magnox, plant. Revision of the liquid authorisation is described in reference 1. Many of the radionuclide discharge limits reduced significantly, notably for Cs-137, Ru-106 and the actinides, to reflect operation of EARP. Increases in limits, of relatively low radiological significance, were granted for tritium and I-129 which would be produced by operation of THORP. An increase for C-14 covered diversion to sea of Magnox gaseous scrubber liquors, so as to reduce the overall radiological impact of these waste streams. Increases for Sr-90 and especially Tc-99 were to allow discharge, after phased processing through EARP, of liquors which have been stored on site for an optimised period to allow radioactive decay. Tc-99 is not treated by EARP, and Sr-90 is treated less effectively than the actinides or radiocaesium.

DISCHARGES IN 1994

At the time of writing this paper, discharge data and results of environmental monitoring are not complete for 1995, and comment is restricted to 1994. The trends in discharges from 1990-1994 are shown as the histograms in Figures 1-5. Following granting of the revised authorisation, active commissioning of THORP began but no active chemical separation took place in 1994. Diversion of the Magnox scrubber streams resulted in increased discharges of C-14 from a pre-existing level of about 2 TBq y^{-1} to about 8 TBq in 1994. EARP began active commissioning, and discharges of alpha emitters, radiocaesium and Ru-106 decreased as a result. Feeds of decay-stored liquors were also processed in EARP, and increases were observed in discharges of Sr-90 and especially Tc-99.

ENVIRONMENTAL MONITORING

MAFF carry out a comprehensive marine monitoring programme in the UK which is kept under review to take account of any changes in such factors as the discharges themselves, the habits of critical groups, and environmental conditions. The results of this monitoring are published annually, most recently for 1994 (2). Selected results of this monitoring are presented in Figures 1-6 to indicate trends in data as a result of changes in Sellafield discharges. In addition, significant monitoring of radionuclides in sea water, especially for Tc-99, has been carried out and the results will be published in due course.

Figure 1 presents concentrations of Ru-106 observed in winkles (*Littorina littorea*) from Nethertown, 5km north of Sellafield, which are of significance for the critical group of seafood consumers. Reference 2 considers sampling and analytical uncertainties; for the purposes of this paper representative ±10% error bars have been ascribed to concentration data. Figure 1 shows that Ru-106 concentrations in recent years have fluctuated mostly in line with the discharges, and the reduced discharges of 1994 have been reflected in lower concentrations.

Figures 2 and 3 present data for Pu-239/240 and Am-241 in winkles from Nethertown. Decreases in concentrations were observed in 1994 in response to reduced discharges. This would appear to indicate a component of uptake due to current discharges, in addition to the influence of the historic inventory in the Sellafield environment.

Figure 4 presents averaged data for C-14 in cod (*Gadus morhua*) and plaice (*Pleuronectes platessa*) sampled from near Sellafield. Concentrations increased in 1994 by about a factor of 2 compared with pre-existing levels. The higher levels of discharges (about a factor of 4) had probably not continued long enough in 1994 for their full effect on fish uptake to be observed.

For Sr-90, (Figure 5), discharges increased from pre-existing levels in 1993 because of changes in operation of the Sellafield site ion-exchange effluent plant, SIXEP, as well as in 1994 because of disposals of decay-stored liquors. An increase in concentrations of Sr-90 in fish, however, was not observed until 1994, indicating a slower rate of uptake than for C-14.

Rates of discharge of Tc-99 (Figure 6) changed rapidly in 1994 due to processing of decay-stored liquors, and discharges are plotted on a monthly basis. Quarterly data for concentrations observed in lobsters (*Homarus gammarus*) near Sellafield are illustrated, again because of radiological significance, and for the seaweed *Fucus vesiculosus* because of its strong uptake of Tc-99 and indicator potential. This seaweed is not eaten but it can be used as a fertiliser. Near Sellafield, the effects of the period of release of Tc-99 in March/April 1994, whilst observed in both species, were not as significant as for the period of September/October 1994. This could have been due to hydrographic factors, because both releases were observed in a more additive fashion in *Fucus* at St Bees, 10km north of Sellafield.

RADIOLOGICAL SIGNIFICANCE

Changes in plant operations at Sellafield have resulted in decreases in discharges of some radionuclides (mainly the actinides, radiocaesium and Ru-106) and increases in others (C-14, Sr-90 and Tc-99). Assessments of doses to potential critical groups, however, have shown continuing reductions (2). The critical group near Sellafield of high-rate fish and shellfish consumers received 0.08 mSv in 1994 compared with 0.10 mSv in 1993 (and higher doses in previous years) using ICRP-60 data. This confirms the minor radiological significance of those nuclides whose discharges have increased. Nevertheless, careful surveillance is continuing to ensure that this remains the case under the developing operational conditions.

^{137}Cs IN SEDIMENTS OF NORTHERN AND MIDDLE ADRIATIC SEA

D. Barišić,[1] S. Lulić,[1] N. Vdović,[1] A. Vertačnik,[1] and M. Juračić[2]

[1] Centre for Marine Research - Department Zagreb, Ruđer Bošković Institute, Bijenička 54, 10000 Zagreb, Croatia

[2] Department of Geology, Faculty of Natural Sciences, University of Zagreb, Croatia

ABSTRACT

The activity of ^{137}Cs in relatively shallow northern and middle Adriatic open sea bottom sediments was obtained on the basis of gamma-spectrometry measurement results of 33 sediment box cores. Cores were sampled during the ASCOP 16 (Adriatic Scientific CO-operative Program) cruise in summer 1990 along seven different transects stretching between the borders of Croatian and Italian territorial waters. ^{137}Cs was determined in the recent sea bottom sediments (0-3 cm) as well as in older, 12-15 cm deep sediment cores. It was found that the lowest caesium concentrations correspond to sands which are spread along the Croatian coast mainly. Parallel to the Italian coast, ^{137}Cs concentrations are the highest in pellets, mud, silt and clay composed bottom. It seems that the influence of Po River is significant for ^{137}Cs activities in recent marine open sea bottom sediments along Italian coast south of Po River delta. Significantly higher ^{137}Cs activities in 0-3 cm vs. 12-15 cm open sea bottom sediment layer can be attributed to the deposition caused by Chernobyl accident. The absence of ^{137}Cs in few middle Adriatic 12-15 cm deep core indicates (inspite bioturbation that caused sediment mixing) significantly lower sedimentation rate in open sea of middle Adriatic vs. northern Adriatic and main deposition area of suspended matter carried by Po River.

INTRODUCTION

The shallowness of the continental shelf, which hardly overcomes 60 meters among Trieste, Venezia, Ancona, Zadar and Pula, and the great quantity of waters flowing from Po and other minor Italian and Croatian rivers, strongly determine the grain size distribution and sedimentation rate in this semi-closed system. The chemistry of northern and middle Adriatic as well as the cycling of nutrients and the fate of pollutants within the ecosystem are influenced by sedimentation characteristics. The countries surrounding northern Adriatic are reasonably contaminated by ^{137}Cs during Chernobyl accident (1-4).

The distribution of mean grain sizes, sediment types and main sediment characteristics in the open northern and central Adriatic sea are generally known (5). Spatial sediment distribution shows that the finest sediments are deposited along the Italian coast (south of the Po River delta) and in the central Adriatic, while sands are spread along the Croatian coast, as well as at stations 1, 4 and 32. The research of ^{137}Cs distribution in sediments of Grado and Marano lagoons (6) showed the influence of river input and grain-size distribution on caesium activities in recent marine sediments relatively near shore. The similar observation results are found in the broader Rhone mouth area (7). Concerning caesium solubility in sea water and significant input of terrestrial material (carried by rivers), the amounts and caesium distribution into recent marine sediments of open northern Adriatic are of special interest.

MATERIALS AND METHODS

The cores investigated in this work were sampled as part of a broader international and multidisciplinary research programme ASCOP, during the ASCOP 16 cruise in the summer 1990. Sediment samples were taken at 33 stations along seven different transects stretching between the borders of the Croatian and Italian territorial waters in the northern and central Adriatic Sea. The sediments were collected by box corer. After sampling, the sediments were sliced, frozen at -18 °C and kept until further use. Surface sediment (0-3 cm) and 12-15 cm-deep sediment samples collected along sampled transects in the northern and central Adriatic sea were prepared for gamma-spectrometric analyses.

Before the analyses, the samples were thawed at room temperature and dried at 106 °C to the constant weight. Dried samples were stored in 125 cm^3 counting vessels. The activity of ^{137}Cs in each sample was determined by gamma-spectrometry method using calibrated low background HP Ge detector system coupled to a 4096 channel analyzer. Spectra were recorded 80 000 seconds. ^{137}Cs activities were calculated from the 661.6 keV peak and the data were recalculated at May 1st, 1990.

RESULTS AND DISCUSSION

The distribution of the material, carried by the Po River and other Italian and Croatian rivers, on the sea bottom of open northern and middle Adriatic sea is the result of the sedimentation processes and the effect of the dominant sea currents. That fact is evident in ^{137}Cs activities in measured sediment cores. ^{137}Cs was detected in all surface sediment samples (0-3 cm) as well as in majority 12-15 cm-deep sediment samples.

The highest caesium activities are found in surface sediments taken at stations located in the Po River prodeltaic area (25.6 ± 0.8 Bq kg^{-1} dry weight at station 9 and 10.9 ± 0.3 Bq kg^{-1} dry weight at station 5). Along Italian coast south of Po River delta, the measured caesium activities in surface sediments are high too, about 10 Bq kg^{-1} dry weight generally. These two areas correspond with main sedimentation area of material carried by Po River. The bottom sediment composition in these two areas is made mostly by clayey sand, clayey silt, silt and clay (5) and has higher organic matter content (8). Relatively high caesium activities in surface sediments are found in the identical composed sediments of the central Adriatic at stations 28, 29, 31 and 33.

The lowest caesium activities measured in surface sediments (less than 2.0 Bq kg^{-1} dry weight generally) are found in samples collected at stations along Croatian coast as well as at stations located in middle part and in north-east part of Corsini Port-Pula and Riccione-Porer Island transects. In this area, the organic matter content in the bottom sediment, composed of sand mainly, is the lowest (5).

The similar spatial distribution of caesium activities was found in the 12-15 cm-deep sediment samples, but measured values were significantly lower generally. The exceptions are stations 9 and 10 with 10.2 ± 0.5 Bq kg^{-1} dry weight and 9.6 ± 0.4 Bq kg^{-1} dry weight respectively. Relatively very high caesium activities in 12-15 cm-deep cores at locations 9 and 10 indicates high sedimentation rate in this area. The lowest caesium activities in the 12-15 cm-deep cores are found in samples collected at stations located in middle part and in north-east part of sampled transects of northern Adriatic. In central part of middle Adriatic at stations 27, 28, 29, 32 and 33, caesium was not found in the 12-15 cm-deep sediment samples.

Inspite sediment mixing, which is caused by bioturbation, the absence of ^{137}Cs in few middle Adriatic 12-15 cm deep cores as well as very low caesium activities in same cores of middle and north-east part of northern Adriatic indicates significantly lower sedimentation rate in central part of middle Adriatic and middle and north-east part of northern Adriatic vs. in west and south-west Adriatic. Significantly higher ^{137}Cs activities in 0-3 cm vs. 12-15 cm-deep open sea bottom sediment layer can be attributed to the deposition caused by Chernobyl accident. Activities of ^{137}Cs in the first 15 cm of open northern and middle Adriatic sea bottom sediment (fig. 1) were estimated on the basis of measured activities in recent sea bottom sediment (0-3 cm) and older, 12-15 cm-deep sediment cores. Evidently northern and middle Adriatic marine sediments with high caesium content correspond with the area of the highest sedimentation rate. That area is the main deposition area of suspended matter carried by Po River.

PLUTONIUM AND AMERICIUM IN THE RHÔNE SEDIMENTS

INTRODUCTION

$^{238,239,240}Pu$ and ^{241}Am are measured in sediments from river ecosystems. These artificial radioisotopes are related to military and civilian activities. Small concentrations require an original radiochemical process, followed by alpha spectrometry. 104 analysis on sediment from the Rhône have been taken since 1989.

THE ORIGIN OF TRANSURANIC ELEMENTS IN THE RHÔNE

The transuranic elements present in sediment from the Rhône originate principally from the atmospheric nuclear tests carried out between 1945 and 1975, fallout from which spread some 1.2×10^{16} Bq of $^{239,240}Pu$ and 2.9×10^{13} Bq of ^{238}Pu into the atmosphere, 80% of which was in the Northern Hemisphere (1). Various accidents have also released transuranic elements into the environment. Such was the case with the SNAP-9A satellite, which burned up in April 1964 and released 5.1×10^{14} Bq of ^{238}Pu, 40% of that in the Northern Hemisphere (2). Fallout from the Chernobyl accident containing α emitters was negligible in France. Irradiated-fuel reprocessing plants (La Hague and Marcoule) are authorized to release α emitters in their liquid effluent. The Marcoule plant is authorized to release 150 GBq per year into the Rhône. In 1991, the Marcoule facility renovated its liquid effluent treatment station. The activities released diminished considerably, as is shown in the following table:

Years	$^{239+240}Pu$ (MBq)	$^{241}Am + {}^{238}Pu$ (MBq)
1990	2.11×10^4	2.07×10^4
1991	1.26×10^4	1.36×10^4
1992	0.33×10^4	0.45×10^4
1993	9.54×10^2	2.18×10^3

Nuclear power generation stations are not authorized to release α emitters in their liquid effluent.

PLUTONIUM AND AMERICIUM DETERMINATION PROTOCOLS

The sediment sample is autoclaved at 110°C, then sifted at 2 mm. A 200-g sample is calcined at 550°C in order to destroy any organic material present. After cooling, the sample receives 20 mBq of ^{242}Pu and ^{243}Am respectively. These isotopes, not present in the sample, make it possible to determine the yield of the various radiochemical operations after the final counting by α spectrometry.

The sediment then undergoes a series of oxidizing acid attacks in order to render the transuranic elements soluble. The solution thus obtained is made up essentially of the stable major elements (Ca, K, Na, Fe) comprising the matrix and the radioisotopes of the artificial elements (Pu, Am, Cm) as ultra-traces. The problem of the analysis is to separate and purify the plutonium and americium using a protocol allowing progressive elimination of the totality of the stable major elements and all of the natural α-emitting radioisotopes. The proportioning protocol uses a radiochemical process whose successive stages make use of coprecipitation, ion-exchange chromatography, and extraction chromatography techniques. Through a first series of coprecipitation of plutonium and americium with calcium oxalate at pH=1.5, the alkalines are eliminated while the iron is maintained in solution through formation of complexes with the oxalate ion. The isolated and dried calcium oxalate precipitate is transformed into calcium carbonate through calcination. The latter is dissolved in a hydrochloric acid solution, diluted with distilled water, and brought to pH=8.00 in order to obtain precipitation of the last traces of iron in the form of ferric hydroxide. Quantitative coprecipitation of the plutonium with a few milligrams of iron makes it possible to eliminate almost all of the alkaline earths. The small volume of solution obtained after dissolving the precipitate in an 8M nitric medium is injected onto an AGIX8 anionic resin, which allows separation of the plutonium from the elements Th, U, Am, and Cm and the rare earths and other metals not eliminated during the coprecipitations. Separation of the americium from the elements Fe, Cu, Ni, and the rare earths requires two further extractions. The first consists of an extraction chromatography done on TRU-spec resin, and the second uses ion-exchange chromatography on AGIX4 resin.

Sequential separation of the elements Pu and Am is done through two electrodepositions, each carried out on a previously electropolished stainless-steel disk. Each electrolytic deposit is then counted in a chamber maintained under vacuum and equipped with an inserted passivated junction silicium detector having a useful surface equivalent to 280 mm^2. Duration of the count can be up to one week. The detection limit made possible both by equipment performance (a detection yield of between 0.25 and 0.30 - an electronic background noise level of < 2 cps/24 hours) and by that of the radiochemistry used (weight of the sample being processed, tracer purity, separation performance, peak resolution) varies between 1 and 10 mBq/kg for each radioisotope proportioned.

Pu AND Am CONCENTRATIONS IN SEDIMENTS

Distribution of transuranic elements in sediment is not uniform throughout the length of the Rhône. The river may be separated into three zones according to the potential source terms:

Sediments sampled upstream from Creys-Malville.

This part of the Rhône is not subject to the influence of any nuclear installation. The concentrations observed are, respectively: 0.017 to 0.086 Bq.kg $^{-1}$ dry for ^{239,240}Pu and < 0.001 to 0.0044 Bq.kg $^{-1}$ dry for ^{238}Pu. ^{241}Am was not measured.

The ^{238}Pu/ ^{239,240}Pu isotopic ratio of 0.043 ± 0.038 (3 significant values) is characteristic of fallout from atmospheric tests (values between 0.02 and 0.08) (3).

Sediments sampled from Creys-Malville to a point upstream from the Marcoule fuel reprocessing plant.

The sediments show concentrations of 0.030 to 0.201 Bq.kg $^{-1}$ dry for ^{239,240}Pu, from <0.001 to 0.017 Bq.kg $^{-1}$ dry for ^{238}Pu, and from <0.005 to 0.076 Bq.kg $^{-1}$ dry for ^{241}Am.

The ^{238}Pu/^{239,240} Pu isotopic ratio is 0.046 ± 0.010 (15 significant values). As in the case of the previous zone, it shows that the plutonium measured is from atmospheric testing fallout. Higher plutonium concentrations were measured downstream from the Creys-Malville plant than upstream in Rhône sediments collected in 1991. But all the isotopic ratios are characteristic of atmospheric fallout. The differences observed are due only to granulometric differences (4). In fact, plutonium radioisotopes have a great affinity for finer particles.

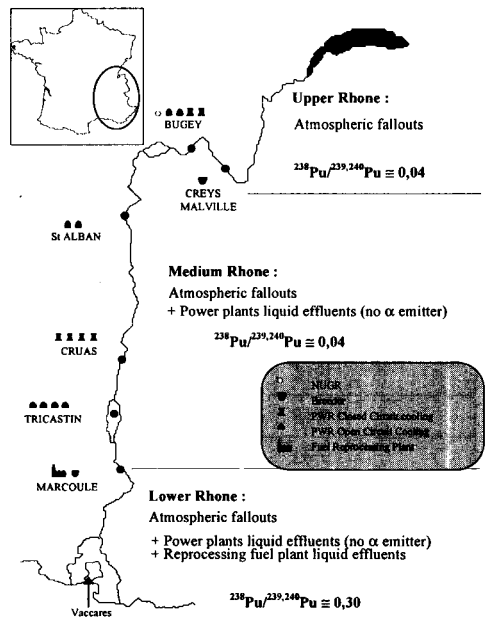

Figure 1. Source terms and Pu ratio in the Rhone river sediments

If the plutonium isotopic ratio departs from this value, this can be a sign that the plutonium is from another source. Thus in the Loire, Martin and Thomas (3) found a ratio of 0.15 to 0.40 downstream from the C.N.P.E. facility at St-Laurent-des-Eaux following an incident in 1982 that led to the melting of two fuel elements in reactor 2. The ratio was less than 0.04 in 1994 (5). Similarly, downstream from the C.N.P.E facility at Bugey, sediment collected in July 1989 had an isotopic ratio of 1.66 (6). This could be explained by an incident at the site's graphite-gas reactor. A second sediment sample collected in 1992 showed a ratio of 0.05, which is consistent with the characteristic value for atmospheric test fallout.

Sediments sampled downstream from the Marcoule fuel reprocessing plant.

In the sediments from this area, concentrations vary between 0.2 and 7.8 Bq.kg^{-1} dry for ^{239,240}Pu, between 0.17 and 2.1 Bq.kg^{-1} dry for ^{238}Pu, and between 0.4 and 5.3 Bq.kg^{-1} dry for ^{241}Am. The plutonium isotopic ratio is 0.280 ± 0.023 (56 significant values), thus greater than that found farther upstream (7). It is characteristic of the plant's liquid effluent (8). The startup of the liquid effluent treatment station in 1991 caused a decrease in the concentrations observed in sediments collected between Marcoule and the Camargue:

Dates	^{239,240}Pu (Bq.kg^{-1} dry)	^{238}Pu (Bq.kg^{-1} dry)	^{241}Am (Bq.kg^{-1} dry)
September 1990	0.77 to 5.49	0.54 to 1.82	< 0.48 to 4.46
September 1991	0.27 to 4.39	< 0.1 to 1.42	< 0.26 to 4.12
September 1992	0.26 to 2.58	0.06 to 0.72	0.13 to 4.14
1993 *	0.07 to 2.59	0.07 to 0.60	0.04 to 2.18

A sediment sample was taken in Lake Vaccarès (in the Camargue) in September 1992. The measurements resulted in the following values: 0.058 ± 0.006 Bq.kg^{-1} dry for ^{241}Am, 0.107 ± 0.010 Bq.kg^{-1} dry for ^{239,240}Pu, and 0.0038 ± 0.0010 Bq.kg^{-1} dry for ^{238}Pu (9). The ^{238}Pu/ ^{239,240}Pu isotopic ratio of 0.035 indicates that the point on the lake sampled is not influenced by the liquid effluent from the Marcoule plant.

CONCLUSION

Transuranic elements measured in sediments from the Rhône are in weak concentrations. In the entire part of the river not affected by effluent from Marcoule, the ^{238}Pu/^{239,240}Pu isotopic ratio is in the area of 0.04, which is characteristic of fallout from atmospheric testing.

Downstream of the Marcoule plant, the ratio is 0.3, which is characteristic of the liquid effluent from the irradiated fuel reprocessing plant. Since 1991, concentrations of transuranics in the sediments have decreased as a result of the startup of the liquid effluent treatment station.

* The level of the Rhône rose greatly in October 1993 and January 1994, flooding a small part of the Camargue region. In the flooded areas, plutonium radioisotopes from sediments from the Rhône were found in the soil of the rice fields. Their isotopic ratio was 0.2, characteristic of Marcoule. Agricultural work reduced the plutonium concentrations by a factor of 3 (0.03 Bq.kg^{-1} for ^{238}Pu and 0.19 Bq.kg^{-1} for ^{239,240}Pu). No significant activity could be measured in the rice.

INDUCTIVELY COUPLED PLASMA SPECTROMETRY AND NEUTRON ACTIVATION ANALYSIS OF RARE EARTHS IN CACHOEIRA RIVER

ABSTRACT

Inductively Coupled Plasma Spectrometry (ICP-MS) and Neutron Activation (INAA) are used for determination of Rare Earths in the water and Sediments of Cachoeira River in State of Bahia - Brazil. Elemental concentration of 10 elements have been measured in 20 ground water and sediments samples collected to different parts of this river. There is a good agreement between the two analytical methods and the results are complementary.

INTRODUCTION

The concentration and physico-chemical State of trace elements in water and sediments is of considerable importance for their transport in nature and then influence on biological systems.
Several methods have been used for measuring the environnent pollution in water, sediments and aquatic plants. Neutron activaction analysis is a classical method for multi elemental determination which has a high sensitivity at trace level[1,2]. The concentration of rare earths is very reliable in environmental control[2]. This technique has been widely used for the analysis of water and sediment[3,4].
Inductive Coupled Plasma Mass Spectrometry may be used for trace analysis of environmental samples. This multi-elemental technique is accurate sensitive and fast[5], allowing a daily processing rate of up 100 samples or more and has recenthy been used to determine the composition of rivers water and for routine trace analysis [6,7] ICP-MS became a prefered method of elemental analysis with detection limits for most of elements of less than 0,1 µg/l [8].This work uses INAA and ICP-MS analysis methods to determine level concentration of rare earths.

EXPERIMENTAL

Water and sediment samples were collected of the approx. 30 km long the Cachoeira river. Water samples were collected near the river bank from a depth 15cm, placed in 125 ml Nalgene bottles and stored at 4°C tempertaure pH and electrical conductivity were measured by each sites.
We had not detected significative variations between the different areas. The average values of these parametres are: temperature 30°C ; pH = 7,2 ; eletrical conductivy = 630 µS.
The sample were taken in duplicate and half of them were acidified on site with 5 drops ultrapur acid nitric (pH =2). This acidification is believed to reduce any absorption on the walls of the bottles[9]. The sediments samples were collected in 20ml polyethylene tube and also stored at temperature of 4°C. They were dried for one day at temperature of 90°C.
Prior to analysis one sediments sample was collected per water sample. The method of neutron activation analysis used in the present experiment consists in the pre-concentrated of water samples before irradiation, 10ml sample were evaporated in the ultrapur quartz ampoules (SUPRASIL) 80°C for during 24h and heat - sealed. The samples and standards were irradiated in Saclay's OSIRIS nuclear reactor at a neutron flux of 1,4 X 10^{14} $n.cm^{-2}.s^{-1}$ for 17h. The Gama rays subsequently limitted were counted for 8 hours, after a decay time of 10 a 20 days, with 100 cm^3 coaxial HPGe PGT detector coupled to a 4096 pulse height analyser. The computational Ko method [9] was used to determine the concentration of elements of interrest.
The sediment samples were irradiated in the OSIRIS for 2h. To enable the techniques of INAA and ICP-MS to be compared, 20ml of 3:1 mixture of HCl and HNO_3 was added to the irradiated sediments samples, the mixture evaporated at 80°C diluted with 20ml of 5% nitric acid and centrifuged. The liquid samples were counted for 4 hours.

The ICP-MS mesurements were corried out using the multi-elemental modes. An analytical program was stablished for both calibration and routine analysis. This program uses a series of automated operations to align the optics, select the analytical wavelenght for the peacks and position the source on the entrenance slit in order to optimize the sinal. The selected analytical wavelenghts are the characteristics lines of the elements which are free from spectral interferance and this avoids the necessites of the corrections at concentration level of interest. The ICP-MS used in this study was a PQ 2 - PQ Vision software. The mesurements were taken in duplicate, using the following operating conditions: - ICP-MS r.f. power: 1,35 Kv; - Coolant Argon flow: 14 l/min; - Nebulizer Argon flow: 0,8 l/min; - Auxiliary Argon flow: 0,8 l/min; - Sample uptake rate: 0,6 - 1 ml/min. The instrument was calibrated with a commercial solutions (SPEX) which contained standards prepared out of 10 ppb multielementary and 1000 ppb Ca solutions. Blanks were also used in order to enable an accurance of 2-3%. The internal standards of samples were 10 ppb solution of In, Re, Be. The relative standard deviation was typically 5 -10%.

RESULTATS AND DISCUSSION

The samples analysed were collected from four diferents areas to Cachoeira river. The resultats (Table 1 and 2) indicate that the rare earths concentration in water and sediments sample is present the maximum concentration in the area « P. do Pitu ». The separation of suspend matter by filtration process permit to distinguish particulate material in suspension from the elements in solution. This process presents the risk of contamination. The centrifugation process reveals a good behavior the effectiveness of the centrifugation process is a function of the centrifuge speed, time and particle density. A centrifugation at 4300 rpm during 10 minutes is convenient.

CONCLUSION

The asssociation of INAA and ICP-MS, two metods of multi-elementary analysis permits to investigate the rares earth elements in water and sediments samples.
The two analytical methods are complementary and in general the results showed a good agreement.

MEASURED TRITIUM IN GROUNDWATER RELATED TO ATMOSPHERIC RELEASES FROM THE MARCOULE NUCLEAR SITE

Françoise Lévy[1], Albert Clech[1] and Philippe Crochet[2]

[1]*COGEMA – Etablissement de Marcoule, Service de Protection contre les Rayonnements, BP 170, 30206 Bagnols-sur-Cèze Cedex, France*

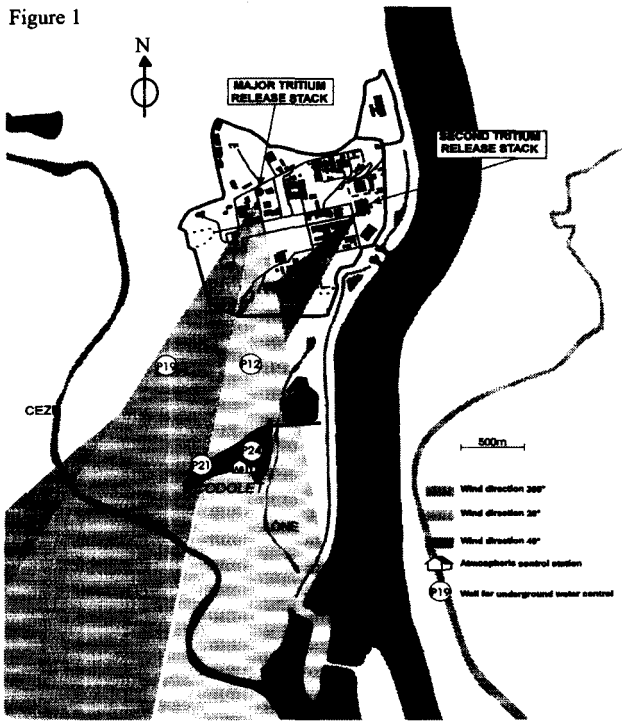
1 - Introduction

Tritium is released into the atmosphere during normal operation from the industrial facilities operated by COGEMA at Marcoule; over a 15-year period covered by this study (1979-1994) the quantities ranged from 4940 to 520 TBq·yr^{-1}. Atmospheric release in rainy weather results in tritium migration into the groundwater by a series of mechanisms associated with the water cycle. COGEMA monitors the groundwater by means of boreholes, four of which are shown here (Figure 1). Atmospheric monitoring is also routinely performed; data on the tritium activity concentration in the air and rainwater are available for the same time period. A simplified observation suggests a relation between the atmospheric tritium release and the groundwater radioactivity .In 1994, the activity ranged from 100 to 200 Bq·l^{-1} in the boreholes located 1 km and 2 km downwind from the point of release, diminishing with the distance to less than 20 Bq·l^{-1} at about 3 km.

Figure 1



The authors attempted to model two types of transfers: atmospheric transfer from the release chimney to the borehole, and transfer in the alluvial groundwater. The aquifer comprises the alluvial deposits forming the Codolet plain extending to the south of Marcoule, downwind from the point of atmospheric tritium release. The hydrogeology of the entire Marcoule site has been described in previous studies by the French bureau of geological and mineralogical research (BRGM) and ANTEA.

2 - Modeling Atmospheric Transfer

COGEMA possesses a site model for Marcoule based on a wind-tunnel mockup representing the local relief, and used to calculate the Atmospheric Transfer Coefficient (ATC). Given the known annual tritium releases, weighted by the frequency of tritiated vapor (HTO) conditions, the ATC values are used to calculate the activity concentration in the air in rainy weather, and to determine the concentration in the rainwater:

$$Ar = Aa.\frac{1}{\rho}.f$$

where Ar : radioactivity in rainwater (Bq·l^{-1})

Aa : radioactivity concentration in air (Bq·m^{-3})

ρ : specific activity of water vapor in rainy weather (12.10^{-3} kg·m^{-3})

f : factor characterizing tritiated water vapor ⇄ rainwater exchange[1] depending notably on distance and intensity of rainfall.

The authors determined an experimental value for f using the weekly measured values in the rainwater and air at the atmospheric monitoring station (AS1): $f = 0.15$. The measured rainwater activity at AS1 correlates satisfactorily with the value calculated by the model (Figure 2). The model may therefore be used to calculate the rainwater activity contributing to the groundwater activity at any point on the plain.

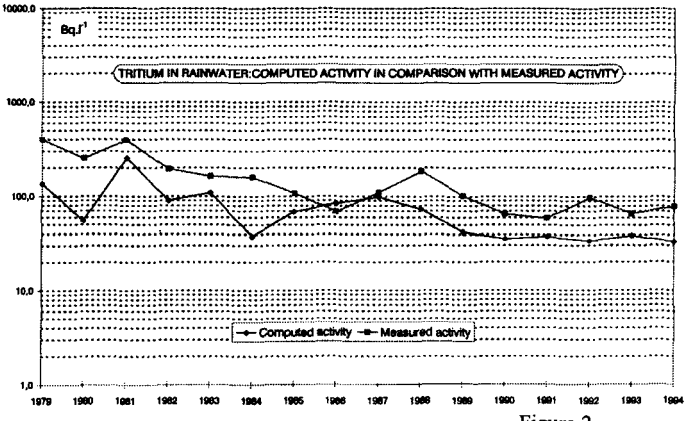


Figure 2

3 - Modeling Rainwater – Groundwater Transfers

When tritium-laden rainwater reaches the ground, the complexity of the subsequent pathways depends on the nature of the soil and its moisture content:

- A negligible fraction enters the surface hydrographic system directly in lakes or waterways.

- Runoff water contributes to the surface water flow.

- Another fraction infiltrates directly into the soil and may enter the evapotranspiration cycle, constituting an available water supply in unsaturated zones, or may slowly percolate down to replenish the groundwater. The rainfall replenishment fraction is subject to specific hydrodynamic mechanisms in the aquifer, and migrates at a rate depending on the hydraulic gradient, the permeability and the storage coefficient in the case of transient variations.

Tritiated water migration in the aquifer is the result of three kinematic phenomena:

- convection, corresponding to the mean fluid displacement;

- kinematic dispersion, due to the heterogeneity of the microscopic flow rates;

- molecular diffusion through Brownian movement of water molecules (this phenomenon is negligible in a permeable aquifer).

3.1 -Calculating the Rainfall Replenishment

Climatological data on rainfall, temperature and insolation obtained from the French Weather Service for the period from 1979 to 1994 were used to determine the evapotranspiration potential (ETP) from the Turc and Penman formulas. Groundwater replenishment by rainfall was estimated using the GARDENIA hydrological model developed by the BRGM, in which a series of reservoirs simulate the principal mechanisms of the water cycle: rainfall, evapotranspiration, infiltration and flow. Transfers from one reservoir to another are governed by simple laws and are adjustable for each reservoir. The model calculates the theoretical water table from rainfall records and from the ETP. The model flow parameters are adjusted by comparison with measured groundwater levels.

The mean annual replenishment calculated in this way over the time period of this study was 145 mm for a mean annual rainfall of 740 mm. The ratio of the two terms, approximately 20%, is consistent with the values commonly observed for this type of aquifer.

3.2 - Hydrodynamic Flow Model

A hydrodynamic model is used to quantify the groundwater flows based on the calculated rainfall replenishment, the aquifer geometry and hydrogeological parameters (permeability, storage, etc.) and boundary conditions. The MARTHE code (BRGM) solves the diffusivity equation using a finite-differences algorithm. In the hydrogeological context of the site, a single-layer regular square mesh was used.

The model was validated for the Codolet plain by comparison with reference data representative of intermediate water conditions from a synchronous piezometric survey conducted in October 1995; under these conditions, the groundwater drains into the Lône and the Cèze.

3.3 - Transport Model

The objective is to account for the tritium activity values measured by piezometers in the Codolet plain based on the various groundwater migration mechanisms using the MARTHE code, which also integrates specific transport equations.

Tritium influx to the groundwater was estimated over monthly time steps from the calculated rainfall replenishment and from the radioactivity measured in the rain by COGEMA. These values were used as input for the model in the form of a mass infiltrated over the entire surface of the Codolet plain.

The model uses the hydrodispersive parameters (kinemattic porosity, longitudinal and transverse dispersion) estimated for the aquifer after several groundwater tracing campaigns carried out earlier on the Marcoule site. The simulations covered a 15-year period from 1979 to 1994. The model calculates the radioactivity of each grid square for each monthly time step to account for the measured variations and the iso-activity maps.

4 - Conclusion

The results show satisfactory agreement between the radioactivity values measured in the boreholes and the calculated values (Figure3). It appears that the tritium activity observed on the Codolet plain may therefore be explained by the contribution of rainfall, based on a deterministic approach taking into account all the physical phenomena involved in the transfer.

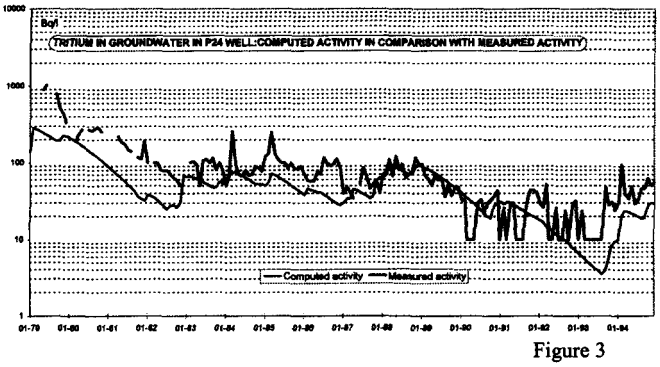

Figure 3

The combined use of several models makes it possible to predict the groundwater radioactivity according to the released activity and the average weather conditions.

RADIOISOTOPE AND STABLE ELEMENT PARTITIONING COEFFICIENTS IN THE DANUBE RIVER

Nina D.Drndarski[1] and Natan Lavi[2]

[1]The Institute of Nuclear Sciences-Vinca, P.O.Box 522, 11000 Beograd, Serbia

ABSTRACT

The analytical measurement results obtained during the last decade for the radionuclide, trace element and heavy metal concentrations in sediment, periphyton and water samples collected from the Danube River were explained with respect to the partitioning coefficients. The periphyton concentration ratios (CR·s) for each isotope were correlated with the sediment distribution coefficients (K_d·s) for that isotope. The K_d-CR relationships obtained were defined by the equation $\lg K_d = -0.70 \lg CR + 3.16$. The K_d-CR relationship determined in this work was compared with the K_d-CR relationships proposed by Baes and Shepard.

INTRODUCTION

The concern for the appropriate partitioning coefficient (distribution coefficient and/or concentration ratio) determination is important for the modelling of aquatic systems and the engineered and/or the natural radwaste barrier systems (1,2,3,4,5,6,7). One of difficulties associated with measurement of partitioning coefficients either in laboratory or in environment is to ensure that the element concentration in sediments/biota is in equilibrium with the element concentration in water (2). The great number of factors-physicochemical form of element, presence of competing ion, colloid formation, co-precipitation, etc. - which affect element assimilation and/or retention account in part for the variability of partitioning coefficient values reported in the literature (3,4,5,6,7). It appears, also, that the applicability of laboratory partitioning coefficients and/or in-situ partitioning coefficients depends on the specific problem studied.

MATERIALS AND METHODS

Sample collection and preparation.

Three locations along the Danube River, from Visnica, 1162 km upstream, to Ostrovo, 849 km upstream, were chosen for samples collection and for the routine control of the river pollution for the last 10 years. Sediments were collected by a grab sampler and periphyton samples were collected manually. Water samples were collected with plastic bottles and acidified with 0.1N HNO_3. Sediments and periphyton were dried in an oven at 105°C to the constant weight. Water samples were filtered and evaporated under infrared lamps.

Measurement procedure.

Energy dispersive x-ray fluorescence spectrometry (XRF) was applied for stable elements concentration measurement in the all collected samples. Excitation with gamma rays

from ^{109}Cd of 370 mBq and ^{241}Am of 3700 mBq was employed. The detector Si(Li) had a resolution of 250 eV FWHM at 5900 eV. From the known intensity ratios of k_α/k_β, the overlapping lines of the neighbouring elements were subtracted. The detector efficiency correction curve was determined by the measurement of standard sample matrix (8).

The radioisotopes in periphyton were analysed on a HP Germanium (ORTEC) well-type detector and those in sediments and water on a HP Germanium (ORTEC) coaxial detector. The same geometry was used for each periphyton and sediment and water sample. The counting times were 85,000 s. The accuracy of the measurement was checked by counting NBS Standard Reference Material-River sediment No 4350 (9).

RESULTS AND DISCUSSION

The partitioning coefficients such as the periphyton concentration ratios (CR·s) and the sediment distribution coefficients (K_d·s) were assumed as indicative of elements bioaccumulation, transport and retardation in the Danube River ecosystem. The determination of the partitioning coefficients was based on the mass balances. Thus the distribution coefficient (K_d) is the ratio of the element concentration in the sediment to the concentration of the same element in the water, $K_d = C_s/C_w$. The K_d·s were expressed in ml g^{-1}. The CR is the ratio of the element concentration in the periphyton to the sum of concentrations of the same element in sediments and water, $CR = C_p/(C_s+C_w)$. The CR·s were expressed in mg g^{-1}. The K_d-CR relationships calculated for the Danube River are shown graphically in Figure 1. Each point in the figure is accompanied with the average standard deviation of all data ($\sigma_{lg\ CR}$ and $\sigma_{lg\ Kd}$). The K_d-CR relationship obtained for the Danube River is defined by the following equation $lg\ K_d = -0.70\ lg\ CR + 3.16$. The significant correlation was -0.75 at $P < 0.05$. The 95% confidence curves and the regression line are shown in the same figure. The K_d-CR relationships proposed by Baes (4) and Shepard (5) were expressed by equations $lg\ K_d = -0.85\ lg\ CR + 1.31$ and $lg\ K_d = -1.12\ lg\ CR + 2.08$ and presented in the Figure 1. Our K_d-CR relationship was used to calculate the missing K_d·s or CR·s for a wide range of radionuclides and stable elements (10) and to compare these values with those found by Baes, Shepard and the other workers (6,7,8). From the other author·s findings and from this work it is evident that it is not possible to establish a single K_d/CR value for each isotope.

^{238}U, ^{232}Th, ^{226}Ra and ^{40}K Radioactivity Levels in Different Types of Fertilizers

Samir Abdul-Majid, Ibrahim Kutbi, Waleed Abulfaraj and Majid BaSabrian

Saudi Arabia import large quantity of inorganic fertilizers each year, from Europe, Midle East and U.S.A. Analysis were made for natural radionuclides in 42 samples of different types, by gamma spectrometry to assess the extend their application to soil would affect the soil radioactivity levels. Out of the 10 phosphate fertilizers samples analyzed, 5 showed very high ^{226}Ra concentrations whose mean value was about 620 Bq/kg, more than one order of magnitude that of soil while the rest 5 showed very low mean values of about 24 Bq/kg. The ^{238}U concentration were high in all the 10 samples and had a mean value of about 2600 Bq/kg. The ratio of $^{238}U/^{226}Ra$ revealed that the two radionuclides were far from being in equilibrium. The ^{40}K was very low of about 90 Bq/kg, about one order of magnitude less than ^{40}K in soil, that of ^{232}Th was about 30 Bq/kg.

The analysis of 32 NPK and potassium types showed very low ^{226}Ra and ^{232}Th concentrations of only few Bq/kg, while the mean ^{40}K was about 1300 Bq/kg. That of trace elements fertilizers showed both low ^{226}Ra and ^{232}Th concentration of few Bq/kg and low ^{40}K level of about 65 Bq/kg mean values.

URANIUM MINING AND MILLING SITES IN ARGENTINA: ENVIRONMENTAL RADIOLOGICAL MONITORING (1981-1994)

A.M. Bomben, J.C. Gómez, A.A. Oliveira

Ente Nacional Regulador Nuclear
Av del Libertador 8250 (1429), Buenos Aires, Argentina.

ABSTRACT

Environmental radiological monitoring in the vicinity of Argentinean uranium mining and milling plants is performed on a routine basis, in order to assess the possibility of a significant environmental contamination due to uranium mill wastes or by mill tailings for the plants still operating or by those plants where the exploitation was concluded.

Dissolved ^{226}Ra and natural uranium concentrations in surface water are measured in samples taken at selected points upstream and downstream from rivers, in the area of influence of the mills.

In the present paper the environmental radiological monitoring program results obtained for the 1981-1994 period are shown, and from the analysis of these data it can be concluded that no remarkable exposure occurs for the population living in the vicinity of the analysed areas due to the uranium mining and milling plants operation or their wastes.

INTRODUCTION

In figure 1 are shown the uranium mining and milling areas included in the environmental radiological monitoring program, their geographical location and the type of exploitation. The uranium industry began its development in Argentina in the '50 and, at present time only San Rafael and Los Colorados plants are still operating.

As a results of plant operation, two types of wastes are obtained, acid liquid wastes that are neutralised before being piped into large evaporation ponds and ore tailings, solid wastes that result after the acid-leach process.

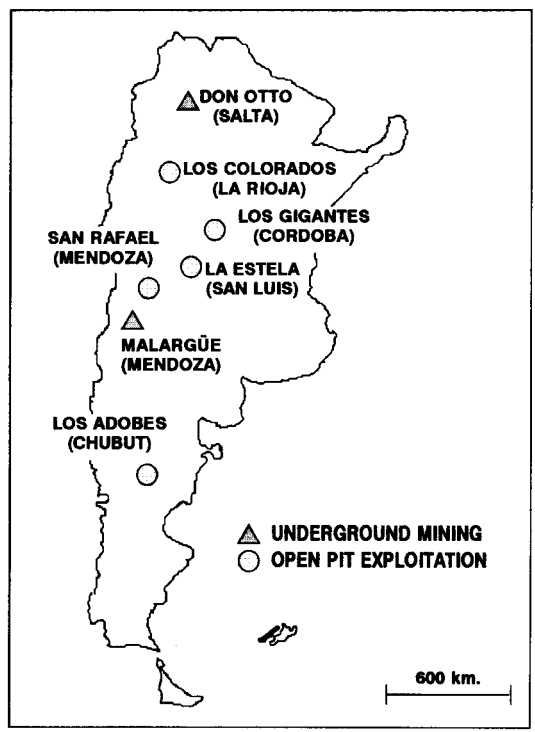

Figure 1: Uranium mining and milling areas included in the environmental radiological monitoring program.

MATERIALS AND METHODS

Surface water samples are taken from river locations upstream and downstream from uranium mills, according to a special monitoring plan set up for each facility (1), in order to allow the estimation of an eventual water contamination.

Dissolved ^{226}Ra in surface water samples were analysed by the classical radon emanation Rushing technique with Lucas cells (2). From 1988 till 1993, gross alpha counting using ZnS (Ag) as a detector was performed on water samples. Only those samples exceeding 70 mBq/L of gross alpha activity were selected for ^{226}Ra analysis. Nowadays, the ^{226}Ra concentration is measured by the ^{222}Rn emanation technique in sealed vials with toluene scintillation cocktail (3). The method consists in a ^{226}Ra co-precipitation with $BaSO_4$ and an alkaline EDTA dissolution before the liquid scintillation counting .

Natural uranium concentration is determined by a direct fluorometric measurement or after a co-precipitation with $CaHPO_4$ as a carrier, in order to enhance the detection limit.

^{222}Rn emanation rate from ore tailings is determined by adsorption on activated charcoal and a gamma measurement of the ^{214}Bi (609 Kev) in equilibrium.

RESULTS AND CONCLUSIONS

Figures 2 and 3 show the range of values of ^{226}Ra activities and the maximum natural uranium concentrations measured in surface water samples taken from the Diamante river and the El Tigre stream, from sampling points located in the surrounding of the San Rafael plant, from 1981 to 1994.

The average ^{226}Ra concentration was 4mBq/L either for samples taken from points < 10 km upstream or those samples taken < 50 km downstream, from the San Rafael mining and milling plant, with a range of values of 0.7-19 mBq/L and 0.7-13 mBq/L, respectively.

For the same period of time considered, the average natural uranium concentration measured was 0.02 mg/L, with a range of values of 0.0009-0.1 mg/L either in samples taken above or below the plant discharge point.

The application of the statistical test of Wilcoxon (4) demonstrated that no significant differences in the ^{226}Ra and natural uranium concentrations were found between the surface water samples from river locations above and below the milling plant of San Rafael, as well as for the rest of mining and milling areas of Argentina, where the environmental radiological monitoring program was performed.

Figure 4 and 5 show the corresponding ranges of ^{226}Ra concentrations and the maximum natural uranium concentrations, obtained for all the uranium sites, for the last year assessed. An important variability was observed in the concentrations of the radionuclides of interest, due to geographical and seasonal causes, but all the results obtained were below the derived limits for drinking water, that taking into account the biokinetic model (5) and dose conversion factors (6) were estimated as 180 mBq/L for ^{226}Ra and 0.12 mg/L for natural uranium.

^{222}Rn emanation rates were measured at San Rafael (1992) and Malargüe (1993) ore tailing sites, and the range of values obtained were 9-11 $Bq/m^2.s$ and 10-17 $Bq/m^2.s$, respectively. The contribution of ^{222}Rn at the natural background concentration, due to the ore tailings, is not significant at a few hundred meters from the emanation points.

Taking into account all the measurements of the environmental radiological monitoring program for the last 14 years, it may be concluded that no remarkable exposure occurs for the population living in the vicinity of the uranium mining and milling sites in Argentina due to their operation or their wastes.

ABSTRACT (See instructions overleaf)

Considering that average environmental daily doses are in the range of 1-5 uGy, it was performed an experiment to check the real capability of the ultra sensitive TL phosphors to detect extremly low doses. The results obtained with four types of TL dosemeters such as LiF:Mg,Cu,P (GR-200A), solid sintered $CaSO_4$:Dy (TLD-2000H), $CaSO_4$:Tm (TLD-2001H), and Al_2O_3:C (TLD-500K), as well as two types of electronic dosemeters, have been studied, taking high pressure ionisation chamber as the reference instrument. The evaluation were performed using different types of TLD readers.

The experiments were also performed in order to study the additivity, stability and thepossibility to detect small variations in daily doses for different exposure periods, from one week to 3 months period.

The dosemeters were exposed to environmental radiation at the selected locations: inside the Institute Vinča, on the site of the Accelerator Installation (in construction) to establish the zero point levels with respect to dose rates, two years before starting, and at the standard environmental measuring location, 1.5km far from the Institute.

It was found that all the dosemeters were capable of reliably measuring these very low doses after an exposure of 1 day, without performing special measurement procedures.

SYSTEMATIC APPROACH TO THE ORGANIZATION OF MEASUREMENT ASSURANCE IN RADIOECOLOGY

I.M.Khaikovich (A.A.Logachyov Institute, VIRG-Rudgeophisika)

A.M.Blumentsev (VNIIGeosystem)

Yu.V.Tarbeyev, V.I.Fominykh (State Research Center, D.I.Mendeleyev Institute for Metrology, VNIIM)

1. Radiation conditions of the environment are characterized by a great number of various parameters which, relative to radiation, describe different objects and for the measurement of which the use is made of various analytical methods in field and laboratory conditions. To ensure the required level of reliability of the results of radioecological studies on large territories, it is suggested to set the list of parameters to be measured depending upon the problem to be solved and the object under study, as well as to establish the requirements for the accuracy of determination of those parameters.

2. All radiometrical methods used in radioecology can be divided into three groups according to the measurement conditions. The first group includes measurements directly in natural beddings, i.e. in blast-holes/wells and on the day surface. Parameters: fractions of total mass and specific effective activity of natural radionuclides (NRN), specific and surface activities of radionuclides of artificial origin (ARN) and value of their reserve per unit of surface, air kerma (dose equivalent) rate of gamma-radiation.

The second group contains radon measurements in the earth (soil) and free air. Parameters: radon concentration, volume effective equilibrium activity of radon and daughter products of its decay.

The third group consists of methods of lithochemical sampling of water and bottom sediments. Parameters: NRN and ARN concentration in water, NRN and ARN content in bottom sediment samples.

3. Parameters characterizing radiation sources in every group are mutually connected. Thus, to provide for the measurement assurance, it is necessary to correlate parameters of standard measuring means (MM) applied for organizing the measurement assurance (MA), by choosing a metrological model reflecting adequately the conditions of measurement of the physical parameters in every group and of certification of the standard MM's by the set of parameters to be measured. The metrological model describing the measurement of parameters with a guaranted uncertainty, must be chosen by the following scheme:

physical object))→ physical model → mathematical model → metrological model

4. Physico-mathematical analysis carried out for the first-group methods, establishes the correlation between the parameters of this group. For this group there are stated requirements to the unified measurement chain for the MA of radiometers applied in complex radioecological studies. Such a chain should have at least three levels.

The first level of standard reference MM's (SRMM) - standards includes:

a) Set of standard reference materials (SRM) of the NRN and ARN content and the ARN surface activity to maintain and reproduce the units of fractions of total mass of NRN's and of specific activities of ARN's in the model "homogenious space" or "homogenious half-space", as well as those of surface activity of ARN's of the

specified content in the model "thin film". SRM dimensions must ensure "saturation by gamma-radiation" in the measurement condition of "difference effect": for 4 geometry - 140 cm in diameter and 150 cm in height with the bulk density 1.5 g/cm^3; for 2 geometry - 100 cm in diameter and 50 cm in height for the model "homogenious half-space" and 30 - 50 cm in diameter for the model "thin film".

b) Working standard to maintain and reproduce the unit of air kerma (equivalent dose) rate of gamma-radiation.

c) Standard multichannel gamma-radiometer (gamma-spectrometer) to control stability of the parameters of the SRM set and to transfer the units to standard and working MM's.

The second level consists of standard MM's. To measure in 4 geometry, standard MM's are built as SRMM's. For ground-based and aerogamma- surveys it is recommended to use as standard MM's the SRM's in the form of testing grounds certified by transferring the unit from SRMM's.

The third level includes working MM's.

5. The suggested measurement chain ensures for working MM's the estimation of parameters by the first-group methods with the confidence basic uncertainty less than 10 % when measuring in 4 geometry. The confidence uncertainty won't be higher than 20 and 30 % (0.95) when measuring the surface activity and air kerma (equivalent dose) rate of gamma-radiation by the methods of ground-based and aerogamma-surveys, respectively.

RADIOACTIVITY CONCENTRATIONS IN SOIL IN THE WESTERN PROVINCE OF SAUDI ARABIA

S. Abdul-Majid, W.H. Abulfaraj and I.I. Kutbi

Faculty of Engineering, King Abdulaziz Uni., P.O.B 9027, Jeddah-21413, Saudi Arabia

INTRODUCTION

Radioactivity in soil was measured in the seven Western Province cities of Saudi Arabia in order to establish radiation data baseline of natural as well as man-made radionuclides. These cities were: Makkah, Taif, Baha,Abha, Madeena, Yanbu and Tabuk, whose locations is shown in Fig. 1.

Worldwide concern about the chernobyl accident caused interest in measuring radioactive contamination. Concern was raised on whether radioactive contamination had reached Saudi Arabia, particularly that few models have predicted that small amount of radioactivity may have reached the country (1,2). Only long lived radionuclides, such as ^{137}Cs, of 30 years half-life would remain after long time. Its concentration would give a good indication of the degree of contamination. The other long lived radionuclide is ^{90}Sr of 28.5 y half-life, but this radionuclide is less volatile than Cs. It is, therefore, expected to travel much less than Cs. The reported $^{90}Sr/^{137}Cs$ is Europe (3) was only few percent. The ratio in Saudi Arabia is expected to be less due to the larger distance from the reactor accident location.

MATERIALS AND METHODS

Seven soil samples each about 2 kg were collected from approximately top 5-8 cm, of undisturbed soil by excavation or construction, from each city. The detector used was a vertical type of 10% relative efficiency HPGe whose FWHM was about 2 keV at 1.332 MeV. It was shielded by lead blocks of 30 cm thickness with additional cooper shielding of 5 mm around the detector, inside the lead shield. Standard sources were prepared from known radioactivity ^{152}Eu and ^{137}Cs sources. The ^{232}Th concentration was found out from its daughters ^{228}Ac, ^{212}Bi, ^{212}Pb and ^{208}Tl, that of ^{226}Ra from ^{214}Bi and ^{214}Pb. The counting time for each sample was 72000 s.

RESULTS AND CONCLUSION

The mean concentration values of ^{232}Th, ^{226}Ra, ^{40}K and ^{137}Cs are shown in Figs.2-4. The concentration values of ^{226}Ra was higher in all cities except in Tabuk. The distribution of samples concentrations of ^{226}Ra, ^{232}Th and ^{40}K belonging to any city was not much different from that of all samples from all cities. Most values of ^{226}Ra and ^{232}Th were between 10-25 Bq/kg and that of ^{40}K between 400-700 Bq/kg.

The concentration of ^{137}Cs is shown in Fig. 4. In the cities of Makkah, Yanbu, Madeena and Tabuk, its values did not exceed 5 Bq/kg, with most values were around 2 Bq/kg, expected to be coming, mainly, from fallout of nuclear explosions above ground. The concentration values in high elevation high rainfall cities of Abha, Baha and Taif was clearly higher. Relatively wider variation in concentration values were observed among the samples. The nonuniform higher concentration is in these cities expected to be due to Chernobyl reactor accident, which may have precipitated by rainfall. The distribution of concentration values of Makka is shown in Fig. 5, and that of Abha in Fig 6, clearly indicating the difference in the concentration distribution fashions

INTRODUCTION

Phosphate fertilizer industry is a source of concern for environment mostly by phosphogypsum resulted as waste in the sulfuric acid attack of phosphate rock. Phosphogypsum is obtained in large amounts and is found in deposits located around fertilizer plants. There are four plants in Romania and the same time four phosphogypsum deposits of approximately 8 millions tons resulted in the dihydrate process of sulfuric acid attack of phosphate rock. The phosphogypsum acumulated all over the world is very large perhaps more than 1 billion tons.

The main problem consists of phosphogypsum radioactivity where all ^{226}Ra from natural sedimentary rock is present being a serious hazard radioactivity source. The radioactivity of romanian phosphogypsum fluctuate between 7 and 30 pCi/g ^{226}Ra.

Due to its radioactivity, restrictions in phosphogypsum use in construction industry or in agriculture have been imposed in many countries. The environmental contamination by phosphogypsum was in attention of many scientists and various studies have been carried out in view of eliminating ^{226}Ra and creating the conditions of its use in various fields (1-4). This study is an atempt to solve this problem.

EXPERIMENTAL

In this work three hypothesis were taken into consideration:

- radium removal from phosphogypsum by treatment with ammonium salt solutions which increase radium sulfate solubility;
- physical concentration of radium with hydrocyclones since experimental data have shown that ^{226}Ra is concentrated in fine grains of phosphogypsum;
- phosphogypsum (calcium sulfate) conversion to sodium or ammonium salts by treatment with sodium hydroxide, sodium carbonate or ammonium carbonate and radium retention on ion exchangers from the solution resulted by dissolution in hydrochloric acid of phosphogypsum conversion residue.

The research work was carried out at laboratory scale and in pilot plant. Phosphogypsum was obtained from SOFERT S.A. Bacau and had an average radioactivity of 17 pCi/g. Technical reagents have been used. Laboratory experiments were carried out in usual glass equipment. The experiments from pilot plant were made in suitable equipment acid and base resistant. ^{226}Ra determination was carried out by emanometric method.

RESULTS AND DISCUSSION

Phosphogypsum treatment by ammonium salts solutions gave no significant results, and the radium rate removal from phosphogypsum was very low. The requirement of unitary washing operations being over hundred.

The hydrocyclone separation using a unit of 100 mm diameter led to two granulometric fractions of phosphogypsum:+45 with radioactivity of 7.8 pCi/g and -45μ with radioactivity 27.9 pCi/g. The +45μ fraction, representing approx.40% weight may be used according to some literature data in the material of

construction industry.

In order to convert calcium sulfate (phoshogypsum) to sodium or ammonium sulphates, the chemical treatment is carried out and the conversion yields obtained are given:90-95% with 700 kg NaOH/t phosphogypsum or 600 kg ammonium carbonate/t phosphogypsum, consumption.

The hydrochloric solution containing radium and calcium, obtained from dissolution of residue resulted in the conversion process of phosphogypsum, by hydrochloric acid with dissolution yield of 98.9% and acid consumption of 600 kg/t phosphogypsum.

The efficiency of various ion exchangers for radium retention from hydrochloric solution was also studied. The best results were obtained with ion exchanger VIONIT CS-34S made by VIROMET S.A.-Victoria (Romania). The loading curve with ^{226}Ra of this resin is given in Fig.1, where experimental conditions are mentioned.

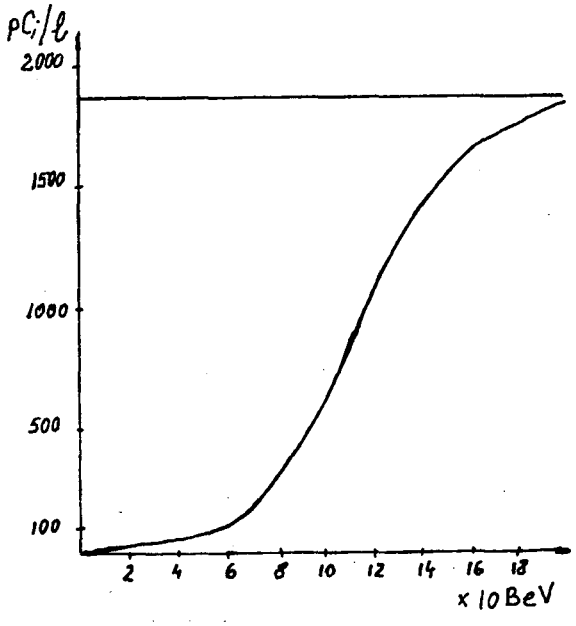

Fig.1. SORPTION ISOTHERM OF ^{226}Ra ON VIONIT CS-34S RESIN.

The pilot plant experimental data have confirmed the laboratory results and led to the flowsheet of the process for radioactive elimination and phosphogypsum conversion as given in Fig.2.

INVESTIGATIONS OF THE BEHAVIOR OF ^{110m}Ag IN SOIL SYSTEMS

Gyula Szabó and Judit Guczi,
"Frédéric Joliot-Curie" National Research Institute for Radiobiology and Radiohygiene, H-1775 Budapest,
PO. Box 101, Hungary;

INTRODUCTION

^{110m}Ag ($t_{1/2}$ 250.4 d) is a little-studied radionuclide that arises as an activation product in nuclear power plants. Although it has featured little in studies of environmental pollution from nuclear reactors, it is present in the low level liquid effluents released from some pressurized water reactors under normal operating conditions (1) and has been reported to be 10% of the total gamma radioactivity in some effluents (2). In 1988 760 MBq of ^{110m}Ag was released into the atmosphere from the Hungarian pressurized water reactor at Paks (3). Its presence in the plume from Chernobyl has been noted (4) and in West Cumbria, in May 1986, monitoring studies revealed that ^{110m}Ag from the Chernobyl plume was 3 - 5% of the ^{137}Cs found on vegetation (5). These releases have prompted us to consider the extent to which radiosilver may move through the environment (6).

The sorption processes of radiosilver on various soil were investigated by batch technique. The effect of the soil:solution ratio have been determined and the results expressed as the distribution coefficient, R_d.

MATERIALS AND METHODS

The soils used in this investigation were sampled from the upper 30 cm layer, stored moist at 4 °C, then air-dried and sieved to 200 μm. Some of their properties are given in Table 1. The isotope, ^{110m}Ag, was obtained from Amersham as the nitrate salt in 1M HNO_3 (44 MBq in 1 cm^3) and was used without further preparation.

Soil suspensions were prepared as follows: soil (1 g) was accurately weighed into polypropylene tubes, then 2-20 cm^3 solution containing 4 mg/dm^3 K^+ and 20 mg/dm^3 Ca^{2+} pipetted to give a solution ratio in the range 1:2 - 1:20 kg/dm^3. The activity of the solution was 10-20 kBq (0.54-1.09 x 10^{-6} g; 4.85-9.90 x 10^{-9} mol). All suspensions were prepared in triplicate. The suspensions were shaken in a reciprocation shaker at 20 °C. Aliquots (1 cm^3) were removed at 10, 30, 60, 120, 240, 1440 and 2880 min. for γ-counting. The γ-activity originating from the radionuclide was determined by counting 658 KeV photon emission of ^{110m}Ag on a γ-ray spectrometer NK-350 with a NaI(Tl) scintillator and an NZ-138 well-type detector shield (GAMMA, Hungary).

[a] Percentage of mineral fraction only

Calculation of the distribution coefficient

The distribution coefficient (R_d) of solid phases was calculated from the counts of the solution taken as follows:

$$R_d = \frac{\text{radioactivity of Ag sorbed kg}^{-1}\text{ sorbent}}{\text{radioactivity of Ag in solution after sorption dm}^{-3}\text{ solution}}$$

RESULT AND DISCUSSION

Kinetic studies are a common prerequisite to equilibrium sorption experiments. By monitoring the distribution ratio (R_d) as a function of time a 'time invariant' value for R_d is obtained. The uptake of radiosilver from solution on different soils was studied for contact times varying from 10 min. to 2 days. From Fig. 1. it can be seen that 'equilibrium' is reached within 2 days in each case and that there are different sorption rates for all the soils. From the Fig. 1. a binding strength order for soils can be set up: $1 < 2 < 3 < 4$. From this order it could be concluded that the mobility of radiosilver in these soils is the reverse.

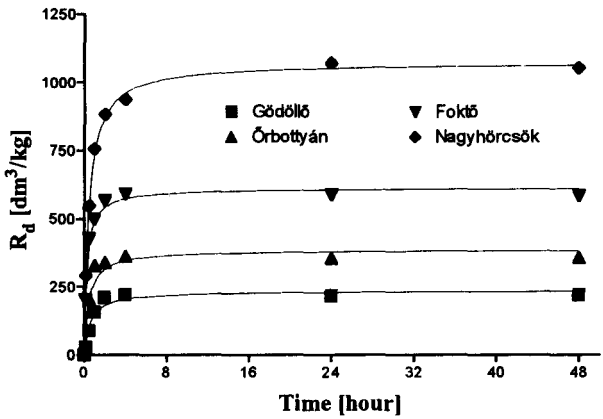

Figure 1. Sorption of ^{110m}Ag on soils vs. time (soil:solution ratio 1:20)

Staunton and Nye (7) used the variation of distribution coefficient with soil:solution ratio to extrapolate to the value of K_d on moist soils. They found good agreement between calculated and measured values of distribution coefficient when it was possible to extract solution by immiscible displacement (8). To use of the distribution coefficient measured in different soil:solution ratio to real natural moist soils we have investigated the effect of soil:solution ratio on the distribution coefficient (R_d). Fig 2. shows the effect of the soil:solution ratio, in the range 1:2 - 1:20 kg dm^{-3}, for each of the four soils. The effect of soil:solution ratio is complex: in general R_d increases as the ratio is decreased. However this is not always the case, for example maxima is observed for Nagyhörcsök. Other authors (9, 10) have got the same results investigating the effect of solid:solution ratio on the distribution coefficient. Unfortunately, adequate explanation for the effects has not been established.

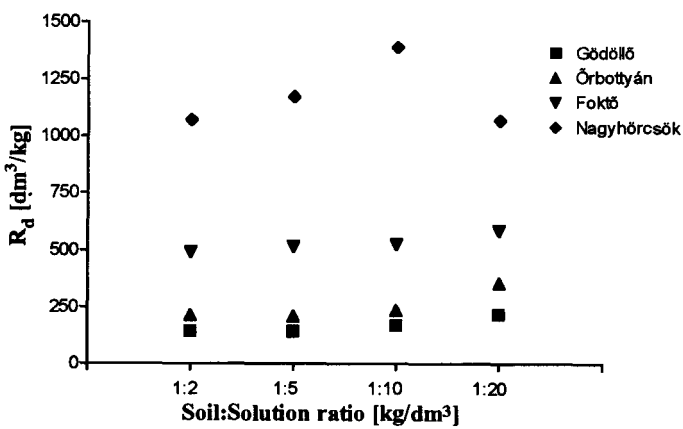

Figure 2. Effect of soil:solution ratio on the distribution coefficient of ^{110m}Ag in soils

Our previous investigation (6) shows that the soil humic matter the main sink for radiosilver in soils. From an investigation of characteristics of studied soils (see Table 1.) we have got positive correlation between radiosilver binding in soils and soil organic matter content (Fig. 3.). From Fig. 3. it is apparent that the R_d values increase monotonously as the humic content of soils increases . Other researchers (11,12) have also noted this positive correlation between Ag^+-binding in soils and soil organic matter.

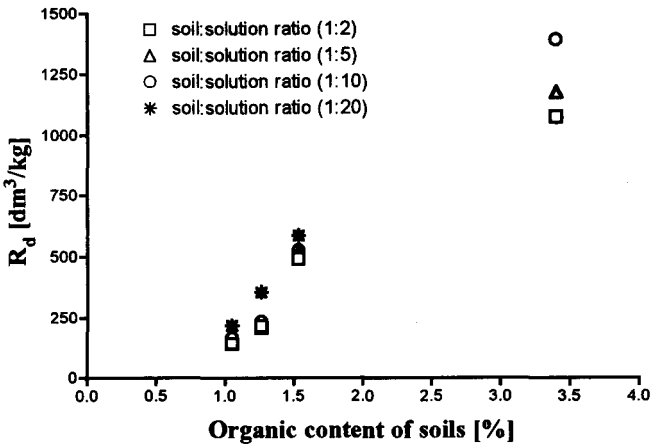

Figure. 3. Effect of soil humic matter content on the distribution coefficient of ^{110m}Ag

CONCLUSION

In conclusion, the distribution coefficient, R_d is a simple, convenient and useful measurement. However care must be taken both to avoid experimental artifacts and in the extrapolation of measurements to *in situ* conditions. In order to extrapolate to an *in situ* distribution, sorption must be studied from different point of view.

This study has shown that soils with different properties bind the radiosilver with different strengths. In addition it has been shown that the main sink for radiosilver in soils is the humic matter.

ABSTRACT

A method for precise determinations of vertical profiles of radioactive contamination in soils is described.

A polyethylene tube is driven into the ground and the tube, together with a soil core, withdrawn. The tube and the core are frozen and the whole sectioned with a diamond saw. The technique produces 'precision engineered' parallel-sided circular discs. Discs of less than 1 cm in thickness can be produced if desired, thus permitting a well resolved soil profile. The individual sections are dried, weighed and analysed.

The method was used in the city of Gävle in Sweden and showed that more than eight years after contamination by fallout from Chernobyl, the radiocaesium concentration in undisturbed soil (sandy loam) peaked at a point several centimetres below the ground surface. Trace amounts of radiocaesium were found to have migrated to a depth of at least 15 cm. The data obtained are suitable for testing models designed to represent downward migration of caesium fallout in soils and for calculating dose-rate over undisturbed soils contaminated with radiocaesium.

INTRODUCTION

Computer modelling, as well as direct dose rate measurements, has shown that when a housing environment has become contaminated by airborne radiopollutants (essentially ^{137}Cs) deposited after a nuclear accident, areas of soil in the environment are often the main contributors to the dose rate. This is the case immediately after the deposition, and as time goes by the relative dose rate contribution from soil areas will normally increase. The reason for this is the relatively strong fixation of radiocaesium in the upper soil layers. Many different decontamination or reclamation procedures have been suggested over the years to reduce the external radiation dose to populations by for instance burial deep in the vertical profile of a thin top soil layer containing almost all the radionuclides or by total removal of a thin top layer.

The crucial question is : how deep a layer should be removed ? This question can not be answered by the generally applicable computer models of radionuclide migration, which are not sufficiently case-specific. If too little is removed, the reduction in dose rate may not be worth the effort, whereas if too much is removed, areas with thin fertile layers (typical of e.g. large areas of the former Soviet Union) could be turned into desserts. It is therefore very important to know the vertical contaminant profile before any clean-up operation is initiated. Refined techniques have been developed, by which estimates of 'mean' penetration depths can be made from in situ measurement spectra obtained at the surface, but these assume an exponentially decreasing pollutant depth profile, and this assumption is not valid in reality. Soil profile sampling is therefore the only certain way to investigate soil radionuclide penetration.

METHODS

Cylindrical polyethylene tubes with an inner diameter of 81.0 mm and a wall thickness of 4.5 mm are driven into the ground using a rubber hammer. When the full length of the tube (about 20 cm) has penetrated the ground, it is withdrawn along with a soil core. The withdrawal is performed with special care to prevent loose material in the bottom from falling out. Therefore, the soil surrounding

the outer surface of the tube is first excavated. The sample cores (still in plastic tubes) are wrapped in a thin plastic film to prevent them from drying out and falling apart. When the sample cores have been transported to the laboratory, 200 ml of distilled water is added to each tube, which is subsequently transferred to a deep freezer (-20°C), where it is left for two days.

The tubes with the samples are then sliced with a diamond saw. The blade of the saw is 2.57 mm thick. Consequently, by this slicing procedure, a corresponding layer of the soil core is lost by each sectioning. A spacing device on the diamond saw makes it possible to accurately adjust the thickness of the slices. The saw blade usually has to be cooled with water, but at this point the samples contain sufficient amounts of water to grease/cool during the slicing process. As the samples are deep frozen the slices keep their parallel-side circular disc shape and even stones in the samples are cut through. The reproducibility of this 'precision engineered' technique has been evaluated through an examination of the sectioned core samples, which shows that the variations in thickness have a standard deviation of about 1 %.

Since the samples stay in the plastic tube during the slicing process, the sliced tube sections form rings around the sample slices. These rings support the samples during the different analysis sequences (drying, weighing and γ-measurement). Further, a removal of the whole soil core from the tube would introduce an unnecessary cross-contamination hazard.

The samples are then dried in 3 days at 60°C. After drying, the density of the samples is established through a weighing, where the mass of the plastic ring is subtracted. Stones and grass roots are not removed. This enabled a determination of the bulk soil density as a function of depth. The density of the sample is also used to allow for the attenuation of gamma-rays through the soil slice while measuring the gamma-activity.

The photopeak count rate of ^{137}Cs (661.6 keV) in each sample is measured in a lead shielded gamma spectrometer which includes a 15.6 % efficiency Ge(Li) detector. In this calibrated detector system the sample was placed directly on top of the upward facing detector end cap.

Finally, the photopeak net count rate is converted to a contamination level (Bq/cm^3 of ^{137}Cs) in the sample, taking into account differences in slice thickness and densities relative to the calibration standard.

RESULTS/DISCUSSION

The above described method was applied in situ in the Gävle area of Sweden in the summer of 1994. This area received high levels of contamination after the Chernobyl accident in 1986. Thus, soil core samples from the area contain sufficient amounts of radiocaesium to perform analyses with good accuracy. The soil profiles were sampled at five different locations in the area. At each location a series of 5 cores was sampled: one in each corner of a square with a side length of 1.40 m and one in the centre of the square.

Measurements of the soil density at the 5 different locations showed almost identical profiles. The bulk density of the surface layer (ca. 1cm) was found to range from 0.36 to 0.47 g/m^3. It was found that the bulk density increases almost linearly with depth through the top 10 cm layer. Below 10 cm, the soil has a nearly constant density, ranging from 1.2 to 1.5 g/cm^3. This is approximately the value that has been used as a default value for the whole profile in existing biospheric transfer models (1,2). Only the top layers of the beach samples were found to differ significantly from the rest. Here, the top layer density was found to be only 0.24 g/m^3, which can hardly surprise since this top layer was sand. The generally lower density of the top layers of the other samples must be attributed to a high content of organic matter, which has previously been recorded by textural analysis of soil from the area (3). This lower density in the top layers is expected to influence not only the shielding against radiation from penetrated radiocaesium, but also the downward migration of radiocaesium in the soil.

Figure 1 shows the recorded vertical soil profiles (averages over 5 cores). Although the total amounts of contamination were found to vary by as much as a factor of 1.5 between the individual cores, the shape of the profile was found to be fairly consistent. The counting uncertainties were less than 1 %. Samples were taken from the lawn in front of the city hall, a local surveyor's office in the city area (Land C.), a lawn in an industrial area (Gevalia), a lawn about 13 km to the north-east of the town

centre (cottage) and a beach area about 11 km to the north of the town centre. Also shown is an estimate made with the computer model MLSOIL (1) of the profile, assuming a k_d value of 37 ml/g, which is actually the minimum value that has been used so far by the model for uncertainty analysis.

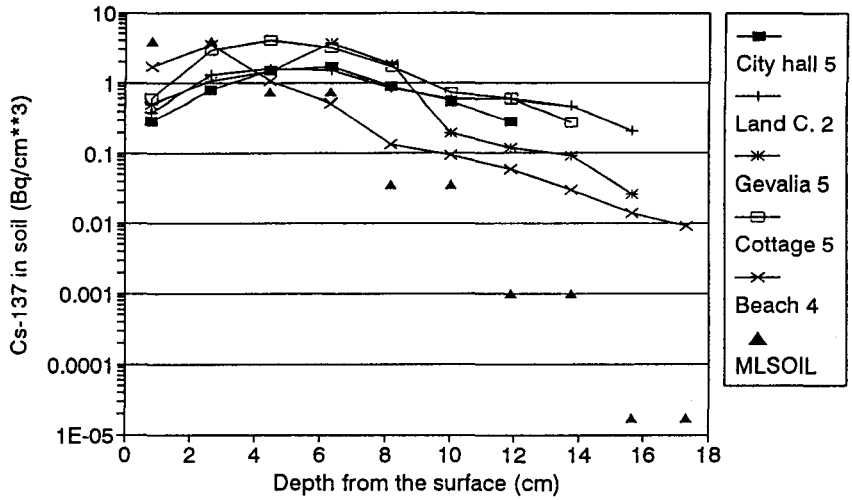

Figure 1. Vertical ^{137}Cs profiles in soil in 5 different lawns in the Gävle area. The sampling results are compared with estimates obtained with the MLSOIL model.

As could be expected from the density measurements, the higher content of organic matter and consequently higher macro-porosity and smaller fixation potential of the top soil layer is reflected in the radiocaesium profile. However, compared with previous investigations in the same area (the lawns termed 'Gevalia' and 'Cottage') in 1988 and 1990 (3), the average depth of the contamination has increased rather much. In 1990 the profile of the 'Gevalia' soil peaked at a depth of about 1 cm. Anyway, it has certainly been demonstrated that the assumption that soil contaminant content decreases exponentially with depth is not generally valid. After longer periods of time, the contaminant content in the uppermost layer can be depleted.

CONCLUSIONS

A specially adapted technique for soil sampling was established and tested in the field in the Gävle area of Sweden. By this method, the sectioning of soil cores can be performed with very good accuracy (ca. 1 %). The gamma analysis of trace amounts of radiocaesium in the soil slices from Gävle (initial contamination level ca. 200 kBq/m^2) was performed with an uncertainty of less than 1 %. Although the total contents of radiocaesium differed between the individual samples taken at a site, the shape of the vertical caesium profile was found to be relatively consistent. The radiocaesium concentration was found to peak at a depth of several centimetres in the investigated sandy loam type soil.

PRESENTING AUTHOR (IF DIFFERENT) A.N. Zabudko

MAJOR SCIENTIFIC TOPIC NUMBER 4.1 (see page 7)

ABSTRACT (See instructions overleaf) The original technique of the I-129 amount measurement in the soil samples using radiochemical and neutron activation methods was developed in the IPPE. Its main stages are the following :

- isolation of iodine from a sample by extraction with transfer of iodine into PbI_2;
- sediment irradiation in a reactor channel in a flow of thermal neutrons not less then 4×10^{13} $n/cm^2 \times s$ for transfer of I-129 in I-130;
- repeated precipitation of PbI_2 in CuI_2 after irradiation for decrease of interfering elements contents (Na, Br, Sb and others) up to a acceptable level;
- measurement of I-130 activity on a gamma-spectrometer device with Ge-Li detector;

The technique was tested on the soil samples which were taken from different regions of Russia contaminated as a result of Chernobyl accident (Cs-137 surface contamination ranges from 5 up to 18 Ci/km^2), and also in the vicinity of nuclear installations (near Obninsk).

The technique permits to determine the I-129 amount in quantities up to 3×10^{10} nuclee/kg at the I-129/I-127 ratio not more then 10^{-12}.

The limits of the technique sensitivity permit to use it not only for the restoration of "iodine impact" characteristics in the first period after nuclear power plant accident but also for the I-129 measurement in global fallout as a result of nuclear weapon tests and registration, control and reconstruction of iodine fallout near nuclear power plants.

Study on the Behavior of Technetium-99 in Soil Environment

S.Morita, H.Katagiri, H.Watanabe, Y.Akatsu and H.Ishiguro

Power Reactor and Nuclear Fuel Development Corporation,
Tokai-mura, Ibaraki, Japan

1.Introduction

Technetium-99 (Tc-99) is an important radionuclide for environmental assessment around nuclear fuel cycle facilities, because it has a long half-life and relatively high mobility in the environment. Its determination method, distribution and behavior in the environment have been studied.

While the method using an anti-coincidence type low background gas flow counter has been principally utilized as the conventional determination method for Tc-99, in recent years other determination methods such as neutron activation analysis and liquid scintillation counting method have also been considered. However, these methods are not effective to determine Tc-99 in environmental samples, because their detection limits are not low enough and measuring times are needed.

Inductively Coupled Plasma Mass Spectrometer (ICP-MS) is a quantitative and qualitative analysis apparatus having superior characteristics such as extremely low detection limit, high resolution, high precision, short measurement time and capability for simultaneous multi-elements analysis.

This study developed an analysis technique to acquire field data. As the results, several information regarding the distribution and behavior of Tc-99 in the surface soil environment was obtained.

2.Experimentation

The ICP-MS utilized was the PMS-2000 manufactured by Yokogawa Electric Corp. Japan. In order to enhance amount of sample feeding into plasma, the MISTRAL, a new type nebulizer made by ARL Corp. Switzerland, was connected with the sample feeding system. A schematic diagram of the ICP-MS is shown in Fig.1. The ICP-MS consisted of a nebulizer, ICP as an ion source, sampling interface, quadrupole mass filter, and detector. A solution sample was nebulized into the aerosol at the nebulizer and then ionized in the ICP. the ionized elements passing through the interface were focused by ion lens and then analyzed by the qua

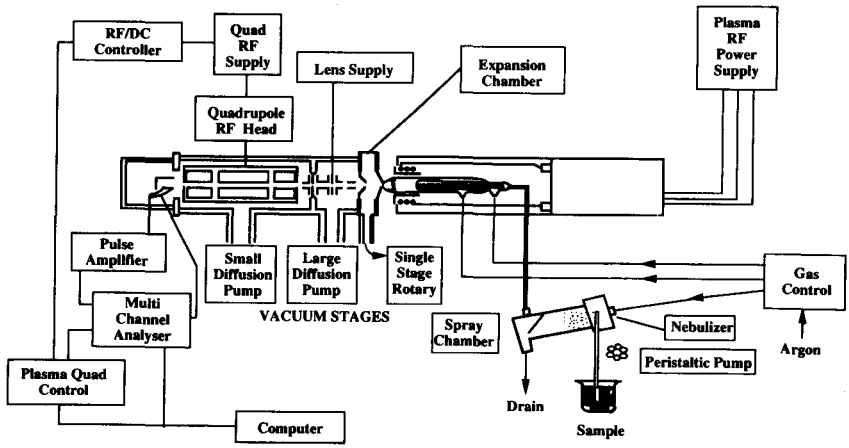

Fig.1 A schematic diagram of ICP-MS

3.Results and discussion

3.1 Development of high sensitivity measurement method for Tc-99

3.1.1 Ashing conditions

Because of high volatility of Tc-99, its volatilization loss might occur, if ashing is applied to dried samples without pretreatment. Therefore, a treatment method in which Tc-99 was changed to a nonvolatile chemical form before ashing with reductive agents such as hydrochloric acid and ammonia solution was investigated. As a result, ammonia solution pretreatment could improve the chemical recovery of Tc-99 to about 90%, which was 10% higher than that without the pretreatment.

3.1.2 Matrix effect on ICP-MS

If the concentration of matrix elements in a sample is high, the signal intensity of each peak in the ICP-MS is decreased due to plugging of the hole on the cone at the sampling interface. Therefore, to overcome this problem some countermeasures such as elimination of organic matrix by dry ashing and elimination of inorganic matrix by combined treatments of iron hydroxide coprecipitation, anion exchange and solvent extraction were carried out.

Table 1 Decontamination factors of Ru and recoveries of Tc for some separation methods

Separation method	D.F. of Ru	Recovery of Tc (%)
Chelate exchange	1.1×10^5	97
Solvent extraction		
TIOA-1M HNO_3	11	96
TBP-0.1M HNO_3	35	91
$C_6H_{10}O$-1M HNO_3	75	71
$C_6H_{10}O$-1M K_2CO_3	1.9×10^5	80
Coprecipitation (TPAC)	27	66

3.1.3 Elimination of the interference elements

If an isobar element is contained in a sample, it becomes impossible to determine the target radionuclide, because both the target radionuclide and its isobar have the same peak position in the mass spectrum. For example, ruthenium-99 (Ru-99) interferes with the determination of Tc-99. A countermeasure for this interference is to eliminate the isobar nuclide by using chemical separation treatments.

The results of decontamination factor tests for eliminating these interference elements using tracers showed that the chelate resin ion exchange method was useful for eliminating Ru-99 (Table 1).

3.1.4 Development of systematic analysis method

The results of the tracer tests indicated that the iron hydroxide coprecipitation method was suitable for separating Tc-99, and that the nitric acid form ion exchange method was appropriate for separating alpha emitting radionuclides such as Np-237 and Pu-239,240. The systematic analysis method developed in this study is shown in Fig.2.

The sensitivity of this method was 10 to 100,000 times higher, and the counting time was 300 to 100,000 times shorter than the conventional

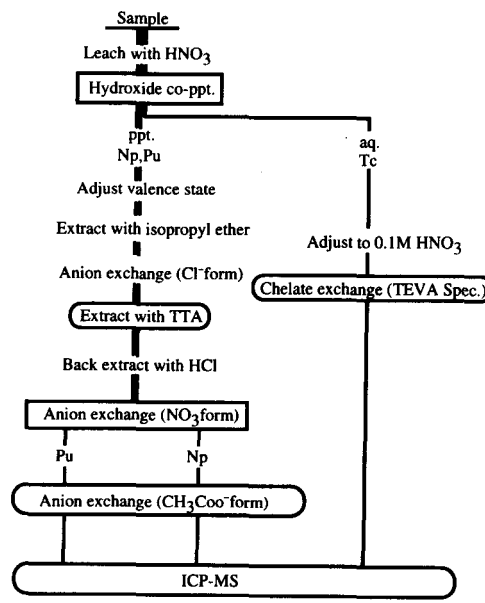

Fig.2 Systematic analysis method for Tc-99, Np-237 and Pu-239,240

radioanalytical methods.

3.2 Determination of environmental samples

3.2.1 Concentration levels of surface soil

The surface soil samples containing abundant amounts of organic materials were collected at nine points. The results for the surface layer soil samples are presented in Table 2. As the table indicates, the concentration levels of Tc-99 in Japan are found to be about 10^{-1} Bq/kg,dry.

3.2.2 Depth profile

Core soil samples were collected by an electric core sampler at one point. The core soil samples were divided into 10 layers of 5cm thickness. The depth profiles of Tc-99 and some long-lived radionuclides are presented in Fig.3. The concentration profiles show that more than 95% of each radionuclide is retained in the surface layer, up to 10cm in depth, which contains more organic materials. The results suggest that content of organic materials in soil is related to adsorption of radionuclides onto soil.

The retainment of Tc-99 onto surface layer appears to be contrary to the hypothesis that Tc-99 would have high mobility in soil, because Tc-99 forms an anion, i.e., TcO_4^- in oxidizable environment.

Table 2 Concentration of Tc-99 in surface soils

Sample	Concentrarion of Tc-99 (Bq/kg,dry)
Mito	$(1.8\pm0.06)\times10^{-1}$
Hitachinaka	$(1.0\pm0.03)\times10^{-1}$
Tokai	$(1.3\pm0.03)\times10^{-1}$
Rokkasyo	$(1.3\pm0.04)\times10^{-1}$
Rokkasyo	$(1.0\pm0.04)\times10^{-1}$
Rokkasyo	$(8.1\pm0.02)\times10^{-2}$
Okuetsu	$(5.8\pm0.09)\times10^{-1}$
Okuetsu	$(4.2\pm0.05)\times10^{-1}$
Fukui	$(1.9\pm0.09)\times10^{-1}$

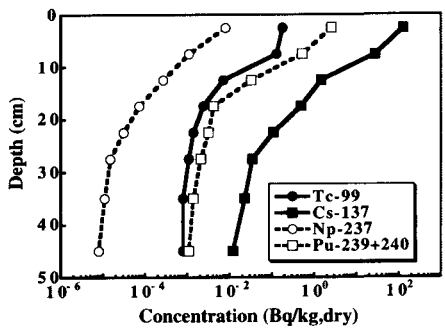

Fig.3 Depth profiles of Tc-99, Cs-137, Np-237 and Pu-239,240 in soil core

4. Conclusion

1. The development of the high-sensitivity determination method for Tc-99 and long-lived radionuclides using ICP-MS successfully improved detection limits as compared with conventional radioanalytical method, and the behavior Tc-99 which has not been elucidated so far to be analyzed from the field data.

2. The results of measurement of the environmental samples showed that the organic materials in the soil affected the adsorption of Tc-99.

3. Since Tc-99 is in an anionic chemical form under an oxidation atmosphere and transfers with water, its vertical transfer rate was considered to be fast, but the results obtained in the field were against this theory. This may stem from the formation of complexes with organic materials contained in the surface soil, reduction by organic acids and selective intake by microorganisms.

RADIOLOGICAL MONITORING IN SLOVENIA

R. Martinčič, M. Korun, U. Miklavžič and B.Pucelj

J. Stefan Institute, Ljubljana, Slovenia

Abstract: In the light of recommendations provided by ICRP, IAEA and other international bodies, an up to date monitoring programme should provide relevant data for a realistic quantative assessment of radiation doses likely to be received by members of the public. Radiological monitoring programmes in Slovenia are explained and discussed.

INTRODUCTION

The form of a monitoring programme is determined by a number of factors: the type and amount of radionuclides likely to be found in the environment, the principle pathways of exposure, the way by which the environment is used by man and the characteristics of the population, its distribution, social activities, means of earning its livelihood, dietary habits and the origin of the food it consumes. Slovenian activities in this field are just one example of how these general issues are being resolved.

MONITORING PROGRAMMES IN SLOVENIA

The overall monitoring programme in Slovenia consists of three major parts:

i. a general monitoring programme of the radioactivity in the country,
ii. three specific monitoring programmes in the surroundings of the Krško NPP, research reactor and Mine at Žirovski vrh,
iii. emergency monitoring programmes.

Basic programme structure is shown in Fig. 1.

The aim of National (general) Monitoring Programme is to control the external radiation and the specific concentrations of radionuclides in the environment and foodstuffs (Fig.2). It defines sampling locations, sampling and measurement frequency and list of interested radionuclides. Yearly assessment consists of dose assessment to the population, environmental contamination assessment and some projections. Unusual results in regular monitoring trigger supplementary monitoring programme which is in fact just an extended regular monitoring programme with an objective to clarify unusual results.

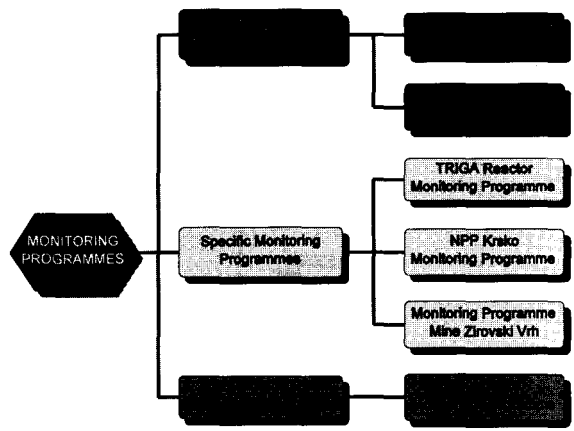

Figure 1. Monitoring programmes in Slovenia

Specific monitoring programmes are performed in the surroundings of nuclear facilities. The most comprehensive one is the monitoring programme around the Krško NPP (Fig. 3). It consists of three sub-programmes:

Programme A -

A-1 regular monitoring programme; it defines locations, methods and frequencies of monitoring of radioactive contamination of air, soil, rivers, precipitation and fallout, drinking water, human and animal feed;

A-2 extended monitoring programme; it defines increased sampling rates and additional sampling locations; it is triggered by unusual results of programme A-1 to clarify the

problem;

Programme B - the programme of effluent and intercomparison measurements;

Programme C - the emergency preparedness programme of the Ecological Laboratory with a Mobile Unit (ELMU).

While *Programme A* represents regular monitoring programme *Programme B* defines sampling locations, representative samples and frequencies of sampling for control measurements of liquid and

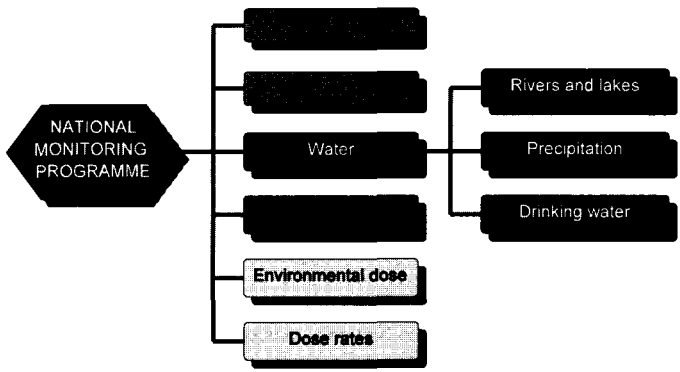

Figure 2. National monitoring programme

gaseous effluents and obvious intercomparison measurements. The aims of *Programme C* are intercomparison measurements between ELMU and Krško NPP, overall tests of emergency capabilities of ELMU, identification of any actual or potential weaknesses in equipment, procedures or team skills, team acquaintance with the surroundings of NPP, routes, measuring points and normal radiological parameters of the environment and finally improvements of the response plans, procedures and co-ordination. *Programme C* is for an adequate and efficient response in radiological emergencies of exceptional importance.

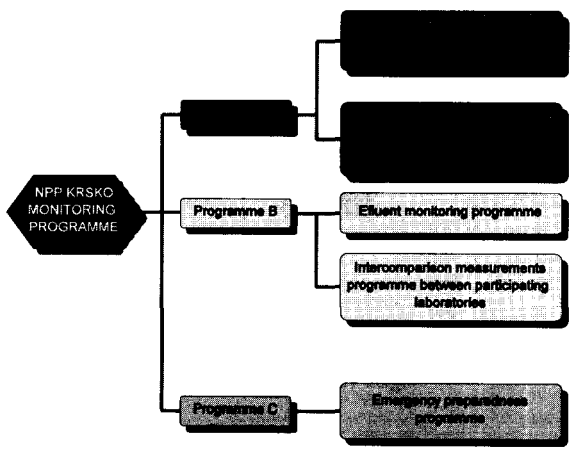

Figure 3. Structure of NPP Krško monitoring programme

Emergency monitoring (Fig. 4 and 5) consists of an early warning system and monitoring in EPZ. *Programme A* offers a sound basis for emergency monitoring. It supports a network of fixed measuring

points, a three circle network of TL dosimeters and a network of automatic meteorological stations with built-in gamma dose rate meters. The three basic networks are further supported by a network of accidental TL dosimeters, a network of fallout sample collection (vaseline plates) and a network of potential, predetermined measuring points.

Continuous monitors (MFM-202 of AMES Co.) with an automatically adjustable time constant supply data with a statistical uncertainty of $2\sigma = 5.4\%$. Thirteen such monitors around the NPP, which are on-line connected over MOBITEL to a central computer, together with 12 others installed at different meteorological stations distributed over Slovenia (so far operating autonomously) form the basis of an *early warning system* now under construction.

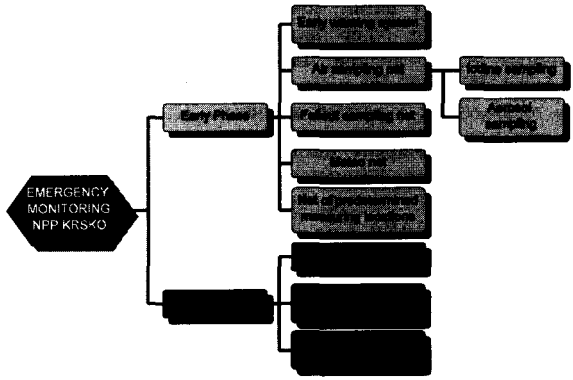

Figure 4. Off-site emergency monitoring programme structure

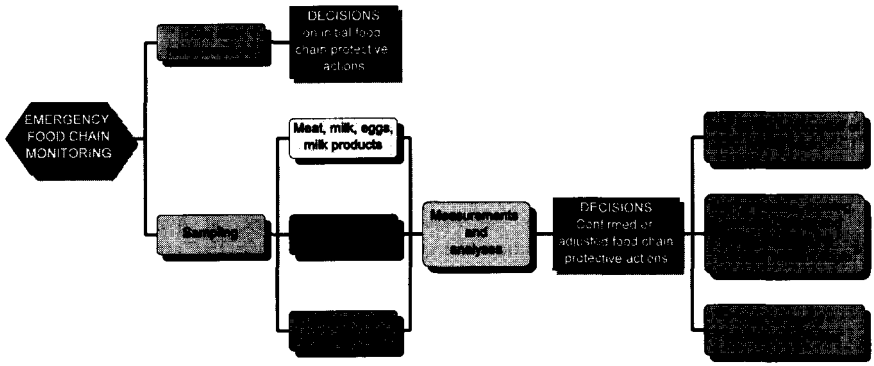

Figure 5. Emergency food chain monitoring

CONCLUSION

All monitored and quantitatively evaluated radiation burdens in the environment in the past 15 years have been in compliance with the licensed values, and well below the authorized limits specified by the competent authorities.

According to these data, the radiological impact on the environment of the Krško NPP for the last fourteen years of operation could be considered of minor significance and of a comparable order of magnitude to other radiological impacts in the Krško - Brežice region, caused by non-nuclear activities (paper - mill industry, hospitals, etc).

LONG-TIME ATMOSPHERIC ^{3}H AND ^{14}C RECORD IN CROATIA

Nada Horvatinčić, I. Krajcar Bronić, and B. Obelić

Ruđer Bošković Institute, Zagreb, Croatia

INTRODUCTION

The natural production of radioisotopes ^{14}C and ^{3}H in the atmosphere is in an equilibrium with their radioactive decay and their world-wide distribution has attained a steady state with subtle variations depending on the latitude, season and solar modulation. This steady state, however, was disturbed significantly during sixties, when the natural activities of ^{14}C and ^{3}H increased due to extensive nuclear bomb tests. ^{14}C and ^{3}H distribution in the atmosphere started to be monitored about at the same time, therefore, the peaks due to the anthropogenically produced ^{14}C and ^{3}H were recorded. Since then, atmospheric ^{14}C and ^{3}H activities are regularly measured as a part of a network (1, 2, 3) or local monitoring (4, 5).

In this paper we present the complete record of ^{14}C and ^{3}H data measured in Zagreb. We present an attempt of analytical representation of our data, and we compare our data with recently published ^{14}C records in Europe (1, 4) and in Canada (5), as well as with the tritium data in precipitation published by IAEA (3).

SAMPLING AND MEASUREMENTS

Measurements of atmospheric ^{3}H and ^{14}C activity have been performed in our laboratory since 1976 and 1978, respectively. Since then, tritium in monthly precipitation samples at Zagreb has been regularly measured, as well as precipitation at Ljubljana (Republic of Slovenia), and these results have been published in IAEA-WMO Technical Reports series (5). For shorter periods of time, tritium in monthly precipitation was measured at Plitvice National Park, SE from Zagreb, and in Rijeka, at the North Adriatic coast. Recently, we started to collect precipitation samples also on Mt. Medvednica, station Puntijarka, at ~1000 m a.s.l., nearby the city of Zagreb. We have been measuring also tritium activity in atmospheric water vapor since 1988 at the Institute and at several sampling sites in down-town Zagreb or in its surroundings, with the aim of studying possible local tritium contamination.

^{14}C in biosphere has been monitored through atmospheric CO_2, annual plants and leaves. Samples were collected at the sparsely populated area of Plitvice National Park and Mt. Medvednica, at the density populated area of Zagreb and in wider area of nuclear power plant Krško, which is located in Slovenia, ~20 km from the Croatian border. Measurements of ^{14}C activity of tree rings grown in the Plitvice National Park, at Mt. Matra (Hungary) and near Krško were used for reconstruction the past radiocarbon in the atmosphere.

Atmospheric water vapour were collected by absorption on silicagel. Samples of CO_2 were collected monthly by absorption on saturated NaOH solution. For ^{14}C measurement in tree rings cellulose samples of individual tree-rings were separated. All the samples for ^{3}H and ^{14}C measurements were converted to gas methane which is used as a counting gas in proportional counters.

RESULTS AND DISCUSSION

^{3}H in the atmosphere

^{3}H concentration in precipitation at three continental stations, Zagreb (1976-1995), Ljubljana (1981-1995) and Plitvice (1980-1982) closely follows each other showing seasonal changes typical for the temperature zone of the northern hemisphere with a decreasing yearly mean values. The yearly mean values in Zagreb and Ljubljana are closely correlated with those at Vienna station (3), as the closest continental station within the IAEA-WMO network. By using this

correlation we were able to reconstruct the past tritium activity in Zagreb (6). The ^3H measurements at Puntijarka station started in 1995. This station is assumed to be less affected by local contamination effects, such as fossil-fuel combustion or tritium release, than the nearby city of Zagreb. The first results show no significant difference in ^3H concentration between Zagreb and Puntijarka station. However, ^3H concentration at the coastal station Rijeka is, on the average, half of that at Zagreb, and is closely correlated to the nearest Mediterranean station Genoa.

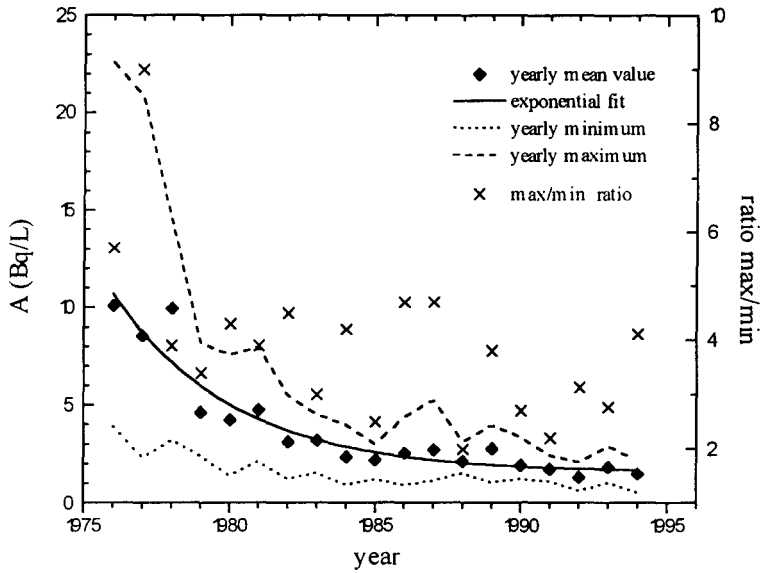

Figure 1. Statistically elaborated ^3H data in Zagreb precipitation.

The twenty year record of ^3H data in Zagreb precipitation is statistically elaborated in Fig. 1. Yearly mean values of Zagreb precipitation decrease from 10.1 Bq/L in 1976 to 0.5 Bq/L in 1994 and the decrease can be well described by the exponential decay curve (full line, Fig. 1). We show the maximal and the minimal activities in monthly precipitation during the year. Both values decrease following again approximately exponential decay. The lowest value, measured mainly in the winter time, in the last three years is 0.5 Bq/L, very close to the assumed natural pre-bomb tritium activities. The maximal value, measured mainly in summer period, are between 2 and 5 Bq/L. Similar activities were measured by Meijer *et al.* (4). We also present the behavior of the ratio of the maximal to the minimal yearly values. The values of max/min ratio fluctuate between 2 and 5 with an exemption in 1977 with a value of 9.

^3H concentration in atmospheric water vapour at Ruđer Bošković Institute was several times higher than that in precipitation from the same period. At all other investigated places the ^3H concentration in water vapour was very close to that in precipitation, so no local contamination similar to that at the Institute was observed. ^3H concentration in water vapour is much more locally affected than that in precipitation and it is a good indicator for local contamination.

^{14}C in the atmosphere

The summary of all ^{14}C environmental and atmospheric results is shown in Fig. 2. Values of atmospheric CO_2 are mean yearly values, those of plants are either single or average values of several plants, and "tree" stands for tree-rings. Curves fitted to the data of Plitvice tree,

period 1964-1986 (full line), as well as Zagreb atmospheric CO_2, period 1983-1995 (dotted line), are shown in Fig. 2. Data in Fig. 2 can be discussed in several time periods: 1) up to 1964, increase of $^{14}CO_2$ activity, 2) 1964-1969, period of fast decay of $^{14}CO_2$, app. 50-65‰ per year, 3) 1970-1979, lower decay rate, app. 20-30‰ per year, and 4) 1980-present, decay rate app. 10‰ per year. Assuming that no new sources will introduce new ^{14}C into the atmosphere and that the rate of fossil fuel combustion will remain constant, the extrapolation of the ^{14}C decay curve to the year 2000 gives $\Delta^{14}C$ value of 116‰ (fitted line, Plitvice tree) and 62‰ (fitted line, Zagreb CO_2), respectively. It means that atmospheric ^{14}C activity will approach 11% and 6%, respectively, above prebomb levels by the turn of the century. For comparison we used atmospheric $^{14}CO_2$ data from Germany (1), from the Netherlands (3) and from Canada (4). All data show the exponential decay of mean yearly ^{14}C activities, with half life of app. 8 years. Data from Canada (Fig. 2) agree very well with ^{14}C activities measured in Plitvice tree, resulting in similar extrapolated ^{14}C activity for 2000. Lower $^{14}CO_2$ activities in Zagreb indicate greater influence of fossil fuel CO_2.

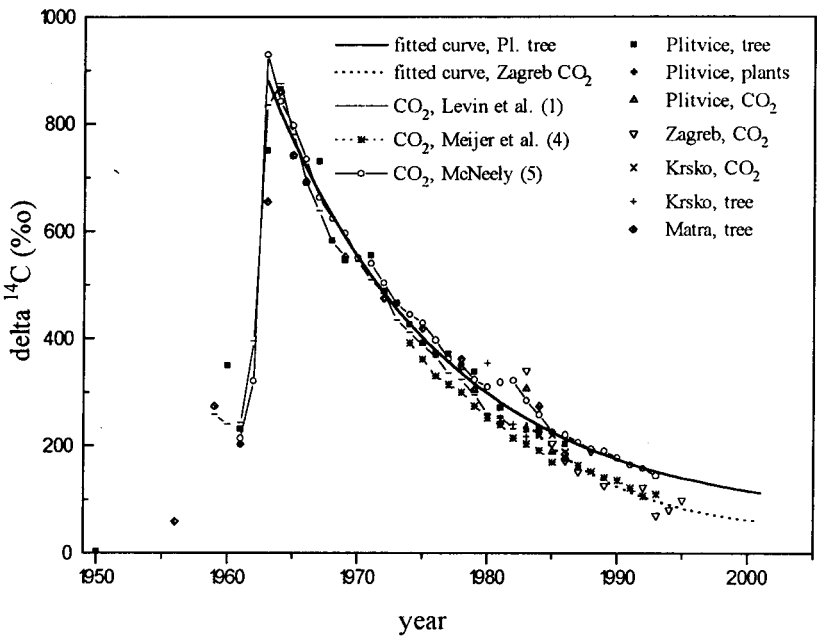

Figure 2. The ^{14}C activity of atmospheric CO_2 and tree rings. Fitted curve for Zagreb CO_2 and Plitvice tree extrapolated to 2000 and compared with the ^{14}C measurements in Germany (1), the Netherlands (4) and Canada (5).

ABSTRACT (See instructions overleaf)

Strontium isotope ^{90}Sr belongs to the group of isotopes which are very dangerous for human health. Therefore ^{90}Sr is regularly determined in natural samples such as soil, drinking water and food. When determining ^{90}Sr in natural samples it is necessary to isolate ^{90}Sr from the sample because ^{90}Sr is a pure β-emitter. As natural samples contain much more sodium and calcium than strontium, it is necessary to isolate a small quantity of strontium from a large sample with simultaneous separation of calcium and other interfering elements.For this purpose an elegant method based on ion exchange chromatography has been developed. Strontium is isolated from the natural sample and simultaneously separated from calcium, sodium, potassium, caesium, iron and some other elements on the chromatographic column filled with strong anion exchanger (type DOWEX and AMBERLITE) and alcoholic acid medium as eluent. Therefore, the paper will show the separation of strontium from caesium, potassium, sodium, calcium, barium and iron on two types of exchangers with different alcoholic acid eluents (ethanol + HNO_3, methanol + HNO_3). The application of the separation on fast ^{90}Sr isolation from a liquid sample will be presented and the possibility of fast and accurate determination of ^{90}Sr after isolation and separation from ^{90}Y on ion exchangers will be particularly considered.

ABSTRACT (See instructions overleaf) In the paper there are presented the results of the radioactive measurements on some main food items like: meat and meat products milk and dairy products; fresh vegetables and fruit, wheat and wheat flour.

The foodstuffs are sampled from six areas:Bechet(plain, near Kozloduj NPP, Bulgaria) Bucharest (plain, the most populated urban area); Cernavodă (plain, future NPP); Neamtz (mountain); Piteşti (hill, nuclear facility); and Sibiu (hill). Those areas are representative both from geographical and dietary point of view.

The measurements have been performed by usual methods of low-level high-resolution γ- ray spectrometry and radiochemical analysis.

The main considered radionuclides were: Cs - 134; Cs - 137, I - 131, Sr - 90, from the contaminating ones and K - 40 and Ra - 226 from the natural ones in the midlle of the 1986 there were identified other radionuclides too.

From these measurements there is also presented the evolution of the radioactive ammounts in the specified foodstuffs for the last decade.

On these basis there is assessed the contribution of the food consumption to the equivalent dose (ingestion dose) for the mean characteristic Romanian diets.

INVESTIGATION OF THE CONTENTS OF NATURAL RADIONUCLIDES IN COAL AND ASHES FROM KOSOVIAN POWER PLANTS

Feriz D. Adrović,[1] D. Todorović,[2] M. M. Ninković [2] and M. Prokić[2]

[1]Faculty of Natural Sciences-Mathematics , University of Priština , 38 000 Priština, Yugoslavia
[2]Institute of Nuclear Sciences " Vinča ", 11 000 Belgrade, Yugoslavia

ABSTRACT

The basic aim of this work was investigation of the contents of natural radionuclides in the samples of coal and in the products of its burning in Kosovian power plants, as the beginning steps to estimate total radioactive effects on the surrordning, having in mind that coal power plants are one of the more influental source of the redistribution of natural radionuclides.

The investigation has been done by gamma spectroscopy analysis using HP Ge detector, with relative efficiency of 20% and resolution of 1,8 keV in energy of 1332 keV ^{60}Co. The activity concentation of natural radionuclides in measuered samples of coal, ashes and slag were from 3,1 to 67 Bq·kg^{-1} for ^{226}Ra; from 1,7 to 32 Bq·kg^{-1} for ^{232}Th; from 0,3 to 6,5 Bq·kg^{-1} for ^{235}U; from 6,5 to 138 Bq·kg^{-1} for ^{238}U and from 14 to 234 Bq·kg^{-1} for ^{40}K.

INTRODUCTION

In the frame of the Kosovian basen there are more than as much as 10 billion tons of coal. In order to use this natural resources have been built some of the Industrial plants such as are : Thermal power plants Kosovo A and Kosovo B with the total instaled capacity of 1470 MW; dry plant with the capacity of 1.220.000 tons, gas plant with the capacity of 48 x 10^7 m^3, fertilizer factory with the capacity of 360 000 tons per year of KAN-a and other plants in the connection with the coal production.

Kosovian coal belongs to the group of the typical lignite. It is known for its high content of ashes (over 15%) and low thermal capacity (from 5 400 kJ·kg^{-1} to 10 500 kJ·kg^{-1}). The largest amount of this coal are used as unrefined energetic solid fuel in Kosovian power plants. The firebox is in the process is deposition of the slag in the firebox what is the cause of the increasing of ashes and the emission floated ashes in atmosphere.

Power plant Kosovo A belong to the old type plant. It is consist of 5 blocks which by its chomneys emits in atmosphere about 15% of producing ashes, what amounts for 5 000 h of yearly working of the plants about 1200 000 t per year. The second power plant is Kosovo B it consists of two energetic blocks and belongs to the contemporary plants. Its emission of ashes is about 1 000 000 t per year.

The air of this work is the monitoring of the content of natural radionuclides in coal and the products of the combustion in the process of the work of Kosovian plants. The influence of chemical products polution like as ashes, dust and gases from the smoke of stacks are is much more than radionuclides do it. To the risk of the radionuclides, which release in the process of the work of the power plants intented for producing of electrical energy, unsatisfactory pays attention and the negative contribution of this sourse becomes significant for the environment. So as it is well known according to estimates that power plant of 1 GW yearly release the collective effective doze of 20 man Sv (1).

MATERIALS AND METHODS

The analysed samples of coal have been collected from the surface mines of Kosovian basen Belaćevac and Dobro Selo. The first patterns were by means of the furrows which are placed in the coal drawings of the mine. But of that manner of collecting the samples gave up because of some reasons: The floors were as high as about 10 m , steeps and incomprehensible and therefore very dangerous for the gatherers of the samples. In addition to these facts, it was umpossible to reach some floors because of enormous maisture of the soil and coal appeared by the underground waters. Taking into consideration that facts the samples of the coal were done by the method of the raudomly samples. The samples were taken from the given quantities of coal on the conveyer belt and the freight cars for definite timing intervals. The samples size of coal were of the piece, cube, nut, hazelnut and coal dust. The samples of coal dust have been taken on coal depos on given places and different depths. The samples of deposited ashes have been taken from all phases of the electriphylters and in the some way on depos and lagoons . The samples of the slags have been taken below of the bunker for the slag

(on that place the slag is in the heaty state) and from the places where are in teh coal state. Some of these samples have been taken from lagoons where ashes and the slag are in the mixture state.

All samples after complex guartering and dreying at 105 % grinded to the granulation of the fine powder and brig down to the some volume. After done of the homogenous of the samples the samples were measuered and filled in the standard Marinelli plates. The Marinelli plates are then welded by beeswax because of the airtight of the samples. Prepared is such way, they are left to repose 30 days (before of the begninung of the measuring) in order to esstablish the radioactive equilibrium. The measuring gamma activity of the radioactive meterials in the samples has done by multy shanel gamma analyzer ORTEC with HP Ge detector with the relative efficiency of 20% and resolution (FWHM) of 1,8 keV at 1332 keV ^{60}Co. The callibration of energy has been done by the standard series of points sources (Coffret d´etalon ECGS-2, Sacle) which contain the radionuclide ^{133}Ba, ^{60}Co, ^{137}Cs, ^{22}Na and ^{241}Am (activity of 10^3 Bq at day 29.11.1977.). The geometrical efficiency was given by the referent material-soil, contaminated by series of radionuclides ^{22}Na, ^{57}Co, ^{60}Co, ^{88}Y, ^{133}Ba and ^{137}Cs with the activities between 122-355 Bq/kg (total 1461 Bq/kg at the day 1.7.1991.) with the total uncertainity of 5% (National Office of Measures OMH, Budapest) (2).

The activity of ^{226}Ra and ^{232}Th is determined, using their descendants ^{214}Bi ,^{214}Pb and ^{228}Ac , ^{208}Tl , respectively. The activity of ^{235}U is determined on energy of 185,83 keV with correction on ^{226}Ra (186keV). The activity ^{238}U we computed using natural relate of the activity of ^{235}U/^{238}U which is 0,04604. The activity of ^{40}K we computed using its only tranzition an 1460,8 keV. The correction taking into consideration the autoapsorption was not done, because there were not significant difference among obtained concentration for ^{226}Ra and ^{232}Th in the selected spectrum lines (3). The time of collecting the pulses i.e. recording time of the spectrum, was from 10^5 to $3x10^5$ s depending of the activity of the samples.

RESULTS AND DISCUSSION

The results of the experimental measuring of specific activity of ^{226}Ra, ^{232}Th, ^{235}U, ^{238}U and ^{40}K in samples of coal are shown in Table 1. It descibes intervals of the concentration of the activity for monitored radionuclides for each kind of the coal samples for diferent radiuses.

In Table 1. has been seen that analysed samples of coal contents almost the same concentracion of the activity of monitored samples with the except the samples of the coal dust. The reason for enlarget concentration of the activity in the coal is affter all in the prensence of the floating ashes emited by the chimney of the power plants and it deposits in the depos. On the base of obtained results may be appraissed that the concentration of activity of the natural radionuclides in the monitoring samples of Kosovian lignite are relatively lower in comparison with the concentration of activity in other countryes in the world (4)

Tabele 1. The range specific activity of the natural radionuclides (Bq kg^{-1}) in the samples Kosovian lignite

Kind of the samples	^{226}Ra	^{232}Th	^{235}U	^{238}U	^{40}K
coal piece	3,1-4,9	1,7-4,2	0,29-0,42	6,5-9,1	14-87
coal cube	4,5-7,7	3,5-4,3	0,43-0,52	9,4-11	19-20
coal nut	3,5-5,8	4,1-4,9	0,56-0,71	12-15	14-25
coal hazelnut	4,2-14	4,8-8,6	0,47-1,1	10-23	25-32
coal dust	7,3-25	8,0-18	0,61-4,5	13-45	49-97

The experimental results of the measuring of the specific activity of ^{226}Ra, ^{232}Th, ^{235}U, ^{238}U and ^{40}K in samples of ashes and slag as the products of the combustion in Kosovian plant are shown in Table 2.

In analysed samples of ashes the biggest concentration of the majorits of the tested radio-nuclides is presented in the samples of ashes of the bottom of the chimney funnel. Because of that fact we my suppose that the content of U and Ra enlarges with the lowering the diameter of the particles (5). In Table 2. can be seen that the concentration of activity ^{40}K is the biggest in the samples of the slag. The reason of that facts we should to try in the physical-chemical features of potassium as and that facts that the slag is waste materials which consists of enough uncompletely burned organic material in coal.

Table 2. The range specific activity the natural radionuclides (Bq kg^{-1}) in the samples of ashes and slag because of burning of Kosovian lignite

Kind of the samples	^{226}Ra	^{232}Th	^{235}U	^{238}U	^{40}K
ashes from the bunker	12-20	14-20	1,9-2,2	43-48	150-199
ashes from the palettyser	15-67	16-31	2,1-4,5	45-138	179-219
ashes from the electrofilter	14-23	16-18	2,0-3,5	46-65	108-179

ABSTRACT

The results of natural (K-40, Ra-226, Th-232, U-235) and fallout radionuclides (Cs-134, Cs-137) activity estimation in mat (surface layers of uncultivated soil) of a mountain region are presented. The samples were collected on locations with limestone, shale or mixed type soil. The activity of the radionuclides was determined on a HPGe detector by standard gamma spectrometry.

Mats of shale soils have higher content of Ra-226 and Th-232 than those of limestone, while for K-40 and U-235 there are no significant differences due to the type of soil. Compared to the samples taken from the depth of 5-15cm, the content of Ra-226, Th-232 and U-235 is lower in the surface layers; for K-40 there are exceptions, mainly on limestone soils. The content of Cs-137 and Cs-134 in mat is much higher than in deeper layers of soil, indicating slow migration, except on the riverside.

INTRODUCTION

The long-term radioactivity investigations in a mountainous part of central Serbia (rich in honey-bee pastures and meadows) indicated two radioecological areas: one with the lower gamma field intensities, mainly on limestone and the other with higher exposure rates, on shale soils (1,3). The exposures were supposed to be mainly due to natural radionuclides in soil (4), but Chernobyl radionuclides (Cs-134, Cs-137) could not be neglected (3,5). These investigations are a part of a project dealing with determination of natural radionuclides and Cs-134 and Cs-137 in meadow flora, soil and honey in the region.

MATERIALS AND METHOD

The samples of mat (surface layers of soil with roots of meadow flowers, 25x25cm) were randomly collected on eight locations in a mountain region (300-1000m above sea level), in summer 1991. The soils differ in physical and chemical

characteristics: limestone is predominant (locations II, IV, VI, VIII, partialy III), but shale soils can be found, too (locations I, V, VIII). The samples were dried on the room temperature, grinded, weighted in standard Marinelli beakers (0.5 l) that were sealed by a honey-wax film and left for 4 weeks to reach the radioactive equilibrium.

The activity of the radionuclides was determined on a HPGe detector(relative efficiency 20%) by standard gamma spectrometry. Geometric efficiency was determined by a reference soil standard (National Office of Measures,Budapest) spiked with a series of radionuclides (Na-22, Co-57,60, Y-88, Ba-133, Cs-137; activities 122-135 Bg/kg on 1.7.91, overall uncertainty 5%).

Counting intervals ranged from 150.000 - 300.000s and the background radiation was checked regulary after or before the sample. Total standard error of the method was 15%.

RESULTS AND DISCUSSION

The activities of natural and fallout radionuclides (Bq/kg dry weight) ± total error of the method are presented in Tables 1 and 2, respectively. On locations where two samples of mat had been taken, both results were presented. LLD denotes lower limit of detection.

Table 1. Activity (Bq/kg) of natural radionuclides in mat

Location	Ra-226	Th-232	U-235	K-40
I1	27 ± 4	36 ± 5	3.0 ± 0.4	378 ± 52
I2	26 ± 4	38 ± 6	2.6 ± 0.4	396 ± 59
II	21 ± 3	35 ± 5	3.1 ± 0.5	528 ± 79
III	38 ± 8	50 ± 8	3.6 ± 0.5	446 ± 67
IV	17 ± 3	22 ± 3	5.1 ± 0.4	307 ± 46
V	25 ± 4	27 ± 4	2.7 ± 0.3	436 ± 65
VI	6 ± 1	5 ± 1	LLD	219 ± 33
VII	50 ± 8	39 ± 6	4.3 ± 0.6	554 ± 83
VIII1	44 ± 7	54 ± 9	4.5 ± 0.7	827 ± 124
VIII2	38 ± 8	49 ± 8	5.2 ± 0.4	731 ± 109

Generally, mats on shaleous soils have higher contents of Ra-226 and Th-232 than on the limestone, while for K-40 and U-235 there are no significant differences due to the type of soil. Compared with the content of natural radionuclides in 5-15cm layers on the same locations (4), the content of Ra-226 and Th-232 is higher in mats, for U-235 no reliable conclusion can be made and for K-40, its content on limestone soil is lower in mat or there are no differences.

Table 2. Activity of Cs-134 and Cs-137 (Bq/kg) in mat

Location	Cs-137	Cs-134
I1	253 ± 38	23 ± 4
I2	161 ± 24	15 ± 2
II	126 ± 19	10 ± 1
III	450 ± 68	38 ± 6
IV	967 ± 145	91 ± 14
V	860 ± 129	76 ± 12
VI	1225 ± 184	118 ± 18
VII	942 ± 138	83 ± 13
VIII1	813 ± 122	69 ± 10
VIII2	1600 ± 240	158 ± 24

The content of Cs-134 and Cs-137 in mat is significantly higher than in deeper layers (5-15 cm), except on a location (I), with typical shale soil where the nearby river caused high washout. The vertical distribution of both cesium isotopes (their ratio confirming their Chernobyl origin) in soil strongly depends of soil configuration and physico-chemical properties (6).

THE RADIATION MONITORING ON THE TERRITORY OF BELARUS.

Ivan I.Matveenko, Vladimir N.Pikalov, Vladimir L.Samsonov.

State Commitee for Hydrometeorology
Centre of Radiation and Environment Monitoring
Minsk, Belarus.

Introduction.

On the territory of the Republic of Belarus works the points network of radiation-ecological monitoring of environmental objects by the special programs.

Accoding to the article 40 of the Low of the Republic of Belarus "About law regime of the territory exposed to a radioactive pollution following the accident on the Chernobyl NPP " the Committee for Hydrometeorology of the MES of RB accomplishes a total estimation of radiation situation on the territory of the Republic [radiation monitoring] and a methodical quidance [see figure 1].

General part.

Air, surface water and earth monitoring within the reference observation network.

From 1963 in the Republic has been realized observations of ambient air radioactive contamination. In the presence on 54 stations every day are measured a power of the exposure gamma-radiation dose rates. The measurements in the 100 kilometres zone of NPP influence are realized every 3 hours. On 24 stations placed on all the territory of the Republic of Belarus is controled the level of radioactive precipitation from the land atmospheric stratum [horizontal plane-tables]. In 6 cities of the Republic [Minsk, Mogilev, Gomel, Brest, Mozir, Pinsk] is daily measured the content of radioactive aerosoles in the air using filter-ventilation installation [see figure .2].

The laboratories of the Committee for Hydrometeorology realize constantly the measurements of gamma-radionuclides, strontium -90 and plutonium in precipitation and aerosole samples.

Systematical control of the radioactive surface water and ground accumulations contamination is carried out on 5 main rivers of Belarus such as Dnepr [range in Retchitsa], Soge [range in Gomel], Iput [range in Dobrush], Besed [range in Svetilovichi] and Pripyat [range in Mozir] run on the contaminated territory.

From 1986 have been accomplished the radiation inspection of all the territory of Belarus including settlements, agricultural and forests areas with the participation of the Academy of Sciences, the Ministry of Agriculture, the Ministry of Forestry and other ministries and departments.

From 1992 the Committee for Hydrometeorology has been accomplished the radio-oecological earth monitoring within the reference network included 18 landscape and geochemical grounds and 181 reference sites.

CONCLUSIONS.

The observations accomplished in the period of 1990-94 showed an availability of the short-time [seasonal] risings of atmospheric air radioactiveness. Futhermore were detected the air radioactiveness rising at the expence of the dust lifting in the time of field works, it was possible the radioactiveness rising during the forest fires. But it should be noted that these risings are short-time. By the data of the Committee the short-time radioactiveness rising in the air during the forest fires doesn't influence on the whole the content of surface earth radionuclides.

For all the observed period from 1987 the excuding of caesium -137 content on the surface water of the main rivers of Belarus has not been observed. The caesium -137 taking out by surface water of the territory of Belarus has been considerably decreased in due course.

The observations showed that the intensity of radionuclides migration on vertical line was losely connected with the genetical peculiarity of the earth. The analysis of received data showed that.

Analysis of collected data shows, the most intensive migration of radionuclides are concentraded in the upper 5-8 layer.

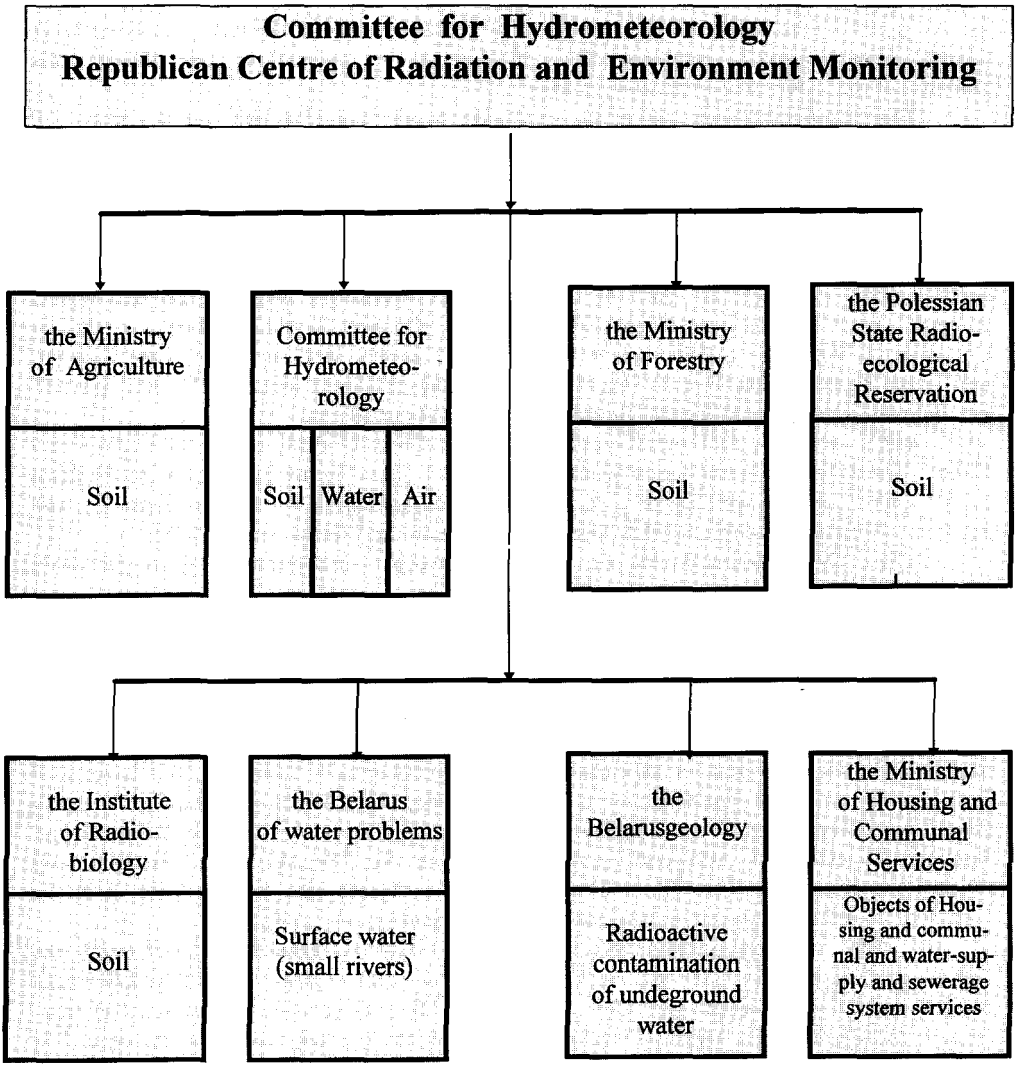
The Radiation Monitoring System

on the territory of Belarus



UP-TO DATE STATE AND DYNAMICS OF RADIOECOLOGICAL SITUATION AT THE EAST-URAL RADIOACTIVE TRACE IN SVERDLOVSK OBLAST

Victor N.Chukanov, Boris A.Korobitsin

Institute of Industrial Ecology, Ural Branch of Russian Academy of Sciences, Ekaterinburg, Russia

The 1957 explosion of a tank filled with highly radioactive waste solutions at the "Mayak" nuclear facility caused a radioactive contamination of the northern part of Chelyabinsk Oblast and the southern part of Sverdlovsk Oblast. The contaminated territory was called the East-Ural radioactive trace (EURT).

In 1992-1994, a detailed radioecological study on territory of the EURT in Sverdlovsk Oblast was carried out by combined efforts of a number of organizations under the scientific guidance of the Institute of Industrial Ecology.

The investigated area was about 1600 km^2. More than 3500 soil samples from 370 testing sites were studied. The 5-10 cm layers of soil were cut horizontally to a depth of 40-70 cm. Radiochemical analyses for ^{90}Sr and ^{137}Cs were carried out.

It was discovered that, to this day, there are significant levels of ^{90}Sr contamination in Sverdlovsk Oblast, especially in the Kamensk district. Along the axis of the radioactive trace there is large territory where the average ^{90}Sr contamination is within 1-3 Ci/km^2, with some spots having activities of over 5 Ci/km^2. These territories include the settlements Rybnikovskoye, Bogatenkovo, Shcherbakovo, Kluchi, Kluchiki, Kodynka, Malaya Kodynka, Cheremkovo, Belovodje and Svoboda with the total population of about 3200. In the southern part of the Kamensk district the width of the trace within the limits of 1.0 Ci $^{90}Sr/km^2$ is 12-15 km and within the limits of 0.1 Ci $^{90}Sr/km^2$ the width is about 30 km.

The present ^{90}Sr contamination of the town Kamensk-Uralskiy varies from 0.06 to 6.9 Ci/km^2. The average contamination levels vary from 0.3 Ci/km^2 in the eastern part of the town to 0.7 Ci/km^2 in the western part. The average contamination of the Bogdanovich and Kamyshlov districts is within 0.2-0.4 Ci/km^2, with a maximum value up to 1.2 Ci/km^2.

The ^{137}Cs contamination levels in the investigated part of Sverdlovsk Oblast are within 0.02-3.1 Ci/km^2, with an average value of 0.3 Ci/km^2.

The plutonium content in samples from three soil sections on the EURT axis in the southern part of the Kamensk district corresponds to the level of surface contamination 0.005-0.03 Ci/km^2.

The concentration of ^{90}Sr in the main wood species ranges at present from 1 to 100 Bq/kg air-dry wood for pine trees, from 2 to 230 Bq/kg air-dry wood for birch trees and from 3 to 470 Bq/kg air-dry wood for aspen trees. The contamination of wood by ^{137}Cs is up to 7 Bq/kg air-dry wood for pine trees, up to 35 Bq/kg air-dry wood for birch and up to 50 Bq/kg air-dry wood for aspen. The contamination of mushrooms in the territory of Kamensk and Bogdanovich districts is 6-53 Bq/kg air-dry mushrooms for ^{90}Sr and 29-143 Bq/kg air-dry mushrooms for ^{137}Cs. The ^{90}Sr soil-to-plant transfer factors (Bq kg^{-1}/Bq m^{-2}) in forest ecosystem in the south-eastern part of Sverdlovsk Oblast are shown in Table 1.

In 1962, when the annual monitoring of the lakes of the Kamensk district was began, the ^{90}Sr concentration in the water of Lake Tygish was approximately 200×10^{-12} Ci/L and of Lakes Sungul' and Chervjanoe ~50×10^{-12} Ci/L. The present ^{90}Sr concentration in the water of these lakes is (7-20)$\times10^{-12}$ Ci/L. During the whole period after the accident the concentration of ^{90}Sr in the water of all three lakes decreased by a factor of two over 15 years, i.e. somewhat shorter than the half-life period of ^{90}Sr (Figure 1).

TABLE 1. THE ^{90}Sr SOIL-TO-PLANT TRANSFER FACTORS, 10^{-3} m^2/kg

FOREST PRODUCT	TRANSFER FACTOR
Pine (wood)	1.1
Birch (wood)	2.4
Aspen (wood)	3.9
Mushrooms	1.7-24

TABLE 2. THE ^{90}Sr CONCENTRATION IN FISH IN 1982-1993, 10^{-9} Ci/kg

LAKE	^{90}Sr CONCENTRATION	
	IN FLESH	IN BONES
Tygish	1.0-4.2	6.4-41.7
Sungul'	0.2-2.0	4.5-23.0
Chervjanoe	0.2-1.0	11.6-34.4

For Lake Tygish which is the most contaminated, the mean concentration of ^{90}Sr in the bottom sediments is $(5\text{-}60)\times10^{-9}$ Ci/kg of dry substance.

The annual measurement of ^{90}Sr concentration in fish of the Lakes Tygish, Sungul' and Chervjanoe was carried out from 1968. In 1982-1993, the ^{90}Sr concentration in fish (crucian and carp) from these three lakes varied in the intervals which are shown in Table 2.

From 1968 onwards, the water-to-fish ^{90}Sr transfer factor (Bq kg^{-1}/Bq L^{-1}) is approximately constant and varies over a range of 15-60 for water-to-flesh transfer and 400-2400 for water-to-bone transfer.

The ^{90}Sr concentration in the water of the Kamenka River, which intersects the EURT, in summer 1993 was $(1\text{-}2)\times10^{-12}$ Ci/L. In the water of its small tributaries, which run over the territory where the average ^{90}Sr contamination is within 1-2 Ci/km^2, it was $(1\text{-}15)\times10^{-12}$ Ci/L. The contamination of the bottom sediments of the Kamenka River by ^{90}Sr in 1993 was $(0.6\text{-}2.0)\times10^{-9}$ Ci/kg dry weight, and the contamination of aquatic plants was $(0.1\text{-}1.9)\times10^{-9}$ Ci/kg dry weight.

To predict the concentration of radionuclides in the water of the rivers which run over the contaminated territory, the washout factor of radionuclide from the catchment-areas to the river water (concentration in water, Bq×m^{-3}/average contamination of the catchment area, Bq×m^{-2}) is usually used. For the small tributaries of the Kamenka River the washout factor of ^{90}Sr from the catchment-areas to the river water is 0.01-0.05 m^{-1}.

The ^{90}Sr contamination of foodstuffs produced in the territory of the EURT in the Kamensk district is approximately in 5 times higher than the average contamination in Sverdlovsk Oblast. In 1993, the average concentration of ^{90}Sr in the vegetables from the most contaminated part of the Kamensk district was the following: milk 15.9×10^{-12} Ci/L, potatoes 9.5×10^{-12} Ci/kg, carrot 116×10^{-12} Ci/kg, cabbage 852×10^{-12} Ci/kg.

Because of the high age of the radioactive fallout the radioactive contamination of foodstuffs is quite stable (Figure 2). A major factor conducive to lowering the radioactive contamination of the territory will be the physical decay of ^{90}Sr.

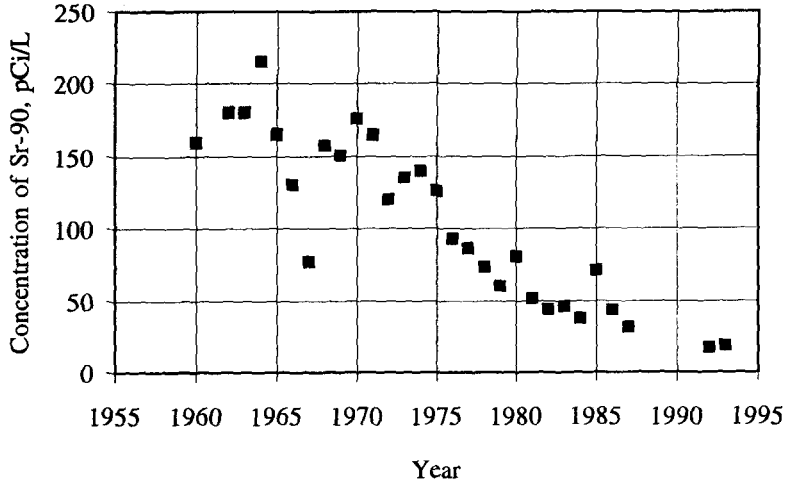


Figure 1. The decrease of the ^{90}Sr concentration in the water of Lake Tygish

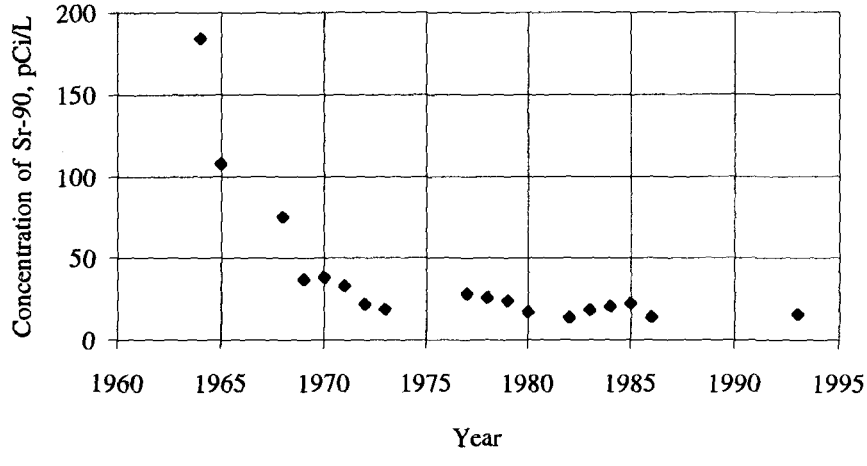

Figure 2. The decrease of the ^{90}Sr concentration in the milk from the EURT territory in Kamensk district

AERIAL MEASUREMENTS WITH HELICOPTERS TO DETERMINE ACCIDENTAL RELEASES FROM NUCLEAR FACILITIES

I. Winkelmann, H. Buchröder, M. Thomas
Federal Office of Radiation Protection, Köpenicker Allee 120-130, 10318 Berlin, Germany

ABSTRACT

Aerial gamma ray spectrometry is a useful tool for providing a rapid and comprehensive assessment of the dispersion and deposition of radionuclides over wide areas in post accident situations in nuclear facilities. This paper describes an aerial measuring system for nuclide specific measurements of soil contaminations and for detecting sources of gamma radioactivity. The measuring device consists of several components that can be separately installed in an Alouette II type helicopter. The central unit is a computerized gamma ray spectrometer with a high purity Ge-semiconductor detector and a 12 l volume NaI(Tl) scintillation detector array. At a flight altitude of 100 m, soil contaminations of some kBq/m^2 of ^{137}Cs can be measured (measuring time: 60 s, flight speed: 100 km/h). This aerial measuring system was for the first time operatively applied for measuring the deposition of artificial radionuclides in the southern part of Germany after the Chernobyl accident. Nuclide specific soil contamination measurements were also performed in the former USSR in a region north of Chernobyl, with values of up to 2 MBq/m^2 for nuclide deposition, and in selected areas in Finland. The results from these measuring campaigns are presented here.

INTRODUCTION

The Federal Office for Radiation Protection has been involved in developing measuring methods for monitoring nuclear power plant emissions and immissions since the early 70ies. There were also early investigations into the possibility of using aerial measuring systems in helicopters for monitoring radioactive substances released into the environment, particularly those due to nuclear accidents. As a result of these investigations the Federal Office for Radiation Protection developed and tested a measuring system to be used for aerial measurements. A prototype of this aerial device - from industrial aspects - was constructed by the Henschel Aircraft Corporation in Kassel in 1990 and developed to the point of serial production. By the end of 1993 five industrially manufactured aerial measuring systems were delivered to the Federal Office for Radiation Protection.

MEASURING SYSTEM

The aerial measuring system consists of several components that can be separately installed in an Alouette II type helicopter. The central unit is a computerized gamma ray spectrometer with a high purity Ge-semiconductor detector of a relative efficiency of 50 %. In addition, a NaI(Tl)-scintillation detector array (three individual prismatic detectors each with a volume of 4 l) is used for detecting sources of radioactivity. Each crystal is equipped with its own photomultiplier tube. The detector array is mounted in an aluminum box on shock absorbers and temperature insulated. The computer is equipped with spectrometric cards, each fitting the high voltage and the power supply for the detectors and, further, with main amplifiers and analog-digital-converters. The adjustment of the individual measurement parameters is computer-aided and all measurement values shown in flight are recorded on a monochrome screen. The altitude is continuously measured by radar altimeter. The indicator gauge instrument is fitted to the instrument panel for easy in-flight viewing by the pilot. The position of the helicopter is determined by a GPS satellite navigation system. In addition, the flight route is recorded by a CCD video camera with wide-angle lens and a video recorder with integrated color display. The technician's remarks are also recorded on video magnetic tape. The instruments are designed to work on a supply of 28 Volts DC available in the helicopter. The installation of all components in the Alouette II type helicopter was done by Henschel Aircraft Corporation. Altogether, five helicopters of the type Alouette have so far been properly refitted to house the measuring device. This includes the radar altimeter with antennas, the indicator gauge, cabling and the necessary power outlets in the cell wall. Likewise refitted were mountings and power cables for the video camera.

At a measuring time of 60 s, a ^{137}Cs soil contamination of some kBq/m^2 can be measured from an altitude of 100 m (flying speed 100 km/h). With the NaI(Tl)-detectors sources of gamma radiation of an activity of some GBq can be detected (altitude 100 m, line spacing 300 m, flying speed 100 km/h). Under such conditions, one helicopter can cover an area of about 30 km^2 per hour.

The entire measuring device can be installed or removed from properly refitted machines by two persons within about 30 min. The equipment has a weight of 120 kg. The expenses for procurement, including refitting costs, are about 400,000 DM per unit. The helicopters are operated by the Federal Border Police. The German Federal Aviation Agency has licensed this system to be operated in an Alouette II helicopter.

RESULTS

Measurements in southern Germany

After the Chernobyl reactor accident aerial measurements were performed to measure the deposition of artifical radionuclides in the southern part of Germany. The region between Danube river and the Alps was flown in parallel routes at distances of 10 km and a flying speed of approximately 100 km/h. The average altitude was 100 m above ground level. A measuring time of 60 s was chosen for each individual spectrum. Under these conditions, each of the measured values represent a mean contamination value over a distance of about 1.7 km. For evaluating the spectra, a ^{137}Cs activity distribution in soil was used as determined from soil sample measurements in areas monitored by these flights. In most cases, fields (unknown activity distribution) and smaller wooded areas were of little influence. Figure 1 shows results from a measurement flight in southern Germany with the highest ^{137}Cs-deposition values. Along this flight route from Munich in the direction of the Austrian border, a ^{137}Cs soil contamination was measured, ranging between 10 kBq/m^2 and 60 kBq/m^2.

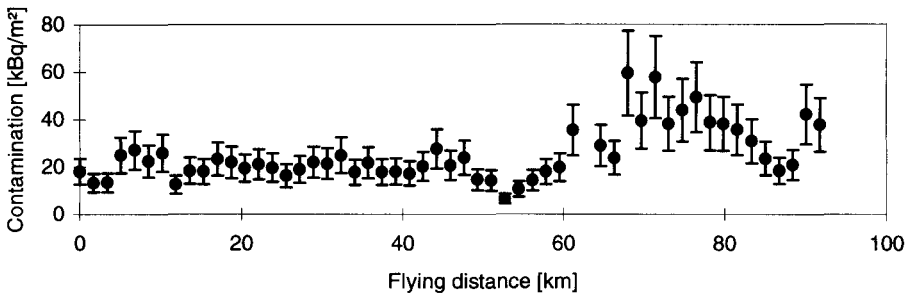

Figure 1. ^{137}Cs soil contamination along a flight route from Munich to the Austrian border.

The measurement uncertainty was estimated to be 30 %. Apart from the uncertainties in determining the photopeak count rate, inhomogenities in the distribution of activity in soil and variations in the altitude above ground contribute essentially to the measurement uncertainty. The measured ^{137}Cs values are in good agreement with the results from measurements obtained by other methods (1).

Measurements in the former USSR

This aerial measuring system (as a prototype) was used for nuclide specific measurements of soil contamination in the former USSR in a region north of Chernobyl with a ^{137}Cs contamination of up to 2 MBq/m^2. One flight was taken from the airport in Mogilov in Belorussia in south-eastern direction to an area near the town Krichev, approximately 100 km south-east of Mogilov and 260 km north of Chernobyl. A further flight was performed south of Mogilov covering a total distance of approximately 200 km. The soil contamination was measured continuously with the HPGe-detector. The flight altitude was approximately 100 m, the measuring time for each spectrum was 60 s. For the evaluation of the measured spectra, a relaxation depth of 6 cm was used. ^{137}Cs and ^{134}Cs could be measured by these flights. As an example, Figure 2 shows the soil contamination due to $^{137137}Cs$, measured during the outward and return flight from the Mogilov airport to the above mentioned measuring site near Krichev. At a flying speed of 150 km/h each value corresponds with a distance of about 2.5 km. At the return flight - another flight route north of the outward flight route - only one area with a ^{137}Cs soil contamination of up to 500 kBq/m^2 could be seen.

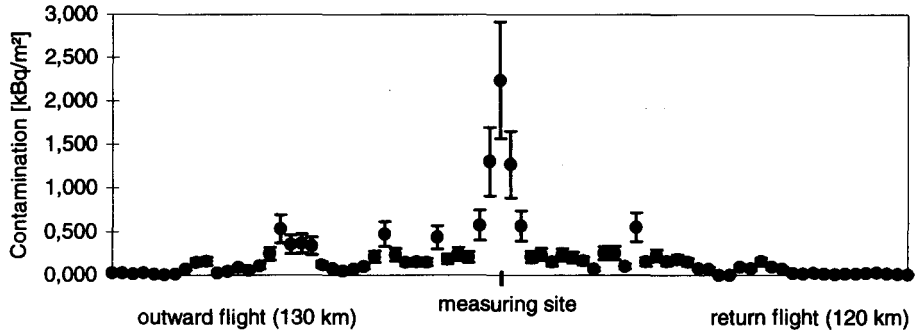

Figure 2. ^{137}Cs soil contamination along the outward and return flight route from Mogilov airport to a measuring site close to Krichev (Belorussia).

The first flight was taken over an area with relatively low contamination in south-eastern direction (< 200 kBq/m^2) to an area with a contamination between 200 and 600 kBq/m^2 in the middle the outward flight route of followed by an area with again low contamination. The following areas with differently high contamination were also clearly detectable. South-west of Krichev at a selected measuring site, a ^{137}Cs soil contamination of more than 2 MBq/m^2 was measured. At this site additional measurements of soil contamination were performed from various altitudes within the scope of an international intercomparison measurement campaign (data not reported here). The measured value for ^{134}Cs was (250 ± 70) kBq/m^2. A comparison with other data show a good agreement within the scope of accuracy (2).

Intercomparison measurements in Finland

In August of 1995, the Federal Office for Radiation Protection had an opportunity to participate in an international measuring campaign in Finland, using the helicopter measuring system. Eleven measuring teams from seven European countries participated in this exercise. Nuclide specific measurements were performed to determine the soil contamination. A selected area (3 km x 6 km), about 120 km north-west of Helsinki, was surveyed in parallel lines at an altitude of about 70 m and in 150 m parallel line spaces. The soil contamination was measured with the here described computerized Ge-semiconductor gamma ray spectrometer. The measuring time for each spectrum was 30 s, corresponding with a flying distance of 850 m (at an flying speed of 100 km/h) for which an average soil contamination value can be measured. For the evaluation of the measured spectra, a relaxation depth of 1 cm was applied, measured from soil samples. Figure 3 shows the results from the 21 flight routes covering this measuring area. The average ^{137}Cs-value was measured to be about 70 kBq/m^2 with a maximum value of up to 120 kBq/m^2.

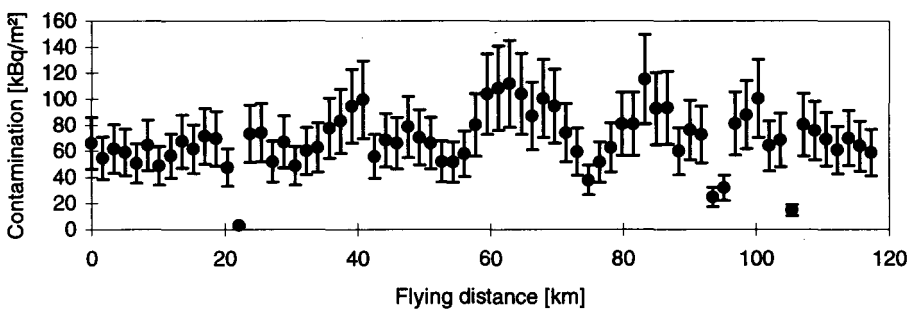

Figure 3. ^{137}Cs soil contamination along the flight routes covering an area of 3 km x 6 km, 120 km north-west of Helsinki (Finland).

INTRODUCTION

Aerial Radiological Measuring Systems (ARMS) developed in the late 1950s for uranium ore prospecting have also provide an invaluable tool in environmental surveillance of nuclear power plants and nuclear processing facilities as well as in emergency response for large-scale radiological accidents. Historically the international concern of the potentialities of such systems was triggered in 1978 by the search and partial recovery of radioactive debris scattered over an estimated area of about 100,000 km^2 as a consequence of the impact in the Northwest Territories of Canada of the nuclear powered Soviet "COSMOS-954" satellite(1). Less than 10 years after, in occasion of the Chernobyl accident, many countries had developed such systems and maps of surface contamination have been collected over several European countries showing a large diffusion of the radioactive fallout originated by the release from Chernobyl nuclear plant (2,3). Also in Italy an ARMS mounted on Agusta-Bell 412 helicopter having as detector large NaI(Tl) counters was used by the group of Physics Laboratory of Istituto Superiore di Sanita' to map the ground surface contamination over the central-southern part of the country(4). From that experience it was deduced that aerial platforms without air sampling and air radioactive contaminants measurement capability can only give quantitative information on ground contamination when the air contamination is negligible and then, in the more critical period when the radioactive plume is passing over the country, it can only be used for qualitative assessments. We have now equipped a fixed wing aerial platform with sampling and measurement capability that can be used to give fully quantitative information on the plume as well as on the ground radioactive contamination in a far field emergency situation.

PARTENAVIA OBSERVER P68 AERIAL PLATFORM

In early nineties, ALENIA and ELECOS (5) have developed a measuring system (called SNIFFER) mounted on Observer P68 aircraft to monitor air quality, with respect to aerosol and gaseous pollutants, at flight height variable between 50 and 1000 meters. Observer P68 is a light two-engined plane with the whole structure in aluminium but the front cap that is made of Plexiglas.
The sampling unit is installed in this cap and the sampling probe goes out from the front part (see Fig. 1). Aerosol is collected on a filter positioned along the sampling line. A meaningful sampling of aerosol is provided through a control system that regulates the air flow according to the aeroplane speed and compensates for temperature and pressure variations as well as for the filter progressive cloggage. In this way an active isokinetic sampling is maintained assuring an entrance flow velocity equal to the aeroplane translation velocity. The entrance flow can be regulated within an error of 1% in the range 35-70 l/minute.
The rotating filter holder has four filter locations, one for each of the possible independent aerosol collections during the same flight mission. Behind the filter that is aligned with the suction line (see Fig. 2), a Geiger counter (external diameter 1 cm) and a small (1x1x1 cm^3) BGO counter, allow real-time measurements of gross-beta activity, total gamma activity and low resolution gamma spectra. Beta counter scaler and gamma spectra are stored in predetermined time intervals that can be as short as 1 minute and that can be changed during the flight mission according to the actual contamination levels. Results of measurements are continuously presented on the on-board monitor. The aircraft is equipped with an advanced Global Positioning System that allows the correlation of stored data with the spatial and temporal localisation. In this way the final result of the mission can be presented mapping out the measured values on the mission path flight.
The smallness and intrinsic poor resolution of the BGO counter makes that the gamma spectrum measured, even when only one radioactive contaminant is present, is very broad (see Fig. 3 left) allowing then a valid assessment only on the presence of the radioactive contamination but hardly the identification of the radionuclide

can be attempted. When a mixture of contaminants, as is always the case for a release from a nuclear plant, is present the identification of gamma emitters is out of any realistic possibility.

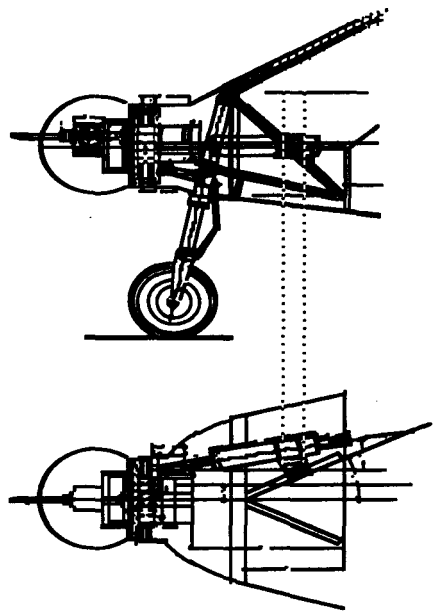

Fig.1 OBSERVER P68 with air sampling unit and HPGe detector

To overcome this failure of the radioactive contaminant measurement, the whole mechanism of the filter holder and connected services has been completely redesigned in a different way in order to allow the insertion of a 20% efficiency, high resolution HPGe detector. A new SNIFFER system with the redesigned mechanical parts was built. In Fig. 2 the scheme of the new system with the insertion of the HPGe detector is shown.

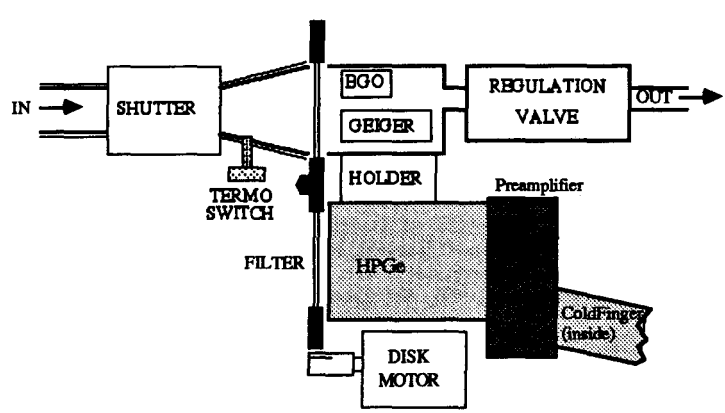

Fig. 2 Schematic diagram of sampling line with radioactive contamination detectors.

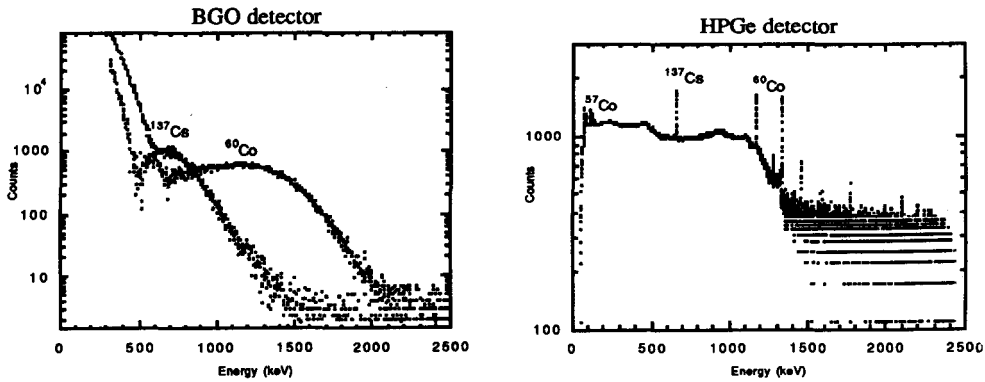

Fig. 3 Left: Separate Gamma Spectra obtained with BGO detector for ^{60}Co and ^{137}Cs sources
Right: Total Gamma spectrum obtained with HPGe detector for the three sources added together

In this way at the end of one sampling period, after the rotation of the filter holder, it is possible to face the filter, that was placed before the rotation along the suction line, to the high resolution detector that allows the identification of each gamma emitting radioisotope in the aerosol sample previously collected. The HPGe detector was specially designed in collaboration with Canberra Semiconductor N.V. to take into account the particular application and the geometrical constraints imposed by the installation of the whole system in the aircraft. A slim Canberra type ACT-1 dewar is used with 12 hour holding time that is well compatible with a flight time duration of 4-5 hours for a single mission. To reduce microfonicity deterioration of the resolution the preamplifier is mounted as close to the crystal as possible. A 20 cm. long cold finger provides the low temperature to the crystal. The resolution of the detector is 2.0 KeV for the 1.33 MeV line of ^{60}Co and 1.28 KeV for the 122.06 line of ^{57}Co. In Fig. 3 right, the spectrum obtained when three sources (^{57}Co, ^{137}Cs and ^{60}Co) are faced to the HPGe is shown. It is possible to see how the improved resolution allows the clear identification of different contaminants. Moreover while with the BGO the minimum detectable energy is little less than the energy of the ^{137}Cs source (661.66 KeV), with the new detector this limit can be lowered up to 100 KeV.

On board of the aircraft, large surface NaI(Tl) counters, which have a much better resolution than the small BGO counter spectrum shown in Fig. 3, and also HPGe high efficiency and high resolution counters are placed to collect gamma spectra from the total environment. From the information collected by these counters after the subtraction of the contribution whose source is in the air, that has been inferred from the air sampling measurements, assessments on the ground contamination can be deduced even in the early phase when the plume, coming from a far field release, cross over the interested country.

ABSTRACT

Several studies have identified an organic fraction of radioactive iodine releases following nuclear accidents, as well as releases arising from reprocessing activities. Methyl iodide has been identified as this primary component of this fraction.

The following paper describes a system for exposing crop plants with methyl iodide, using ^{125}I as an analogue for ^{131}I and ^{129}I. From these experiments deposition velocities to a leafy green vegetable were calculated at several points within the growth cycle. The subsequent fate of the ^{125}I was monitored until the crops were harvested at maturity.

INTRODUCTION

Radioisotopes of iodine are important radiologically, because of their ability to accumulate in the thyroid gland and their rapid transfer through the foodchain. Emission of radioiodines from nuclear facilities can occur in both routine operation and accident scenarios. Studies of the speciation of radioiodine have reported that a significant fraction is in an organic form (1,2), this is believed to methyl iodide (3). To date there is some work reporting deposition velocities for CH_3I (4,5), but little on its subsequent fate in the crop. The work outlined below was undertaken to rectify this situation by measuring the movement of activity between exposure and final harvest.

MATERIALS AND METHODS

The methyl [125]iodide was prepared by the reaction of potassium iodide and dimethyl sulphate. The resulting $CH_3^{125}I$ was transferred in a stream of helium passing through the reaction vessel and cryotrapped in the exposure vessel which was submerged in liquid nitrogen. Following preparation c.350kBq of $CH_3^{125}I$ was retained in the exposure vessel. To reduce confounding effects from dissociation of the methyl iodide, sources were prepared on the day of use and stored in the dark until required.

Cabbage (cv. Greyhound) seeds were sown in 3 l pots in John Innes no.2 compost on 5/4/95 and thinned to one plant per pot two weeks after germination. Plants were kept in an outdoor enclosure and irrigated automatically, a multipurpose feed (Phostrogen; Phostrogen, UK) was applied fortnightly.

At three occasions during the season, 76, 128, 159 days from sowing (DFS), plants were exposed to the prepared $CH_3^{125}I$. Twenty four hours before exposure twelve plants were transferred to a perspex chamber (0.7m x 0.7m x 0.8m, w x d x h) within a plant growth cabinet. The perspex chamber was part of a recirculating system of pipework that allowed the atmosphere of $CH_3^{125}I$ to be passed over the plants for one hour. The pump of the recirculating system was started after plants were placed in the chamber this allowed the conditioned air of the growth cabinet, 20°C and 50% RH, to enter the exposure system. On the day of fumigation the front of the perspex chamber was sealed and the activity immediately dispensed into the incoming air stream of the chamber. The activity was injected into the chamber by displacing the gas from the exposure vessel with water. The activity circulated within the system for the exposure period of one hour. The air concentration of the ^{125}I in the chamber was derived from a suck sample of 400 cm^3 min^{-1} passed through TEDA impregnated charcoal throughout the exposure period.

At the end of the exposure four plants were randomly selected and dissected into leaves, stems and roots. The remaining plants were returned to the enclosure for three later harvests; two days following exposure, a middle harvest and final harvest at maturity. The plant material was then oven

dried and direct counted on a gamma counter (Compugamma, Wallac). From these counts deposition velocities and the loss of activity from the crop calculated.

RESULTS AND DISCUSSION

The mass normalised deposition velocity (Vd) did not vary significantly between harvests (Table 1.) This suggests that the uptake of $CH_3{}^{125}I$ is directly related to the live weight of the crop. This finding indicates that as the crop grows throughout the season the total deposition of activity per unit area will increase. The rates reported here agree well with those of Voillque and Keller (4), but are an order of magnitude lower than those of Atkins *et al.* (5).

Exposure	Mass normalised deposition velocity ($\times 10^{-3}$)(+\- s.e.) (cm3 g-1 s-1)	Crop
76 DFS	1.51 +\- 0.376	Cabbage
128 DFS	1.38 +\- 0.306	Cabbage
159 DFS	1.27 +\- 0.589	Cabbage
	3.0	Grass (3)
	50	Grass (4)

Table 1. Deposition velocities of crops exposed to $CH_3{}^{128}I$.

The activity directly after exposure was concentrated in the aerial parts at all exposure dates (Figs 1.,2.,3.). As the season progressed activity was lost from all plant components, this loss was more rapid from leaves compared with roots. In fact there appeared to be an indication of transport from the leaves to the roots between 0 and 2 days after exposure. This later finding may be of importance when considering root crops. There may also be the possibility of transfer from the soil to the roots following uptake by the soil during the exposure period, a transfer factor of 9 was reported for the movement of iodine to rice roots (6). The apparent increase in the total activity between 0 and 2 days following exposure at 76 DFS was a result of larger plants at the 2 day harvest (mean weight 0 days from fumigation 18.0 g, mean weight 2 days from fumigation 42.8 g).

The loss of activity from the cabbage plants was greater than that expected from radioactive decay following exposure at 128 and 159 DFS (Fig. 4), Unfortunately the data from the 79 DFS exposure were confounded by the high values recorded 2 days after exposure as discussed previously. There are two possible pathways for this loss of activity, shedding of old leaves containing activity or gaseous re-emission of activity from the plant tissue. Loss of radioiodine in a gaseous form following absorption has been observed (6,7).

In future modelling of the uptake by vegetation of radioiodine as methyl iodide, it should be noted that a significant deposition is observed and that the biological half-life is shorter than that attributable to radioactive decay. The fate of the losses from the system needs further investigation, as these will be of importance for movement of the long lived ^{129}I isotope within an ecosystem.

INTRODUCTION

The Chernobyl accident has clearly demonstrated the importance of establishing environmental monitoring systems for obtaining rapid information in accidental situation on the radiological conditions at the affected area and providing suitable data to the competent authorities for decision making. Mobile units suitable for monitoring of radiological impact at any selected location in the field play an important role in emergency preparedness for various types of nuclear accidents:

1. A major accident in a domestic nuclear power plant.
2. Accidents in nuclear power plants abroad especially in neighbouring countries. To this category should be added the risk from military nuclear power accidents.
3. Re-entry of nuclear powered satellites. The probability is small but it can not be excluded. This type of accident would result in highly radioactive fragments and particles that would have to be located.
4. Accidents when transporting radiation sources.
5. Illegal handling of radioactive sources and nuclear material.

For monitoring of large contaminated areas especially the possibility of airborne monitoring is important. Airborne systems can be used for the measurement of dose and dose rate in wide range, nuclide specific ground surface contamination and nuclide specific activity concentration in air (with special attention to iodine in aerosol) as well as particle size distribution.

METHOD

For the Radiation Monitoring Network of the Czech Republic a prototype of the small system for dose rate measurements and nuclide activity estimates suitable for aerial gamma spectrometric determination of ground contamination was designed calibrated and tested in National Radiation Protection Institute (1).

The system consists of semiconductor HPGe detector, scintillation 3"x 3" NaI(Tl) detector, two multichannel analyzers, high pressure ionization chamber or proportional counter and portable computer working in multitasking mode for storing and evaluating of the spectra as well as for dose rate data handling, recording, storing, searching and presentation. One of three available HPGe detectors with relative efficiency from 15 to 55% can be used. Parameters of detectors are summarized in Table 1.

Table 1 Parameters of semiconductor HPGe detectors used for airborne spectrometry

Detector	Manufacturer	Rel. efficiency [%]	FWHM [keV]	diameter [mm]	length [mm]
JAKUB	Canberra	16.2	1.8	50	37
FERDINAND	Canberra	35.8	1.9	59.5	53.5
ISIDOR	EG&G Ortec	55	1.8	63.3	84.6

For accumulation of spectra the MCA Portable Plus a InSpector (Canberra Inc.) are used. The information about actual position is provided by the global positioning system (GPS) Garmin on-line connected to the computer. This information is used later on to create the maps of contamination using small desktop mapping (GIS) system. The system is powered from inner batteries or from external 12V car batteries.

One of the most important parameters of the system is the time needed for transferring the spectrum from MCA to storage medium (either PC or tape). Storage on tape takes for MCA S10 about 4 minutes which at the aircraft speed about 120 km/h leads to path uncovered by measurement of about 10 km. This time can be substantially shorten using MCA with remote control directly from PC down to about 5s. Further shortening is possible using the plug-in card emulating MCA in computer and communicating directly via bus. This solution is, however, rather demanding from the point of view of power supply on board of the aircraft and also the use of small notebooks is limited. Other possibility is to use special processors e.g. transputters, but this solution is quite expensive. In NRPI the MCA PortablePlus with LapTop computer Toshiba 1600 (PC AT 286, 12MHz,

math coprocessor, 3MB RAM, 40MB HDD) were tested. The storage time of the 4K spectrum using ASAP software was optimised to 8s. The use of the MCA InSpector together with 486/DX2-66 notebook with 8MB RAM and with Genie-PC software running under IBM OS/2 operating system led to further shortening of storage time to approx. 4s.
Whole system was repeatedly tested on the deck of both fixed wing aeroplane and helicopter with the flight speed of 120 - 130 km/h. The flight height was 60m for the helicopter and 80m for the aeroplane. Spectra were accumulated 60s which represent about 2.2 km of flight.
The classic scintillation spectrometer for geophysical surveys was used for comparison and verification of calibration. The spectrometer consists of NaI(Tl) detectors with total volume of 33.6 L. One additional detector with the volume of 4.2 L is used for measurement of the cosmic component contribution to the spectrum. Measured spectra are accumulated in 256 channel analyzer GR 800 D (Geometrics). The energy range of measured spectra is 0.2 - 3 MeV. The energy calibration is are stabilized using the ^{40}K peak. Measuring time is 1 s which represents about 40 m of flight. The spectrometer was calibrated on calibration pads with known amount of K, U, Th.

RESULTS AND DISCUSSION

The system was calibrated using standard method for in-situ spectrometry, elaborated by Beck. The calibration was verified by measurement with detector ISIDOR (55% relative efficiency) on the deck of MI-17 helicopter hanging 50m above the area with known deposition and depth distribution of ^{137}Cs and known specific activity of ^{40}K. For ^{40}K the homogeneous depth distribution was assumed. The activity of ^{137}Cs and ^{40}K and the depth distribution of ^{137}Cs activity were determined by the on-ground in-situ spectrometry and by soil samples measurement in the laboratory. Detection limits for two tested detectors for ^{137}Cs with various depth distribution in the soil, measuring time 60s and height of flight 80m are summarized in Table 2.

Table 2 Detection limits for two tested detectors for ^{137}Cs

Detector	relaxation depth [cm^{-1}]	MDA [kBq.m^{-2}]
FERDINAND	0.3	5.6
	∞ (plane source)	3.3
ISIDOR	0.3	2.9
	∞ (plane source)	1.7

The system was intercompared with scintillation spectrometer for geophysical surveys on two partly overlapping areas of about 100 km^2 each. The areas were chosen with regard to level and inhomogeneity of Chernobyl fallout i.e. there was spots both high and low deposition of ^{137}Cs. The minimum deposition of ^{137} Cs in chosen area was about 2 kBq/m^2, the maximum deposition was about 40 kBq/m^2. The average activity of ^{137}Cs was about 15 kBq/m^2, i.e. high enough to be reasonably measured also by semiconductor spectrometer. The distance of flight lines was 250 m. For comparison the mean values of activity of ^{137}Cs and ^{40}K from 60 measurements by scintillation spectrometer covering the measuring intervals of semiconductor detector were used. The example of ^{137}Cs activity along one flight line as determined by detector ISIDOR is in Figure 1.

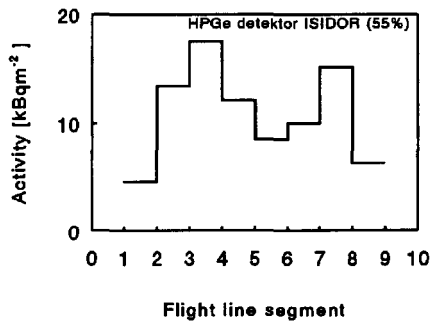

Figure 1 ^{137}Cs activity along one flight line

For detector FERDINAND (36% relative efficiency) the results of 65 measurements of ^{137}Cs deposition were compared with scintillation spectrometer, the mean ratio of activity determined by the system with semiconductor detector and the activity determined by the scintillation spectrometer is 1.11 with minimum of 0.55 and maximum of 1.97. It should be noted that due to the extreme inhomogeneity of fallout in chosen area there were also places where the activity of ^{137}Cs was very near or even below the detection limits of both systems. The extreme values of the ratio were found on such places.
For detector ISIDOR (55% relative efficiency) the results of 214 measurements of ^{137}Cs deposition were compared with scintillation spectrometer, the mean ratio of activity determined by the system with semiconductor detector and the activity determined by the scintillation spectrometer is 1.28 with minimum of 0.55 and maximum of 3.13 (Figure 2). Again it should be noted that due to the extreme inhomogeneity of fallout in chosen area there were also places where the activity of ^{137}Cs was very near or even below the detection limits of both systems. The extreme values of the ratio were found on such places. Efficiency of detector ISIDOR is high enough to enable also the determination of activity of ^{40}K in soil.Results of 214 measurements of ^{40}K activity were compared with scintillation spectrometer, the mean ratio of activity determined by the system with semiconductor detector and the activity determined by the scintillation spectrometer is 0.86 with minimum of 0.53 and maximum of 1.41 (Figure 3).

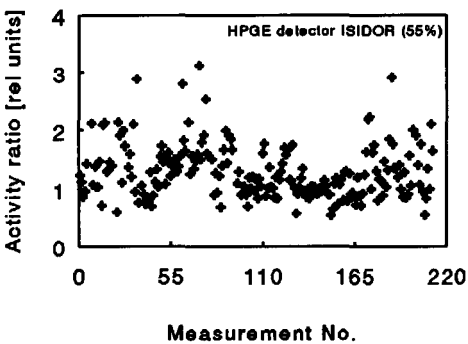

Figure 2 Ratio of ^{137}Cs activity determined by the system with semiconductor detector and by the scintillation spectrometer

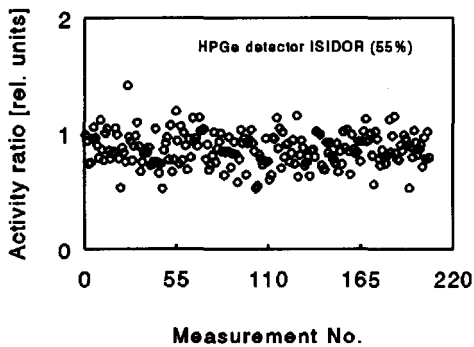

Figure 3 Ratio of ^{40}K activity determined by the system with semiconductor detector and by the scintillation spectrometer

CONCLUSION

The test use of the system with HPGe detector proved that it can be used for contamination mapping on large areas especially in the case of a nuclear accident when its lower sensitivity (in comparison with scintillation spectrometer) can be even an advantage and when one can make full use of its excellent energy resolution for analysis of complex spectra.

ABSTRACT (See instructions overleaf)

The fallout resulting from the atmospheric nuclear weapon tests represented the dominant route of the radioactive contamination of the Adriatic sea, until 1986 Chernobyl nuclear accident. For the post-Chernobyl period ^{137}Cs and ^{134}Cs were found to be major sea-water and therefore marine organisms' contaminants, while ^{90}Sr activity levels were not affected.

For the post-Chernobyl period transfer of radiocaesium from fallout to sea water and finally to marine organisms' was studied. A simple mathematical model was used to describe decrease in radiocaesium activity in marine organisms. Turnover time for radiocaesium in various marine species was calculated to be approximately two years.

Accumulation of Radionuclides under Determined Conditions in Trouts and Carps

K.Hübel, J. Litzke
Bayerische Landesanstalt für Wasserforschung, München

1)Introduction

In the literature [1] the value of the biological half-life of the nuclides Co-60, Zn-65, Sr-85 and Cs-137in fish ranges from 10 to 1000 days. The object of this study was to determine the intake of radionuclides from water and contaminated food by trouts and carps, two important freshwater fishes, to estimate the biological and effective half-lives, to compare or verify the found values with in the literature and to estimate the transfer factors food/fish after feeding the fishes with contaminated food in aquarium experiments. This study also examines the effect of the salinity of the water an the accumulation of the radionuclides.

2)Results and Discussion

2.1 Accumulation of radionuclides from water:
The accumulation of the radionuclides is expressed by equation (1):

$$[R]_t = [R]_\infty\{1 - \exp(-kt)\} \qquad (1)$$

$[R]_t$ and $[R]_\infty$: concentration of radionuclide at time t and steady state concentration (Bq/kg fresh weight
k : excretion rate of 0,692/ t 1/2, t 1/2 being the biological half-live (days)

All radionuclides with the exception of Co-60 in carps were found in the two species. By fiiting the rapidly increasing part of model curve to measured points the steady state concentration $[R]_\infty$, the rate constant k and the biological half-live are obtained.. With the mathematical formula (2) the effective half-live can be estimated. The calculated values are shown in table 1. The sign "-" means: No determination

$$0.693/T(\text{Eff.}) = 0.693/T(\text{Bio.}) + 0.693/T(\text{Phys.}) \qquad (2)$$

Table 1: Biological and effective half-lives (days) after intake from water in carp and trout.

Nuclide	Carp		Trout	
	T(Bio.)	T(Eff.)	T(Bio.)	T(Eff.)
Mn-54	27.2 ± 2.0	25.2 ± 1.7	27.6 ± 10.1	25.4 ± 8.2
Co-60	-	-	14.5 ± 0.9	14.4 ± 0.9
Zn-65*	-	-	37.4 ± 2.8	32.2 ± 2.1
Sr-85	9.0 ± 4.6	7.9 ± 3.4	26.5 ± 3.9	18.8 ± 2.0
Cs-137	38.7 ± 6.0	38.6 ± 6.0	38.9 ± 4.4	38.7 ± 4.4

* A good fit for zinc to obtain was unavailable. The biological half-lives for Cs-137 agree very well with those determinated in field experiments. In the literature [2] half-lives of 55 days are reported for one-to-two-yeras old trouts and for two-years-old roaches, related to carps.

Potassium and calcium are non-isotopic carrier elements of cesium 137 and strontium 85. If the carrier elements are homeostatically controlled, the concentration factor AF(R) of the radionuclides will be given by the equation (3).

$$AF(R) = q\,[C]_i/[C]_w \qquad (3)$$

$[C]_i$ and. $[C]_w$: Concentration of non-isotopic carrier element in organism or tissue i (µg/kg FS) and concen tration in water (µg/l)
q : Discrimination factor
The disrimination factor is expressed by equation (4):

$$q = \frac{[R]_i/[C]_i}{[R]_w/[C]_w} \qquad (4)$$

$[R]_i$: Concentration of the radionuclide in organism i
$[C]_i$: Concentration of the non-isotopic carrier in organism i
$[R]_w$: Concentration of the radionuclide in water
$[C]_w$: Concentration of the non-isotopic carrier in water
As mentioned above calcium and potassium are non-isotopic carrier elements of Sr 85 and Cs137, i.e. the AF(R)

of these nuclides should decrease with increasing concentration of the carriers. Taking the natural logarithm of each side of equation (3), the equation (5) is obtained:

$$\log AF(R) = \log q\,[C]_i^{-} - \log [C]_w \qquad (5)$$

Sincee $[C]_i$ is a constant, a plot of log AF(R) versus log $[C]_w$ should have a slope of -1, if q is constant. The trouts were kept in water compartments with an average potassium concentration of 1 mg/l, 10 mg/l, 100 mg/l und 200 mg/l and an average calcium concentration of 80 mg/l and 160 mg/l and the carps in one with an average pozassium concentration of 1 mg/l, 100 mg/l and 200 mg/l and an average calcium concentration of 80 mg/l and 160 mg/l. An increase of the calcium concenztation is not possible because a higher calcium concentration may be poisonous [3].The figures 1 - 2 show the results in double logarithmic presentation.

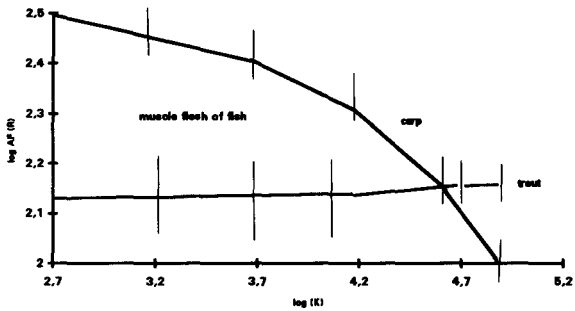

Fig 1: The dependence of the accumulation factors of cesium 137 in the muscle of carp and trout on the concentration of potassium in water.

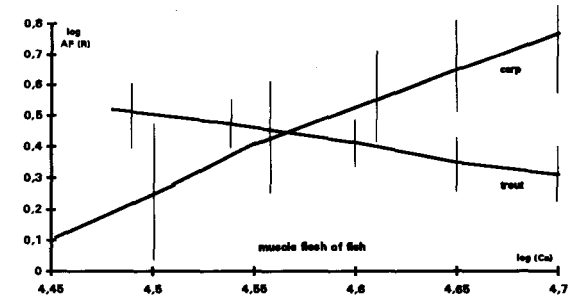

Fig .2: The dependence of the accumulation factors of strontium 85 in the muscle of carp and trout on the concentration of calcium in water.

In contrast to Vanderploeg et al [4], but in accordance with Whicker et al. [5], who examined trouts from mountain lakes in Colorado/USA the potassium concentration was of no effect on the intake of cesium in the muscle of trouts, kept in our compartment. The carps show a decrease of the accumulation factors by increasing potassium concentration from 1 mg/l to 200 mg/l..
The accumulation factor of strontium in the muscle of trout decreases with increasing calcium concentration, a phenomenon which was observed by Templeton et al [6], too. In contrast to the trouts the carps show an increase of the accumulation factor of strontium in muscle with increasing calcium concentration in water.

2.2. Intake of radionuclides from contaminated food:

All radionzclides in the food were found in both species. The accumulation of radionuclides may be described by the equation (1), too. By fiiting the fast ascent of model ,curve to measured points the steady state concentration R_{oo} and hence the biological and effective half-lives are obtained. The values are listed in table 2.

Table 2: Biological and effective half-lives of the radionuclides (in days) after intake of contaminated food in carps and trouts.

Nuclide	carp		trout	
	T(Bio.)	T(Eff.)	T(Bio.)	T(Eff.)
Mn- 54	41.3 ± 8.1	36.5 ± 6.5	15.2 ± 5.8	14.5 ± 5.2
Co- 60	26.5 ± 0.6	26.2 ± 0.6	10.3 ± 1.7	10.2 ± 1.7
Zn- 65	31.8 ± 2.5	28.1 ± 2.0	33.2 ± 5.6	29.2 ± 4.3
Sr- 85	8.0 ± 4.0	7.1 ± 3.6	12.4 ± 0.5	10.4 ± 0.4
Cs-137	39.0 ± 1.8	38.9 ± 1.8	46.7 ± 1.5	46.5 ± 1.5

The half-lives for cesium 137 agree well for the two species already quoted in the literature . There is reported a half-live of 47,2 days for the speckled trout [7] and a one of 35 days for carp[8], both determined after being fed with contaminated food.

The intake of contaminated food by fish is a two-comparment system. The transfer of the nuclides from the compartment food into the compartment muscle will be descibed by the formula (6).

$$T = [R]_{fish} / [R]_{food} \; 1/V \qquad (6)$$

T : transfer factor
$[R]_{fish}$: concentartion of the radionuclide in fish (Bq/kg fresh weight)
$[R]_{food}$: concentration of the radionuclide in food (Bq/kg fresh weight)
V : amount of feed (kg/day)

The calculated transfer factors (day/kg) are listed in table 3.

Table 3: Transfer factors (d/kg) of radionuclides for the pathway food/fish

Nuclide	carp	trout
Mn-54	$2x10^{-3}$	$3x10^{-3}$
Co-60	$2x10^{-3}$	$7x10^{-3}$
Zn-65	$2x10^{-2}$	$4x10^{-3}$
Sr-85	$2x10^{-2}$	$5x10^{-2}$
Cs-137	$6x10^{-2}$	$1x10^{-1}$

The transfer factors do not differ distinctly in the single nuclides in the two kinds of fish.

After 198 years of long sleep, Mt. Fugen of Unzen Volcano has revitalized its volcanic activity in November 1990. Since May of 1991, large scale pyroclastic flows repeatedly occurrred in Mt. Fugen area have caused serious disasters. Pyroclastic flow, which has temperature of 500～650℃ at central portion and 300～400℃ at marginal portion, had frequently occurred since May of 1991. Because the boiling point of cesium and its compounds is known to be rather low (Metallic Cs : 678℃, Cs_2O : 490℃), fallout Cs-137 accumulated on surface soil will be vaporized by the interaction of high temperature pyroclastic flows. Vaporized Cs-137 will likely be exhaled into the atmosphere through extremely porous pyroclastic deposit of which porosity is measured to be ～40 %. In the present paper, we will show the experimental evidence of resuspension of fallout Cs-137 caused by pyroclastic flow.

Samples and Cs-137 measurement

Sampling of volcanic ashes (V), air-borne dusts (A), pyroclastic flow deposits (P), volcanic cinders (C), surface soils (S), leaf mold (L), moss (M) and rain waters (R) were made mainly after the occurrence of pyroclastic flows (from 28 May 1991 to 31 January 1994). Exceptional case is the sampling of volcanic ash from Fugen Pond (17 February 1991). Sampling locations are shown in Fig. 1. Airborne particles were collected immediately after the outbreak of pyroclastic flow at 3.6 and 13 km NNE (leeward of prevailing wind). Sampling was repeated two or three times at one hour interval. Rain waters were collected to evaluate the contribution of fallout Cs-137 derived from rain fall at 8 km E and 11 km NE points (Shimabara City), 35 km NW point (Omura City) from Mt. Fugen. As a control, airborne dusts and rain waters were also collected at Matsue City in Shimane Prefecture located about 420 km NE from Mt. Fugen.

Non-destructive gamma ray spectrometry has been performed to measure radionuclides particularly focusing on Cs-137. In the case that Cs-137 activity is extremely low, Cs-137 was measured by Compton suppression mode using NaI(Tl) detectors as guard counter.

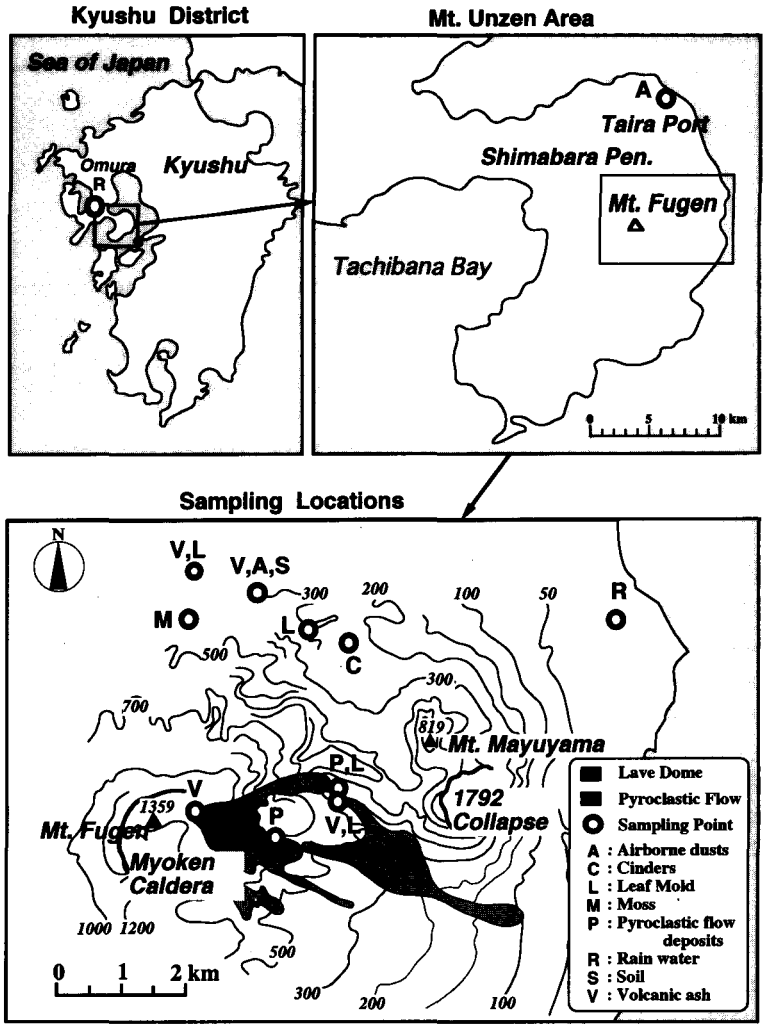

Fig. 1 Sampling locations of volcanic samples of Mt. Fugen, Unzen Volcano.

Results

Results of Cs-137 measurement are summarized in Table 1 and 2. Table 1 shows Cs-137 activities measured for volcanis ashes. As known from the table, Cs-137 was not detected in the sample collected from the shore of Fugen Pond (crater created by 1st eruption) on 17 February 1991 and pyroclastic deposit collected on 28 May 1991. On the other hand, high amount of Cs-137 up to 0.92 Bq/kg was detected in volcanic ashes collected on the same day and thereafter. Cs-137 could not be detected in the volcanic ashes collected since 16 July 1993 due to the reason that the ground surface accumulating high amount of Cs-137 was covered with thick volcanic ash and/or pyroclastic deposits.

Table 2 gives the concentration of Cs-137 in the airborne dusts collected immediately after the outbreak of pyroclastic flows on 28 May 1991 and 21~22 May 1993. As known from the table, Cs-137 activity in the airborne dusts decreased rapidly to 1/4~1/6 in the second sample collected only one hour later. Since Cs-137 was not detected in the airborne dust collected at Matsue, Cs-137 in airborne dusts of Mt. Fugen area may be attributed to the outbreak of pyroclastic flow. Cs-137 detected in volcanic ashes and airborne dusts is considered to be originated from re-suspension or volatilization of Cs-137 (probably as a cesium oxide) accumulated in the surface soils due to the heating by pyroclastic flows and deposits and not from the rain fall.

Above assumption is supported by the fact that Cs-137 was not detectable in rain water collected at Shimabara and Omura City. Concentration of Cs-137 was found to be increasing with depth of volcanic ash accumulated on ground surface soils suggesting that Cs-137 was supplied by underlying soil due to volatilization. Above assumption was supported by other evidences such as Pu-239,240/Cs-137 activity ratios measured for airborne dusts and volcanic ashes.

Abstract

At the request of the Association of Radiological Problems of Russia(ARPR), in charge of environmental measurements and clean up of contaminated territories by Chernobyl accident, an instrument measuring continuously the radioactivity of aerosols in the environment was installed and operated for demonstration during a complete annual cycle in NOVOZYBKOV, Briansk Region (RUSSIA), in order to determine locally residual atmospheric contamination.

This measuring campaign was carried out using the so called RADAIR instrument. This campaign was organised in the framework of a Russian - French cooperation between IPPE (Institute of Physics and Power Engineering, OBNINSK), SEC-SNIIP (Scientific and Engineering Center "SNIIP" , MOSCOW) , IPSN (Institut de Protection et de Sûreté Nucléaire , Fontenay-aux-Roses) and MGP-Instruments (LAMANON).

The first step of the operation consisted in a preliminary verification of the instrument calibration in the site, using aerosols sources deposited on filters . This calibration carried out on specialised facilities of IPSN(1) and SEC-SNIIP(2) showed a satisfactory agreement between different results.

The second step consisted in exploiting the instrument. Beside the demonstration that the instrument worked suitably during its continuous operation in variable climatic conditions, the results obtained showed :
- that the indicated volume activities of α and β emitters were low and near the instrument minimum values (for α : 4.10^{-3} Bq.m^{-3} and for β : 10^{-1} Bq.m^{-3}) ;
- that the indicated volume activities of ^{222}Rn lie between 2 and 30 Bq.m^{-3} (the high values are obtained in favourable climatic conditions : no wind, no rain or snow, soil not covered by snow and not frosted, etc.) ;
- that the indicated environmental dose rate values at the point of measurement were of the order of 0.15 μGy.h^{-1} (150 nGy.h^{-1}).

This paper summarises all the results obtained.

1 - INTRODUCTION

In order to survey the air volume activity of a region, for the purpose of radiation protection, most industrialised countries have installed air measuring networks. The characteristics and performances of measuring instruments in the network are specified in IEC standards.

The type testing of these instruments, according to these standards, gives the demonstration that the volume activity indications lie within stated requirements. It is also necessary to study the characteristics of the instrument in the real field and to give to the user the possibility to exploit it, in order to have feedback experience.

In february 1993, in response to a request from the Russian Association of Health Physics Problems (ARPR), the organisation in charge of environmental measuring and clean up of regions contaminated by Chernobyl accident in the Briansk area, and within the framework of BNEN protocol (Office for Standardisation of Nuclear Equipment) a recommendation was made to install and to operate for demonstration purposes, an instrument for continuous measuring aerosol radioactivity in the environment. This project was carried out jointly by IPPE (Institute of Physics and Power Engineering, OBNINSK), SEC-SNIIP (Scientific and Engineering Center "SNIIP", MOSCOW), IPSN (Institute of Nuclear Protection and Safety, Fontenay-aux-Roses and Saclay) and MGP Instruments (LAMANON). It has received financial support from the French Ministry of Foreign Affairs.

(1) ICARE : Installation de Calibration à l'aide d'Aérosols Radioactifs Etalons.
(2) SAS : Special Aerosol Source.

This project was designed for the following objectives :

1. to test and to exploit an instrument, the so called RADAIR, in the real field where climatic conditions might vary from severe cold winter to hot summer, during a year cycle ;

2. to measure continuously the aerosol radioactivity after ten years from the Chernobyl accident in NOVOZYBKOV (Briansk region), specially during seasons where aerosol resuspension might occur ;

3. to receive on line RADAIR data transmitted to Saclay by ARGOS system, so to survey the operation and the status of the instrument.

Prior to this operation, an intercomparison of activity deposited on filters produced by SAS facility (SEC - SNIIP) and ICARE facility (IPSN) serving during type testing of this kind of instruments was organised. The purpose of this intercomparison was to prove that calibration of α and β deposited activities in Russian and French laboratories are comparable within know limits.

2 - INTERCOMPARISON OF ACTIVITY MEASUREMENTS OF RADIOACTIVE AEROSOLS COLLECTED ON FILTERS

This intercomparison took place in 1993-1994 for the reason mentioned above. Filters of the same type, millipore membrane, AAWP 0.8 µm thick, were used. The characteristics of deposited activities were the following :

- for SEC - SNIIP Laboratory ^{239}Pu , ^{90}(Sr + Y) and natural U were deposited by generating with SAS facility polydispersed aerosol of the inhalable sizes.
- for the IPSN Laboratory ^{239}Pu and ^{137}Cs were deposited by generating with ICARE facility monodispersed aerosol of 0.4 µm.

The measurements were carried out in SEC-SNIIP and IPSN Laboratories using absolute and instrumental methods without knowing the values. The results were published in the reference [1]. They showed that calibration in Russian and French Laboratories of deposited activities, when the uncertainties are between ± 2 % and ± 5 %, for all radionuclides, except natural U, are comparable within ± 10 %. For natural U, the deviation of ± 20 % is due to uncertainties in the methods of measuring this radionuclide. Moreover, the fact that instrumental method gave comparable results with absolute one for submicron aerosol particulates proved that their penetration in the filtering media can be considered as negligible. This was a confirmation of the choice of these membrane as a reference filter.

3 - OPERATIONAL PRINCIPLE OF RADAIR INSTRUMENT

This instrument was chosen for the following reasons :

1 - it is rugged, easy to install in open air and to exploit ;
2 - it separate finer thoracic aerosol fraction of less than 10 µm for continuous measurements, while segregating the course extra-thoracic fraction and iodine in a collecting cartridge for later gamma spectrometry analysis.

The operational principle was published in reference [2]. Essentially for the continuous measurement function, RADAIR instrument carry out, on four measuring channels, the following readings :

- volumes activities of α and β artificial emitters in Bq. m^{-3} ;
- volume activity of natural radon in Bq. m^{-3} ;
- ambient γ dose equivalent to ^{137}Cs in µGy.h^{-1}.

The volume activity readings are derived from pulse counting in cycles of 1000 s of the activity deposited on AW 19 filter by sampling the environmental air. The filter automatically moves after remaining 24 hours in front of the stack of two semiconductor detectors. The first detector located above the filter, delivers a net pulse counting rate proportional to the deposited activity. The discrimination between artificial and natural radionuclides is achieved by the following way :

- radial collimating grid is placed between the filter and this detector to improve α resolution ;
- AW 19 membrane filter is chosen because the aerosols are collected superficially and so the α resolution is better ;
- pulse amplitude selection associated with α and β processing algorithms separate artificial from radon daughters emitters.

The second detector located above the previous one corrects the counting rate of the first detector from the influence of γ radiation and by this way performs ambient γ compensation. The counting from the second detector in cycles of 1000 s is converted to a γ dose rate display.

4 - PROJECT IMPLEMENTATION

Russian and French experts worked on the preparation of the project for three months before it became operational (from august 1994 to october 1994).

On october 30, 31, 1994, a RADAIR instrument was installed on site at the interdepartmental Radiology Laboratory in Novozybkov, located about 180 km from Chernobyl. An operational test was performed november 1, 1994. Calibration verifications were performed november 2, 1994, using aerosols of ^{239}Pu, ^{137}Cs and ^{90}(Sr + Y) deposited on filters, which were manufactured by methods using ICARE (IPSN) and SAS (SEC-SNIIP) installations. The results of these calibration tests were published in reference [3]. Taking into account that RADAIR uses a fixed efficiency of 3.10^{-2} pulses.s^{-1} /Bq to convert pulse rate into activity, it was found that deviations of indicated values from the nominal ones were within ± 15 %.

Since november 2, 1994, the instrument was in continuous operation and under surveillance of two IPPE persons who worked in rotation. Between november 2, 1994 and october 13, 1995, various calibration checks were performed. The results of these checks were the same as those obtained at the time the instrument was put into operation, november 2, 1994.

The RADAIR filters which have aspiration tracks lasting from 46 hours 40 minutes and 15 hours were analysed using α spectrometry (technique using a grid chamber or a silicon semiconductor). ^{226}Ra and products of ^{222}Rn and ^{220}Rn were found to be present in the α spectra.

5 - CONCLUSIONS

After examination of the IPPE exploitation report obtained using the results from the volume activities and dose rates indicated by RADAIR printer, the following conclusions have been drawn :

1 - overall, the volume activities of artificial α and β emitters are low and close to the minimum values (for α : 4.10^{-3} Bq. m^{-3} and for β : 10^{-1} Bq. m^{-3}).

2 - in general, the activity concentrations of radon remained lower than 30 Bq.m^{-3} .

The highest concentrations were obtained under the following conditions :

- light wind (speed of $\leq$ 2 m.s^{-1}), and high atmospheric pressure (P > 740 mm of mercury),
- no precipitation, and no snow or ice groundcover.

The lowest values, lower than 5 Bq.m^{-3} , were obtained under the following conditions :

- high winds (speeds of $\geq$ 5 m.s^{-1}), and low atmospheric pressure (P < 730 mm of mercury),
- groundcover of snow or ice,

3 - The γ dose rates were around 0.15 μGy.h^{-1} (150 nGy.h^{-1}).

This project has demonstrated that overall, the RADAIR instrument operated correctly in very severe climates (temperatures as low as -30°C, snow, high winds,...). The static calibration checks show the stability of the readouts, within statistical fluctuation limits.

Considering the minimum values mentioned above, the measurements show that, during winter the air contamination is not abnormally high. It was expected that during agricultural work and harvest in spring and summer resuspension might occur, but this was not observed. Similar results were obtained in United Kingdom and Japan [4], [5] in spring season from april to june. They were explained by the action of natural filter played by the vegetation, grass, trees... . From august to september 1995, volume activity readings more than the minimum values were not observed, even though the natural filter is expected to drop as indicated by the references mentioned above. Several examples shown as daily graphs (24 h), taken from the counting of the activity deposited on the RADAIR filter for the α, β, and ^{218}Po channels in 1000s cycles, and before algorithm processing, confirm these conclusions.

I INTRODUCTION

In correspondence with the decision of the Co-ordinating Board on territory rehabilitation of Ural region, intercomparison runs on determination of Sr-90, Cs-137 and Pu-239/240 specific activity in three type of soils, sampled in environmental surroundings of "Mayak", were carried out in 1993-1994 within the Radiation Measurements Quality Assurance Programme under supervision of Principal State Centre of Measurements Unity (VNII Mendeleev, St.-Petersburg), V.G.Khlopin Radium Institute (St.-Petersburg), "Mayak" (Chelyabinsk-45).

Soil samples have been treated and homogenised by special programme. Two of these samples were certified as Standard Reference Material of Russian Federation on specific activity of Sr-90, Cs-137, Pu-239/240. Certified values of radionuclides specific activity are shown in TABLE 1.

TABLE 1. Certified values of Cs-137, Sr-90 and Pu-239,240 specific activity in Standard Reference Materials of soil (Bq/kg).

SRM	Cs-137	Sr-90	Pu-239,240
SOIL-10	48.2 ± 2.2	16.7 ± 2.2	10.6 ± 2.4
SOIL-24	2440 ± 140	560 ± 70	2.2 ± 0.35
SOIL-3	157 ± 8	87 ± 9	1.7 ± 0.3

II. MAIN RESULTS OF THE INTERLABORATORY RUN.

26 laboratories including 6 foreign laboratories participated in the interlaboratory run

Programme of intercomparison runs implied determination of Sr-90, Cs-137, Pu-239/240 specific activity in two type of soils (SOIL-10, SOIL-24). In addition some laboratories analysed third type of soil - SOIL-3. As a rule, a number of parallel determinations for each radionuclide in soil sample was 3-6. On the basis of the reported data an mean weighted activity value ($\overline{A}_i$) for i-th laboratory was calculated together with appropriate value of standard deviation.$S_{\overline{A}_i}$.Those data, which did not

meet a condition $|A_i - \overline{A}| \rangle 3 \bullet S_{\overline{A}}$, were rejected as outliers and not used for calculation of interlaboratory mean activity value. Main results of the interlaboratory run and some statistic for the measurement data obtained by the participants are given in TABLES 2-4.

TABLE 2. Summarised data for Sr-90 obtained by the participants of the interlaboratory run (Bq/kg).

SRM	Range of Lab Data A_i	Lab Mean Values and SD $\overline{A}_i \pm S_{\overline{A}_i}$	Number of data deviated from certified value less than 10%	Number of data deviated from certified value less than 25%
SOIL-10	13 - 57	18.6 ± 2.8	22%	67%
SOIL-3	60 -179	86.5 ± 9.6	38%	69%
SOIL-24	490 -950	550 ± 50	58%	84%

TABLE 3. Summarised data for Cs-137 obtained by the participants of the interlaboratory run (Bq/kg).

SRM	Range of Lab Data A_i	Lab Mean Values and SD $\overline{A}_i \pm S_{\overline{A}_i}$	Number of data deviated from certified value less than 10%	Number of data deviated from certified value less than 25%
SOIL-10	42 - 63	50.8 ± 1.4	75%	95%
SOIL-3	138 - 199	160.5 ± 6.5	80%	100%
SOIL-24	1840 - 2640	2480 ±140	85%	100%

TABLE 4. Summarised data forPu-239,240 obtained by the participants of the interlaboratory run (Bq/kg).

SRM	Range of Lab Data A_i	Lab Mean Values and SD $\overline{A}_i \pm S_{\overline{A}_i}$	Number of data deviated from certified value less than 10%	Number of data deviated from certified value less than 25%
SOIL-10	2.6 - 11.9	8.4 ± 2.9	22%	44%
SOIL-3	0.3 - 3.3	1.67 ± 0.26	33%	53%
SOIL-24	1.4 - 3.0	2.4 ± 0.4	41%	71%

II. CONCLUSIONS

The following conclusions could be made from analysis of the reported data:

- in majority of the laboratories (17 from 20) semi-conductive gamma-spectrometric method for determination of Cs-137 allows to obtain reliable data both at low and high levels of Cs-137 content. For instance, mean weighted value of Cs-137 specific activity in sample SOIL-10 as received from results of interlaboratory runs is 49.8±3.2 Bq/kg. Certified value of the specific activity in the same soil is 48.8±2.2. So, within the measurement error (±4%) these results are satisfactorily agreed with each other.

- after evaluation of reported data on Sr-90, systematic errors were detected in 11 laboratories from 18. Analytical methods in four laboratories shall be tested thoroughly because these methods can not be applied for environmental control on Sr-90 content in soils in range 15-100 Bq/kg and lower.

- as a whole, analysis on Pu content resulted in rather poor quality especially in case of SOIL-10 and SOIL-3. Eight laboratories from 18 reported non confident data for SOIL-10 and 8 laboratories from 15 reported non confident data for SOIL-3. One of the main reason for that (in case of SOIL-10) is application of analytical methods based on partial dissolution of (the many times leaching by acid mixture) of soil subsample. Our special investigations have shown that Pu exists in poorly soluble form in SOIL-10. Total dissolution (≥ 99.5%) of the subsample is required for analysis of this type of soil because only in doing this confident data can be obtained. SOIL-3 contains rather low concentrations of Pu (1.7±0.3 Bq/kg) and sensitivity of analytical methods in some laboratories are not enough.

- in total, the number of confident determinations of radionuclides specific activity in three type of soil from Ural region is as it follows:

Cs-137 - 85 % (47 from 55)
Sr-90 - 75 % (40 from 53)
Pu-239,240 - 60 % (30 from 50)

- the laboratories who have shown positive results in the intercomparison runs could certify their analytical methods in D.I.Mendeleev VNIIM together with V.G.Khlopin Radium Institute.

The laboratories who have reported non confident data may correct their analytical methods accounting for results of intercomparison runs and certified values of soil SRMs.

ANALYSIS OF GAMMA ACTIVITY OF HEAVY WATER AT RB REACTOR

M. Pešić, V. Ljubenov, T. Milovanović, S. Avdić, S. Milovanović

Nuclear Engineering Laboratory,
P.O.Box 522, 11001 Belgrade, Yugoslavia

Abstract

The RB experimental nuclear reactor still works with heavy water obtained in 1959 from the former USSR. Gamma activity of heavy water was periodically controlled during the past time. In this experiment measurements were carried out with two samples: D_2O taken from RB reactor and D_2O that has never been used in reactor. Two germanium spectrometers were used as detectors. Gamma spectra's data were evaluated manually and using several computer codes. Results of the experiment show that gamma activity D_2O of RB reactor is at the level of background in "Vinča" Institute, without contamination with fission products.

Key words: Reactor RB, heavy water, gamma activity

1. Introduction

The RB zero-power, heavy water reactor started operation in 1958 with heavy water obtained in former USSR. That water was removed to RA reactor at the end of 1959, when the RA reactor was put in operation. New heavy water was obtained from USSR and it is still used in RB reactor, after 37 years of continual operation. This heavy water is controlled each year, and even more frequently if it is necessary. Control is related on isotope composition of heavy water, it's pH factor and it's possible contamination with fission products.

2. Experimental procedure

Gamma activity analysis of RB reactor heavy water was performed in 1995, for the first time on low-background (Pb shielded) germanium spectrometer. Using that measurement system, analyses of gamma background were carried out up to energies of 2.85 MeV with average integral count rate of 0.5 cps. Gamma background spectrum was also, as usual, measured using coaxial Ge detector with corresponding nuclear electronic modules, placed in experimental room of the RB reactor. These measurements were carried out in energy range between 50 keV and 1.85 MeV, with average integral count rate 16.167 ± 0.009 cps, because it has no special shielding from the background radiation.

For the first time, in order to verify results of measurements, compared gamma activity analyses were carried out with samples of D_2O taken from the RA reactor. That heavy water was bought in former USSR in late 1980's and never used in reactor.

Calibration gamma radioactive sources were used in energy range from 30 keV and 2.7 MeV for energy calibration and determination of the efficiency of the low-background Ge gamma spectrometer. These sources were specially made solutions of naturally gamma radioactive materials in water, placed in plastic bottles of 300 ml volume, "Cedevita" type. One of these calibration sources

contains 12.633 g of KCl solved in 300 ml distillate water, and it provides gamma line with energy 1460.8 keV from ^{40}K nuclide. Second calibration gamma source was made as a solution of 15.063 g $La(NO_3)_3 \times 6H_2O$ in 300 ml distillate water, and it provides gamma lines with energies 788 keV and 1436 keV from ^{138}La, as well as gamma lines with energies 154 keV, 270 keV, 351 keV, 403 keV and 832 keV from radioactive successors in ^{227}Th natural radioactivity chain.

Energy calibration and absolute efficiency curve were determined by using gamma lines and their absolute activities determined from pulse amplitude spectrum, collected in Canberra series-35 MCA with 100 MHz ADC and 8192 channel memory:

$$E_\gamma[keV] = 0.34999 \cdot ch + 8.711, \quad ch \in [1,8192] \tag{1}$$

The absolute activities of calibration sources were determined using known mass of radioactive nuclides in the solution. The absolute efficiency of the spectrometer in whole energy range was obtained by least square fitting method, through efficiency-energy points, as a hyperbolical function:

$$\varepsilon = \frac{4.65699}{E_\gamma(keV)^{1.04466}} \tag{2}$$

Samples of 300 ml of heavy water from RB and RA reactors were prepared on the same way as the calibration sources (in plastic bottles of 300 ml volume, "Cedevita" type) and analyzed by low-background Ge gamma spectrometer. Measurements of the samples of heavy water from RB reactor were carried out for 240000 s, with total integral of 135093 counts, that provides average integral count rate of 0.563 cps (i.e., at the gamma background level of the spectrometer). Measurements of the samples of heavy water from RA reactor were carried out for 96 000 s, with total integral of 55751 counts, which provides average integral count rate of 0.581 cps (i.e., again at the gamma background level of the spectrometer).

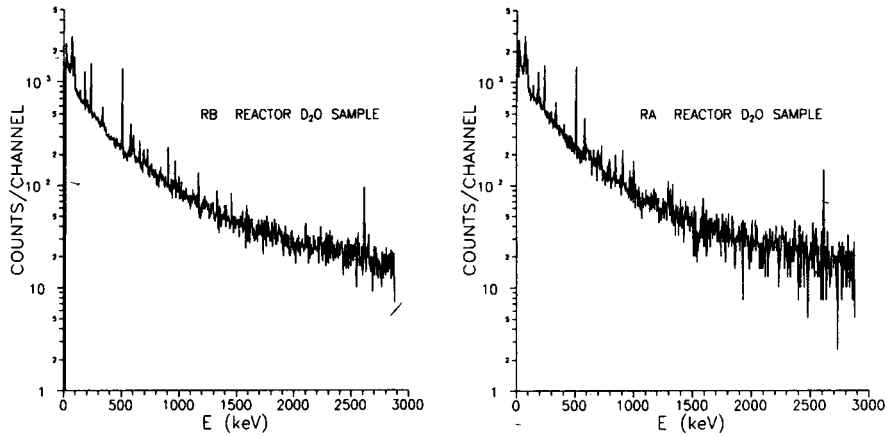
Germanium gamma spectrometer system, used in the experimental room of RB reactor, was energy and efficiency calibrated with several point sources on different distances from the detector axis. These calibrations were verified with four volume gamma radioactive sources in two energy points. These volume calibration sources were made as solutions of KCl in distillate water (with concentrations of 1 g K in 50 ml and 5 g K in 50 ml), and solutions of ^{137}Cs in distillate water with activity of 137.7 ± 5.5 kBq and 275 ± 11 kBq on 1995-03-29. Samples of heavy water from RB and RA reactor and calibrated solutions were made in plastic bottles of 54.0 ± 0.1 ml volume.

RB reactor's heavy water gamma activity analyses were carried out at 15 cm distance from the detector, during 231678 s, with total integral $3{,}7766 \cdot 10^6$ counts, which provides average integral count rate of 16.301 ± 0.009 cps, what is at the gamma background level of the spectrometer. Measurements of gamma activity of the samples of heavy water from RA reactor were carried out for 352449 s, with total integral of $5.6809 \cdot 10^6$ counts, providing average integral count rate of 16.118 ± 0.007 cps, (i.e., at the gamma background level of the spectrometer).

3. Results of measurements

Data from measured gamma spectra were evaluated manually, as well as with several computer codes. Three of used computer codes are commercial ones, GANAAS [1], MicroSAMPO [2] and APOGEE [3] from Canberra Inc., and the fourth one is ANA computer code [4] developed in Laboratory NET. Only representative gamma lines in measured spectra are given. The measured

amplitude gamma spectrums for both samples of heavy water (from RA and RB reactors), obtained at the low-background Ge spectrometer are shown at Figure 1. Results are evaluated at the same measuring time of gamma spectra: 240000 s.



a b

Figure 1. Gamma spectra of heavy water sample from RB reactor (a) and heavy water sample from RA reactor (b)

4. Conclusion

Gamma activity analysis of RB reactor heavy water, including comparations with gamma activity of sample of heavy water (obtained from RA reactor) never used in reactor, shows that its gamma activity is on the gamma background level in "Vinča" Institute, without contamination by fission products.

IN-SITU GAMMA SPECTROMETRY INTERCOMPARISON EXERCISE IN SALZBURG / AUSTRIA NUCLIDE SPECIFIC EXPOSURE RATE MEASUREMENTS

F. STEGER, E. LOVRANICH, E. URBANICH and S. STREIT

Austrian Research Centre Seibersdorf, Department for Radiation Protection
A-2444 Seibersdorf / Austria

ABSTRACT

In-situ gamma spectrometry has become a useful method to assess the nuclide concentration of artifical and natural gamma-emitters in the soil. With such measurements the determination of activity concentration in the soil can be calculated and also the nuclide specific exposure rates. So it will be possible to decide which radionuclide contributes the main part of the exposure rate in a given radiation field. For the quality assurance of the measurements periodically intercomparison exercises are essential. To meet this requirement exercises were organised in different European countries since 1989. The last exercise in September 1994 was organised in Salzburg / Austria. The participation of 24 measurement teams from all over Europe emphasises the importance of the inter comparison. Salzburg was selected because the Province of Salzburg / Austria was among the heaviest contaminated region outside the former USSR by the Chernobyl fallout. Two different typical sites were selected for the measurements: Site 1 was inside the urban area of Salzburg on intensively used agricultural land which had not been disturbed since the fallout. This site is representative for intensively used agricultural regions in the Province of Salzburg. Site 2 was in the mountainous region of the Tauern on elevated altitude of approx. 1700 m. This site represents the soil and contamination conditions of the Alpine region. Both sites differ significantly in terms of different soil distribution and contents of natural and artifical radionuclides. The main origin of the specific exposure rates in this regions depends from this facts. Results are presented.

INTRODUCTION

In-situ gamma-spectrometry has become an important method for the rapid detection of radio nuclides in the environment, since its development in the late sixties and at the beginning of the seventies. Behind the determination of activity concentrations in the soil also nuclide specific exposure rates can be calculated after such measurements. So it will be possible to decide which radio nuclide contributes the main part of the exposure rate in a given radiation field (1). The development of semiconductor detectors improved the usefulness of this method for the quantitative determination of natural and artificial radio nuclides as well. After the reactor accident in Chernobyl periodical inter comparison exercises applying in-situ gamma-spectrometry have been organised by different institutions of the EU member states and neighbouring countries in order to improve the scientific basis of the method, for information interchange of the scientific community and of increasing importance also to develop methods and to gain a good basis for quality assurance. In-situ gamma-spectrometry is used by an increasing number of radiation protection institutions, governmental and provincial environmental monitoring laboratories and authorities, health physicists of nuclear power plants and scientific institutions. The great importance is documented by the ever increasing number of participants at the in-situ inter comparison exercises in the past.

Considering the technical aspects of the method and its applicability for the determination of radioactive contamination and the nuclide specific exposure rates, the problems of the determination of activity concentrations are closely related with the age of the fallout, whereas the exposure rates estimates are much less sensitive to variations in radio nuclide distribution and soil characteristics and so very accurate estimates of individual nuclide contributions to the total external exposure rate can be made from the field spectra.

In-situ gamma spectrometry can be applied for the measurement of natural and for artificial gamma-ray emitters as well. The photon flux of the gamma-emitters in the soil and also the exposure rate is a function of soil parameters (density, humidity), the radio nuclide, of soil-depth distribution and the spatial variation of the fallout within the affected area.

METHODS, IMPLEMENTATION AND OBJECTIVES

The inter comparison exercise was implemented in the Province of Salzburg at two different sites. Three reasons determined the selection of these sites:

* The contamination by the Chernobyl fallout in the province of Salzburg was rather high varying between 10 kBq/m² and 80 kBq/m² at the time of the fallout deposition in April 86
* The contamination on site 1 / (Krauthuegel, city of Salzburg) was studied in detail (2).
* The two sites selected represent two different specific environments in the Province of Salzburg: Site 1 (Krauthuegel, city of Salzburg) is typical for low-lying land used intensively for agricultural purposes;

Site 2 (Nassfeldalm, Badgastein) represents mountainous environment with extensive seasonal usage for agriculture and the natural radioactivity of both sites varies significantly.

The specific task of this exercise was the calculation of the specific activities for natural and man-made gamma emitters and mainly for this work their contribution to the exposure rates.
The participants used HpGE-detectors exclusively (3 n-type and 21 p-type detectors), mounted 1m above ground, with relative efficiencies ranging from 10% to 54% of relative efficiency. At measurement site 1 13 positions and at measurement site 2 15 positions were predefined for gamma-spectrometric measurements. Each position was marked and numbered, on average between 6 and 8 measurements of approximately 1/2 hour acquisition time were made.

RESULTS AND DISCUSSION

The participating measurement groups were from different institutions encompassing environmental measurement laboratories, radiation protection institutes, research centres and university institutes as well. Though soil depth profiles for ^{137}Cs were distributed to the groups, only a few participants used this information as a basis for the calculation of the site-specific photon flux and thereby the concentration for $^{137,134}Cs$ in the soil [$Bq.m^{-2}$]. Not all participants informed the authors about the methods they used. Out of those who provided this information most of them used for the calculation assuming real distribution appropriate α/ρ factors (α = reciprocal of the relaxation length of the assumed exponentially distributed source activity with depth, cm^{-1}. ρ is the soil density, g/cm^3) for an exponential distribution derived by BECK (1) or factors recommended in the ICRU report (3). Only a few applied other methods including double exponential distribution, assuming Lorentz-distribution or calculation of the flux based on the experimentally derived depth distribution. For the photon flux calculation and thereby the specific activity of the natural radio nuclides [$Bq.kg^{-1}$] uniform distribution was assumed. The exposure rates were then calculated to take into account conversion factors from Beck (1) [eg. $nSv.h^{-1}/Bq.m^{-2}(kg^{-1})$].
The results of the calculation for the exposure rates of $^{137,134}Cs$, ^{226}Ra, ^{232}Th ^{40}K and the total exposure rates for the two measurement sites are shown in Table 1 and 2 and on Figure 1 and 2.

Table 1: Results of exposure rate measurements, Krauthuegel, Salzburg [$nSv.h^{-1}$]

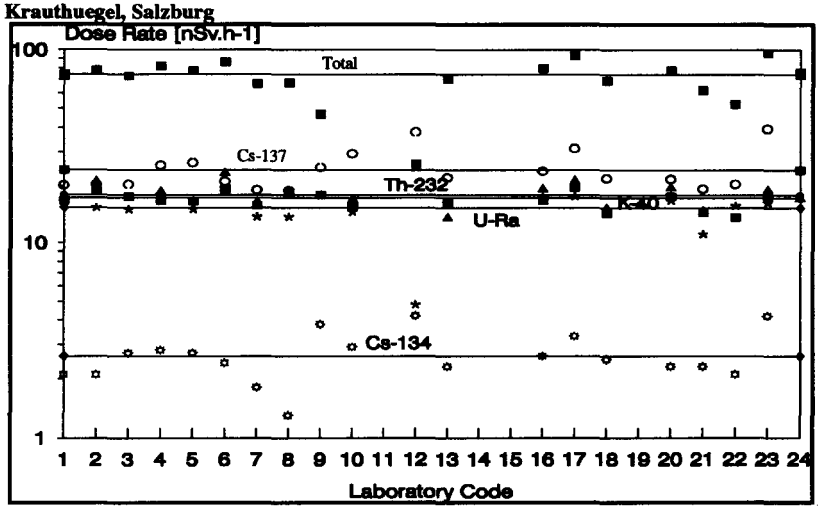
Statistical parameter	Uran-Radium Series	Thorium Series	^{40}K	^{137}Cs	^{134}Cs	Total
Mean	15,3	17,9	17,3	24,3	2,6	77,4
[%]-Total	19,7	23,1	22,4	31,4	3,4	100
SD	4,2	4,8	3,2	6,1	0,8	12,4
SD(%)	27,5	26,8	18,5	25,1	30,8	16,7
Number n	18	18	19	19	19	18
Min	13,7	14,8	11,9	20,4	2,0	73,1
Max	18,0	20,9	20,4	28,2	3,1	79,2

Table 2: Results of exposure rate measurements, Nassfeldalm, Badgastein [$nSv.h^{-1}$]

Statistical parameter	Uran-Radium Series	Thorium Series	^{40}K	^{137}Cs	^{134}Cs	Total
Mean	19,4	16,3	16,9	51,4	5,2	109,2
[%]-Total	17,7	14,9	15,5	47,1	4,7	100
SD	8,0	4,8	2,5	7,6	0,4	13,7
SD(%)	41,2	29,4	14,8	14,8	7,7	12,8
Number n	18	18	19	19	19	18
Min	14,5	13,0	15,0	43,8	4,2	93,3
Max	22,3	19,6	19,5	57,1	6,0	117,2

For each group a mean value was calculated from the results obtained from the different measurement positions of that measurement site. The mean values of each laboratory for a measurement site are the data-basis for the calculation of the statistical parameters given in Table 1 and 2. The inter comparison shows that the most of the laboratories got acceptable results, some of the participants have to spend more work for the calibration of their devices. As an interesting result of the inter comparison we found, that in Salzburg and a little bit more in Badgastein the dose rates of the artificial radio nuclides are in the same range as the natural radio nuclides (without cosmic radiation) !

Krauthuegel, Salzburg



Nassfeldalm,Badgastein

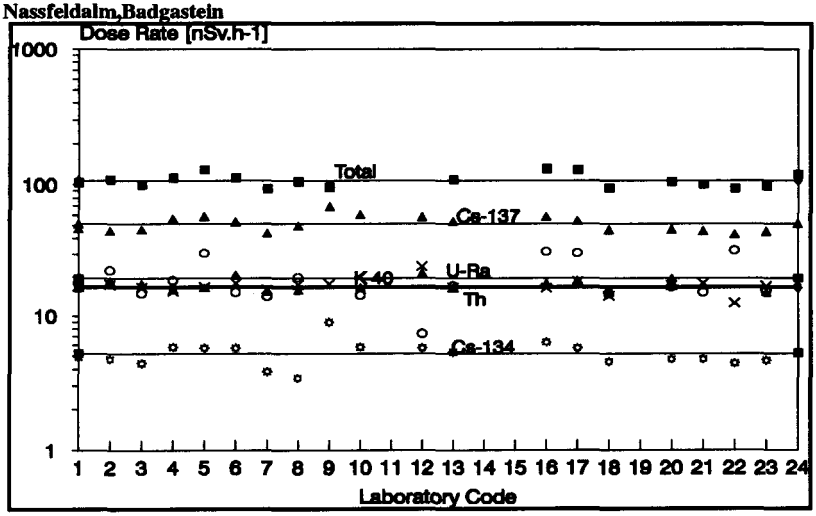


Figure 1 and 2: Mean values for dose rates, calculated from all points measured from each group for the measurements sites. Mean values are shown as horizontal lines.

CONCLUSION

The periodical organisation of inter comparison exercises will be an acceptable basis for quality assurance by providing a unique opportunity for the participants to check the reliability of their calibration and calculations, which will be most important for the control and safeguards of nuclear power plants and official authorities.

ABSTRACT

Beside the determination of the distribution coefficients for individual elemnts of interest, radiological measurement including total alfa, total beta as well as the specific activity for both artificial (H-3, Cs-134, Cs-137) and natural (Uranium and Actinium series:Pb-212, Pb-214, Tl-208, Bi-214, Ac-228, Rn-222 and K-40) radioisotopes presents in different environmental (water, soil, food and atmosphere)samples along the Vardar river, were performed.

Taking into consideration the results obtained so far and by application of adequate radioecological model, a global view on radioactivity of the investigated area, its origin, pathway of transport and places of accumulation as well as their influence on the total irradiation of the population have been evaluated and partly presented in this paper.

INTRODUCTION

Various assignment of the surface and underground water flows of the Vardar river (water supply, irrigation etc.) to which gravitate cca 2/3 of the total population of the Republic of Macedonia /see Fig.1/,are subject of particular interest regarding their protection and rational usage.

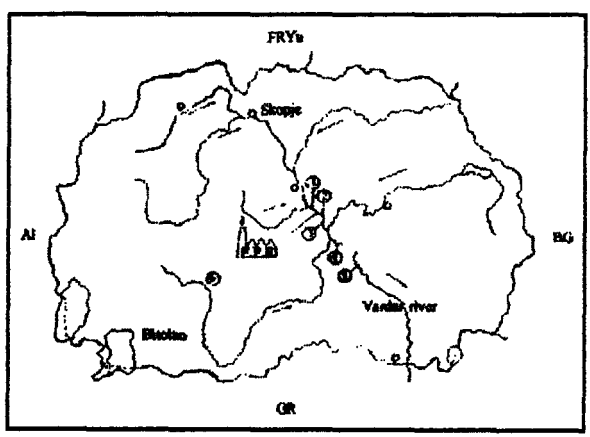

Fig.1 Location of sampling pints along the Vardar river basin
1-T.Veles, 2-Zgropolci, 3-Nogaevci, 4-Ulanci,5-Krivolak,
Pelagonija, FPF-factory for phosph. fertillizers

Parallel to the other investigations related with the determination of the bio-chemical pollution of the Vardar river basin (1), radioecological investigations took a significant attention, too. In this sense,several profiles along the Vardar river had been selected and collection of various samples on a regular base were performed.

In the very begining, starting with the determination of the distribution coefficients for individual elements in various components of the Vardar River Basin(2),showing the place of their accumulation, radiological measurements /determination of the total - α and total- β as well as the specific activitiy of individual natural (Pb-212, Pb-214, Tl-208, Bi-214, Ac-228, Rn-222 and K-40) and artificial (Cs-137, Cs-134 and H-3) radioisotopes/ in different environmental (water, soil, food, and atmosphere) samples along the Vardar river , were also introduced, identifing on such way the samples and locations with the increased level of radioactivity.Different the total -α and total -β measurements which were done on Canberra - 2200 ,anticoincident gas proportional counting system, specific activity for individual radioisotopes were performed on Tricarb , M 3320, Packard instrument, β Liquid Scintillation Counter or Canberra γ – spectrometer suupplied with MCA - 40 and high resolution semiconducting detector.(3).

These investigations gained in their importance specially after the Chernobyl accident.This was a period when an increased environmental radioactive contamination has been registerd particularly in the regions which are known to have received the highest amounts of precipitations during the period following the Chernobyl release(4).

By application of an adequite mathematically supported radioecological model (5-7) and taking into the consideration all relevant parameters (human habits, food chain etc.) ,the annual effective equivalent dose received (through ingestion , the most important pathway) by the local population, was calculated.

RESULTS AND DISCUSSION

While the values of the total-α activity in the investigated water samples from the Vardar river, for the last 10 years, were in the range between 0.02 and 0.4 Bq/L, the other samples showed values increased up to 63,7 Bq/kg in case of cultivated soil, with a maximum value following the period of Chernobyl release /26th of April,1996/, common for the other radiological measurements, too.

Values for the Total - β activity for Vardar river water and other samples are registered to be below 2.76 Bq/L and 5210 Bq/kg, respectively, with K-40 as a dominating radionuclide.For an example, on Fig.2 , the values for Total - β activity in water samples from the Vardar river /profile - Krivolak,which

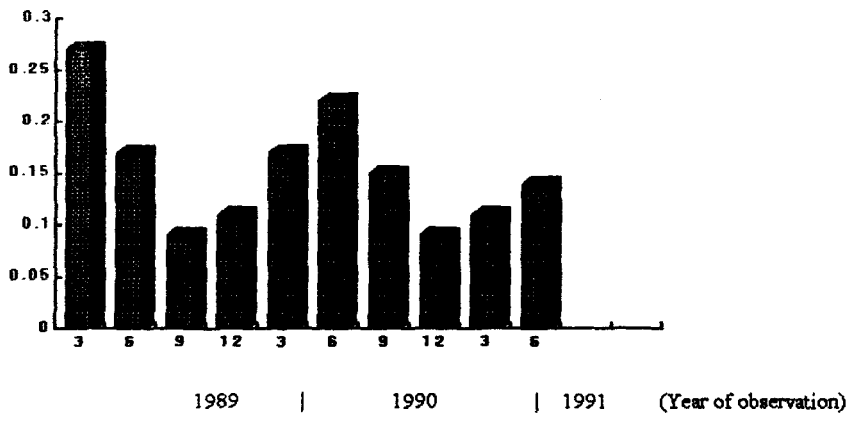

Figure 2. Total –β activity in water samples from the Vardar river /profile-Krivolak/

together with the previous up stream profile -Nogaevci,showed an increased activity/ with time is presented.It is evident that the changing of the total - β activity is following the shape of sinusoidal oscillation.Although this function is periodical, some characteristics of damped oscillations due to the decreasing of the amplitude with time, are evident.This can be explained by washing out of the contaminated soil during the melting period of snow /March - June/ .

Different the tritium concentration in Vardar river water samples showing values between 5 and 15 T.U.[1] falling down to the level of the period before 1952 (starting period of thermonuclear explosions), the valus for Pb - 214 and Ac- 228 are increased specially at Nogaevci and Krivolak profiles. In particularly the concentration of Pb-214 in the sediment samples during the 1989-1991 period is reaching the value 125 Bq/kg which is several times higher in comparison with the previous observations.The reason for such an increasing of the mentioned activities has to be looked and related with the activities of the factory for phosphatic fertillizers, located upstream of these profiles.

Analysing the results obtained by the determinatin of the Cs-isotopes,it has been found out that the concentration of Cs-134 in comparison with this of Cs-137 during the period of increased contamination i.e. after the Chernobyl release,was twice less and disappeared earlier due to its shorter half life time.The concentration of Cs-137 in water samples from Wardar river for longer period of observation(`86-`95) showed a tendency of faster activity decreasing comared with the natural decay, themost probably, due to the presence of other comparative processes of dissolving,extraction,diffusion etc, approaching the level of early eighties (5).

Different the specific activity of the observed radionuclides (Cs-137, Pb-212, Pb-214, Tl-208, Bi-214 and Ac-228) in cultivated and uncultivated soils which showed values between 10 and 70 Bq/kg, various food samples had values below 25 Bq/kg or L, see Figure 3.

Figure 3.Average specific activity for the observed radionuclides in various food samples for the period `89 - `91

It is worth to mentioned the milk samples whose values were not higher than 4 Bq/L.This is of particular interest for the radiation burdening of children, dominantely consuming this product.

On the basis of the above mentioned results and by application of an adequite mathematically supported radioecological model (6-8),taking into the account all relevant parameters(human habits, fodd chain etc.), the anual effective equivalent dose received through ingestion(the most important pathway of the human irradiation) was calculated for the period `89-`91 and the value of 1.5mSv/y was obtained, while the Cs-137 contribution significantly decreases in comparison with the early period following the Chernobyl accident(5), and was not higher than 60 μSv/y .

ABSTRACT:

It is the common knowledge that liquidation of Chernobyl accident consequences was carried out with significant losses: personnel had been exposed by great dose of irradiation, in most cases unwarrantedly great. This could be explained by deficiency of experience in accident consequence liquidation of such scale. Now we have got such experience. Huge amount of experimental data has been collected, a number of reports regarding Chernobyl accident consequences liquidation have been issued. But this experience must be generalised, main problems should be realised, and steps for their solution should be defined.

One of these problems is absence of equipment which would be specially designed for situations like Chernobyl accident. It seems to us that apart from everything else it is necessary the equipment for solution of three following tasks:
1. Estimation of radiation situation at various objects.
2. The search of local sources of ionising radiation in hardly accessible places.
3. Defining of radioactive areas in the country and measurements of surface radioactivity.

These three tasks must be solved at minimal personnel irradiation. This could be reached with help of remote controlled robot systems or by measurement of radiation effect at sufficiently large distance from the object, when parameters of radiation field are calculated according to definite algorithm.

Possible ways of such equipment designing in application to all three tasks are considered in presented paper. The search of local sources of ionising radiation in hardly accessible places with help of special measuring equipment placed on remote controlled vehicle (in other words - mobile robot) is considered in detail.

Abstract. A prototype of an automatic station of environmental monitoring has been designed and manufactured. In the design advanced technologies tested at NPO Energia when developing space technology were used. The general view of the station is presented in the Figure.

The station provides monitoring of water and atmosphere parameters, can be set stationarily or transported by telephone cables or a radio channel (including a satellite as well).

The station power supply is provided from the electric mains and in distant and difficult of access regions from an off-lain solar array wind facility or micro HEPP.

An equipment complex of the station has been developed and manufactured to measure the concentration of harmful gases in the atmosphere, the chemical composition of aerosols, to provide a detailed radiation analysis.

The equipment characteristics are given, the concept of using stations in large cities and around ecologically dangerous productions is discussed.

Key words: environmental monitoring, automatic station, monitoring of atmosphere, monitoring.

MAJOR SCIENTIFIC TOPIC NUMBER ..... (see page 7)

Among ecological problems the task of performing the monitoring of environment radiation parameters is of great importance. In the given report the experience concerning the development of equipment intended for carrying out the complex inspection monitoring of state of both dwellings and industrial rooms including the monitoring of RADON content in the air is presented.

In accordance with the conception of radiation safety being adopted in the Russian Federation, the versions of equipment "REKS" and "REKS-alpha" have been developed. The equipment provides the conduction of inspection monitoring of external radiation dose equivalent rate, density of beta radiation flux from surfaces and RADON concentration in the air according to the value of "latent" energy.

The equipment versions differ by the method of measuring the "latent" energy value and by additional capabilities. In "REKS" version the procedure of measuring the beta activity of the air sample being taken at filter is used. The removable sensor being included into "REKS" composition permits to perform the specific activity measurements of liquid and loose samples (calibration is carried out by Cs-137). In "REKS-alpha" version the procedure of measuring the sample alpha-activity is used. The removable sensor being included into "REKS-alpha" composition permits to perform the measurements of the radon concentration, being averaged over the exposure time, with the use of carbon adsorbers. "REKS-alpha" version is an equipment which corresponds by its metrological parameters to the best similar equipment being known in the world.

PC CREAM: A PC PACKAGE TO ASSESS THE CONSEQUENCES OF RADIOACTIVE DISCHARGES DUE TO NORMAL OPERATIONS

C A Fayers
National Radiological Protection Board, Chilton, Didcot, Oxfordshire, OX11 ORQ. UK.

INTRODUCTION

PC CREAM is a Windows™ based software package which implements CREAM (**C**onsequences of **R**eleases to the **E**nvironment: **A**ssessment **M**ethodology). CREAM was developed to assess the consequence of radioactive discharges as a result of normal operations, a description of the methodology was published by the European Commission (EC) (1). The methodology consists of a series of interlinked models which describe the transfer of radionuclides through the atmospheric, terrestrial and aquatic environments, the pathways by which people may be exposed to radiation and the resulting health detriment. The package contains models for the following processes; atmospheric dispersion; external irradiation from activity in air; transfer through foodchains; resuspension of deposited activity; external irradiation from deposited activity; dispersion in the marine environment; discharge to river systems; external irradiation from both marine and freshwater sediments. PC CREAM has been developed to calculate radiation exposure to individuals as well as the collective dose to specific population groups.

SYSTEM REQUIREMENTS

PC CREAM has been designed to run on a Personal Computer with Microsoft Windows version 3.1 or later, 4 Mb of RAM, a 3½ inch floppy drive and a mouse.

PACKAGE DESCRIPTION

PC CREAM consists of a main assessment package CREAM, with a number of supporting interlinked models, as illustrated in Figure 1. The supporting models can be used alone to provide intermediate data such as activity concentrations in air or activity concentrations in marine and terrestrial foodstuffs, or to supplement the default data sets supplied with the assessment package. A brief description of each of the supporting models is given below.

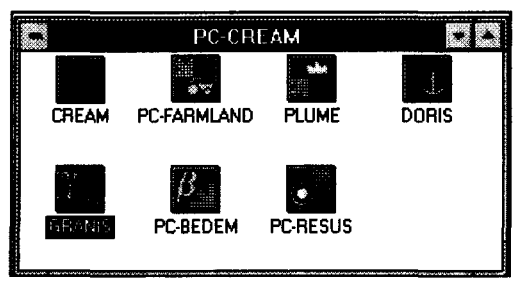

Figure 1 The PC CREAM program group.

- PC FARMLAND - A terrestrial foodchain model capable of modelling radionuclide transfer into foods from a continuous deposition from atmosphere. The output being activity concentrations in the following foods: Cow meat, liver and milk, Sheep meat and liver, leafy green vegetables, root vegetables and grain products.

- PLUME - A Gaussian plume atmospheric dispersion model incorporating models for deposition and external gamma exposure from activity concentrations in air.

- DORIS- A marine dispersion model for European waters capable of calculating activity concentrations in seawater, seafood and marine sediments.

- GRANIS- A model for calculating external gamma doses from deposited activity in a number of media.

- PC BEDEM - A model for calculating external beta doses from deposited activity.

- PC RESUS - A time dependent resuspension model for calculating activity concentrations in air due to the resuspension of previously deposited activity.

Discharges to river systems are intrinsically site specific, for that reason the two river models in PC CREAM,

a simple dilution model, and a more complex dynamic river model, are contained entirely within the main assessment package (CREAM).

THE ASSESSMENT PACKAGE CREAM

The assessment package follows many of the conventions of other Windows™ based applications, making use of familiar features such as buttons, check boxes and list boxes. The package has been design to lead the user through an assessment in a logical and straightforward manner, the welcome screen is illustrated in Figure 2. The assessor initially selects the site details such as type of facility and location. The location, population distribution and agricultural production distribution for the major European Union sites are held within CREAM for the purpose of collective dose calculations. Assessments may be undertaken for discharges to either the atmospheric or aquatic environments, or more comprehensively, releases to both environments may be considered. Site and assessment specific details are recorded as the user progresses through the data entry screens. An example data entry screen is illustrated in Figure 3. Having entered such data as radionuclide discharge rates, the location and age group of the exposed individuals, the assessor can select from a comprehensive list of exposure pathways. When all the relevant data has been entered and selected the assessment can be run. The calculated doses are written to a file or may be displayed within CREAM in a tabular or graphical format. An example pie chart is presented in Figure 4.

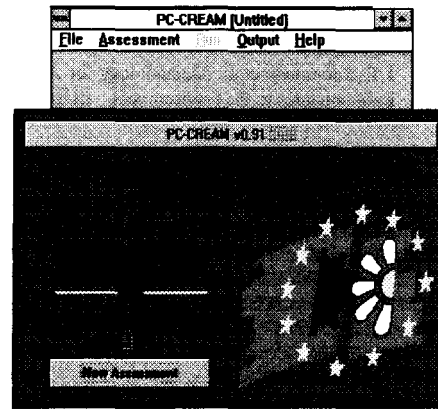

Figure 2 CREAM welcome screen

At all points throughout the assessment a comprehensive online help facility is available.

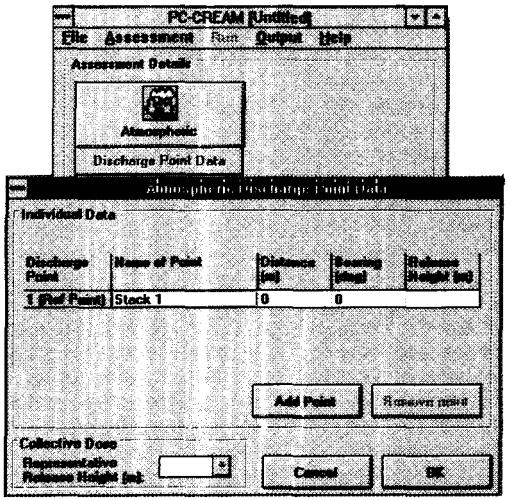

Figure 3 Atmospheric discharge point data entry screen

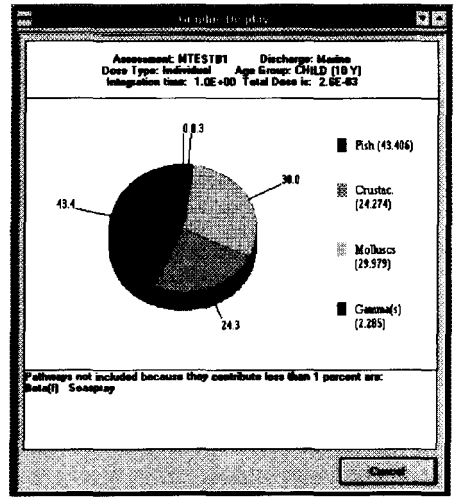

Figure 4 Graphical output from CREAM

SUMMARY

PC CREAM can be used to assess the radiological impact of releases from virtually any type of installation including nuclear power plants and nuclear fuel cycle facilities. It is envisaged that one of the main uses of the package

will be for prospective assessments of the consequences of proposed new plants, or for discharge authorisations. The development of PC CREAM has been carried out under contract to the EC.

The PC CREAM screens presented in the figures of this compact were taken during the development stage of the package, there may be slight differences in the final version.

PROBABILITY SAFETY ASSESMENT (PAS-LEVEL 3) AND EMERGENCY PLANNING

László Sági and László Koblinger

KFKI Atomic Energy Research Institute, P.O.Box 49, Budapest, H-1525 Hungary

INTRODUCTION

To assess the radiological and health consequences of hypothetical accidents of Paks NPP the PC COSYMA program (1) was used. Probabilistic runs with cyclic sampling (using 144 samples) have been carried out. In the calculations 16 sectors (22.5° each) and 10 distance bands (from 0.4 to 450 km) were used. Detailed calculations were performed on the border of an exclusion zone of 3 km around the reactor. Whenever the estimated maximum value of early dose exceeded the limits of countermeasure criteria, the impact of protective measures on the early and late health effects have also been calculated. The code has been previously adapted to Hungarian circumstances (using site specific data on meteorology and population). The DATA library of PC COSYMA is filled with actual data on agricultural productivity using a grid of 10 km x 10 km taken from the Statistical Yearbook of Hungary (2).

CALCULATIONS ON DBA EVENTS

The consequences for the population of Hungary of the above postulated accident scenarios from early (7 days) and chronic (50 years) exposures have been estimated. The calculated doses and health effects are presented in Table 1. for the smaller (Ø 73 (A), Ø 93 (B), Ø 111 (C), Ø 233 (D)) and larger (Ø 492 in cold leg (E), Ø 492 in the hot leg (F), steamline break (G), collector cover opening (I)) accidents.

At the events listed above in case of estimation of radiological and health consequences not any protective measures were taken into account, since even in the worst case (results in parentheses in Table 1): Pasquill category F, and rainy weather, the calculated doses were much lower than the dose criteria given for any countermeasure.

Table 1 Calculated radiological and health consequences for postulated accidents at the border of exclusion area of Paks NPP

Event	Doses, 90th percentile (max)		Health effects, 90th percentile (max)	
	Early [Sv]	Collective committed [manSv]	Early [Number of total mort.]	Late [Number of total mort].
A	3.6E-14 (1.4E-12)	4.3E-09 (9.1E-09)	-- --	-- (4.1E-10)
B	6.0E-14 (2.4E-12)	1.8E-08 (2.4E-08)	-- --	-- (1.1E-09)
C	1.0E-13 (4.0E-12)	3.2E-08 (4.2E-08)	-- --	-- (1.9E-09)
D	5.6E-13 (2.1E-11)	1.6E-07 (2.2E-07)	-- --	-- (1.0E-08)
E	8.3E-09 (8.5E-07)	7.0E-03 (1.1E-02)	-- --	-- (5.5E-04)
F	5.2E-09 (3.5E-07)	5.4E-03 (9.9E-03)	-- --	-- (5.0E-04)
G	1.3E-07 (1.3E-05)	4.2E-02 (2.9E-01)	-- --	-- (1.4E-02)
I	5.1E-06 (5.3E-04)	1.31 (3.8)	-- --	-- (1.8E-01)

EARLY EFFECTS

Deterministic runs for the critical direction (from the radiological point of view) of the plume have been made and compared with the results of probabilistic runs with cyclic sampling. Detailed calculations have been carried out at two preselected distances (at the border of exclusion area and at the center of Paks town (5 km)). At the calculations of dose contributions from cloudshine, groundshine, inhalation and resuspension an integration time of 7 days was taken into account. The dose contributions from various pathways and organs at the border of exclusion area are presented in Table 2.

Table 2 Mean individual 7 day doses at 3 km

		Percentage			
Organ	Dose (Sv)	Cloud	Ground	Inhalation	Resuspen.
Lung	1.3E-04	2	38	59	1
Thyroid	1.5E-03	0	4	93	3
Eye lens	5.7E-05	6	94	0	0
Ovaries	6.0E-05	3	74	22	1
Effective	1.6E-04	2	29	67	2
B. Marrow	7.4E-05	3	64	33	0
GI-Tract	1.7E-04	1	25	73	1

The number of people and the magnitude of land [km^2] affected by various protective measures are presented in Table3.

Table 3 The number of people and the magnitude of land affected by countermeasures

Countermeasures	Number of people affected		Magnitude of affected (km^2)	
	Maximum	Mean	Maximum	Mean
Evacuation	9.6E+02	3.8E+01	5.3E-00	5.4E-01
Sheltering	6.4E+03	6.8E+02	4.7E+01	6.6E+00
Stable-iodine	1.0E+03	7.8E+01	5.3E+00	1.0E+00

Respecting that the expected doses - even in the most pessimistic deterministic case (where the maximum values are encountered) - will be much lower than the threshold for deterministic health effects, no early morbidities or mortalities are detected in our calculations.

LATE EFFECTS

Latent dose and health effect calculations are made for bone marrow, bone surface, breast, lung, stomach, colon, liver, pancreas, thyroid, gonads, which are the organs most important from the radiological point of view. Calculated doses are given also by pathway and by organ and for doses up to 50 years (this last involves cloudshine, groundshine, inhalation, resuspension) at the border of the exclusion area in Table 4.

Table 4 Late dose contribution by organs and by pathway at severe accident

Organ	Percentage			
	Dose (Sv)	Ground	Inhalation	Resuspen.
B. Marrow	1.237E-03	67	31	2
B. Surface	1.577E-03	56	41	3
Breast	9.623E-04	88	11	1
Lung	1.072E-03	82	17	1
Stomach	9.162E-04	85	13	1
Colon	1.012E-03	74	24	1
Liver	9.152E-04	85	13	1
Pancreas	8.484E-04	85	14	1
Thyroid	4.227E-03	23	71	6
Gonads	9.350E-04	86	13	1
Remainder	1.011E-03	86	13	1
Effective	1.192E-03	71	27	2

The maximum value (119) is due to the weather sequence 62, where the meteorological parameters are very unfavourable from the radiological point of view (e.g. Pasquill F category, dry weather, wind direction is toward Budapest, and heavy rain, when the plume reaches the highly populated areas of Budapest). Fortunately, these occurrences (where the population maximum and the contamination maximum is in coincidence) are very rare. The contributions to the total late mortalities by organs are presented in Table 5.

Table 5 Number of total late mortalities (contributions by organs)

Organ	Mean	Maximum
Bone Marrow	0.30	12.6
Bone surface	0.01	0.4
Brest	0.43	19.3
Lung	0.52	22.7
Stomach	0.45	20.3
Liver	0.17	7.5
Colon	0.23	10.5
Pancreas	0.24	10.9
Thyroid	0.17	5.2
Remainder	0.21	9.6
TOTAL	**2.73**	**119**

CONCLUSIONS

In calculation on DBA events doses are below the countermeasure reference levels even if the steam generator collector cover opens (spiking assumed). As a consequence of calculated low doses there are no early fatalities and even number of late fatalities is always less than one. In case of severe accidents no early morbidities or mortalities are detected in our calculations. Even the maximum of late effects are negligable (120) in comparison the natural cancer mortality. (New patients with malignant neoplasm was 23,900 in 1993 (2)).

INTERACTIVE SIMULATION OF ENVIRONMENTAL CONSEQUENCIES OF NUCLEAR ACCIDENTS

László Koblinger[1], István Németh[1], Péter P. Szabó[1] and Andor Kerekes[2]

INTRODUCTION

A program system has been developed to follow the consequences of radioactive releases of a (hypotetical) nuclear accident. Atmospheric dispersion, plume depletion by dry-out and wash-out, cloudshine and groundshine doses, dose commitments from inhalation and ingestion, early and late health effects are computed. Effects of the introduction of countermeasures are taken into account.

Actual values of all major quantities (from core inventory to countermeasure criteria) can be specified quite arbitrarily by the user, however, defaults are offered for all data. Meteorological conditions can be user-specified (and refreshed by every step) or selected automatically from a library containing data observed for one year (8760 hours).

MODELING GOALS

A towfold task is fulfilled by the program:

- it is a tool for education: it helps the training of those people who are responsible for introducing countermeasures;
- in case of a real accident: the program gives fast, easy-to-understand visual information on the radiological state of the environment and on expected consequences.

SIMULATOR FEATURE

The program works as a simulator: various scenarios can be specified (different emissions, meteorological conditions, countermeasures, etc) and results obtained by these scenarios can directly be compared to each other. Computations are carried out in one hour steps upto a maximum of 48 hours, meteorological and emission parameters can be newly set and results are given for analysis at each step. There is a possibility to step back to earlier phases and repeat the simulation under different conditions. Simulation is terminated by user request, or at 48 hours after the very beginning, or when the total plume leaves the border of the country (or other preset region of interest).

SOURCE MODELING

The emission of 16 isotopes are followed. There is a built-in inventory, present default values refer to a medium burned core of a 440 MW VVER reactor. (At the beginning of each run the user can change the defaults for his/her actual inventory). Release rates (i.e. fractions of the inventory released to the environment in the given hour) can be specified either to isotope groups (e.g. noble gases), or to each isotope individually. The dispersion of the iodine isotopes emitted in vapour form is followed separately.

Building dimensions, release height and the release of sensible heat are also needed, the latter being used for buoyancy calculations.

A maximum of four (not necessarily adjoining) emission phases can be defined within one run.

ATMOSPHERIC DISPERSION

Each hour's emission is cut into 9 puffs, each carrying one-ninth of the emission. Since meteorological data (wind direction and velocity, precipitation and stability class) are changed at one-hour steps, the 9 puffs travel always parallel to each other. A Gaussian dispersion of the puffs is assumed, with total reflection at the ground and at the inversion layer, the dispersion parameters are corrected with surface roughness). Deposition (both dry and wet) is computed for 16 wind direction sectors and 34 rings, i.e. altogether for about 500 segments.
Puffs are depleted at the end of every hour according to deposition and radioactive decay.

DOSE CALCULATION

External gamma air kerma rates, organ doses and effective doses are computed for all segments due to cloudshine and groundshine. Skin beta doses are also determined.

Inhalation doses are calculated from the clouds passing and from resuspension. Foodchain pathway is included in the computation of the committed doses.

Effects of shieldings by housing are taken into account according to user-specified occupancy and shielding factors.

In addition to the individual doses, collective doses are derived by taking into account the population data (for several doses, adult and child doses are calculated separately.

HEALTH EFFECTS

Early morbidities and mortalities (fatalities) are estimated from deterministic health effect models. Late effect probability calculations are based on the no-threshold, linear dose-effect relationship hypothesis.

COUNTERMEASURES

Three types of short-term countermeasures can be implemented during the simulation: sheltering, iodine prophylaxis and evacuation). Warnings are given to introduce these countermeasures, whenever preset criteria are reached or exceeded for one, ore more of the segments. The actual decision (for the implementation) is for the user. Or, and this is a unique advantage of the interactive simulator, the user can execute two parallel runs — with and without countermeasures — and compare the consequences.

For the long term countermeasures (relocation and food ban: which are to be introduced after finishing the direct simulation but whose introduction affect the dose commitments) actions are assumed to be taken automatically if the preset levels are exceeded.

Two types of countermeasure scenarios can be introduced by the user: intervention criteria may be based on either activity concentration or dose type quantities.

COMPUTATIONAL ENVIRONMENT - DATA FILES

Since the program is intended to serve education and to present quick information for laymen, one of our main purposes was that it had to be easy-to-handle and results had to be presented in an easy-to-understand, demonstrative manner. To fulfill these tasks the program works under WINDOWS operation system with the usual menu system, with dialog and message boxes. Results (path of the plume, contaminated area, doses, health effects) are displayed on maps with spectacular symbols, and/or in tables showing the computed values.

In the version first developed and presented the emission point is taken to the site of the Paks nuclear power plant. The maps, four maps with increasing magnification, cover the area of Hungary. All the site-specific data bases are relevant to Hungary (population and food consumption data) or even to the Paks site/reactor (meteorology, core inventory, building dimensions). The segmented structure of the program, however, makes the adaptation for another site relatively easy, assuming that the required data relevant to that site are available.

MAJOR SCIENTIFIC TOPIC NUMBER ..... (see page 7)

ABSTRACT (See instructions overleaf)

Although every precaution is taken about the use of nuclear energy, the occurrence of a major accident cannot be totally ruled out. The Institute of Protection and Nuclear Safety set up a Technical Crisis Centre to face such an eventuality. This centre is often tested through crisis exercises. In order to meet the needs in environmental consequences assessment of nuclear accidents a Software called « ASTRAL » (technical assistance in post-accidental radioprotection) is under development. It allows to : characterise the radioactive state of the environment, forecast its evolution in time and space, estimate the efficacy of rehabilitation actions and countermeasures and compare the calculated values with regulatory levels.

The ASTRAL software is based on the following elements :

- A **data bank** containing information such as :
  - population, land use, characteristics of nuclear facilities, potential radionuclides releases, counter-measures
  - computation parameters such as transfer factors, radiological data...,
  - specific crisis data.
- A **cartographic module** based on a Geographical Information System, used to visualise the concerned zone, extract data, and display results,
- a **calculation module** integrating dynamic mathematical models, especially developed or coming from the literature (ECOSYS, AIEA...),
- tools for the **graphical presentation** of results,
- an **ergonomic interface** Machine - Man in order to manage the system.

Special attention has been given to the simplicity of use in the case of a crisis and to the minimisation of the risk of errors.

COMPUTERIZED SYSTEM TO CREATE RADIATIONAL AND HYGIENIC PASSPORT OF SITE AND TO RESEARCH THE PROGNOSTICATED CONSEQUENCE SENSITIVITY DUE TO COUNTERMEASURES

A.A. Niggiyan, Yu.N. Bragin, V.N. Gerashchenko, S.I. Yanov

Institute of Biophysics, Moscow, Russia

Information system "Rahypnap" consists of data presented as a radiation-hygienic passport of settlement, that contains information on demography, nutrition regimes and radiation conditions. Initial data preliminary is collected in off-site sanitary and hygienic offices and written into special paper forms of passport. It includes 19 different forms according to data kinds. Special screen form was created to input, correct and view data in computer for each paper form of passport. Data base also contains tables of transforming coefficients from surface contamination density and food-stuff contamination density to annual individual effective dose. Those coefficients can be modified according to supposed countermeasures.

System's data base permits mean individual dose computations in 5 population groups of different age and for adults (age of 18-59), beside that, in 6 professional groups for urban and rural settlements apart; it also permits the collective dose computations for the distinct settlements and their compositions.

Dose computing procedure is based on the linearization of individual absorbed dose in a finite time period presented as a function of radionuclide contamination density of environmental objects (surfaces, food-stuffs).

System's interface is realized as a menu set that is structured as a tree. It provides an object selection: passport data forms, standard viewing and printing forms, up to 5 user defined forms and calculations. Corresponding set of operations is provided for each object: data input and correction (for passport data forms), data view and data print (for all objects), form design (for user defined forms), initial data actualization, coefficients set correction and performing (for calculations). All operations with data base are performed for preliminary selected region or single settlement only.

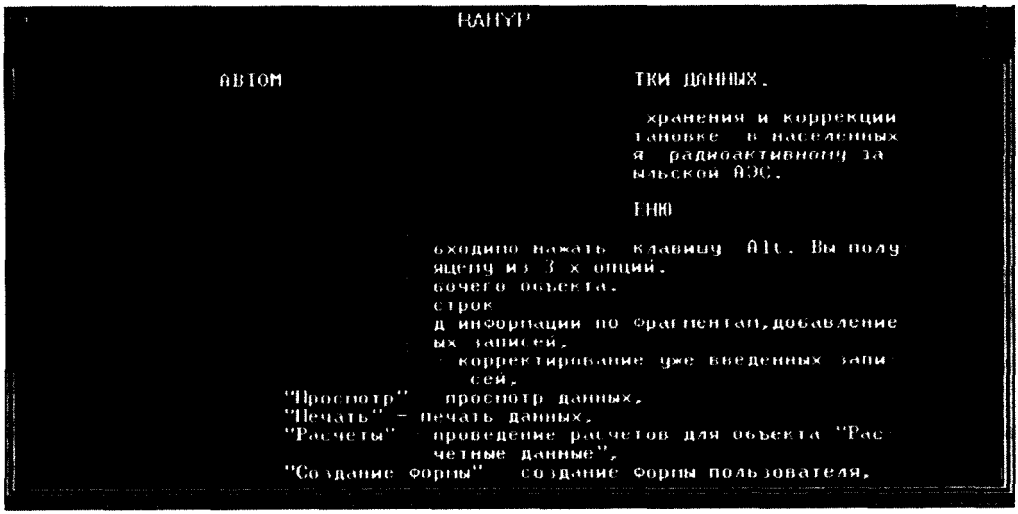

Figure 1. Sample of standart output form selection

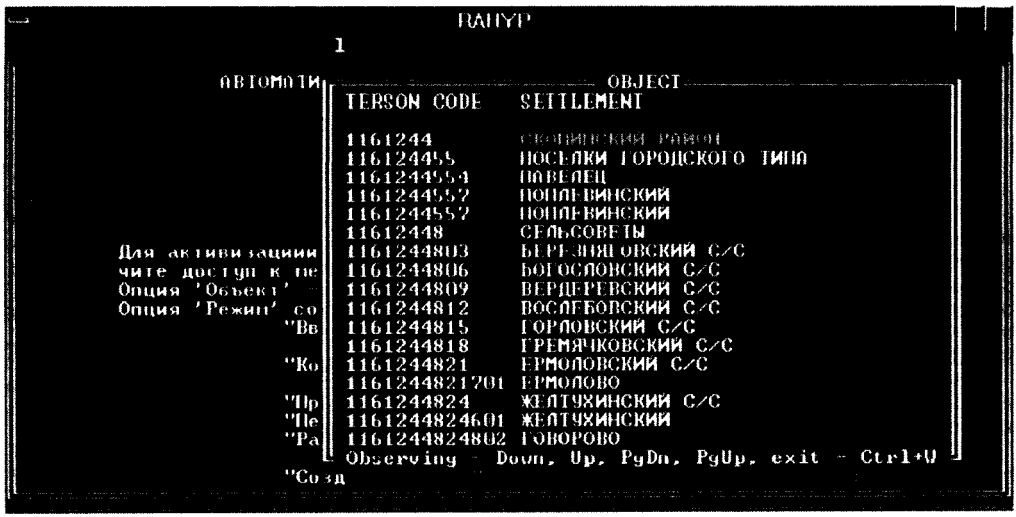

Figure 2. Sample of region selection

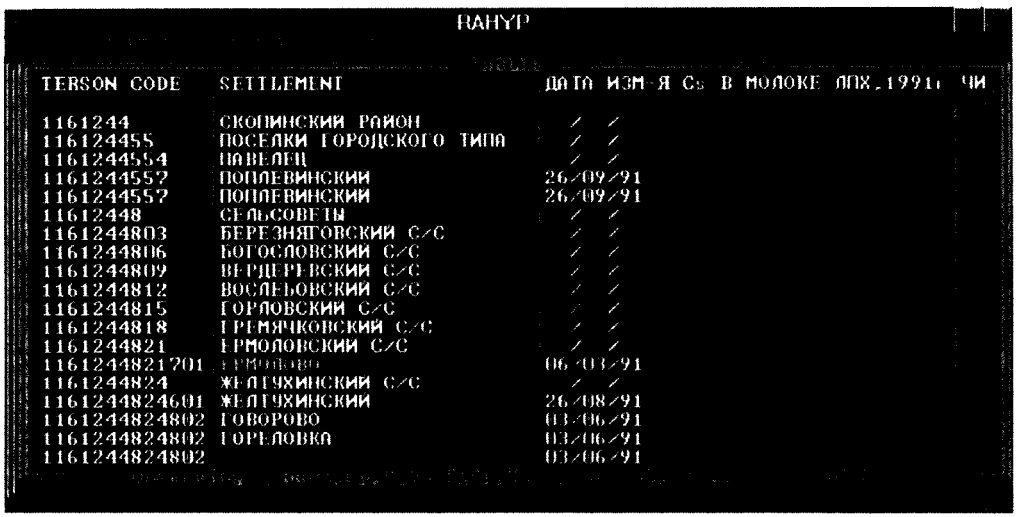

Figure 3. Sample of output standard form view on the screen

System was applied to estimate radiation consequences of Chernobyl accident for central European part of Russia: Ryazan, Tambov, Lipetsk and Kursk areas. System's interface is very easy and useful. It allows to use this system not only by scientists, but by staff of local sanitary and hygienic offices without special training. It was a key to successful distribution of system and following promotion of local data selection and integration.

RADAL: A DYNAMIC MODEL FOR THE TRANSFER OF RADIONUCLIDES THROUGH AGRICULTURAL FOOD CHAINS.

Sergio F. Jerez Veguería,[1] P. F. Jerez Veguería,[2] I. Frómeta Suárez[1]

[1]Instituto de Medicina del Trabajo, Apartado 9064, CP 10900,C. Habana, Cuba.
[2]Centro Nacional de Seguridad Nuclear, C. de la Habana, Cuba.

ABSTRACT

The contamination of agricultural products by radionuclides is a mechanism which results in radiation dose commitment to the population, following fallout deposits from the atmosphere to the landscape. This paper describes the structure of the dynamic food chain model RADAL. This model simulates an acute environmental transport of fallout radionuclides through agricultural food chains to man and estimates the levels of radiation doses resulting from consumption of contaminated food. The development of RADAL was based on different existing models. For mathematical representation the transport of radionuclides was modeled through compartments representing environmental elements and/or food products. The model solves a set of linear, first-order, differential equations to estimate the concentrations of radionuclides in soil, vegetation, animal tissues and animal products as a funtion of time following their deposition. Dynamic physico-chemical processes of the model include the following: deposition and foliar interception, weathering, foliar absorption, soil resuspension, transfer from soil surface to the root zone, absorption by plant roots, transfer to deep soil, transfer to animal products, and human consumption of agricultural products. A parameter sensitivity analyses, performed for the main parameters of the model, showed that the foliar interception constant and resuspension factor are the most influential parameters over the radiation doses / model output.

INTRODUCTION

The deposition of the radiactive material on the land surface has associeted a radiological risk to man because of ingestion of contaminated food. There is a short time risk resulting from direct deposition of radioactive fallout on the agricultural products and a long time risk due to migration of contaminants through the human food chain.

The practice of the radiological assessment models in the environment, has been taken great importance nowardays. In recent years several more dynamic models for evaluation of the radionuclides behavior in the terrestral food chain and human intake, have been developed, e.g. ECOSYS (1), FOOD-MARK (2), RADFOOD (3) and PATHWAY (4). It is proper to remark that the trend has been toward more complex models; however, the increased complexity has not necessarily improved the accuracy of estimates of dose and, in certain cases, has had the opposite effect (5).

In the present paper the simple dynamic assessment model RADAL for simulation of an acute environmental tranfer of radionuclides through agricultural food chains to man, has been developed.

GENERAL DESCRIPTION OF THE RADAL MODEL

RADAL took as models of reference mainly those described by Koch J. and Tadmor J. (RADFOOD) and Whicker F. W. and Kirchner T. B. (PATHWAY), taking

into account a more understanding and complete dynamic assessment model to represent the transfer of radionuclides through food chains following release into the environment. With the present study we are offering a simple dynamic model where potentially important pathways, ten groups of vegetables and animals food and forage, and the critical radionuclides (Sr-89/90, Ru-106, I-131, Cs-134/137 and Pu-239) that can contribute to the radiation dose resulting from consumption of contaminated food, are identified. Fig. 1 shows the general structure of RADAL.

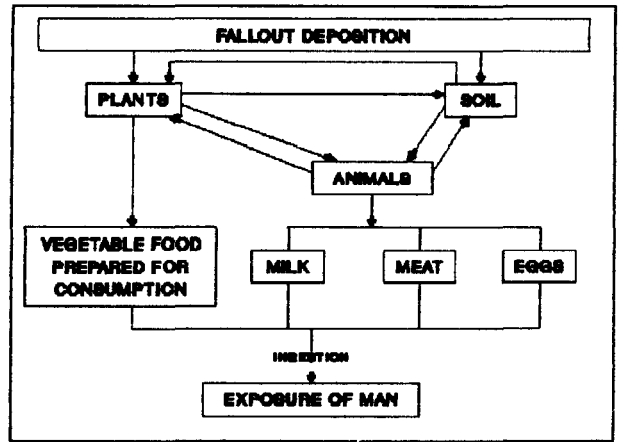

Figure. 1 The general structure of the dynamic model RADAL.

Mathematical model for the environment

The mathematical modelation of the agricultural food chais for a dynamic analysis of radionuclides transfer is carried out considering that environmental elements are united compartments between them by the transport process of mass. The description of radioactivity behavior in the determined compartment, knowing possible processes of transport and exchange between the contiguous compartments, leads us to obtain a set of differential equations with correspondent initial conditions. This model employs nine compartments or state variables, comprising the fruit surfaces, plant leaves, internal tissues of fruits, soil surface, root-zone soil, deep soil, milk, meat and eggs.

Physico-chemical processes of the model

The following transfer processes of radionuclides through agricultural food chains are considered in RADAL.

1. Deposition of radioactive fallout onto the soil surface and the fraction intercepted by leaves and fruits of plants.
2. Removal of deposited radioactivity on the plant and fruit surfaces by weather factors such as wind and rain, and other factors too.
3. Transfer of radionuclides from external parts of plants to internal tissues. Foliar absorption.
4. Resuspension of deposited material on the soil surface and subsequently deposit on the ground and/or vegetative surfaces.
5. Transfer of radionuclides from soil surface to the root zone.
6. Absorption of radionuclides by plant roots.
7. Transfer of radionuclides in soil from root zone to deep soil.
8. Ingestion of contaminated pasture and soil by animal.
9. Transfer of radioactivity to meat, milk and eggs, as well as other fractions are given back to the soil by excretion.
10. The fodstuffs obtained from animals may be treated and/or storaged. In these cases the physical decay is taken into account.

Radioactive decay reduces the radionuclide inventories in all compartments of the model over time.

Model parameters

The determination of environmental model parameters is a hard work that requires of a long time of research. For the RADAL model different radionuclide-dependent and independent parameters and methodology to determine them on reported literature (4-6-7-8-9) have been selected. Some specifical parameters of Cuban crops, soil and human diet, have been recorded.

Equations that describe process

The kinetics of the radionuclides transfer is described by a set of linear first-order differential equations that caracterize variation of state variables of system (10). Each equation corresponds to a state variable and expresses the change with time of radioactivity concentration in the compartment. In reference (11) the equations of RADAL are shown. The model estimates the levels of radiation doses resulting from consumption of contaminated food (12)

APPLICATION AND SENSIVILITY OF THE MODEL

The application of assessment model RADAL is to screen for the more important radionuclides and exposure agricultural food chains. The model solves a set of differential equations using a Runge-Kutta method (10), by a computer program elaborated by the authors.

A rigorous uncertainty analysis has not yet been performed, but a preliminary sensitivity analysis showed that the foliar interception constant and resuspention factor are the most influential parameters over the radiation dose/model output. The dose is not sensitive to changes with the tranfer parameters in soil.

CONCLUSIONS

RADAL as the dynamic model, solves in a simple and understandable way the transfer processes in the agricultural food chains. The internal radiation dose resulting from consumption of contaminated food, is estimeted too. This model may be used for prognostic and evaluation of the radioactive contamination in agricultural food chains following an acute release into environment, and so estimate, guide and be able to take immediate decisions to minimize the health detriment of the population by ingestion of contaminated foodstuffs.

INTRODUCTION

After a large-scale nuclear fallout the early prediction of the exposure of the population to be expected is of great importance to enable early decisions on countermeasures to be taken and to optimize such decisions to ensure an maximum reduction of the expected exposure if required. This includes the prediction of the contribution of each exposure pathway, in particular the ingestion path, and the contribution of important foodstuffs to this path.

The prediction should be fairly precise which requires a number of data at an early stage after the accident on a nation-wide scale. This is impeded by a number of limitations in availability of data in the early phase which are caused by various reasons: Some important data such as the activity concentration integral in air, total wet and dry deposition and radionuclide concentrations in important fodder are not available before the end of the passage of the plume and the resulting fallout. But also the time delay in taking samples of relevant items on a nation-wide scale, delivery of the samples to the measuring laboratories and the need of sample preparation especially with regard to certain non-gamma-emitting radionuclides contribute to this unavailability of data relevant for the prediction in the early phase.

Despite these problems responsible authorities require a realistic assessment of the situation and a prediction of the exposure to be expected at an early phase of radionuclide release and fallout.

Therefore, in Austria the decision was taken to perform the required predictions of the ingestion exposure at various stages during and after the fallout ensuring that a very rough prediction of the exposure pathways is available at a very early stage and improvements of the prediction quality are obtained at various stages after fallout along with the arrival of more reliable and more accurate data in the course of the event. In addition, predicted values of activity concentration in fodder and in foodstuff are compared to actually measured values as they become available and the calculated values are improved accordingly.

PREDICTION PHASES

The prediction of the exposure was segmented into 4 major chronological stages at which certain data or data sets are expected to be available. These stages and the relevant input data which are presumed to be available or most reliable among those available and which are used for the calculations, are given in table 1.

Phase Nr.	Time after start of plume [d]	Criteria for initiating the prediction calculation	Scope and Accuracy of prediction	Relevant input parameters
1	2 - 4	after passage of a significant part of the plume	very rough	- activity concentration in air - gamma dose rate monitoring stations - precipitation data
2	4 - 6	after the passage of the major part of the plume	refined prediction	- activity concentration integral in air - activity concentration in precipitation - precipitation data
3	6 - 12	after the passage of the total plume	regionally refined prediction	- activity concentration integral in air - act. conc. in precipitation and soil samples (wet and total deposition) - precipitation data
4	10 - 16	after availability of fodder and foodstuff activity measurements	very refined, taking activity concentrat. in foodstuff into account	input data as in phase 3, further refinement by comparison to actually measured values in foodstuff

Table 1 Stages of exposure prediction after nuclear fallout

Computational predictions are performed with the prediction model ECOSYS (1) which had been adapted to Austrian climatic conditions and food consumption patterns several years ago and thereafter named OECOSYS (2). In order to enable proper predictions, the code requires a set of data independent of date of occurrence and the activity in the plume. These are preset as described before (3,4). Other input parameters are only established at or after the fallout. These comprise:

activity concentration integral in air [Bq h m^{-3}]
wet deposition of each radionuclide [Bq m^{-2}]
amount of precipitation [mm]

The regional distribution of these values is required if for a specific region the exposure of persons living only on local foodstuff is to be derived, but also if the exposure of the general population in that area is to be predicted taking into account the transport of foodstuff from different regions of different fallout and growth stage levels within one country or in Europe.

In the early stage of a nuclear fallout only a few parameters will be readily available for evaluation in Austria:

1. data of the early warning system (336 gamma dose rate monitoring stations distributed all over Austria and transmitted in real-time and on-line to a central coordination and warning centre
2. activity concentration in air by a 6 on-line aerosol monitoring stations (total β-activity) and aerosol samples evaluated by gamma spectroscopy at a few places, mainly large cities and the Research Centre Seibersdorf
3. precipitation values by appr. 100 on-line meteorological monitoring stations which are also well distributed over Austria (TAWES - Teilautomatisches Wetter-Erfassungs-System)

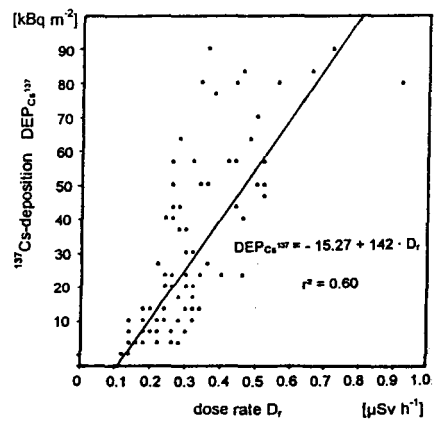
DERIVATION OF DEPOSITION VALUES FROM GAMMA DOSE RATE MONITORING

It has been demonstrated that from the on-line dose rate D_r monitoring early warning system the ^{137}Cs-activity deposition on ground $DEP_{Cs^{137}}$ (dry and wet) may be derived if data on radionuclide spectra are available (2,5):

$$DEP_{Cs^{137}}(t) = -15.27 + R_{Cs^{137}} \cdot D_r = -15.27 + 142 \cdot \frac{\sum k_i(x) \cdot g_i \cdot e^{-\lambda t}}{\sum k_i(\text{Chernobyl}) \cdot g_i \cdot e^{-\lambda t}} \cdot D_r \qquad (1)$$

k_i is the ratio of each radionuclide to ^{137}Cs, and g_i is the conversion factor D_r / DEP for each radionuclide. This takes into account that a relationship between dose rate monitored by the early warning system and ^{137}Cs-deposition values already was derived after the Chernobyl accident as displayed in Figure 1. Since the ratio of dose rate versus ^{137}Cs-deposition depends on the radionuclide distribution at the time of evaluation, the conversion factor may be arithmetically derived from the sum of the contribution of each radionuclide to the dose rate.

The deposition calculated by formula 1 is rather crude, but gives a quick and fairly reliable geographical distribution due to the large number of monitoring stations involved. The major reason for the rather crude estimate at this early stage is the fact that neither the complete activity concentration integral in air nor the total radionuclide deposition will be kown. Also the relationship between ^{137}Cs-activity deposition and gamma dose rate depends on the homogenuity of radionuclide distribution and on local variations of the ratio of the gamma dose rate displayed by the early warning station and ground deposition (2).



radio-nuclide	conversion factor g_i D_r / DEP	nuclide ratio on 10 May 1986	dose rate contribution
^{99}Mo	$0.8.10^{-4}$	0.07	0.004
^{103}Ru	$3.0.10^{-4}$	1.29	0.38
^{106}Ru	$1.4.10^{-4}$	0.32	0.04
^{132}Te	$1.7.10^{-4}$	1.19	0.16
^{131}I	$2.6.10^{-4}$	4.22	1.07
^{132}I	$13.0.10^{-4}$	1.19	1.25
^{133}I	$3.6.10^{-4}$	0	-
^{134}Cs	$9.4.10^{-4}$	0.56	0.53
^{137}Cs	$3.8.10^{-4}$	1.00	0.38
$^{140}Ba/La$	$16.4.10^{-4}$	0.28	0.43
$\sum k_i(\text{Chernobyl}) \cdot g_i \cdot e^{-\lambda t}$			4.00

Figure 1 Relationship between gamma dose rate monitored by the early warning system and ^{137}Cs-activity deposition on 10 May 86 and contribution of radionuclides to dose rate

With a plume possibly passing for 2 - 8 days, the inhalation of air-borne activity and also the fallout will not be finished at the first prediction date. Therefore, as soon as the major part of the plume passed (4 - 6 days), a fact given when the amount of activity concentration in air is less than 5 % of original values and no further increases due to changing wind direction are forecasted, the second prediction calculation is performed. The input parameters include activity concentration in precipitation (wet deposition) replacing the less accurate deposition values derived from the early warning system by formula 1.

After 6 - 12 days the plume definitely has passed and besides precipitation activity also activity concentration of soil samples which had been collected and evaluated gamma-spectroscopically, will be available. This gives more reliable data on total wet deposition than precipitation activity data (times precipitation values) and therefore will replace these values in the input data set for the ECOSYS-prediction calculation.

ON-LINE VALIDATION PROCEDURE

After the end of fallout and with sufficient data for the primary input to the prediction code, a further improvement of the prediction is achieved by measuring samples of fodder and foodstuff and comparing the activity of these with values predicted by the model. A set of samples as given in table 2 is taken over the whole territory of Austria. The major fodder samples taken would be grass, maize and barley. The relative amount varies according to season. The dominant foodstuff considered in this evaluation of prediction accuracy will be milk since milk samples taken in the dairies from one milk collecting tour will average over an area of app. 0,05 - 0,25 km^2 (6), thus providing very reliable data for prediction comparison. Also other foodstuff samples would be taken in order to assure that activity concentrations of these are adequately predicted, but these are of less importance than milk and therefore a lower number of samples is being foreseen. The sample collecting plan fixes the type of sample taken, the approximate number of samples, the authority responsible for taking the sample, the measuring laboratory and the transport means of the sample to the laboratory in advance.

type of sample	appr. sample number	sample specification	sample taking spot
maize - fodder	80	1 kg of leave and 1 kg of cob *	near TAWES station
barley - fodder	80	1 kg corn at harvest or 1 kg plant 14 d before	near TAWES station
beets - fodder	80	1 kg beet (well cleaned of soil) *	near TAWES station
milk	~ 600	1 l (frequency depending on season)	each milk collecting tour
cereals	100 - 150	minimum 0,8 kg corn, 0,4 kg straw *	1 sample per 400 km^2
potatoes	50 - 80	1 kg at harvest or 1 kg plant 14-30 d before	1 sample per 800 km^2
leavy vegetables	80	1 kg, only outdoor plants,according to season	1 sample per 800 km^2
fruit vegetables	80	1 kg, several types of plants at season	1 sample per 800 km^2
fruit	80	1 kg, several types of fruit, at season	1 sample per 800 km^2
meat	~ 6000	min. 0,7 kg	statistical selection **

Table 2 Samples taken nationwide to test and improve on accuracy of prediction model
* mixed sample of 10 individual samples out of several fields
** beef: each 50th animal, veal: each 30th animal, pork: each 300th animal

CONCLUSION

The prediction model established in Austria to guarantee a rapid and reliable prediction of the activity concentration in foodstuff and the resulting ingestion dose after a nuclear fallout has been considerably improved by performing the required predictions at various stages after the arrival of the plume. The first very rough prediction uses the readily available data of on-line transferred data from the gamma dose rate stations of the early warning system and the meteorological monitoring system. In further prediction computer runs more refined input parameters such as precipitation and soil activity concentrations are used to obtain more precise results. In the later stage fodder and foodstuff activity concentrations as actually measured are used to further refine the model predictions.

ABSTRACT (See instructions overleaf)

The objective of the works on development of the computer system indicated is: development of up-to-date approaches, models and program tools for investigation of the consequences of contamination of lands with long-lived radionuclides; estimation of effectiveness of countermeasures (CMs) in agro-industry; creation of the computer decision support system on protection and rehabilitation measures in areas subjected to contamination as a result of a nuclear accident. The work is close to the several studies in Europe, USA and Japan; however we pay special attention to the problems of CM-strategy including comparison different (agricuitural, administrative) CMs. The developments have some features: complex character (agro and radioecological, radiobiological, demographic, socio-economic, etc., models and databases); development of methods for assessing/comparison of a wide class of CMs on the basis of radiation protection principles and documents; the possibility of assessments using laws of distribution of values and parameters being used through the main chains under investigation; use of raster and vector GISs; creation of an open computerized system based on the principles of object-oriented programming that makes it possible to use any module (model) from the library; creation of the multilevel DSS, both in the aspect of the scale of the object being investigated (region-district-[farm]-settlement) and from the point of view of the subject of investigation (three-level interface). These works are participated by specialists from several institutes of Russia (RIARAE (Obninsk), RRC "Kurchatov Centre" (Moscow), RRC-VNIIEF (Kremlev); collaboration is planned with institutes of the CEC countries and Japan.

ABSTRACT (See instructions overleaf)

Methodological aspects in realization of Probabilistic Methods (PM, i.e., those taking into consideration the corresponding distribution laws for values used) are scrutinized. The idea of using PM in radiology is not new; however, the major part of the works describe inhomogeneities observed (distribution laws) and do not deal with the problems of including the values under consideration in more complex estimation based on operations with these values. Besides, any analysis of problems connected with the use of PM is lacking; so, groundless optimism appears in practical operations with random/distributed values. The wish to "improve" prediction of some values under investigation by using the PM can face ambiguous estimates which cannot be verified in many cases. The problem of final presentation of the values' distribution is far from limited to differences in the modes of integrating the distributions characterizing different compartments. There is also the problem that no distribution laws for source values exist a priori; distribution law can be considered only after detalizing the probabilistic spaces. Significance of the differences appearing in determination of the structure of plant and animal products contamination is considered by concrete examples of contaminated areas. The main charakteristics of production contamination structure connected with the use of alternative methodological approaches, different kinds of distribution of input values, as well as ambiguous choice of the main parameters of these distribution are considered.

HUMAN RADIATION DOSE RESULTING FROM FORESTS CONTAMINATED BY RADIONUCLIDES: GENERIC MODEL AND APPLICATIONS TO THE CHERNOBYL ECOSYSTEMS

Igor Linkov[1,2] and William R. Schell[1]
[1]GSPH, University of Pittsburgh, Pittsburgh PA 15261, USA
[2]Physics, Harvard University, Cambridge, MA 02138 (current address)

ABSTRACT

Forest ecosystems have been found to contribute significantly to the human radiation dose in the intermediate and long terms following radionuclide releases. Evaluation of the internal and external radiation dose for these critical population groups requires knowledge of radionuclide transport processes in forest ecosystems, as well as the extent of forest utilization by these populations. The high complexity of the problem requires the use of models to define and analyze the properties of the forest as well as to evaluate the ecosystem response to possible human intervention. A generic FORESTPATH model is used to calculate the internal and external radiation doses for different critical groups of consumers at different times following radionuclide release. The model is tested using the information available for contaminated forests in Belarus. Uncertainty of the model predictions are estimated by means of Monte-Carlo simulations.

EXPOSURE ASSESSMENT

Several pathways exist whereby people are exposed to radionuclides from contaminated forest ecosystems. In general, external and internal components of the total radiation dose can be distinguished. The external dose results from direct irradiation due to the radionuclides present in the local environment, while ingested and inhaled radionuclides contribute to the internal dose. In the case of contaminated forest ecosystems, the external dose can be received by the general public via the direct gamma shine while walking in the forest or through irradiation from radionuclides incorporated into construction materials and paper. Occupational exposure can be received by working in the contaminated environment and by irradiation from by-product materials and from timber cut for forest industries and for fuel. The internal dose arises from the ingestion of forest products (berries, mushrooms, birds, game, etc.) and from inhalation of resuspended radionuclides from soil and plants; in addition, radiation dose is received from ash caused by forest fires and from wood burned for heating purposes. These exposure routes can affect populations far removed from the contaminated zones.

A scenario is considered for a rural population inhabiting an area near the Exclusion Zone of Belarus contaminated by 5 Ci/km^2 of ^{137}Cs. This population consumes forest products collected from a pine forest near the village which has 5 Ci/km^2. Large segments of this population are involved in forestry and agriculture activities. Work in the forests implies an annual occupational exposure of about 1,000 hours in areas characterized by a surface deposition of 20 Ci/km^2. Table 1 presents probability distributions for the average annual consumption of forest products, exposure time for occupational forest use, forest characteristics which are typical of the 30-year-old pine plantations in Belarus and conversion factors.

Table 1. Parameters used for probabilistic modeling of risk associated with contaminated forest ecosystems

Parameter	Notation	Unit	Distribution			Reference
			shape	mean	range	
residence area contamination	RAC	kBq/m^2	constant	185		site-specific
forest contamination	FOC	kBq/m^2	constant	740		site-specific
Organic Layer accumulation	OL	% initial inventory	triangular	55	15 - 75	1
Organic Layer biomass	OLB	kg/m^2	triangular	3.1	2.4 - 4.5	2
Understory biomass	UN	% initial inventory	triangular	0.2	0 - 2.2	1
Understory biomass	UNB	kg/m^2	triangular	0.5	0.01 - 1	estimates
mushroom consumption	MUC	kg/yr	triangular	10	5 - 15	3
mushroom processing retention	MPR	fraction	triangular	0.2	0.1 - 0.4	4
berry consumption	BEC	kg/yr	triangular	6	5 - 20	3
berry processing retention	BPR	fraction	triangular	0.6	0.7 - 0.8	4
external dose rate factor	DRE	(nSv/yr)/(Bq/m^2)	triangular	24.5	22 - 30	3
internal commited dose rate	DRI	nSv/Bq	triangular	13	10 - 22	3,5
occupational time spent in forest	FOO	hr/yr	triangular	1000	500 - 2000	estimates
dose-fatal cancer risk conversion factor	DRC	Sv^{-1}	uniform	0	0.08	6, estimates

Two major routes of exposure for this population are the external irradiation due to gamma emission from the forests and the internal exposure due to radionuclide ingestion from forest berries and mushrooms. The resulting average external dose for the i-th year following the deposition can be calculated using:

$$EP_i = (RAC_i + FOC_i * FOO) * DRE \quad (1)$$

where EP_i is the annual average external dose (mSv/yr).

The average internal dose can be calculated using:

$$IP_i = ((OL_i/OLB) * MUC * MPR + (UN_i/UNB) * BEC * BPR) * DRI \quad (2)$$

where IP_i is the annual average internal dose (mSv/yr),
OL_i is the radionuclide concentration in the Organic Layer (% of initial inventory),
UN_i is the radionuclide concentration in the Understory (% of initial inventory),

Additional irradiation dose can be encountered due to radionuclide resuspension by soil or ash (if timber is used for heating purposes), use of contaminated construction materials and paper, forest fires, consumption of the game, etc. The resulting dose from these and other processes is a subject for future investigation and is not considered in this paper.

The risks of low-dose-rate external exposure to radiation have been obtained by extrapolation from high-dose-rate data (5). Recent compilation of the available data for different exposed population (7) provides reasonable doubt that low-level radiation is harmful. Thus, a uniform distribution from zero to twice the value recommended in (5) was used for dose-risk conversion factor in risk calculations:

$$R_i = (EP_i + IP_i)) * DRC \quad (3)$$

RADIATION DOSE AND RISK

The FORESTPATH model (1, 8) is used to establish the radionuclide distribution among forest compartments. In this paper, coniferous forest ecosystems which are typical for the Chernobyl Exclusion Zone are considered. An initial contamination density of 5 Ci/km^2 and generic FORESTPATH parameters (1, 8) were used, as well as the forest characteristics presented above. The current radioactivity of mushrooms is significantly higher than that found in berries because mushrooms take up nutrients and, therefore, absorb radionuclides from the Organic Layer (1, 8). On the other hand, the activity in berries, which have a deeper root zone and extract their nutrients from the Labile Soil, is shown to increase with time reaching a maximum at about 10 years following the accident (1, 8).

Figure 1a presents the external radiation dose resulting from living in an area with contamination density of 5 Ci/km^2, as well as the additional radiation doses due to occupational exposure in the forest and to forest product food consumption. Work in a contaminated forest of 20 Ci/km^2 leads to an annual external dose of 4.2 mSv (sum of public and forest worker exposures) for the fifth year following the accident. This is about 2.5 times greater than the average external dose received by the non-forest-worker population in this area. Dose rate measurements for forest workers were conducted at several Belarussian sites (2). Their occupational exposure was found to be 1.75 to 2.9 times higher than the external dose to the general public living in the same area, which is in agreement with the model predictions. After eight years, the human radiation dose is slowly decreasing with a half-time of about 30 years due to the physical decay of ^{137}Cs.

Monte-Carlo simulations were conducted to address the influence of the uncertainty in input parameters (Table 1) to the internal radiation dose (Figure 1b). Each Monte-Carlo simulation produced 300 estimates of the internal dose resulting from the berry and mushroom consumption seven years following the contaminating event. Parameter values were selected using the random Latin Hypercube method. Cumulative distribution functions for internal dose reveal a wide range of variation depending on consumption of the forest products and site contamination.

The cumulative distribution function for the risk of developing a fatal cancer for the general public is presented in Figure 2a. The high range of variation results from the uncertainty in input parameters (Table 1). To find the most important parameters for the model performance, a sensitivity analysis was conducted using the technique of partial rank correlation (Figure 2b). The uncertainty in the DRC (dose-risk conversion factor) dominates the range of model outputs. Unfortunately, current literature does not allow any better estimation of this parameter. All other parameters are significantly less important. Among the other parameters, the organic layer contamination (OL) and internal commited dose rate (DRI) are relatively important.

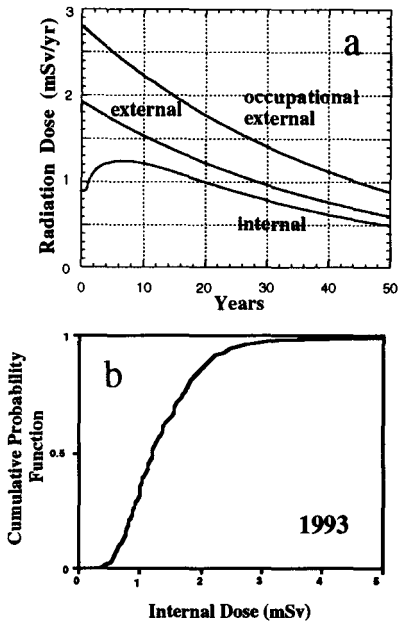

Figure 1. Excess radiation doses received by different populations (a) and cumulative probability function for internal dose received in 1993 (b).

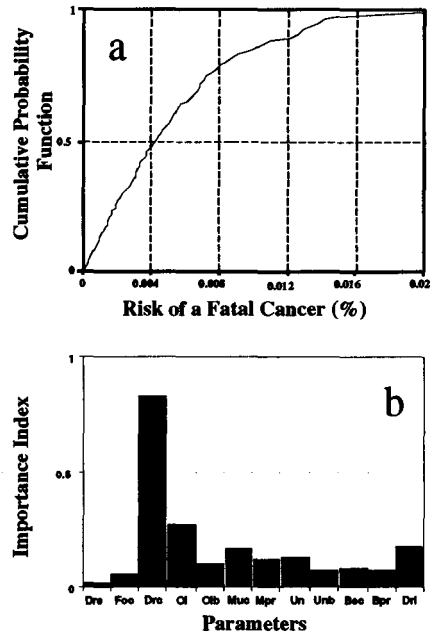

Figure 2. Cumulative probability function for risk of a fatal cancer due to consumption of forest product by a critical population group (a) and importance index for model parameters (b).

CONCLUSIONS

The complex problem of radionuclide contamination in forest ecosystems requires the use of a model to synthesize and analyze the properties of the entire ecosystem. Modeling can provide not only estimates of the radiation dose but also can predict future trends of dose accumulation. The generic forest model developed and used here provides a starting point for evaluating internal and external radiation doses and risks over long time periods. Contaminated forests constitute a significant hazard to the public over long periods of time depending, in a major part, on the forest food intake. Occupational exposure can be several times greater than that for the general public. The use of a dynamic model can facilitate the decision-making process and helping to design efficient abatement, and remedial and social policies in radionuclide contaminated regions.

ABSTRACT

Global fallout from nuclear weapon tests in the 1960s revealed the potential of fungi as an enhanced accumulator of radioactivity. Data derived from Chernobyl fallout sampling has shown fungi to be a major accumulator of radiocesium and an important food-chain contributor to the human radiation dose. Fungi can significantly affect the radionuclide cycling in forests. According to experimental data and estimations, forest microflora, particularly fungi mycelia, could retain up to 40% of radiocesium. This paper illustrates the application of the dynamic model FORESTPATH to evaluate the contamination dynamics in fungi and the relative importance of fungal species for forest cycling. Only a few studies have been made to model fungi contaminated by radionuclides and these utilize Transfer Factors to describe soil-to-fungi uptake of radionuclides. Such an approach has serious limitations, since equilibrium conditions and specified soil sampling depths must be assumed. The FORESTPATH model uses rate of uptake and residence half-times for radionuclides to describe this process. The model was applied to describe radionuclide dynamics in fungi for the case of chronic deposition and for the accidental release of radionuclides. Experimental measurements of fallout from nuclear weapon tests and from the Chernobyl accident were used to test the FORESTPATH predictions.

INTRODUCTION

Data derived from sampling of the areas contaminated by the Chernobyl fallout have implicated the Organic Layer as being a major accumulator of radiocesium (1, 2). Fungi are the highest living biomass in the decomposing organic layer and are the primary sources of the enzymes necessary to degrade the litter and, thus, are very important for radionuclide migration in forests. Fungi mycelia and fruit bodies are mainly located in the upper part of the organic layer. Although above-ground mushrooms are a minor contributor to the total fungal biomass (according to Olsen (3), this contribution may be as low as 1%, leaving 99% in the below-ground biomass) they can contribute significantly to the human radiation dose being consumed as a food.

Very little is known about the mechanisms involved in the radionuclide uptake and retention by fungi. Fungi can play a significant role in radionuclide retention by the organic layer. Olsen et al. (4) estimated that some 32% of the total Chernobyl-derived radiocesium present in a forest soil in Norway is contained in fungi. This estimate was confirmed by experimental data (5). Their experiments with artificial washout of humus samples show that forest microflora (particularly fungi mycelia) could retain up to 40% of radiocesium. The absorption of nutrients (and thus radionuclides) by fungi from the ground occurs in aqueous solution usually from the soil solution. Fungi use enzymes to break down macromolecular complexes in solution for digestion. Once broken down, most substances are thought to move into the *hyphae*, being bound to specific carrier molecules. The rate of this uptake by both saprophytic and symbiotic fungi depends on concentration of the ion, moisture content of the soil, the growth rate of the plant and, in the case of symbiotic fungi, the transpiration rate of the host plant.

Several studies have examined the differences in the ability of saprophytic and symbiotic fungi to accumulate radiocesium. Results of several studies (5, 6) indicated that the symbiotic fungi accumulated, on average, statistically higher concentrations of radiocesium although both types of fungi collect radiocesium quite effectively. These observations can be explained by the differences in mycelium location in the soil profile as well as the migration of Chernobyl-derived radiocesium through forest soil. Other hypotheses include differential retention of radionuclides by fungi (5).

The life cycle of soil fungi may have an impact on the time of immobilization of radionuclides in mycelium. Differences exist between the life time of different species of fungi. According to Olsen et al. (4), the lifetime of mycorrhizal fruit bodies (mushrooms) is normally between 10 and 17 days. The life of fungal biomass in

soil is not as well understood and is suggested to be on the order of two years. After death, the release of nutrients proceeds primarily by leaching. As water comes in contact with the cell wall of the fungi, nutrients such as K^+ diffuse across their concentration gradient and into solution. Another less important release pathway is due to animal consumption.

Quantitative evaluation of the relative fungi contamination is a challenging task. The traditional approach is to evaluate the Transfer Factor (TF) for soil-to-fungi transfer. TF can be defined as the ratio between the activity in plant (Bq/kg dw) divided by the activity in soil (Bq/kg dw) or by the deposition per unit area (Bq/m^2). Large variability in the TF values has been reported. TF across different species varies over several orders of magnitude (7).

The TF approach has serious fundamental limitations because it is applicable only to equilibrium situations, which can only be achieved in natural ecosystems a long time after the contamination event (10-20 years for the case of forest ecosystems (1,8)). Multi-layered soil structure with variable depth of soil horizons of the natural environment and inhomogenuity of the radionuclide deposition and its soil migration requires definition of conditions for sampling depth and volume. By including an estimate of the depth to which the radiocesium has migrated (i.e., Cs-134/Cs-137), Guillitte et al. (5) were able to obtain a more accurate estimate of the ability of a particular fungi species to take up radiocesium. Thus, it is problematic in defining the soil volume where nutrient uptake occurs. The dynamics of fungal biomass growth and decay are not well understood and questions remain regarding the nutrient requirements of this plant over time.

MODELING OF ORGANIC LAYER AND MUSHROOM CONTAMINATION

The FORESTPATH model (1, 8) calculates a time series of inventories for a specific radionuclide distributed within the following six compartments: Understory, Tree, Organic Layer, Labile Soil, Fixed Soil and Deep Soil. In this paper, the model was developed further to incorporate details of radionuclide migration in the Organic Layer and fungi. The Organic Layer is represented by three horizons: Ol (litter), Of and Oh. Reported residence time for Cs in these horizons (see (1) for review) along with values for other FORESTPATH parameters for Chernobyl forests (1, 8) were used for model simulations. Figure 1 shows radionuclide accumulation by the Organic Layer as well as by the Labile and Fixed Soil compartments, in a coniferous forest in Chernobyl described in (1, 9) (an initial deposition of 5 Ci/km^2 was assumed in the calculations). Organic Layer compartments exhibit complex time dynamics. The litter compartment is significantly contaminated immediately after the deposition, but looses all its activity during the first year due to wash-off and leaching towards deeper layers. Of and Oh horizons show accumulation peaks at about two and four years respectively following the initial deposition.

Mushroom mycelia exist in different soil horizons. Given the complexity of the nutrient uptake by mushrooms and lack of theoretical description of this process, it could be assumed that mushrooms have the same contamination density as the layer in which their mycelia are located. Using this methodology, calculations have been made for contamination of two types of mushrooms in coniferous forests. The first type has mycelium developed in the Of horizon, while the second type has mycelium located in the Oh-upper layer of mineral soil. A representative edible mushroom species of the first type is *Boletus badius* (or *Xerocomus badius*) (10), while *Boletus edulis* is representative of the second type (5). Based on the FORESTPATH model, *Boletus badius* would be expected to have the same dynamic of contamination as the Of horizon (i.e., have maximum accumulation during the second year following the accident (Figure 1). *Boletus edulis* which takes nutrients from the labile soil, would be expected to increase its contamination during the first decade following the accident.

MODEL VALIDATION

Model predictions are validated based on: 1) compilation of the reported ^{137}Cs concentrations in these two mushroom species in Central Europe (generic model), and 2) concentrations reported for contaminated forests in the Exclusion Zone (site-specific model). Figure 2 shows compilation of the existing literature values for mushroom contamination (see (1) for compilation tables). It is clear that *Boletus badius* exhibits an accumulation peak around 1988, while *Boletus edulis* concentration still increases (at least until 1991). Significant variability in the reported data can be explained by different contamination levels, climatic conditions, soil structure and types, etc. In the Chernobyl forests, *Boletus badius* and *Boletus edulis* exhibit the time dynamics expected for plants with roots developed in Of and Oh-Mineral Soil compartments (Figure 3). Predicted values from the FORESTPATH are about two times larger than the values measured by the Forest Research Institute, Belarus. Due to the fact that the experimental data were obtained based on reported values for the TF, the differences of a factor of two can be explained by the large uncertainty incorporated in the TF determination.

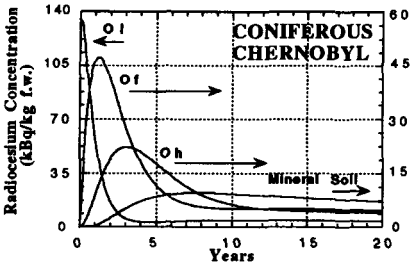

Figure 1. ^{137}Cs concentration in soil compartments of a coniferous forest in Chernobyl over 20 years from an initial acute deposition (kBg/kg f.w.). The scale of the ordinate is 140 kBq/kg for the Ol horizon and 60 kBq/kg for all other compartments.

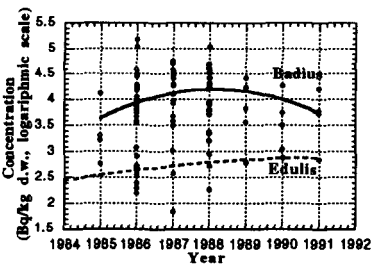

Figure 2. ^{137}Cs concentration in *Boletus badius* and *Boletus edulis* collected in European countries.

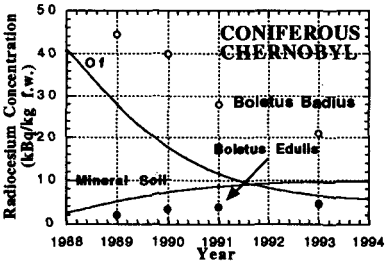

Figure 3.
Cs-137 concentration in Boletus badius and Boletus edulis collected in Chernobyl forests (circles, after Ipatyev (11)) compared to those predicted by FORESTPATH for species having mycelia in Of and Mineral Soil horizon (solid lines).

CONCLUSIONS AND RECOMMENDATIONS

FORESTPATH can be applied for detailed evaluation of the radionuclide accumulation in a specific forest compartment. The model predicted an enhanced accumulation by fungi with shallow mycelia during the first years after an acute deposition, while the accumulation peak for deep-rooted species is delayed. These predictions have been validated based on the experimental data collected in Europe (generic approach) and in the Chernobyl Exclusion Zone (site-specific application).

ABSTRACT

The report deals with some ecological problems in artificial radioactivity of Belarus and Ukraine in the atmosphere, soils, Black sea, rivers and forests after Chernobyl accident.

INTRODUCTION

The accident at the Chernobyl nuclear power station and the global scale of consequences had spurred intensive research on radioactive contamination of Black Sea waters.

Among more than 30 radionuclides detected in the blow-outs from the destroyed reactor, cesium-137, cesium-134, and strontium-90 radioisotopes are of greatest interest as the half-life of other isotopes with significant activity lasts for several days. Also, plutonium radioisotopes, which accounted for 3 % of the overall discharged by the reactor, are was of great interest (Information, 1986). Given this setting, the soviet investigators concentrated on the study of the concentration of cesium and strontium radioisotopes in Black Sea waters.

EXPERIMENTAL

Figure 1 exhibits the results of measurements of cesium-137 concentration in Black Sea surface waters carried out in the period from 15 to 23 June, 1986 (Cruise 33 of the R/V AKADEMIK VERNADSKY). The largest cesium-137 concentrations were documented at st. 35 - 720 Bq/m^3 of cesium-137, cesium-134 concentration being 372 Bq/m^3 . The range of variation of cesium-137 and cesium-134 concentrations is within 34 (st.30) - 720 and 17-372 Bq/m^3 , respectively. The density of cesium-137 distribution at station 35, located off the South Crimea, reached 32.3 KBq/m^2 (876 mCi/m^2) in the upper mixed layer. From Polikarpov's data (Polikarpov and Kulebakina, 1989) the cesium-137 concentration attained the value of 815-840 Bq/m^3 in this area in May 1986 [1].

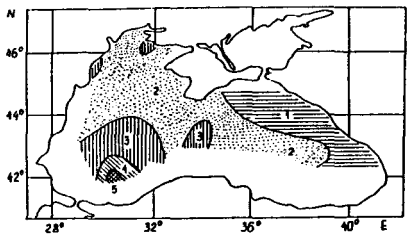

Fig. 2. The distribution of Cs-137 concentration in the Black Sea surface waters. December, 1986. (See Fig. 3.8 for denotements).

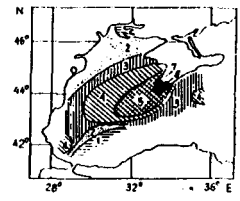

Fig. 1. Cs-137 distribution in the surface waters of the western Black Sea in June 1986.
1 = less 100 Bq/m³; 2 = 100- 200 Bq/m³;
3 = 200- 300 Bq/m³; 4 = 300- 400 Bq/m³;
5 = 400- 500 Bq/m³; 6 = 500- 600 Bq/m³;
7 = more 600 Bq/m³.

The data given in Figure 1 are smoothed, compared to the real field of cesium-137 distribution in the Black Sea surface layer, not only because of the rarity of stations. Obviously, in June 1986, an important role in smoothing of the originally patchy contamination of surface waters belonged to physical mixing processes. Against the general background of Black Sea surface water contamination, the northwestern shelf area (where in June 1986, the lowest cesium-137 and cesium-134 concentration, being about 100 Bq/m^3, was registered) stands out. From our data, the mean Cs-137 and Cs-134 radionuclide content reached 272±171 Bq/m^3 and 136± 86 Bq/m^3 , respectively. It should be noted then that their mean values for the northwestern shelf amounted to 107,20 Bq/m^3 and 56±9 Bq/m^3 respectively. The Cs-134/Cs-137 ratio acquired for the period at issue equalled 0.50,0.005. The variation coefficients for cesium-137 and cesium-134 concentrations and the Cs-134/Cs-137 ratios reached 63 %, 63 %, and 10 %, respectively. This points to the simultaneous input of cesium radionuclides into the Black Sea surface waters. The temporal trend of cesium isotope surface concentration identified in (Livingston et al., 1989) at the same stations can be explained by the water mass mixing. All the investigators note that Cs-137 and Cs-134 concentrations in the surface waters, both in June and September, vary dramatically within the range between the two sampling stations. We can explain this by the variability of Chernobyl radionuclide deposition to the Black Sea surface. Livingston et al., (1989) emphasize that in September, compared to June, a growth in cesium radionuclide concentration resulted from the surface circulation and transport of the more active waters from the norhern Black Sea to the Bosporus region. This pattern implies that the Chernobyl radioactive depositions in the northern Black Sea are higher than in the southern area. This is confirmed not only by meteorologic models (World Health, 1987)

but also, by the results of the investigations implemented in November-December 1986 practically throughout the Black Sea, except for the Turkish economic zone (Chudinovskich and Eremeev, 1990).Figure 2 depicts the distribution of cesium-137 concentration in the surface waters during this period. The sampling stations are marked by points. Obviously, over the seven months, since the moment radionuclides had entered the Black Sea, considerable smoothing of the initial patchy contamination took place.

In the spring of 1987, the flood was awaited with particular concern. Patterns in the spring snow thaw showed the possibility of considerable injection of radioactive products into the Black Sea shelf zone. The greatest alarm was caused by the radioactive situation in the northwestern shelf, whose fluvial discharge accounted for 80 % of the total run-off into the Black Sea.

Analysis of the results obtained permits us to claim that no appreciable influx of cesium radionuclides with river waters into the northwestern shelf area occurred. Over the year after the accident the mean values of cesium-137 and cesium-134 concentrations had essentially decreased. In June 1987, these amounted to 96± 47 and 25 ± 13 Bq /m^3 , respectively, for the western Black Sea. A different situation occurred in the spring and summer of 1987 in the eastern Black Sea. In the waters off the Caucasus, the concentration of cesium radionuclides increased 1.5 - 2 times. The cesium-137 concentration in the surface waters in December 1986 being 150 Bq/m^3 , at most, in June 1987, it varied within the range of 200 - 300 Bq/m^3 .

The mean values of cesium-137 and cesium-134 concentration in November-December 1986 reached: - 102 , 39 and 45 ± 15 Bq/m^3 in the eastern Black Sea, and 177 ± 80 and 81 ± 41 Bq/m^3 in the western Black Sea part, respectively. It should be noted that despite the general decrease in the mean values of the surface radiocesium concentrations in December 1986, as compared to June, their presence in the waters of the northwestern shelf slightly increased. In June, the mean values of cesium-137 and cesium-134 concentrations in the shelf areas reached 107 ± 20 and 56 ± 9 Bq/m^3 , respectively, whereas, in December, they were 143 ± 63 and 59 ± 19 Bq/m^3 , respectively. The increase in radionuclide concentration may have occurred both through transfer of the more contaminated waters as a result of surface circulation and the delivery of radionuclides with river waters during the period of autumn flood. We will not elaborate on the features of radioactivity inputs by the river run-offs, as this problem will be considered further.

The cesium radionuclide concentration distribution in the eastern Black Sea during this period was uniform and lay in the range of 50-150 Bq/m^3 (Fig. 2).

The intensive snow thaw in the mountains and the influx of cesium radionuclides with melting waters. The mean values of cesium-137 and cesium-134 concentration for the entire eastern Black Sea during this period reached 119 ± 83 and 30 ± 21 Bq/m^3 , respectively.

The range of variation in cesium-137 concentration lies within 25 and 280 Bq/m^3 , and for cesium-134, the variation was from 7 to 70 Bq/m^3 .

From data compiled by the same authors, Sr-90 concentrations in the Black Sea waters in 1987, on average, reached 35,2 Bq/m (the range of measurement being within 25 - 78 Bq/m^3) in the northwestern corner, 22.9 Bq/m^3 (17 - 31 Bq/m^3) in the western area and 22.6 (17 - 24) Bq/m^3 in the eastern area. On the whole, the mean values of Sr-90 concentration for the Black Sea reached 19.6 Bq/m^3 . Similar investigations were conducted in 1988-1994.

During the ten years since the Chernobyl accident and radionuclides input into the Black Sea a gradual decrease in cesium-137 and cesium-134 concentration was observed in Black Sea surface waters. In 1991 the cesium-134 concentration in the majority of samples was already too low to be accurately determined, whilst Cs-137 concentration did not exceed 50 Bq/m^3.

Thus, the Black Sea surface waters have exhibited a great capacity for "self-purification". It is obvious that "self- purification" of this kind occurs, primarily, because of the processes of water mixing and radionuclide redistribution between the surface and deep waters, as well as because of the physico-chemical processes and bioaccumulation leading to sorption and absorption of radionuclides and, finally, their transfer into bottom sediments.

RADIOACTIVE CONTAMINATION IN BELARUS

In the Republic of Belarus, 23% of the territory (3,666 sett lements) have been contaminated by radiation with a density of Caesium -137 contamination of more than 1 Ci/sq. km. The highest density of Caesium -137 contamination, exsept for a zone of 74 settling out, is revealed in Chericovsky region of Mogilev oblast (146 Ci/ sq.km). There were a total of settlements in a zone of primary settling out (more than 40 Ci/ sq.km with the Caesium 137). The area of agricultural territories contaminated by radioactive Caesium with densities more than 1 Ci/ sq.km equals 1.6 mln. hectares. About thousand hectares of fofest are contaminated by radionuclides [2].

The contamination by Strontium -90 has more local character. The sites with the contamination levels of 3 Ci/ sq. km are found out in Hoiniky region, particular sites with densites 2-3 Ci/sq.km are found in Hoinikovsky, Braginsky, Dobrushsky and Vetcovsky regions of Gomel oblast. The soil contamination by Plutonium-238, -239,-240 higher than 0,1 Ci/ sq.km is revealed basically in a zone settling out, particular spots are presente in a number of regions in the Gomel oblast.

RADIOACTIVE CONTAMINATION OF WATERS OF BELARUS

The monitoring system for the radionuclides content in surface waters of the main rivers of Belarus (the Dnepr, the Sozh, the Priryat, the Iput, the Besed) showed that immediately after CNPP accident, the concentration of Sr-90 in down stream of the Pripyat river have exceeded permissible concentration of this radionuclide in water, but already in May 1986 its concentration in water has descreased to $1\ 10^{-10}$ Ci/l and in 1994 was already $1.0\ 10^{-12}$ Ci/l. For the whole monitored period since 1987, the excess of Cs-137 content in surface waters of the large rivers of Belarus was not recorded. Caesium-137 loss by surface waters on the territory of Belarus considerably descreased over time. The substantial share of Cs-137 comes into the Dnepr river from the Belarus-Bryansk Caesium spot with warer of the Sozh and Iput rivers. One should note, that because of the Sozh river, the Cs-137 loss descreased over time from 280 Ci/year (1987) to 20 Ci/year (1994) (Fig.3 and 4).

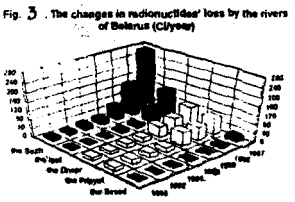

Fig. 3 . The changes in radionuclides' loss by the rivers of Belarus (Ci/year)

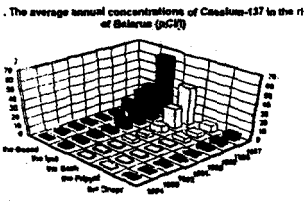

Fig. 4 . The average annual concentrations of Caesium-137 in the rivers of Belarus (pCi/l)

If in the first days after accident at CNPP the increase of radionuclides concentration in water was stipulated by direct fall of radionuclides on wares surfaces, now the contamination levels of water systems by secondary processes: exchange with bottom sediment, radionuclides washing out from surface of the river catchment, as wellas at the expebse of thawed and flood waters.

RADIATION CONTAMINATION OF THE SOILS AND FORESTS

As the result of CNPP accident, 4.8 mln. ha of the teritories Belarus are contaminated by radiation, including 1.2 mln. ha (14.5%) of the republic's forests. The main weight of radionuclides is concentrated in the top 5-centimetre soil statum. In sandy unbogged soils with attributes of redundant humidifying, the depth of radionuclides penetration is 8-9 cm., in the same soil, but alluvium -16-17 cm, in gleyey and gley soils- 11-12 sm. Strontium-90 because of less strong link with soil absorbing complex, migrates faster than Cs-137. The depth of its penetration lies below 15 cm statum.

THEORETICAL INVESTIGATION

The mathematical theory of diffusion and convective transfer of radionuclides in vaious media (atmosphere, seas and ocean, riwer and other) are discussed. The main bounlary-value direct and inverse problems of radionuclides transfer through plane, celindrical, spherical walls were solved under the conditions of diffusion, convective transfer radioactive fussion, absorbtion fnd relaxation process. The discrete spectrumof direct problems was determined, the eigen function of spectral problems and their roots were built. Using of the eigenfunctions the solutions were built in the form of discrete spectral decompposition, the concentration distribution of the diffusion and convective flow in the dispertion and porous media were calculated at different radionuclide disrtributions in the volume and at the bound of the fields.

The new integral transfomation in the finite and infinite were built using eigenfunction of the spectral problems. A number of invers problems are formulated.

The migration of natural and artifical radioactive isotopes in the turbulent atmosphere and stratified lake and sea are studied. The equations global and vertical transfer of radionuclides in the turbulent boundary layers with classical and generaliszed boundary conditions are presented.

Mathematical models,numerical algoritms and computer programs for numerical solutions of diffusion in atmosphere, lake and sea are presented.

ABSTRACT

The migration of natural and artificial radionuclides in the turbulent atmosphere in the Black sea region and Belarus after Cherobyl accident are discused.

INTRODUCTION

Investigations of radioactive contamination of the near surface atmospheric layer in the Black Sea region were conducted by MHI, Ukrainian Academy of Sciences, from May 1986 through March 1994. FPP filters were used to concentrate air radionuclides. The air was supplied to the filters by the blast blower. The volume of the air that passed through the filters reached (120-200)*10 m , the averaging period being 6-7 days. In the investigations accomplished in May-June 1986, the period of testing lasted 12-24 hours. Measurements of gamma-activity in the filters were conducted using the low-background gamma-spectrometer featuring a semiconducting detector. Later on, when air aerosol gamma-activity was basically formed by cesium radionuclides, measurements were carried out using a scintillation sensor with a crystal of NaI(Tl).

EXPERIMENTAL

Figure 1 illustrates the gamma-spectrum of air aerosol in the sample taken in June 1986 in the near-surface atmosphere of the Black Sea. The spectrum given does not display lines of short-lived isotopes (I-131, Te-132), whose concentration was too small to be accurately measured [1].

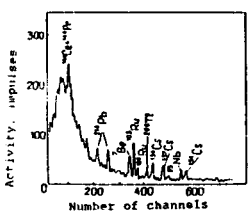

Fig. 1. Gamma-spectrum of the air aerosol of the Black Sea near-water atmospheric layer in June, 1986.

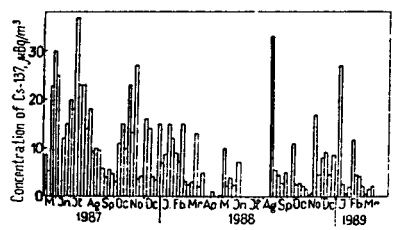

Fig. 2. The diagram of variations in Cs-137 and Cs-134 concentrations in the Black Sea near-water atmosphere (st. Katsiveli). May,1987-February, 1989.

Cesium radioisotope concentrations are given for the moment of sampling. The variation in concentration of cesium radionuclides in the near-water atmospheric layer during the investigations ranged from 1.0 to 5.5 mBq/m^3 for cesium-137 and from 0.62 to 2.79 mBq/m^3 for cesium-134. The mean value of the Cs-134/Cs-137 ratio reached 0.53±0.3 (the ratio of cesium isotopes, which was observed in the radionuclide flux in the area of the reactor accident (Buesseler, 1987). The root-mean-square deviation was 0.07, i.e., the variation coefficient equalled 13%, which was within the margin of error for nuclide concentration determination.

The peak values of cesium-137 and cesium-134 radioisotope concentration registered during the investigations were in the central Mediterranean Sea. In transition from the Mediterranean to the Black Sea, cesium radionuclide concentration in the near surface atmospheric layer had decreased. The largest values of radiocesium concentration obtained exceeded several times the identical values over the Mediterranean Sea in 1963, i.e., just after the nuclear tests in 1961-1962. During this period Cs-137 concentration ranged between 0.7 and 1.1 mBq/m^3 (The radioactive contamination, 1964). The total concentration of cesium-134 radioisotope, which were absent in the global fallouts, and cesium-137 concentration in the near-surface atmosphere of the Black Sea and the Mediterranean one month after the Chernobyl accident exceeded cesium-137 concentration documented during the most intensive nuclear weapon tests, by almost a factor. The peculiarity of the situation after the Chernobyl accident consisted in the fact that after the passage of the radioactive cloud, formed during the most intensive discharge of fission products from the reactor, a drastic decrease in radionuclides concentration in the atmosphere was observed over several areas. From the analysis of the data

presented in (Izrael et al., 1987) it may be deduced that radiocesium concentration in the nearwater atmosphere of the Black Sea during the transport of the radioactive cloud (May 1-8, 1986) reached a value of the order of 20-200 mBq/m^3 . The radiocesium concentrations measured at the end of May in the near-water atmosphere of the Black Sea were already lower than those measured in the Mediterranean Sea between 18-23 May 1986. The most likely explanation for this may be that the time between the transport of the radioactive cloud and the moment of sampling was longer for the Black Sea than for the Mediterranean.

For two years, beginning from May 1987, the radioactive cesium concentration in the near-water atmospheric layer of the Black Sea off the Crimea coast (stl. Katsiveli) was being contunuously measured. The averaging period was 7 days. Figure 2 gives a diagram of the variation of cesium-137 and cesium-134 concentration over the period of investigation. The range of variation of cesium-137 concentration was within 3.2-38 mkBq/m^3 ; and for cesium-134, it was 1.4-28 mkBq/m^3 . Thus, as compared to May 1986, cesium radionuclides concentration in the atmosphere decreased more than 100 times.

From the mean cesium-137 and cesium-134 concentrations one may trace a tendency for a decrease in radionuclide concentration in the near-water atmospheric layer. Cesium-134 concentration decreases faster than that of cesium-137. There are at least two reasons for it. The first reason is associated with the radioactive decay, as the cesium-134 half-life (T = 2.07 year) is much shorter than that of cesium-137 (T = 30.17 years). The second reason is the injection of cesium-137 accumulated in the stratosphere as a result of nuclear weapon tests. The lack of experimentally-determined concentrations of cesium-137 before the Chernobyl accident has not allowed us to determine the fraction of globally deposited cesium radionuclides in the nearwater atmospheric layer of the Black Sea. Regular observations of the concentration of man-made radionuclides in the near-water atmospheric layer the Black Sea region were carried out during the intensive nuclear weapon tests. In 1960, cesium-137 concentration was of the order of 10-100 mkBk/m^3 (The Radioactive contamination, 1964). After the Chernobyl accident, radiocesium concentration was 100-1000 times higher than the values mentioned above. In the spring of 1987, however, this fell to the level of 5-30 mkBq/m^3 . 'To estimate the ratio between global radiocesium in the atmosphere and that of Chernobyl, one can use the presence of cesium-134, the only source of which is Chernobyl. At the moment of the blow-out the Cs-134/Cs-137 ratio equated 0.53. Cesium-134 may be used as "Chernobyl" tracer only provided the behaviour of both radionuclides in the atmosphere is identical. The analysis of the observations conducted in 1986-1989 showed, however, that an intensive isotope fractionation took place there. Cesium-134 concentrations are given for May 1, 1986. Incidentally, in the absence of isotope fractionation, the radionuclides ratio remains constant. Actually, during the first two years after the Chernobyl accident, cesium-134 was mainly removed from the near-water atmospheric layer. As a result, the Cs-134/Cs-137 ratio dropped to the value of 0.05. The cause for isotope fractionation in the atmosphere, in our opinion, lies in the processes related to the formation of radioactive aerosols at the moment of condensation, as well as to the concentration of cesium -134 and cesium-137 on particles of various sizes. Some evidence of radionuclide distribution on aerosol particles of various sizes may be obtained from the data in (Iost et al., 1986). The measurements were accomplished in Switzerland but they may refer to other areas where the Chernobyl radionuclide fallouts were observed. The peak of I-131 activity is shown by particles with an overall size of 0.35 and 0.71 m for Te-132, Cs137 and Ru-103.

The measurements taken in Sweden, Finland and Germany (Devell et al., 1986, STUK-B-VALO, 1986; Lockhart et al., 1965) showed that 80 % of I-131 were in a gaseous phase. Cs-137, Te-132 and Ru-103, conversely, may have been released by the reactor in the form of particles or were readily sorbed on fine-sized aerosols, which coagulated then with other particles during transport. It can be appropriately supposed that some inorganic iones (sulphates, nitrates or ammonium) may have transported radionuclides over great distances. For example, Chernobyl-derived Cs-137 distribution, in agreement with the size of particles, proved to be similar to that of the nuclear test (Lockhart et al., 1965). Today, the absence of information on the distribution of cesium-134 in agreement with the size of aerosols deprives us of the possibility to consider the likely mechanisms for cesium radioisotopes fractionation in the near-water atmosphere of the Black Sea.

RADIOACTIVE CONTAMINATION IN BELARUS

After the accident on CNPP the concentration of Stontium-90 in the lower reaches of Pripyat river exceeded maximum permissible concentration of this radionuclide and was 4.0 10 Ci/l, but now does not exceed 1.10^{-12} Ci/l. Caesium -137 loss from the most contamined spot has descraesed from 280 Ci/year in 1987 to 20 Ci/ year in 1994.Now the levels of water systems contamiation are determined by the secondary processes: excange with ground sediments, washing of radionuclides from a surface of the river water header, but also at the expense of thawed and spring flood waters.

In the Republic of Belarus, 23% of the territory (3,666 settlements) have been contaminated by radiation with a density of Caesium -137 contamination of more than 1 Ci/sq. km [2].

The highest density of Caesium -137 contamination, exsept for a zone of settling out, is revealed in Chericovsky region of Mogilev oblast (146 Ci/ sq.km). There were a total of settlements in a zone of primary settling out (more than 40 Ci/ sq.km with the Caesium 137). The area of agricultural territories

contaminated by radioactive Caesium with densities more than 1 Ci/ sq.km equals 1.6 mln. hectares. About thousand hectares of fofest are contaminated by radionuclides.

The contamination by Strontium -90 has more local character. The sites with the contamination levels of 3 Ci/ sq. km are found out in Hoiniky region, particular sites with densites 2-3 Ci/sq.km are found in Hoinikovsky, Braginsky, Dobrushsky and Vetcovsky regions of Gomel oblast. The soil contamination by Plutonium-238, -239,-240 higher than 0,1 Ci/ sq.km is revealed basically in a zone settling out, particular spots are presented in a number of regions in the Gomel oblast.

RADIOACTIVE AIR CONTAMINATION IN BELARUS

The monthly average values of aerosol radioaktivity concentration in regional centres in 1994 (Caesium-137) canged from 3.10^{-6} Bq/cub. m up to 46.10^{-6} Bq/ cub.m. The monthly average value of Strontium -90 in aerosol samples in 1994 was increased from $0{,}01.10^{-5}$ Bq/cub.m up to $0{,}24.10^{-6}$ Bq/ cub.m in regional centres. Radionuclide concentration in a lower statum of atmosphere is determined by the content of dust in the air of sities, i.c. by the processes of secondary wind rise and radionuclide transfer. Gamma radiation exposure dose rate is daily measured and the level of the radioactive precipitates from the ground statum of the atmqsphere is monitored on 22 stations, the measurement of gamma-radiation from radionuclides,Strontium-90 and Plutonium is carried out using samples of precipitates and aerosols.

THEORETICAL INVESTIGATION

The migration of natural and artifical radioactive isotopes in the turbulent atmosphere and stratified lake and sea are studied. The equations global and vertical transfer of radionuclides in the turbulent boundary layers with classical and generalised boundary conditions are presented.

Mathematical models,numerical algoritms and computer programs for numerical solutions of diffusion in atmosphere, lake and sea are presented.

The risk to human health from exposure to vapors can be assessed by first quantifying an individual's potential exposure to, or dose of, the toxicant of concern. This is followed by a comparison of the exposure with an ascribed hazard determined from a known exposure-response relationship or exposure limit.

Occupational exposures to chemicals occur as a result of inhalation of workroom air contaminated with the vapor or aerosol of the chemical. The first step in the dose assessment process usually involves a determination of the concentration of the toxicant in the air that might be inhaled by the worker. Second, an estimation is made as to how much contaminated air would be inhaled. Next, the amount of toxicant potentially absorbed into the body, transported to potential target organs, and available for physiological response is estimated. The final step in the total assessment process is to compare the estimated potential human dose with the dose response from a toxicological/radiological data base. In the case of inhalation of a toxicant with an established exposure limit, the process needs only to determine the concentration in the workroom air and actual exposure time. Comparison of the workroom air concentration with an established limit,often is considered an adequate inhalation risk assessment.

A simple but usually very conservative approach to inhalation exposure assessment is to calculate the concentration of contaminant in air. The indoor air pollution model (also known as general ventilation model) describes the concentration of contaminant in the workroom air as a balance between the total input of contaminant, and the removal of contaminant from the workroom air by general ventilation with mixing volumes of clean air and the loss of contaminant from the combined sources of absorption, adsorption chemical transformation and radioactive decay.

In addition to the above temporal elements, the modeler also must deal with spatial factors that impact on workplace concentrations of airborne toxicants. It is intuitively obvious to most observers that the aiborne concentrations around point sources in large industrial rooms are much higher near the source, than at more distant locations in the room.In consecuence we can find a gradient of airborne concentration versus distance from the source.

This gradient is inversely proportional to air movement in the room, which in turn is a function of temperature gradients, movement of physical objects within the room and ventilation rate.

A rational approach would be to determine or estimate the rate of contaminant diffusion in a room.

This information is used to determine the subsequent dimensions of a volume around the source in wich the majority of the contaminant concentration would be found relative to the time frame choosed. This conceptual model is the affected volume, and it assumes omnidirectional (random) air movement at any point in the room. Its dimensions are determined by the manner in wich the air contaminant is dispersed from the source.

Diffusion theory is based on the random motion of the diffusing molecules resulting in net movement of the molecules from areas of high concentration into areas of low concentration. The rate at wich the concentration of diffusing particles change with time is equal to the flow into the

region less the flow out. Each flow depends on the flux of particles, or flow per unit area. The flux of particles in a fluid from point to point is directly proportional to the difference in the concentration of the particles, at the two points.

The coefficient of proportionality is called the diffusion coefficient, or D and its value must be determined experimentally.

The relation between flux and the rate of change in the concentration is known as Fick's Law. The mathematical formulation of this physical state of affairs leads to a differential equation called the diffusion equation. The solution is a mathematical expression that gives the concentration of the diffusing substance at every point in the space for every time. For example, if the diffusing substance is initially concentrated on the surface of a permeable membrane that divides a box in two at its center, the solution of the diffusion equation is a family of bell-shaped curves. The center of each curve coincides with the center of the box and as time passes the curve becomes broader and flatter.

There is another way to interpret each bell-shaped curve. Every point on the curve can be considered the probability density for the diffusion of a single Brownian particle from the central membrane in the box. The probability density multiplied by an appropriate measure gives rise to a probability. For the bell shaped curve the appropriate measure is a lenght, it is the distance between two points along the horizontal axis of the graph. The product of that distance and the average height of the bell-shaped curve in the interval between the two points is a probability.

The probability that the Brownian particle will be found in a region of the affected volume at a given time is the area under one of the bell-shaped curves between two vertical lines. Each vertical line passes through one of the two points on the horizontal axis that correspond to the boundaries of the given region in the box. According to this interpretation, the solution of the diffusion equation is not an expression that gives the distribution of molecule concentrations, instead the solution is a probability distribution. A convenient probabilistic measure of the displacement of a Brownian molecule is the root-mean-square displacement, or R.M.S. displacement. The probability that a Brownian particle diffuses at most as far as the R.M.S. displacement away from the central membrane in the box is 0,68; the probability that it travels more than twice as far as the R.M.S. displacement is less than 0.5.

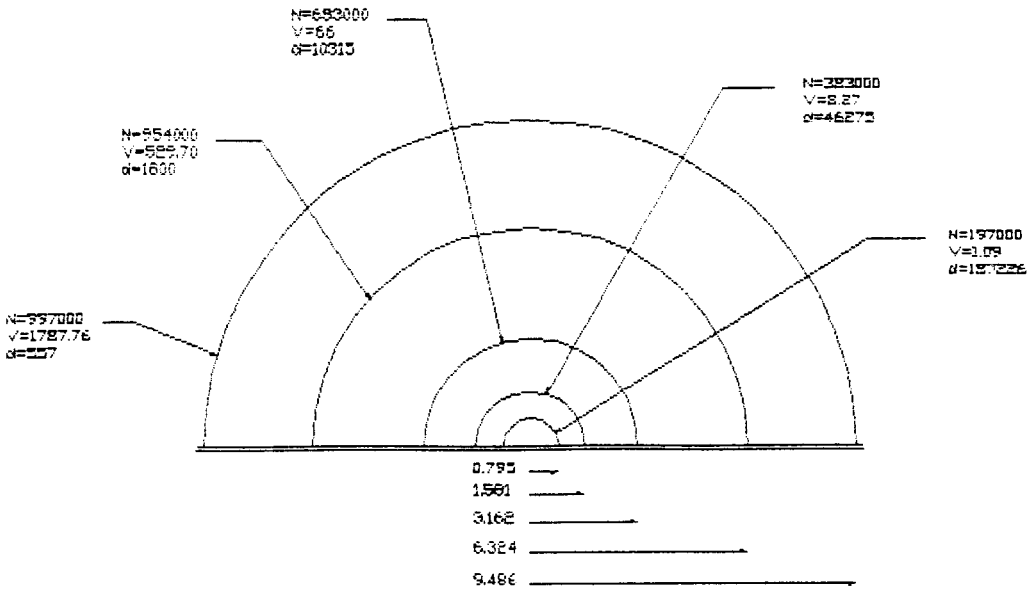
The R.M.S. displacement of a Brownian molecule diffusing away from the membrane in the box is $(2.D.t)^{1/2}$ where D is the diffusion coefficient and t is the time. Thus if a particle diffuses on the average one centimeter in one second, it will require four seconds to diffuse two centimeters and nine seconds to difusse three centimeters. So we can conclude that the radial displacement of a particle diffusing in any direction away from a central point "is not proportional to time, but proportional to the square root of time".

Consider now the instantaneous release of 1.000.000 μCi of a gaseous contaminant from a point source in the center of a large industrial room that has 12 mixing changes of air/hour or 5 minutes/mixing air change. Given 5 min. in an eddy diffusion field (D = 1 m^2/min), the R.M.S. distance from the source containing 68% of the diffusing molecules is calculated from:

$$R.M.S.= (2xDxt)^{1/2} = (2x1 m^2/minx5min)^{1/2} = (10\ m^2)^{1/2} = 3,162\ m$$

Thus, approximately 68% of the gas will be within one R.M.S. distance or a 6,324 m diameter sphere. One would find 95% of the gas within 2 R.M.S. distance or within a 12,648 m diameter sphere with the source at the center.The following table was made by calculating the volume and average concentration from the normal probability density for concentric spheres with radii of 1/4, 1/2, 1, 2 and 3 R.M.S. It shows the average concentration of the various volumes around the source, 5 min. after instantaneous release of 1.000.000 "molecules" of gas.

R.M.S.	Ø 1/2 Sph.	Volume(m^3)	Nø Molecules	C=Nø/Volume
1/4= 0,790	1,581	1,0	197.000	187.226
1/2= 1,581	3,162	8,2	383.000	46.275
1 = 3,162	6,324	66,2	683.000	10.315
2 = 6,324	12,648	529,7	954.000	1.800
3 = 9,486	18,972	1787,7	997.000	557



Repeating this procedure for succesive periods of 5 min. we can see how the affected volumes that contains the majority of the contaminant molecules is growing with time, and in consequence diminishing the contaminant concentration (mass/unit volume)

As mentioned above, actual worker exposure or delivered dose results from the time-weighted integration of contaminant concentration and uptake rate. Obviously, concentration modeling alone will not suffice to answer completely questions of how much toxicant was delivered. Ultimately the models or combination of monitoring/modeling must render an acceptable estimation of dose and be validated against measured worker exposure data in various occupational settings.

The atmosphere is the main media to transporting and dispersing the radioactive and/or chemical contaminants in accidental situations. The atmospheric models can be used to simulate the transport of contaminants in typical aocidental cases and for realistic meteorological conditions. This report describes an approach in simulating of the Chernobyl accident and similar hypothetical cases. The study is based on an atmospheric model extended by the additional equation that is modeling the transport of a certain radioactive concentration. A step mountain synoptic model, called ETA model (well-known model for weather forecasting), is used to investigate the transport and deposition of radioactive material in the Chernobyl accidental zone. Calculation was done in two steps for five 48-hours forecast periods. The first step is consisted in calculating of meteorological fields over Europe using horizontal resolution of 0,5 degrees. The second step is based on integration the same version of ETA model. The model is completed by the new prognostic equation for contaminant, with high horizontal resolution (about 20 km). The meteorological fields obtained by first step are used for initial and boundary conditions. The results of calculations are discussed by comparison with measurements. It is demonstrated that the model can reproduce certain observed characteristics of deposited material at the earth's surface inside the Chernobyl accidental zone.

MEASUREMENTS AND MODELLING OF ^{137}Cs MIGRATION INTO VARIOUS TYPES OF SOIL

Edith Koblinger-Bokori[1], Pavel Szerbin[1], László Koblinger[2], István Végvári[1]

[1]National Research Institute for Radiobiology and Radiohygiene, Budapest, Hungary,
[2]KFKI Atomic Energy Research Institute, Budapest, Hungary.

INTRODUCTION

The behaviour and migration of long-lived radioisotopes is an important part of information in the prediction of the consequences of radioactive contamination in agricultural areas. Therefore, the investigation of radiocaesium migration in soil is a focus of several research all over the world (1,2).

The level of soil contamination in Central and Eastern Europe after the nuclear accident at Chernobyl has been high enough to study the vertical migration of radicaesium under natural conditions. In Hungary, ^{137}Cs measurements have been carried out regularly since the Chernobyl accident at several location to determine the long-term migration of radiocaesium in soil system (3).

In the project presented here, the distribution of ^{137}Cs activity concentration has been measured and analyzed over the period of 1987-1996. On the experimental data collected during these ten years a model has been developed which can be used for long-term prediction of radioisotope penetration.

SAMPLING AND SAMPLE PROCESSING

Approximately 30 * 30 cm^2 areas on plane, grassy, uncultivated fields are sampled at each of five sites. Seven layers extending from the surface down to a depth of 20 cm are excavated at each of 11 sampling times (12, 14, 17, 24, 29, 36, 41, 48, 53, 83 and 118 months) after the accident. The distances between the sampling spots of the same site never exceeded 10 m.

The samples are first dried at 105 °C, then homogenized and the grains exceeding 1.25 mm diameter are removed. After this processing activities of 400 cm^3 volumes are measured by HpGe semiconductor gamma spectrometry in Marinelli geometry.

SOIL CHARACTERISTICS

Five sites have been selected to represent five different soil types, characteristic in Hungary. Several measured soil parameters are given in the Table below.

Identification	black rendzina	humic sandy soil	meadow soil	typical Ramann brown forest soil	brown forest soil with clay illuviation.
Site	Ady-liget	Szada	Domony	Galgamácsa	Dobogókô
pH (KCl)	5.5	7.5	7.3	7.2	4.2
$CaCO_3$ (%)	-	0.5	7.2	4.2	-
org. matter (%)	3.9	1.3	4.6	3.1	5.1
cation exhange capacity (me/100g)	43.0	9.8	26.8	31.0	23.1
changeable K (me/100g)	0.6	0.04	1.12	1.65	2.72
density (g/cm^3)	1.14	1.70	1.45	1.24	1.13

ERROR SOURCES

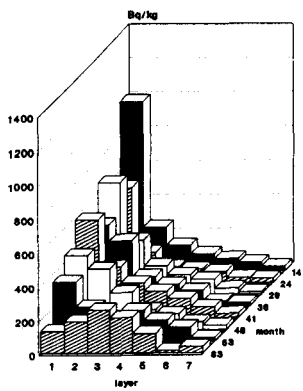
There are many sources of errors and uncertainties in the final results: short-range soil inhomogenities, the roughness of soil surface, the uncertainties in soil layer thicknesses, and errors of the spectrometric measurements.

To improve the error estimation at the last but one sampling three samples were taken and evaluated parallelly at each site. The standard deviations of the three sample sets are in the range of 25-40 %

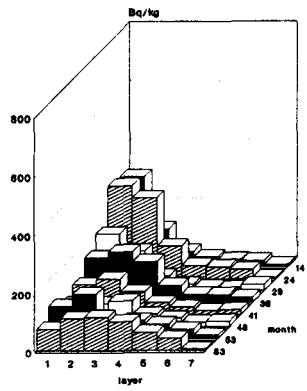
The effect of the sampling uncertainties are decreased by determining the actual weights of the layers, in g/cm^2, and using these values in the evaluation, rather than the nominal thicknesses in cm.

MEASURED CONCENTRATIONS

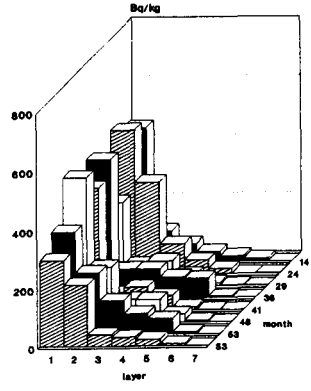
As an illustration, the measured activity concentrations are shown for three types of soil



brown forest soil with clay illuviation (Dobogókő)



meadow soil (Domony)



humic sandy soil (Szada)

MIGRATION MODEL

The physical and chemical processes of the migration are assumed to follow the diffusion-convection model. Let the initial surface concentrations from the Chernobyl and nuclear test fall-outs be a_{Ch} and a_{nt}, respectively, then the concentration a at depth z, at time t after the Chernobyl accident is

$$a(z,t) = a_{Ch}\exp[-\lambda t]\frac{1}{2[\pi Dt]^{1/2}}\exp\{-\frac{[z-ut]^2}{4Dt}\} + a_{nt}\exp[-\lambda(t+\tau)]\frac{1}{2[\pi D(t+\tau)]^{1/2}}\exp\{-\frac{[z-u(t+\tau)]^2}{4D(t+\tau)}\},$$

where
- $a(z,t)$ is the activity concentration (Bq/cm^3) at time t and depth z,
- a_{Ch} is the Chernobyl fall-out on the soil surface (Bq/cm^2),
- a_{nt} is the fall-out of the nuclear weapon tests on the soil surface (Bq/cm^2),
- D is the diffusion coefficient (cm^2/month),
- u is the convection velocity (cm/month),
- λ is the decay constant of ^{137}Cs (1/month),
- τ is the average time between the nuclear tests and the Chernobyl accident (set to 300 months).

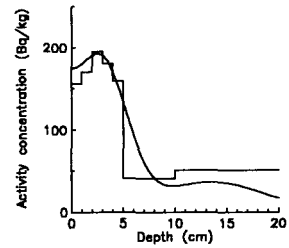
Furthermore, a total reflection at the air-ground interface is assumed.

The best fits of the initial surface activities, the convection velocities and the diffusion coefficients obtained by applying a Monte Carlo technique are given in the next table.

Identification	black rendzina	humic sandy soil	meadow soil	typical Ramann brown forest soil	brown forest soil with clay illuviation
Site	Ady-liget	Szada	Domony	Galgamácsa	Dobogókô
a_{Ch} (Bq/cm^2)	0.76	0.61	0.53	0.70	1.43
a_{nt} (Bq/cm^2)	0.61	0.84	0.76	0.68	1.14
u (cm/y)	0.082	0.042	0.220	0.106	0.424
D (cm^2/y)	0.343	0.053	0.400	0.041	0.433

According to the best fits the ratio of the maximum and minimum convection velocities is about 10, and the diffusion coefficients vary also within a factor of about 10.

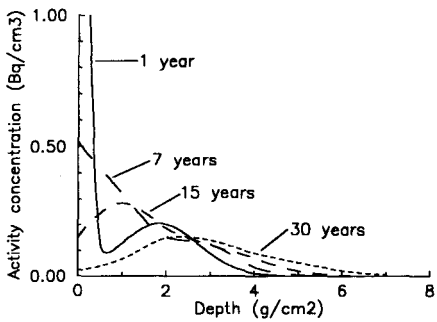
As an illustration, the measured activity concentrations (hystogram) and the fitted depth profile (continuous curve) for brown forest soil with clay illuvation (Dobogókô) are given in the figure for 83 months after the accident.



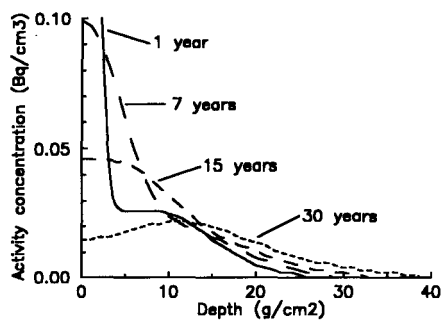
The goodness of fit is somehow characterized by the fact that the initial surface activities are in the range of 0.6-0.8 Bq/cm^2, both for Chernobyl and the nuclear tests, as expected form earlier measurements at these sites around Budapest, i.e. at one of the most contaminated areas of Hungary. Both values are slightly but significantly higher at Dobogókô, where samples were taken at a site with higher precipitation.

MODEL PREDICTIONS

Assuming the correctness of the model for longer time periods, predictions can be made for future times. Activity concentration curves computed for 15 and 30 years are given in the next figures for two types of soil.



Humic sandy soil (Szada)



Meadow soil (Domony)

CONCLUSIONS

The penetration of caesium into the soil is a very slow process, the majority of the activities is still in the top 1-5 cm layer.

According to the measurements carried out in the first ten years following the Chernobyl accident the migration can well be modelled by the diffusion-convection model. Since the uncertainties are relatively large, further measurement series are required to confirm the validity of the model and to improve the parameter estimations.

ADAPTABILITY OF THE MATHEMATICAL MODEL IN ^{137}Cs LEACH-RATE AND EFFECTIVE COEFFICIENT OF DIFFUSION DETERMINATION FROM THE MORTAR MATRICES

Aleksandar Perić
Institute of nuclear sciences "Vinča", P.O.Box 522.,11000 Belgrade,Yugoslavia

ABSTRACT

Mortar materials were used in the radioactive waste liquid effluent, containing ^{137}Cs, immobilization processes. As a matrix material, two types of the mortar formulation were used: the first one, prepared in ordinary manner, where the aggregates used were stone particles of average diameter of 2 mm, and the second one, where the polyethylene of low density granulates of average diameter of 2 mm were used. Both sample groups were introduces on leaching in aim to determine their physico-chemical characteristics, mainly ^{137}Cs leach-rates and indirectly coefficients of inspected radionuclide effective diffusion. Leaching tests were performed for 200 days. Measured ^{137}Cs leach-rates were the base parameter in mathematical modelling of the leaching process. From the postulated differential equation, that represents the leaching process, radionuclide diffusion coefficients, as well as deposition coefficients inside the mortar matrices were calculated, using programme packages for nonlinear fitting. When these coefficients were calculated for the samples of the finite geometry, with the sample's surface completely open to contact leachant, e.g., distilled water, numeric values were returned in the mathematical model, and the cumulative leached fractions of the radionuclide, that represents the matrix behaviour due to leaching in the prolonged time periods, were obtained. Differences between the ^{137}Cs leach-rate values, obtained experimentally and by mathematical modelling of the leaching process, were noticed. Mathematical model underestimates the leach-rate values until the completed hydratation of the cement in the mortar matrix and overestimates leach-rate values after the cement hydratation was done. These differences could be explained by adopted approximations, when postulating the mathematical model of the leaching process, neglected saturation concentration of the radionuclide inside the matrix and variations of the deposition coefficients of the radionuclide concerning two types of applied granulates in mortar formulations. Nevertheless, these differences do not exceed 5 percents for the leach-rate values, which permits to postulate opinion on mortar-radwaste matrix behaviour in the prolonged periods of time.

INTRODUCTION

Mortar was used as a matrix material in an immobilization process of radioactive waste material, $^{137}CsCl$ solution. Low density polyethylene, PELD, was used as granulates in preparing the mortar matrices, parallel with the preparation of the matrix mixture samples that were made with stone granulates. PELD was in a granulate form of 2 mm diameter. PELD was used instead of ordinary used granulates, usually little stone particles, in aim to decrease porosity and density of the mortar matrix and to avoid phenomenon of stone particles segregation on the bottom side of the immobilized radwaste cylindric form [1]. Satisfying this aim, we tried to obtain better physico-chemical characteristics of the radwaste mortar mixture forms, especially radionuclide leach-rates. Quality of the final radwaste form should be discussed due to: a radionuclide immobilized in the mortar matrices leach-rates, as well as to the appropriate coefficient of diffusion. Calculating the radionuclide coefficient of diffusion for the investigated mortar matrices, made either in ordinary manner or with PELD granulates, it is possible to predict behaviour of the final radwaste form in the prolonged periods of disposal time, considering the most undesirable disposal conditions, e.g., flooding of the disposal site. When discussing the phenomena that have influence on the radionuclide leach-rate from the concrete matrices: diffusion, dissolution of the matrix and deposition of the radionuclides on the pore walls inside the matrix, the assumption is made that the radionuclides are leached from the surface and interior of the cylindrically shaped sample geometry. In aim to simplify a mathematical modelling of the leaching process of ^{137}Cs from the orthocylindrical sample, we made an assumption that the concentration of the examined ionic type is uniform in every segment of space and time, and equal to the saturation concentration of the ionic form. In this manner, the dissolution factor could be neglected in leaching process consideration, and postulating the following differential equation, Equation 1., which describes the processes that occur inside the matrix material, and whose solutions, for the defined initial and boundary conditions for finite cylindrical geometry, give the radionuclide leach-rate from the matrix-radwaste mixture form [2].

$$\frac{\partial C}{\partial t} = D \cdot \left(\frac{\partial^2 C}{\partial r^2} + \frac{1}{r} \frac{\partial C}{\partial r} + \frac{\partial^2 C}{\partial z^2} \right) - \delta C \qquad (1)$$

where: C-radionuclide concentration in prospected time of experiment in the leachant volume (mol), δ-radionuclide deposition velocity constant (1/s) and D-diffusion coefficient (cm^2/s).
Solution of the Equation 1., gives the possibility of calculating the cumulative ^{137}Cs leached fraction from the sample of finite geometry. Experimentally obtained values of the cumulative leached fraction of the ^{137}Cs were

fitted on adopted mathematical model of the leaching process, which is solution of the Equation 1. Modified programme packages for nonlinear fitting, using method of the least squares, were used, with the parameters of effective diffusion and deposition. Using PELD as granulates in the radwaste mortar mixture, weight of the final, full size immobilized monolith would be significantly lower than one, prepared with stone granulates.

EXPERIMENTAL

Mortar-radwaste mixture samples, that were used in leaching processes, as well as in mechanical strength characteristics examinations, were made using mixture formulation: cement (PC-20 MPa), either stone particle aggregates (0-2 mm) or PELD granulates of 2 mm diameter, mixing additives and water. PELD granulates, have following properties, that underlined their addition in the mortar matrix formulation: density of 0.940 g/cm^3, dilution index of 0.3 g/10 min., breakable temperature of $T_b \cong$ -120°C, resistance on aggressive liquid environment and influence of mechanical forces, e.g., 30 kp/cm^2 under temperature of 60°C. The water used for mortar preparation was doped with ^{137}CsCl solution (pH=1.2). A water-to-cement ratio, W/C, of 0.36 provides density of 2.145 g/cm^3 for mortar matrices prepared with stone granulates and density, from 1.953 to 1.960 g/cm^3 for the mortar matrices prepared with PELD. The mixing period for a 3 litre mortar batch was ten minutes, using a planetary mixing device. Radioactive waste mortar mixtures were poured into plastic molds to harden. After one day, the samples were taken out from the molds and cured in an atmosphere of 65 percents relative humidity and T=20°C for a period of 28 days [3]. Hardened samples all have approximately the same level of bound activity ($A_0 \approx$ 10 kBq). In these investigations, matrix formulation was not optimized, because of the high water-to-cement ratio, W/C and absence of radionuclide sorbents in the experimental matrix formulation. The composition used in the experiments was design to allow easy leaching of ^{137}Cs from the mortar monolith. Solidified orthocylinder shaped samples, H=4.5 cm, with the exposed surface area completely open to contact leachant medium, were used in prospecting physico-chemical characteristics of mortar-radwaste mixture forms. After curing period, samples were placed inside clear plastic beakers, each containing leachant media and introduced to leaching. The leachant media used was distilled water (pH=6.2). Experiments were carried out at a room temperature of T=20 ± 1°C. The leachants were renewed periodically: 5 times in the first month and approximately once per month in the first 200 days, in order to obtain longer periods in which leachants remained in contact with the specimens [3,4]. Radionuclide ^{137}Cs presence in the leachants were measured by a gamma-spectrometer.

RESULTS AND DISCUSSION

Process of radionuclide leaching from the mortar matrices, prepared in described manner, is divided in two stages. The first stage is the initial "wash-out" period, when the radionuclides, immobilized in matrix material, are "washed-out" from the radwaste-mortar monolith surface. Duration of this stage, when the leachants are frequently exchanged, is up to hundred days. The second stage of radionuclide leaching from the matrix material, in which the most of radionuclides are structurally bonded, is a relatively steady-state process [1,2,3]. Measured leach-rate of the inspected radionuclide,^{137}Cs, from the radwaste mixtures prepared with PELD was the same level of order, but significantly lower than ones for the monoliths prepared in ordinary manner. For each treated matrix formulation, effective coefficients of diffusion of radionuclide incorporated in mortar matrix were calculated, presented in the Table 1.

Table 1.-^{137}Cs Diffusion and deposition coefficients for different matrix compositions after 200 days of leaching.

Characteristic	Matrix with stone granulate		Matrix with PELD granulates	
	Experimental	Math. model	Experimental	Math. model
$\frac{\sum a}{A_0}$ (%)	4.51	4.71	3.51	3.69
D_e x 10^9 (cm^2/s)	1.481		1.088	
δ x 10^7 (1/s)	1.414		1.800	

Parameters obtained in this manner, were returned into the appropriate mathematical model and used in calculation of the ^{137}Cs cumulative fraction that could be leached in postulated leaching experiments[2]. In such manner, behaviour of the radwaste-mortar matrix mixture in the prolonged disposal period, under the most conservative and undesirable environmental conditions, could be predicted. Differences between ^{137}Cs cumulative

leached fractions experimentally obtained and those calculated by the mathematical modelling of the leaching process are neglectable, as it is shown at the Figure 1.

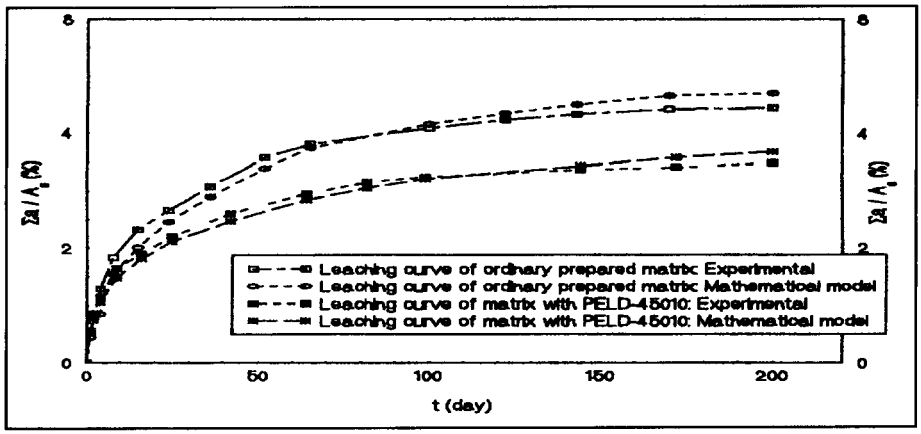

Figure 1. ^{137}Cs cumulative leached fraction from the mortar matrix prepared with PELD-45010 granulates and in ordinary manner,using stone granulates, obtained experimentally and by mathematical modelling of the leaching process.

Good homogeneity, relatively uniform distribution of the granulates in the radwaste-mortar matrix and low percent of the void space inside the bulk material, that could results from the segregation pathways of the stone granulates inside the matrix during matrix hardening and increasing the monolith porosity, as well as absence of the phenomenon of particle segregation on the bottom of the matrix material, may results in better physico-chemical characteristics of the radwaste-mortar matrices prepared with PELD. Taking into account that the full scale solidified radwaste forms prepared with PELD will have at least one fifth lower weight than monoliths prepared with stone granulates, advantages of the PELD granulates in the immobilization processes of the radwaste materials are obvious.

CONCLUSION

In our paper, we have shown that there is a possibility of improving physico-chemical characteristics of the radwaste-mortar mixture, by the PELD granulates addition in the mortar matrix, instead of the stone particles. When mathematical modelling the leaching process, differences between the ^{137}Cs leach-rate values, obtained experimentally and by mathematical model, were noticed. Mathematical model underestimates the radionuclide leach-rate values until the completed hydratation of the cement in the mortar matrix and overestimates leach-rate values after the cement hydratation was done. These differences could be explained by the influences of the adopted approximations, when postulating the mathematical model of the leaching process, neglected saturation concentration of the radionuclide inside the matrix and variations of the deposition coefficients of the radionuclide concerning two types of applied granulates in mortar formulations. Nevertheless, these differences do not exceed 5 percents for the leach-rate values, which permits to postulate opinion on mortar-radwaste matrix behaviour in the prolonged periods of time. Examinations considering optimization of the matrix formulations, by varying the different weight percentage of the PELD granulates presented in matrix formulation, in aim to increase mechanical strength and decrease radionuclide leach-rates should be performed.

MATHEMATICAL MODELLING OF RADIONUCLIDE BEHAVIOUR IN THE VIENNE RIVER DURING ROUTINE RELEASES OF THE CIVAUX NUCLEAR POWER PLANT

A. HITA, F. SICLET, Ph. CIFFROY, S. MANDELKERN, Ph. GOSSE
DIRECTION DES ETUDES ET RECHERCHES, ELECTRICITE DE FRANCE, CHATOU, FRANCE

INTRODUCTION

The Civaux nuclear plant, currently under construction, is located on the Vienne river in west centre of France, a river with a minimal monthly average flow rate of 23 m^3/s. Special attention was given to the prediction of radioactive contamination of the river due to the routine discharge of liquid wastes at low flow during summer. To address this issue, a one-dimensional unsteady model, named CALIDO, was developed to simulate radionuclide transport along the 120 km stretch of the Vienne river, from Civaux to the confluence with the Loire river. It takes into account the processes governing sediment transport and radionuclide exchange between water and suspended matter. The model's aim is to assess the radiocontamination of the three main compartments of an hydraulic ecosystem, the water, the suspended matter and the bottom sediments.

THE CALIDO MODEL

CALIDO is a one dimensional non stationary model taking into account longitudinal dispersion. It calculates the distribution of activity concentration in water, suspended matter and bottom sediments as a function of time and space. With this aim in view, the river is divided into longitudinal sections according to the flow stream. The model calculates both the interactions between the environmental compartments and the linkage of the successive river sections as shown in figure n° 1.

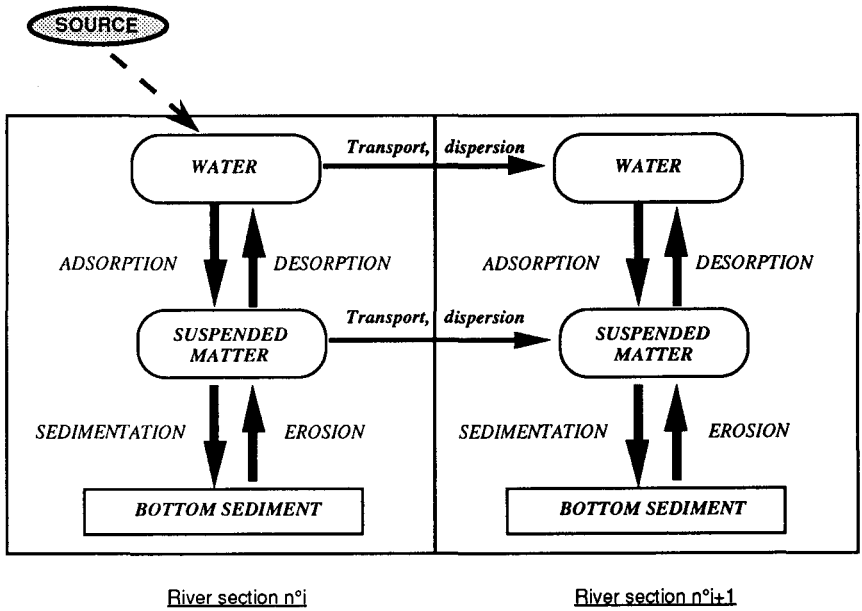

figure n°1 : Processes included in the model and linkage of successive river sections.

The global model is subdivided in three coupled submodels:
- The hydrodynamic submodel assesses river flow, depth and velocity in each section. We use a fully complete 1D hydraulic model named LIDO which solves free surface flow problems in rivers. LIDO requires a very accurate bathymetry to describe the natural form of the river. It calculates hydraulic parameters in sections of a few hundred meters long.
- The sediment model uses the results of the hydraulic model, it simulates the transport and the dispersion of suspended matter in water column. The processes of sedimentation and resuspension are modelized by the classical laws of Krones and Partheniades. Sedimentation and resuspension (which are regulated by two parameters: settling velocity and erosion rate) occur at constant critical shear stresses which have to be calibrated.

- The exchange model describes the exchanges of radionuclides between the dissolved and the particulate phases. The exchanges are modelized using a kinetic equation for a one step reversible reaction which leads to an equilibrium characterized by the distribution coefficient K_d.

CALIBRATION OF THE MODEL

The hydrodynamic submodel : the bathymetry of the Vienne river (data of main section profiles) was achieved and we performed several tracings of the river in order to calibrate the roughness coefficients of each river sections.

The sediment submodel : to obtain site-specific values of the four submodel parameters (settling velocity, erosion rate, critical deposition and erosion shear stress) a concentrated effort at field data collection downstream of Civaux was required :

- during the summer period, the concentration of the suspended matter in the river was measured every 8 hours at a few selected locations along the river. These measurements were used to calibrate the submodel by comparison between measured and calculated results. A field survey of bottom sediments was undertaken at low flow to gain information on the thickness and size distribution of the sediment layer. The vertical profile of the suspended matter was examined at a low velocity location of the river. It allowed us to calculate the settling velocity of particles. Samples were collected weekly for size distribution analysis (measured by laser beam diffraction, using a Coulter particle size analyser). Besides, the organic fraction of the suspended matter was distinguished from the mineral fraction. These analyses were undertaken in order to calibrate the submodel for different granulometric or qualitative classes of the suspended matter.

The exchange model : in order to determine K_d and kinetic parameters for each radionuclide values, we performed both in situ and laboratory experiments. The radioactivity associated with suspended matter was measured in the Loire river during scheduled discharges from low activity waste tanks of the Dampierre nuclear power plant. The obtained results were compared with laboratory experiments aiming at studying the behaviour of some selected radionuclides in Vienne river water.

EXAMPLES OF CALCULATIONS

The first example shows the evolution of activity in water and suspended matter after a constant release in stationary conditions. The term source is a constant release of ^{58}Co with a 100 Bq/m^3 activity over a period of 4 hours. The river flow rate is about 23 m^3/s and the contaminated wave is followed over a period of 3 days from the site of release, Civaux. The results are presented in figure 2.

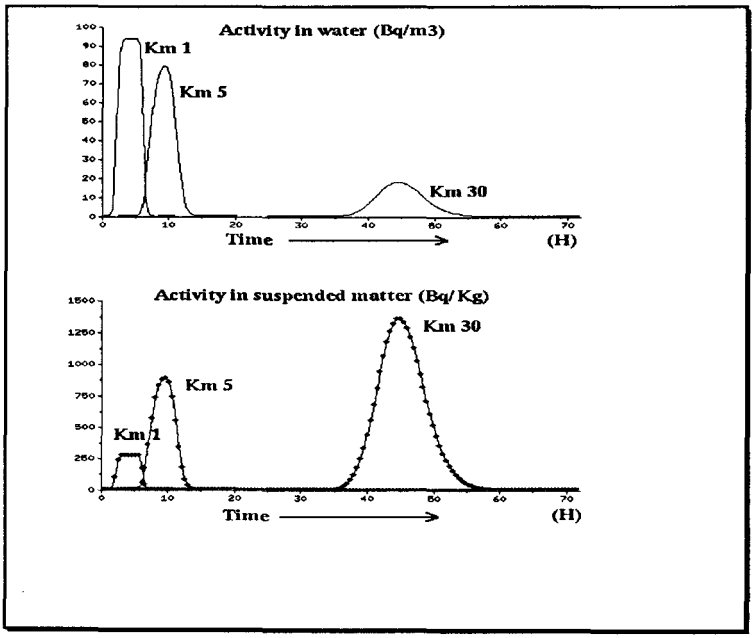

figure n°2: Calculated activities in water and suspended matter as a function of time presented at different distances from the site of release.

As a result of dispersion and adsorption, the concentration in water decreases and, simultaneously, the concentration in suspended matter increases.

The second example is the simulation of the routine functioning of the Civaux nuclear plant over the 1987 hydrologic conditions. Based on the daily river flow rate, a power plant effluent model simulates the daily release of radionuclides. The suspended matter concentrations at Civaux are also computed as a function of the daily river flow rate. Taking the example of ^{58}Co, one of the main released radionuclides, CALIDO model simulates its behaviour in the three compartments of the river during all the 1987 period. With such a kind of non stationary model integrating all the variability of meteorological conditions, it is possible to assess the radiocontamination of the river taking into account all the successive passings of contaminated waves. Figure n°3 focuses on the contamination of the bottom sediments at the end of summer 1987 between Civaux and the confluence of Creuse river. Expressed in Bq/m^2, the main contaminated areas are located just in front of major dams.

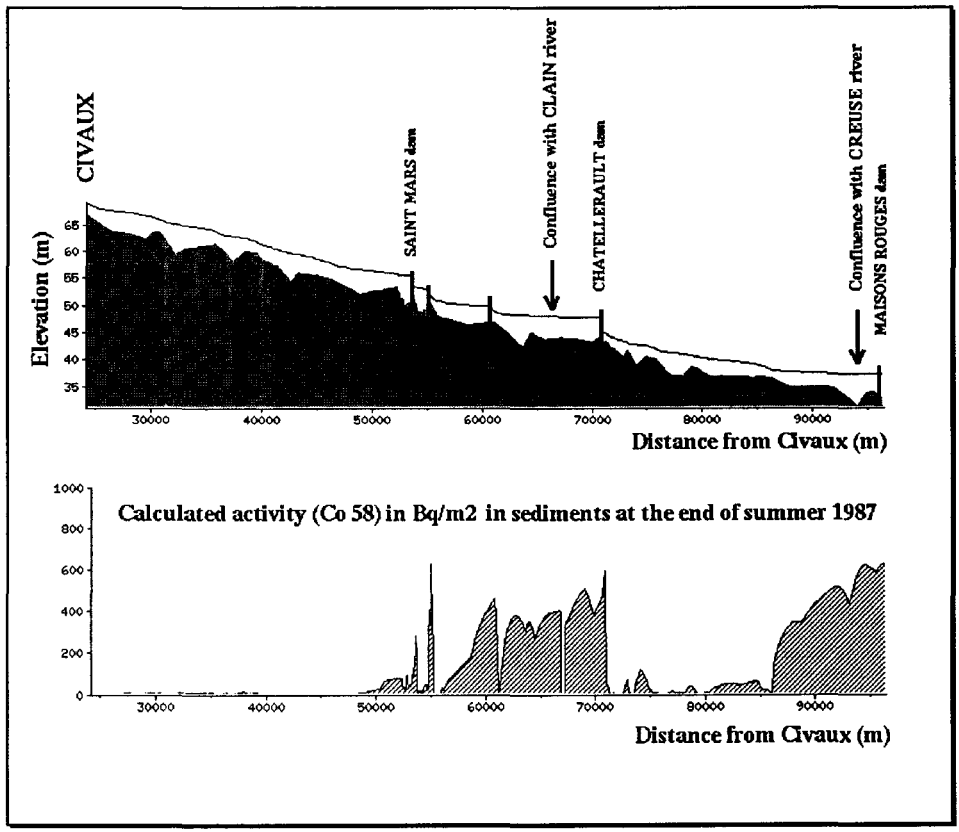

figure n° 3 : Calculated activity in sediments as a function of space at the end of summer 1987, after 9 months of simulated routine functioning of Civaux nuclear plant.

PROSPECTS

CALIDO is currently used with a single class of sediment. We are working at including different classes to integrate all the results of experiments.

The model will be coupled with other biological transfer models (transfers to biomasses) to assess the contamination of the upper level of the river food chain. The radiocontamination of the different compartments is a pathway to the contamination of man.

Properties of deterministic models for prediction of radionuclide concentrations in river systems

M. Tschurlovits, G. Winkler

Atominstitute of Austrian Universities, A-1020 Vienna, Austria

Abstract

A deterministic model was used for predicting the activity concentration of radionuclides in rivers. The model was validated in the framework of VAMP, aquatic working group, river subgroup, where scenarios as Clinch-Tennessee rivers as well as Dnjepr river were provided. This was a good chance to test the predictive power of the model. Some of the results of this exercise are presented.

Description of the model

The model was developed by /Sc 76/ and modified to predict the activity concentration the river Danube/Pr 82/. It is a simple deterministic model, taking into account interaction with suspended material, radioactive decay and sedimentation. The model seems promising, because of the small numbers of parameters needed for evaluation.

The basic equation is :

$$C_{i,j}=C_{(i-1),j}\cdot W_{(i-1)}\frac{1}{W_i}\cdot e^{-(k'+\frac{\lambda}{v})x}(1-E_{i,j})\cdot\frac{1}{1+k_d S}$$

C_{ij}	activity concentration of radionuclide i at site j [Bq/m³]
Q_i	annual release of radionuclide [Bq/a]
K	conversion factor s→a = $3.17\cdot10^{-8}$ [a/s]
W_j	mean annual flow at a point j (m³/s)
k′	depletion factor for sedimentation (m-1)
λ	decay constant (s^{-1})
x	distance (m)
v	flow velocity (m/s)
K_d	K_d-factor (l/kg)
S	amount of suspended material (kg/l)

The scenarios are sufficiently described in the final report of VAMP (in press).

To apply this model to the scenarios some assumptions had to be made:

The discharge of radioactive effluents is continuous and instantaneous mixing with the river or reservoir water takes place.

The activity removed by biological materials can be neglected.

The river system is divided into several parts, representing the boxes of the model

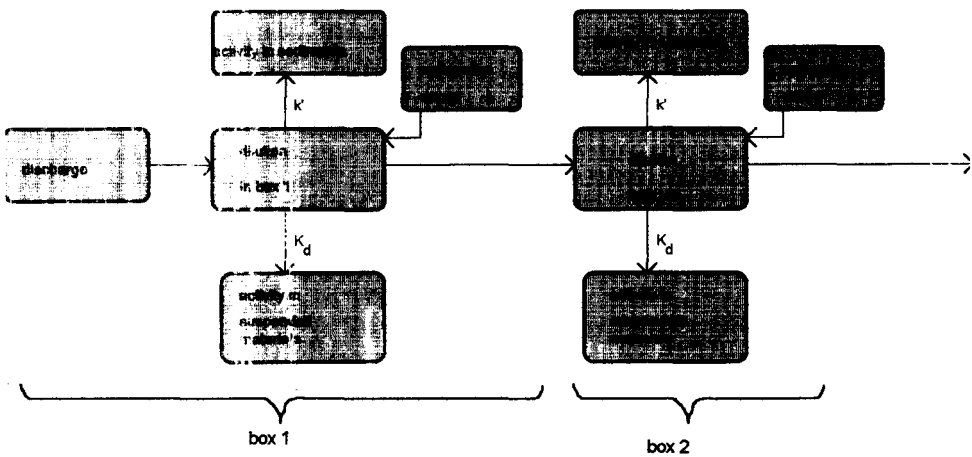
Some parameters as flow velocity, amount of suspended materials of the water body are constant in a box.

There is no resuspension of radioactive material absorbed by the sediments.

Reduction of radioactive materials due to chemical processes are not considered.

The cross section area of the river can be described by mean values of width and depth.

The processes simulated by the model and the mechanism are shown in figure 1:



Large river systems like the Clinch Tennessee rivers or the Dnjepr cascade have to be divided into several segments. The choice of the number of boxes is arbitrary, but the modelist must find segments in which the properties are well known and of interest. As a consequence of using a deterministic box model results, are not time dependent and also the transport of the activity concentration downstream will not be simulated correctly. The model was initially developed to provide yearly averaged values of the activity concentration. Modelling the Clinch Tennessee rivers the experience was made that the model led to reasonable results, when using adequate parameters When monthly averaged values had to be calculated, the model still led to satisfying results, as there are high flow velocities. Modelling the Dnjepr cascade monthly averaged values of the activity concentration were not in a good agreement with the experimental data. The were two reasons: the first was that the same parametrisation as for the Clinch Tennessee rivers could not be used, and the second reason was that the correlation between the calculated and the experimental data was not satisfying. The second one sets up on the big range of the reservoirs of the Dnjepr cascade (each reservoir is longer than 100 km) and on the very slow flow velocities. To improve the time dependence a new term for the dilution was used, which was based on a differential equation. The new term, describing dilution, considers how the activity concentration changes, when the inflow has a different activity concentration as the flowing off. As there was not enough hydrological data (e.g. reservoir depth in each month) the assumption was made , that the capacity of each reservoir was constant.

Choice of parameters

As mentioned above, choice of parameters is very important. The first approach for the Clinch Tennessee rivers was don by using "default parameters". K_d was taken from /IA82/, and the k' as suggested by /ME 79/. Using the same parameters for the Dnjepr cascade and comparing the results with the experimental data, the experience was made that especially for longer distances the calculated values underpredicted the measured values. A calibration with the monthly averaged data of the Dnjepr cascade was carried out and a new set of values was obtained. With this new set of parameters all values were recalculated, what led to an improvement in the quality of the results.

Sensitivity analysis

To identify the most important parameter and variables of the model, a sensitivity analysis was carried out. For each parameter and variable, a range of its value was determined. Regarding variables, the maximum and the minimum of the observed data were taken. For the parameters the maximum and the minimum found in the literature were taken. A sensitivity index SI /Ho 83/ was calculated. The model is sensitive for the parameter when SI is close to 1. The calculations show that the flow rate is a very important parameter for all radionuclides. In addition, for radionuclides as Cs-137, which strongly interact with suspended material and bottom sediments, the depletion factor for sedimentation and the amount of suspended materials are of even more importance.

Table 1: table of sensitivity indexes for Cs-137 and Sr-90, Kiev reservoir

	sensitivity index	
	Cs-137	Sr-90
flow velocity	0.0032	0.0040
flow rate	0.5055	0.6278
suspended material	0.9356	0.4990
Kd-factor	0.3764	0.0151
k'-factor	0.9047	0.5938

INTRODUCTION

The Chernobyl nuclear accident provided a sudden contamination of many European water bodies with radiocaesium, followed by a rapid partial immobilization. As a result, activities and concentration factors of radiocaesium in biota fluctuated strongly over several years before reaching quasi-equilibrium, with patterns significantly differing between organisms. To model these dynamic relaxation processes, mass balance equations for ^{137}Cs in aquatic food chains were developed on the following basis: a) potassium acts as a biogeochemical equivalent of caesium; b) the concentration of potassium in fish and other biota is rather constant; c) the main source of potassium in freshwater fish is the dietary uptake.

MODEL DEVELOPMENT

The model describes the fate of a contamination pulse in the water and in associated food chains. The decline of the activity concentration in the water, which is considered as the secondary source of ^{137}Cs, can be well expressed by a two-component exponential function corresponding to a fast (**F**) and a slow (**S**) component in the immobilization of Cs:

$$\mathbf{A_W(t) = K_W^F \cdot \exp(-\lambda_F \cdot t) + K_W^S \cdot \exp(-\lambda_S \cdot t)}$$

where **t** is time, **A** are activity concentrations, **K** are transfer coefficients, and λ are rate constants.

The food chain considered here includes the following compartments: fish food organisms such as zooplankton and zoobenthos (**Z**), non-piscivorous fish (**NP**), and piscivorous fish (**P**). In every compartment the turnover rate of caesium is considered as constant over time. If potassium acts as a biogeochemical equivalent of caesium, the uptake of Cs in animals is proportional to the ratio of assimilation efficiencies of Cs and K, and the elimination of Cs is proportional to the ratio of turnover rates of Cs and K. Since homeostasis requires that uptake and elimination of K are equal, mass balance yields the following equation for the member **j** of a food chain:

$$\frac{d\mathbf{A_j}}{dt} + \lambda_j^{Cs} \cdot \mathbf{A_j(t)} = \mathbf{T_{j-1}^j} \cdot \mathbf{A_{j-1}(t)}; \quad \text{with} \quad \mathbf{T_{j-1}^j = k_{\lambda j} \cdot \lambda_j^{Cs} \cdot \frac{\alpha_j^{Cs}}{\alpha_j^K} \cdot \frac{C_j^K}{C_{j-1}^K}} \quad \text{and} \quad \mathbf{k_{\lambda j} \equiv \frac{\lambda_j^K}{\lambda_j^{Cs}}}$$

where **A** are radiocaesium activity concentrations, **C** are potassium concentrations, **T** is a complex transfer coefficient, α are assimilation efficiencies, and λ are first order decay rate constants describing the biotic elimination (turnover) of Cs.

An analytical solution of this equation is given by:

$$\mathbf{A}_j(t) = \exp(-\lambda_j^{Cs} \cdot t) \cdot \left[T_{j-1}^{j} \cdot \int \mathbf{A}_{j-1}(t) \cdot \exp(\lambda_j^{Cs} \cdot t)\, dt + Const \right]$$

where *Const* is determined by initial conditions:

$$Const = \left[\mathbf{A}_j\right]_{t=0} - \left[T_{j-1}^{j} \cdot \int \mathbf{A}_{j-1}(t) \cdot \exp(\lambda_j \cdot t)\, dt\right]_{t=0}.$$

When applying this model to a food chain after combination with the water model, solving the equations adds one exponential term for each compartment. For piscivorous fish, the following equation is obtained:

$$\mathbf{A}_P(t) = T_W^P \cdot \left[K_P^F \cdot \exp(-\lambda_F \cdot t) + K_P^S \cdot \exp(-\lambda_S \cdot t) - K_P^Z \cdot \exp(-\lambda_Z \cdot t) - K_P^{NP} \cdot \exp(-\lambda_{NP} \cdot t) - K_P^P \cdot \exp(-\lambda_P \cdot t) \right]$$

where T_W^P is the bioconcentration factor and $\mathbf{K}$ are complex transfer coefficients.

MODEL VALIDATION

The model was tested with post-Chernobyl data from long-term studies in different European lakes [1-6]. For each compartment, a transfer coefficient ($\mathbf{K}$ or α) and a rate constant λ was fitted iteratively to the data. An example from one lake is shown in Fig. 1. The model provided a good description of several important aspects: a) the differences in contamination levels and contamination dynamics between predatory and non-predatory species (trophic level effects); b) the dependence of ^{137}Cs activity in fish on the potassium concentration in the water (bioavailability); c) time scales of contamination and depuration in different fish species (prognostic tool). Evaluation also showed a significant effect of growth rate on the turnover rate (biological half-life) of ^{137}Cs in fish.

CONCLUSIONS

The complex contamination dynamics in aquatic food chains after an accidental release of radiocaesium can be adequately described with a physiological model, using equations that can be solved analytically. These solutions describe the ^{137}Cs activity concentration in every compartment as a series of exponential functions, of which some are derived from the concentration in the water (source pattern), and the others determined by the caesium turnover rate in each food chain compartment.

MODEL VALIDATION : THE USE OF HUMAN MEASUREMENT DATA

S L Prosser and K A Jones

National Radiological Protection Board, Chilton, Didcot, Oxfordshire, OX11 0RQ, U.K.

ABSTRACT

Measurement of radionuclides in individuals provides the most direct method of evaluating the results of modelling procedures used to estimate the uptake and distribution of radionuclides in humans, for both environmental and occupational exposure. This paper describes recent and on-going comparisons of human measurements with model predictions and considers the benefits and difficulties associated with this approach to model validation.

INTRODUCTION

One method which can be adopted to establish the adequacy of the results of modelling procedures used to estimate radionuclide uptake by individuals, is to compare predicted radionuclide contents with measurement data obtained for the population under examination. This paper summarises two studies where such comparisons have been undertaken. In the first, measurement data for inhabitants of Seascale, a village close to the UK Sellafield nuclear reprocessing plant, were compared with model predictions based on methodology utilised to assess the risks of radiation-induced leukaemia and other cancers in children and young persons living in the village[1]. A second study is also in progress to compare plutonium concentrations measured in individuals resulting from atmospheric weapons testing with predicted values based on current ICRP models.

SEASCALE COMPARISON

Human measurement data for the Seascale population are available in the form of radionuclide concentrations in tissues taken at autopsy (plutonium-239+240 and caesium-137), measurements of plutonium in fetal tissues and whole body radiocaesium measurements. The assessment methodology used to determine the radionuclide uptake, and thereby the internal doses received by the inhabitants of the village, was based on estimations of the annual inhalation and ingestion intakes of a range of radionuclides, in association with the most recent dosimetric and biokinetic models. These calculated intakes were derived, as far as possible, from direct measurements of radionuclides in environmental materials, air concentration measurements and habit data. Where measurement data were insufficient, intakes were estimated using a combination of discharge data and environmental transfer models.

The comparison of measured and predicted whole body radiocaesium levels for the period 1957 - 1989 is given in Figure 1 and shows that the radiocaesium contents of individuals are generally in good agreement with the mean radiocaesium contents measured in groups of subjects prior to 1969. The overestimation in whole-body contents for the late 1970s and 1980s is probably due to the pessimistic assumption that all fish consumed by the Seascale residents was locally caught: consumption of foodstuffs of marine origin providing a large contribution to the radiation dose received during these years. An increase in both predicted and measured values can be observed for 1986, the year of the Chernobyl accident.

The autopsy data detailed in Table 1 suggests that the modelling procedure tends to overestimate radionuclide concentrations in the skeleton and liver, but leads to underestimates of the concentrations of plutonium-239+240 in the lung. The reason for this discrepancy is unclear but, may be due to the assumption made in the modelling procedure that the absorption from lung to blood of all inhaled plutonium compounds could be characterised as Type M (moderate absorption rate) as defined in the current ICRP Human Respiratory Tract Model[2]. In reality, it is more likely that the inhaled plutonium would have behaviour intermediate between Type M and Type S (slow absorption rate), which would result in a greater retention in the lung and lower concentrations in the liver and skeleton. The default absorption parameters for Type M material were used in the modelling procedure since this is the more cautious assumption with regard to dose to the red bone marrow, the tissue thought to be at risk when considering leukaemia induction. Table 1 also shows a

comparison of concentrations of plutonium-239+240 predicted for the fetus at full term, with measurements in fetuses following termination. All measurements were below the limit of detection of the technique, giving considerable support to the conclusion that uptake of plutonium is unlikely to have been significantly underestimated in the modelling procedure.

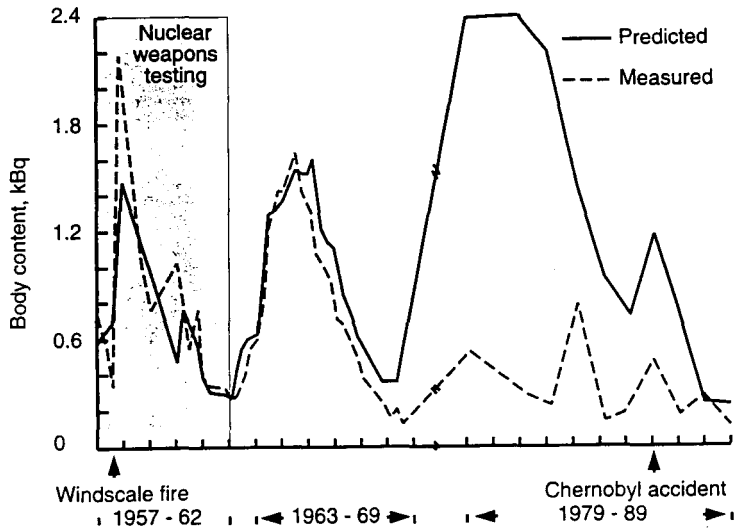

Figure 1: Measured and predicted radiocaesium body contents for 1957-89

	Skeleton		Liver		Lung		Fetus	
Radionuclide concentration	Measured	Predicted	Measured	Predicted	Measured	Predicted	Measured*	Predicted
$^{238}Pu + {}^{240}Pu$ (mBq kg^{-1})	7	153	68	342	12	2	AND <1.5	0.1
^{137}Cs (Bq kg^{-1})	-	-	4	11	-	-	-	-

* AND = Activity not detected, followed by the 95% detection activity

Table 1: Comparison of mean measured with predicted radionuclide concentrations in autopsy and fetal tissues

WEAPONS FALLOUT COMPARISON

Worldwide autopsy measurements of plutonium-239+240 have been collated and median activity concentrations determined on a yearly basis for each location where data are available. In the cases examined, intakes of these radionuclides has arisen from atmospheric weapons testing and not from occupational exposure. Using an adapted version of NRPB's LUDEP (Lung Dose Evaluation Program)[3], which implements the new Respiratory Tract Model[2] and uses the new ICRP biokinetic model for plutonium, coupled with estimations of plutonium intake, activity concentrations for lung, liver, skeleton, lymph node and kidney were predicted. Annual intakes of inhaled fallout plutonium-239+240 were estimated using air concentration measurements of these radionuclides where possible. In the absence of these data, estimations were based on strontium or caesium air concentration measurements by utilising the radionuclide ratios, measurements made at similar latitudes or modelled data. Inhalation of plutonium was the only route of intake considered, this being the predominant exposure pathway.

Two sets of predicted values were calculated based on i) Type S and ii) Type M parameters. The comparison undertaken for one organ, lung, is illustrated in Figure 2. Taken with preliminary comparisons for the other organs, the results indicate that absorption of plutonium from lung to blood lies between Type S and M parameters. This study does appear to suggest that there is reasonable agreement between measured and predicted concentrations, given the inherent uncertainties in the process.

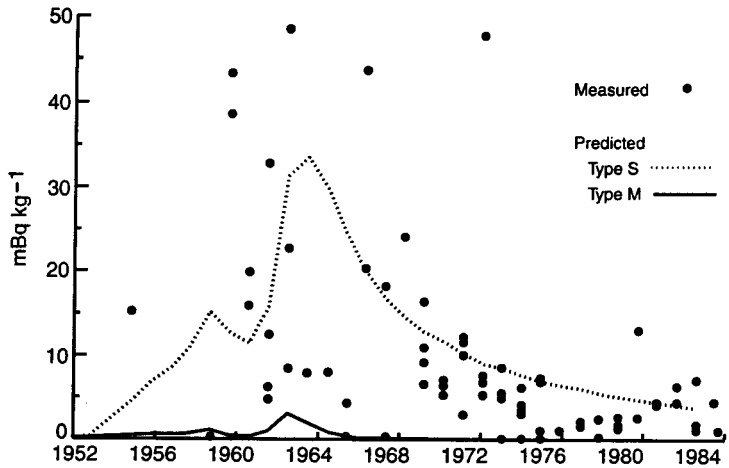

Figure 2: Measured and predicted plutonium lung concentrations

CONCLUSIONS

Human measurement data have been shown to be a valuable source of information to substantiate the data and methods used in model predictions. The Seascale comparison has shown that modelling procedures used to determine the radiation doses tend not to underestimate radionuclide intakes and deposition, and often overestimate them. Preliminary results of the weapons fallout study appear to indicate reasonable agreement between measured and predicted concentrations.

The benefits of using human measurement data for model validation are immediately obvious: it is only measurements of individuals which provide direct evidence of the level of radionuclide uptake by a population. There are disadvantages associated with this approach however, since in order to provide a reliable estimation of the radionuclide uptake by a population it is necessary to have a large number of measurements to ensure that the distribution of radionuclide uptake by the population has been adequately represented. Human data are by their very nature scarce and therefore for the purposes of these comparative studies, the measured radionuclide contents of studied individuals have been assumed to be representative of the population under investigation.

GUIDE-LINES FOR AN EARLY EVALUATION OF A NUCLEAR ACCIDENT, CALCULATED WITH THE COMPUTER MODEL PARK

J. Gregor, L. Kammerer, J. Peter
Bundesamt für Strahlenschutz, Institut für Strahlenhygiene, 85764 Neuherberg, Germany

Introduction

For a nuclear accident where large areas are contaminated, it is necessary to predict the exposure of the population as early as possible in order to plan appropriate countermeasures. The radioecological computer model PARK (Program System for the Assessment and Mitigation of Radiological Consequences) [1,2] is part of the German decision support system IMIS (Integrated Measurement- and Information System for the Surveillance of Environmental Radioactivity) [3] for a fast assessment of contaminations and doses. In this paper PARK is used to investigate the dose relevance of the exposure pathways, of ingested radionuclides, and of foodstuffs in relation to the date of the event.

Model Description

The following example is based on an assumed nuclear accident with core melting according to the release category no. 2 (FK-2) of the 'Deutsche Risikostudie Kernkraftwerke' [4]. Major portions of the activity inventory of a 1300 MW_{el} nuclear power plant are released into the environment by a leak in the containment of 30 cm in diameter. Within the scope of this scenario, the entire inventory of noble gases is released one hour after the end of nuclear fission. The respective percent portions are: 40 % iodine, 29 % caesium, 19 % tellurium, 3 % strontium and 0,26% lanthanides and actinides, res..

For approximating the atmospheric transport a dispersion model developed by NRPB [5] is used. The radioactive cloud is reaching the investigated distance 11 hours later, at a distance of approximately 200 km from the reactor, since the IMIS system is designed for long range contamination, and not short range distances. Physical decay and production of daughter nuclides are being considered. The ratio between the fraction of elemental iodine, aerosol bound and organic bound iodine is assumed to be equal.

These assumptions lead to an integrated activity concentration of 10^6 Bq·h/m³ for I-131, $7{\cdot}10^4$ Bq·h/m³ for Cs-137, and $1{,}5{\cdot}10^7$ Bq·h/m³ for total activity at the investigated distance. These values are used as input for PARK which then estimates the effective dose by all exposure pathways without countermeasures and change in living habits. PARK is based on the radioecological model ECOSYS [6], and therefore takes into account the state of plant growth and the effects of food processing. As a result, a total effective dose of about 700 mSv is calculated assuming a dry deposition taking place on July 1st. The figures however are scaled, so that this dose corresponds to a value of 1. In the case of wet deposition, it is assumed that the activity in air is entirely deposited on the soil and vegetation.

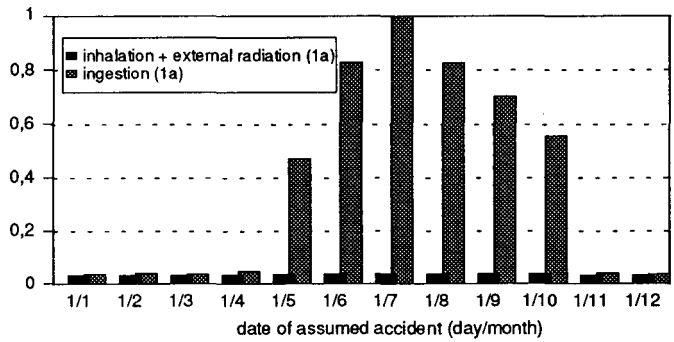

Fig. 1: Effective dose due to inhalation and external radiation (1 year) and from ingestion of contaminated foodstuffs over the first year following the assumed accident at a distance of 200 km, for adults and standard German living habits.

Relevance of Exposure Pathways

Different radiation pathways are considered: external exposure from the cloud and from the surface as well as internal exposure from inhalation and ingestion. Fig. 1 shows the results from the assumed accident occurring

in different months of the year. Ingestion is identified as the most relevant pathway in case of a nuclear accident during the period between May and October, whereas during the remaining months ingestion doses are assessed to be nearly of the same magnitude as those of the external exposure and inhalation.

Relevance of Ingested Radionuclides

Subdividing the ingestion dose into the proportions of radionuclides, only Cs-134, Cs-137 and I-131 are essentially contributing, altogether by more than 90 percent. This result is unexpected, since a set of 30 radionuclides has been included into the calculations [7] but may be understood by regarding the radiological transfer processes and dose coefficients.

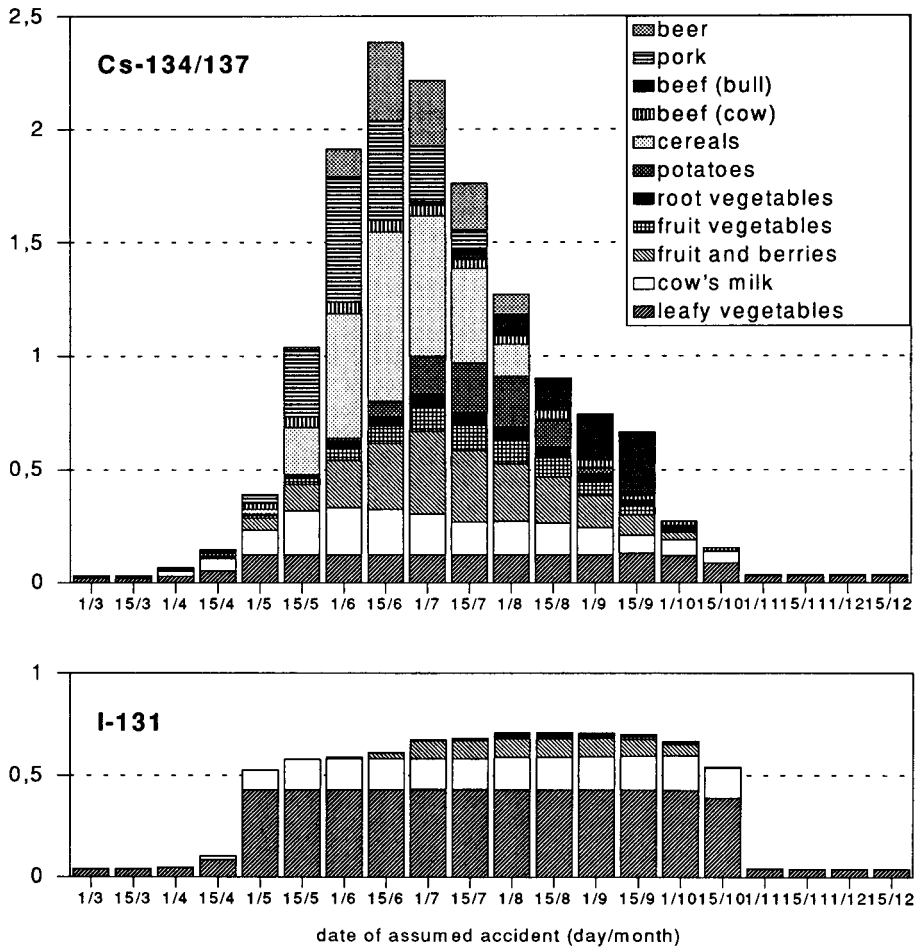

Fig. 2: Effective dose following an ingestion of contaminated foodstuffs during the first year after an assumed nuclear accident at a distance of 200 km. Average consumption rates for German adults are presumed.
***Note:** This diagram does not show a time series but shows each bar as representative of the life time dose related to the given date of the accident*

Relevance of Ingested Foodstuffs

Fig. 2 shows the expected contribution from main foodstuffs to the effective dose from the ingestion of radiocaesium and radioiodine at given dates of wet deposition during the first year. For the purpose of comparison the same scale is used for Fig. 1 and Fig. 2. It is obvious that the dose from ingestion varies by more than one order of magnitude with time of the event [8]. The highest doses can be expected in summer when the vegetation is developed. During this period, the contamination of the plant surface and translocation are predominant compared to the root uptake. Following an accident in spring, the contamination subsequently is reduced by the increased mass of the plant. The dose from the ingestion of leafy vegetables does not vary much between May and October because surface contamination is here the main factor. The dose contribution from other products, however, varies in a wide range and causes the maximum of the total dose during summer. This is most pronounced from products such as cereals, beer (brewn from summer barley), pork (fed with winter barley), beef (fed with corn) and fruits, which are easily contaminated with radiocaesium in summer from wet deposition.

Discussion and Conclusions

Between May and October, scenarios are possible where only limits for contamination of food products are exceeded while the other pathways contribute very little to the total dose. In this situation, countermeasures affecting the agriculture, e.g. restricting the consumption of fresh products, are very important. The results have been verified by using the radiation doses determined for several regions of Germany [9] after the Chernobyl accident which happend in the end of April. With values for the ingestion doses taken from Fig. 2, it is evident that the highest dose contribution results from iodine in combination with leafy vegetables and milk. The dose from caesium was also reduced by countermeasures that were taken. Severe consequences, especially from the caesium contamination, must be faced if such an event is taking place during summer. Our results show that it is not recommendable to rely on the experience from the Chernobyl event only, when assessing consequences from future radiological accidents.

INTRODUCTION

All ecological systems have an inherent fundamental peculiarity to accumulate and strongly keep back radionuclides got into them. Maximal ammount of radionuclides in ecosystem, which doesn't yet violates its general trophic functions (productivity, conditioniarity and reliability), can be named as a radiocapacity of a given ecosystem (1).

Let us consider some problems connected with radiocapacity of ecosystems (for example a water body system).

RADIOCAPACITY CALCULATIONS

Water bodies consist of three components: water, soil and biota. Getting into water, radionuclides rapidly and evenly are distribute in it. At the same time radionuclides transfer to the floor of the water body and various live organism (biota). As time goes on, radionuclides which get into a water body in amounts of A, are distributed by its components according to the formula

$$A = B \cdot S \cdot (H + h \cdot K_1 + c \cdot H \cdot K_{2)}), \qquad (1)$$

where B is the critical amount of radionuclides per unit volume of water; S is a surface square of water body; H - its average depth; h - thickness of the sorbing layer of body floor; c - concentration of biota in water body; k_1 and k_2- transfer coefficients of radionuclides into biota and body floor (usually $k_1 \approx k_2 \approx 10^2$-$10^3$). If $h >> c \cdot H$ (it is usually observed), then formula (1) is simplified to formula (2):

$$A = B \cdot S \cdot (H + h \cdot K). \qquad (2)$$

One can see, a term connected with biota is vanished. However, in any water body contaminated with radionuclides, biota plays a role of three functions: accumulation of radionuclides from water; transfering them to the floor of water body; and what's more important - maintenance of such a type of physical-chemical state of floor deposits, which prevent desorption of radionuclides from them.

A firm sorption of radionuclides in floor deposits is observed at pH≥7.0. Under the lower magnitude of pH a desorption process is started, which comes close to its maximum value at pH≈5.0. The decreasing of pH from 7.0 to 5.0 is generaly associated with biota dying off in water body.

Biota state determines a critical value of radionuclides in contaminated water body, such a concentration B, to which biota is still able for normal operating ($B \approx 10^3$-10^4 Bk/l).

RADIOCAPACITY FACTOR OF ECOSYSTEMS

By performing some necessary investigations it is easy to determine S, H, h, and k for any water body. To compare radiocapacity of various water bodies one can use the following unitless quantity:

$$F = \frac{h \cdot K}{h \cdot K + H}. \qquad (3)$$

It can be named as an 'radiocapacity factor'. It shows what part of radionuclides is firmly sorbed by floor deporsits. For the majority of water bodies (exept swamps) F≈0.7-0.9.

The radiocapacity factor F and a critical value B of radionuclides into the ecosystem can be estimated for different types of ecosystems (see table 1)

Table 1. Approximate values for F and B for different ecosystems

Ecosystem	F	B (Bk/km^2)
Desert	0.1	10^{11}
Meadow	0.3	10^{13}
Like, river	0.9	10^{12}
Woodless slope	0.2	10^{11}
Forest slope	0.6	10^{12}

Knowing F and B for different landscapes, one can estimate their possible role as desactivators in the case of radionuclide contamination. All that gives us a possibility to make a forecast when and what kind of countermeasures must be taken.

PROGNOSIS OF POLLUTION OF THE DNIEPER CASCADE WATER BODIES

After the Chernobyl accident radionuclides pollutions of large areas of Byeloruss, Russia and Ukraine take place.Practically, all these areas are arranged about the Dnieper cascade square. Bellow Chernobyl the Dnieper consists of six large water bodies which drain into the Dnieper-Bug lagoon. Water exchange is quite small in these water bodies (close to $3 \cdot 10^2$ volume per year), that allows one to apply the method described above to this system.

Evaluation of the basic parameters of the Dnieper water bodies is presented in table 2.

Table 2. Factors of radiocapacities of the Dnieper cascade water bodies.

Water body	S (km^2)	H (m)	h (m)	k	F
Kiev	920	4	0.1	100	0.7
Kanev	690	4	0.1	50	0.6
Kremenchug	2250	6	0.1	800	0.8
Zaporozhye	570	4	0.1	100	0.7
Dnieper	410	8	0.1	230	0.7
Kakhovka	2150	8	0.1	280	0.7
Factor of radiocapacity of the whole cascade					0.9994

Calculations in three last columns are done for ^{137}Cs. We notice, the factor F for the whole cascade is much higher (about 0.9994) than for each water body in separate. It implies that floor deposits sorb and firmly keep back 0.9994 part of initial ^{137}Cs radionuclides during

water transportation over the cascade from the Kiev water body to the Kakhovka one. Only 0.0006 part arrives to the Dnieper-Bug lagoon. Estimations have been done in 1988 (2).However, seven years later the differences between radionuclides contaminations of Dnieper cascade water bodies are approximately the same, as they were forecasted soon after Chernobyl accident.

CONCLUSION

The notions of `radiocapacity of ecosystems' and the `factor of radiocapacity' are determined. It is shown, that analysis of ecosystems in radiocapacity terms allows one to forecast for a long time the distribution of radionuclides over the polluted areas and determine countermeasures in all regions susceptible to risk. For example, the Dnieper cascade water bodies is observed.

ESTIMATING AIR QUALITY CLOSE TO RADIUM-BEARING WASTE PILES

Yves Belot
Institut de Protection et Sûreté Nucléaire, DPEI / SERGD
BP6, 92265 Fontenay aux Roses Cedex, France

INTRODUCTION

In the last decades, with the advent of regulatory air pollution programs came the need for practical tools to estimate transport and diffusion of pollutants from continously emitting sources. The Gaussian plume model has become widely accepted for this need. Computer codes based on it and applicable to single sources were further extended to multiple sources and area-sources (1-4). Such models are still in wide use despite their age and limitations. In the last few years, recommendations have been made to improve models of this type (5,6). The present work has the objective to propose an adaptation of the Gaussian model to produce reasonable estimates of radon air concentration above or in the vicinity of well-characterized ground level area-sources.

The FLURAD-AREA model developed in the present work is basically similar to many other sector-averaged models. It consists of replacing each area-source by a set of equivalent point-sources and summing up the contributions of these points. The formula used to determine the average atmospheric concentrations due to an elementary point source is derived from the Gaussian plume formula, assuming that each direction in a wind sector centered on the source is equally probable over a long period of time. But the new model differs from the previous ones in the treatment of the plume advective speed. In former models, the wind speed that appears in the dispersion formula is held constant throughout the computation and assumed to be equal to some reference wind speed (measured at a reference height of 10 m for instance). This seems quite unrealistic in case of a ground level source, since the average advective speed of the pollutant is obviously very low at small distances from the source and much greater at larger distances, due to the vertical extension of the plume. In the new model, this is taken into account by considering that, for each point-source, the average advective speed of the emitted pollutant increases with distance from the source. The new model is believed to give more realistic results that the former ones, particularly at short distances from the sources where the wind speed effect is of great importance.

BASIC FEATURES OF THE MODEL

The model utilizes a user-specified grid of terrain elements which describes the local environment around the release zone. Each rectangular element in the grid can be characterized by terrain roughness, height of vegetation and radon fluence rate. It can be subdivided into several tens of small area sources which are assimilable to point sources. The contributions of all the sources are summed up to determine the radon-in-air concentration at the grid nodes.

The basic equation in the model is the well known sector-averaged equation for a ground-level continuously emitting point source. Wind direction is assumed to be specified in sectors of angle ω. For any period of averaging, it is assumed that all wind directions within a given sector occur with equal probability. The average concentration at the sampling height h, for a particular combination of meteorological conditions at any receptor point at distance ρ within the given sector due to a point source with emission rate Q is:

$$\chi_{ij}(\rho) = \frac{0.798}{\alpha_j(\rho)} \frac{Q}{\bar{u}_i \sigma_j(\rho) \omega \rho} \exp\left(-\frac{h^2}{2\sigma_j^2(\rho)}\right) \qquad (1)$$

where $\bar{u}_i$ is the wind speed at z=10 m representative of the wind speed class i; $\alpha_j(\rho)$ a ventilation factor, to be defined later, that does not appear in the original equation; $\sigma_j(\rho)$ is the standard deviation of the vertical concentration distribution for a ground-level emission. The vertical standard deviation is a function of the distance ρ from the source and the atmospheric stability class j.
Equation (1) is evaluated to determine the effect of each equivalent point source on a receptor (at a grid node) for each possible combination of atmospheric stability and wind speed. The relative

frequency of occurrence of each such meteorological combination is then used to weight the calculated concentrations; the resulting weighted concentrations are summed over all meteorological combinations and all sources. Thus the long-term average radon concentration at the receptor is obtained by:

$$\bar{\chi} = \sum_i \sum_j \sum_n F_{ij}(d_n)\, \chi_{ij}(\rho_n, d_n) \qquad (2)$$

where d_n indicates the wind direction sector in which transport from a particular source (n) to the receptor occurs; ρ_n is the distance from the particular souce to the receptor; $F_{ij}(d_n)$ denotes the relative frequency of winds blowing into the given wind direction sector d_n, for a given wind speed class i, and atmospheric stability class j.

The relative frequencies $F_{ij}(d_n)$ can be derived from hourly meteorological data, the stability classes being defined for instance on the basis of the Turner's objective criteria. If, however, specific meteorological data are lacking, one may use simplified regional data, for instance the frequencies of occurrence of the stability classes and their associated mean wind speeds at 10 m, all wind direction being confounded. The approximation then is that the frequency of weather categories is independent of wind direction. This may be a reasonable assumption for many sites.

TREATMENT OF THE ADVECTIVE SPEED

In the original model, the advective speed of the substance being dispersed was held constant thoughout computation and arbitrarily assumed to be equal to the wind speed $\bar{u}_i$ measured at the reference height z=10 m. In the new present model, the advective speed is now $\alpha_j(\rho)\bar{u}_i$, where $\alpha_j(\rho)$is a ventilation factor which is the ratio of the true average wind speed in each vertical cross-section of the plume, to the wind speed at 10 m formerly considered. Due to the large gradient of wind speed in the atmospheric layer adjacent to the ground, the ventilation factor is much less than unity at small distances from the source where the plume is still close to the ground, and increases at greater distances with the vertical extension of the plume.

It was shown by Smith and Singer (7) and by Horst (8) that the average horizontal speed of the pollutant molecules is approximately equal to the wind speed at the height $0.6\,\sigma_j(\rho)$ above ground-level. If $u_{ij}(z)$ is the mean vertical profile of wind speed for the wind speed class i and the stability class j, then the ventilation factor in the formula (1) is the following function of the distance ρ:

$$\alpha_j(\rho) = \frac{u_{ij}\left[0.6\,\sigma_j(\rho)\right]}{u_{ij}(10)} \qquad (3)$$

In this equation, the wind speed profiles above and beneath the top of vegetation can be respectively approximated by the classical log-linear formulas taken from Businger (9) and the exponential function from Meroney (11):

$$u_{ij}(z) = \kappa(u_*)_i \left[\ln\frac{z-d}{z_0} - \Psi\left(\frac{z-d}{L_j}\right)\right] \qquad (z \geq H) \quad (4)$$

$$u_{ij}(z) = u_{ij}(H)\exp\left[-\beta\left(1-\frac{z}{H}\right)\right] \qquad (z < H) \quad (4bis)$$

where κ is the Von Karman's constant; $(u_*)_i$ the friction velocity; H the height of vegetation; d the zero plane displacement height; z_0 the roughness length; L_j the Monin-Obukhov length that characterizes the atmospheric stability class j according to the correspondance shown by Golder (10); Ψ a corrective term whose expression is given in reference (9); β a factor between 1 and 3 depending on the density of the canopy foliage .

INFLUENCE OF SOIL COVER

The pattern of radon-in-air concentration above an area source of limited horizontal extension is very sensitive to the characteristics of the atmosphere boundary-layer close to the ground. Each sampling point situated above the source is at close distance from any point of the ground-level area source. Consequently, the advective speed $\alpha_j(\rho)\bar{u}_i$ to be used in equation (1) is much smaller than the wind speed $\bar{u}_i$ measured at 10 m. The concentrations above the source that are derived from the new model are thus much higher than those derived from the former model in which the advective speed was assumed to be $\bar{u}_i$ throughout calculation. The difference between the new concentrations and the old ones are strongly dependent of the nature and characteristics of the vegetation cover which determine the wind speed profiles in the first meters above ground level.

The concentrations of radon above a source of given strength are the smallest for a well ventilated area such as a flat surface with only low vegetation. In these conditions, the dampening of wind speed in the lowest layers of the atmosphere is relatively limited and does not induce the build-up of high concentrations. On the contrary, if the source is situated in a ill-ventilated woody area, the wind speed is strongly attenuated close to the ground, which results in the development of higher concentrations above the source itself. The influence of the vegetation cover, such as described in the new model, corresponds to the intuitive feeling that the radon concentration pattern should depend on the site ventilation.

The main difficulty encountered in the implementation of the new model is to characterize the boundary-layer over a terrain of variable roughness. The boundary layer properties and particularly the vertical wind speed profiles given in the literature as representative of low level boundary-layer properties over the land are those observed over fairly extensive flat plains with no more cover than homogeneous forest or low vegetation. The relevant surface properties are frequently affected by the patchiness of the vegetation cover and the presence of individual obstacles ranging from bushes and hedges to woods and buildings, and also to some degree by the natural topography of the landscape. While this spatial inhomogeneity does not affect very much the medium-range dispersion of pollutants from high stacks, it becomes of prime importance when the source is at ground level and the receptor very close to the ground at a short distance from the source.

By applying the new model to the typical case of a square source of 100 m x 100m, which emits radon with an homogeneous fluence rate of 1 Bq m^{-2} s^{-1}, it appears that the yearly averaged radon-in-air concentration above the source itself can reach values of a few tens of Bq m^{-3}. The concentration rapidly decreases as one moves away from the border of the source and becomes quite negligible beyond a few hundred meters from the source. This confirms the usefulness of trying to predict the radon air concentrations in the near-field of the emitting sources, which is the only place where the excess of concentration over background may be significant. Due to the difficulties and limitations aforementioned, the new model is only a tentative one. Further work is needed to improve the model and validate it by comparing predicted and measured values above and close to well-defined sources.

Sorption/Desorption phenomena in uranium mill tailings : Study of the distribution of radionuclides on pure solid phases and application to the modelling of source term.

Sylvain BASSOT and Denise STAMMOSE

Institut de Protection et de Sûreté Nucléaire, DPRE, SERGD, BP6 92265 Fontenay-aux-Roses, Cedex, France

Abstract

The mining and milling of the uranium raw material are processes which leave substantial volumes of uranium mill tailings. These radioactive waste products may have an environmental impact in far future. The health hazards occur in a number of pathways via radioactive gas emanation, external exposure, radioactive dust and through contamination of surface and ground waters. For long term consequences, modelling has to be performed to predict future exposures. Of course, the necessity of using predictive models requires a basic understanding of the relevant physical, chemical and geochemical properties of the system components.

In a previous paper [1], we have reported data obtained on uranium tailings deposited in Lengenfeld (Germany) 20 years ago. The solid phases (determined by XRD) are mainly quartz, dolomite and kaolinite. The lack of data concerning the mechanisms responsible for the retention of radionuclides on these solids has led us to perform batch experiments on pure solid phases. In this paper, we present the influence of the solution composition (pH, ionic strength) on the sorption of radium onto a solid phase (kaolinite). The variations obtained have allowed to define the mechanisms controlling the sorption and to determine the associated constants. The introduction of these values in geochemical codes based on thermodynamic equilibrium will allow to predict the mobility of radium in presence of these phases.

Key words

Uranium mill tailings, radium, distribution coefficient, kaolinite, ion exchange

Introduction

Uranium mining and milling have left behind great amounts of tailings containing both radionuclides (radium and uranium) and toxic elements (As, Ni,..) which may be released in the geosphere. The control of the release rate of potential contaminants from the wastes is the most important objective of long term management of these residues. Therefore, the knowledge of the original ores, the milling and extraction processes and the chemical and mineralogical characteristics of the tailings are required in order to predict the migration of the contaminants throughout the tailings.

Among numerous mineralogical phases, clayous phases (smectite, kaolinite) are quite important because of their high sorption capacity. Few data concerning the radium sorption onto solids phases are available in literature [2] and in most of cases, the radium behaviour is assumed to be quite similar to those of divalent cations (strontium, baryum...). This paper is devoted to the study of the sorption of radium onto kaolinite as a function of sodium concentration and pH in order to elucidate the mechanisms responsible of the radium sorption.

Experimental part

The studied solid was kaolinite provided by Sigma. This solid was purified in order to saturate all the sorption sites by Na^+ cations. The study of Na^+ sorption on this kaolinite by L. GORGEON [3] has led to determine a Cation Exchange Capacity (CEC) of 4.2×10^{-2} meq.g^{-1} whereas the cobaltihexamine method has indicated a CEC value of 2.8×10^{-2} meq.g^{-1}. This difference was due to the presence of two reactionnel sites as we could see in our results. The specific area of the purified kaolinite was estimated to 13.2 m^2.g^{-1} $\pm$ 0.1 m^2.g^{-1} and the exhangeable cation was sodium. The solution of radium was obtained by dilution of tracers in sodium chlorure (226×10^3 Bq of ^{226}Ra solution provided by Amersham). All other chemicals were reagent grade.

All the sorption experiments were performed in batch at 22°C. No attempt to exclude air was made. The ratio volume of solution to mass of clay was fixed to 20 ml.g^{-1}. The solution containing radium was added to the solid and then the mixing was shaken (3-D shaking). After one day (result of kinetic study), the slurry was centrifugated (4900 rpm, 30 mn). The pH was then measured in the solution with a Sentron pH-meter and

the radium concentration in solution was determined by gamma spectrometry with a high resolution hyperpure germanium spectrometer.

Radium distribution coefficients D were calculated as the amount of radium sorbed on the solid divided by the amount of radium remaining in solution :

$$D_{(ml.g^{-1})} = ([Ra]_{solid}/[Ra]_{solution}) \times V/m \qquad (1)$$

Results and discussion

Time dependence

For different sodium concentrations, the sorption has been studied as a function of time (Figure1).

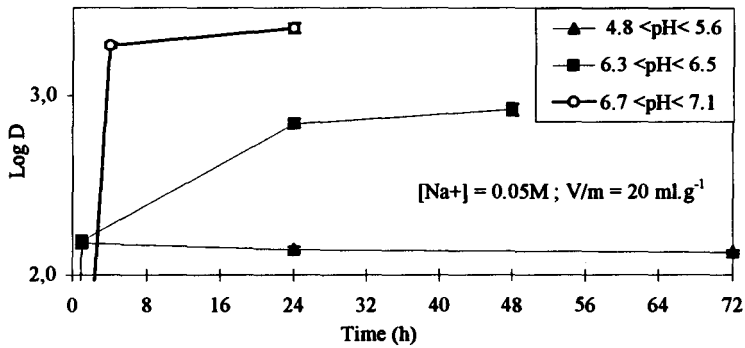

Figure 1 : Time influence on the radium sorption on kaolinite

A two steps kinetics is observed. The first step (rapid) is attributed to the sorption onto the surface, while the second often continuing for days is attributed to a diffusion process of the species through the first hydrated layers of the solid [4]. To avoid a possible alteration of clay for long settling time and considering the low variations of the amounts sorbed after 24 hours, all the experiments have been conducted with an equilibrium time of 24 hours.

pH dependence

The variations of the amounts of sorbed radium as a function of pH for different sodium concentrations are presented on Figure 2.

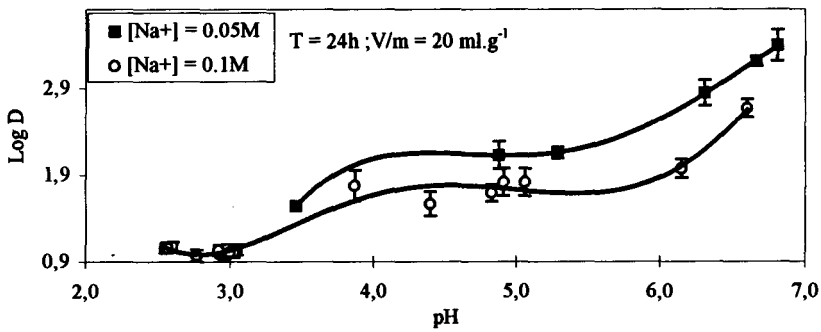

Figure 2 : pH influence on the radium sorption on kaolinite

For the two sodium concentrations, the distribution coefficient increases with pH excepted a plateau between pH 4 and 5.5 for which logD is constant. A possible explanation of this shape is a competition between H^+, Na^+ and Ra^{2+} at low pH. For pH>4, only competition between Na^+ and Ra^{2+} occurs and the distribution coefficient remains constant with increasing pH. For pH>6, D increases sharply. A similar curve has already been mentioned elsewhere [3] and has been attributed to another kind of sorption sites on kaolinite.

[Na^+] concentration dependence

The ionic exchange mechanism between radium and sodium can be written:

$$2\{X^-Na^+\} + Ra^{2+} \Leftrightarrow \{(X^-)_2Ra^{2+}\} + 2Na^+ \qquad (2)$$

$\{X^-Na^+\}$, $\{(X^-)_2Ra^{2+}\}$ = sorbed species

$$\text{and } K_{Na/Ra} = [(X^-)_2Ra^{2+}]\,[Na^+]^2 / [X^-Na^+]^2\,[Ra^{2+}] \qquad (3)$$

$K_{Na/Ra}$ = selectivity coefficient between sodium and radium for sorption on kaolinite

Combining (1), (2) and (3), we obtain the relation :

$$\log D_{Ra} = \log K_{Na/Ra} + 2\log CEC - 2\log[Na^+] = \text{Constant} - 2\log[Na^+] \qquad (4)$$

This model predicts a linear variation of D with the electrolyte concentration. The sorption of radium as a function of sodium concentration has been studied in a pH range 8 to 9. At high pH value, the H^+ concentration in solution is widely lower than Na^+ concentration and the sorption sites are occupied by sodium. The data expressed as $\log D = f(\log[Na^+])$ are plotted on Figure 3.

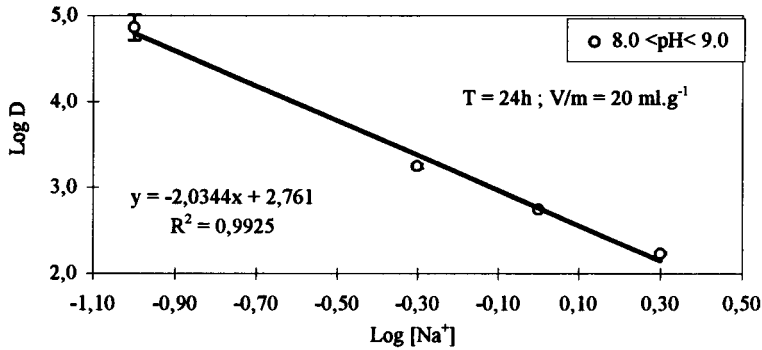

Figure 3 : Influence of Na^+ concentration on the radium sorption on kaolinite

The straight line obtained has a slope of -2.0344 (R^2 = 0.9925), which confirm the cation exchange mechanism between radium and sodium. The selectivity coefficient $K_{Na/Ra}$ can be estimated by the intercept of the curve and the CEC value measured by L. GEORGON [3]. A very high value (3.2×10^5 $g.ml^{-1}$) is obtained corresponding to a stronger affinity of radium than sodium for the sorption sites on kaolinite.

This study has allowed an estimation of the Na/Ra selectivity coefficient. Moreover, the strong influence of pH on the cation sorption onto kaolinite has been clearly observed, due to the competition between Na^+, Ra^{2+} and H^+ for sorption sites.

METHODOLOGY OF ENVIRONMENTAL IMPACT STUDY AND OPTIMIZATION OF RELEASES
Application to the Study Centre of CADARACHE

FRENCH ATOMIC ENERGY COMMISSION
by
JC CARIES (Health Physics Department)

OBJECTIVES :

- Impact study.
- Optimization of releases.

PRINCIPLES :

- Activities in the air and the water computed independently.
- The dose error contains more information than the dose itself ; it is representative of the knowledge evolution of the site.
- Computations of sensitivity and global error are essential in the modelling - experimentation interaction.
- Assessment of doses in the organs.
- Information feedback of the data-processing tools of a CEA subsidiary company (CISI) : modularity and flexible operation.

PROCEDURE :

- Source term : Spectrum of the radioelements.
- Impact study (per station).
  - * computations of transfers to both food and man ; sensitivities and error computations,
  - * main parameters with regard to the value : dose + error (d+Δd)
- Surveillance plan of the site.
  - * computations of the number of stations to be studied for a fixed percentage of (d + Δd),
  - * reduced equation of transfers , mapping and meshing of the site,
  - * exposures and food activities computations in every mesh, and filing.
- Optimization of releases (critical station)
  - * determination of the boundary level of exposures,
  - * successive iterations with the source term of the impact study and tests with different spectra of the source term.

RESULTS : Liquid transfers : Δd = (7 to 10)×d - Atmospheric transfers : Δd = (3 to 7)×d

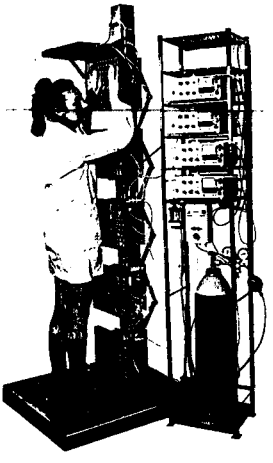
Body Contamination Monitors - State of the Art and Future Development

Rainer Gerlach, Rados Technology GmbH

History

Since the introduction of large-area proportional counters in the mid-1960s, it is possible to efficiently test large parts of the body for contamination. Initially, simple hand/foot monitors were used with these detectors, but already by the end of the 1960s there were personnel contamination monitors for also measuring large parts of the body. These devices were constructed according to the materials available and with simple analogue electronics. Some of these devices are still in use today, more than 25 years later. Now personnel contamination monitors are a constituent part of monitoring controlled areas. Since their introduction they have been subject to massive on-going development in almost all sectors. Detectors can be manufactured with almost any dimensions to match requirements and with appropriate electronics are also suitable for simultaneous alpha measurement. The geometrical arrangement of the detectors has been improved so that almost all areas of the body are measured. The application of the extremely powerful computer techniques that are available nowadays has brought about substantial improvements in many respects: background subtraction, comprehensive service and calibration support, user guidance through the combination of modern sensor technology with monitor displays and speech output, networking and data storage.



Body Contamination Monitor built in 1970

Classification and Application

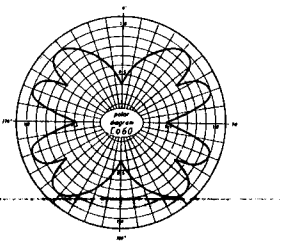
Personnel contamination monitors can be classified into three categories: **Hand/foot clothing monitors:** These just monitor the hands and feet simultaneously. The clothing must be measured with moveable clothing probes. The application extends to areas with a low throughput of personnel. **Pre-Monitors:** These also measure parts of the clothing simultaneously with the hands and feet, but normally only have a simple measurement geometry. The field of application covers checks within the controlled area with the objective of suppressing the spread of contamination. **Exit Monitors:** These measure the complete body with an optimum measurement geometry and are installed at the exits of controlled areas with high throughputs of personnel. The highest demands are placed on these monitors

Basic principles

In almost all countries there are laws and directives which stipulate the requirements for the monitoring of controlled areas. Here, the limits for the contamination monitoring are defined. This is mainly based on just the type of radiation or, as in Switzerland, is differentiated according to nuclides. The legal regulations are supplemented by standards such as the DIN standards in Germany or the IEC at an international level. Added to this, come recommendations from radiation protection commissions. Internationally the most important for personnel contamination monitors is IEC 1098 which was issued in 1992 ("Installed Personnel Surface Contamination Monitoring Assemblies for Alpha and Beta Emitters"). It regulates the minimum requirements on this kind of product and prescribes a range of tests with point and large-area sources.

- The determination of the uniformity of sensitivity is found with alpha and beta sources which are used for measuring the sensitivity distribution at specified measurement points within the measurement area of 15 x 10 cm^2 for hand detectors and 30 x 10 cm^2 for foot detectors. The sensitivity profile for the complete detector array is recorded for the body measurement (only beta). The horizontal profile based on a polar graph and the vertical profile based on an axial scan are recorded. An elliptical phantom with a 95 cm circumference and a 35 cm major axis is used as a basis.

- The sensitivity for the determination of the detection limits for the hand and foot monitors is made with large-area sources of 15 x 10 cm^2 (hands) and 30 x 10 cm^2 (feet). The mean of the axial and horizontal scans is used as the basis for the detection limits of the body measurement. Computational rules are also given for the determination of the detection limits in the quoted standard. However, a draft ISO standard (ISO 112929): "Determination of the lower limits of detection and decision for ionising radiation measurements")[1] already exists. In modern monitors with automatic adaptation of the measurement period the appropriate formulae in this draft standard are already taken into account.



Polar Response Diagram according to IEC 1098 (Split -Delta Geometry)

Development and Problems in the Measurement Geometry

The fact that IEC1098 makes the measurement geometry a decisive quality feature due to the requirement for recording the polar and axial scan diagrams indicates how important geometrical properties have become. In actual fact the capability of a monitor to detect contamination reproducibly over as much of the body as possible mainly depends on the size and arrangement of the detectors. After all, the detector response is very dependent on the distance to the source. This particularly applies to low-energy radiation and K capture radiation.

Whereas formerly monitors monitoring the front and back of a person simultaneously in one measurement phase were common, monitors measuring the front and back sequentially have become more established due to a major problem with the one-step method. The advantages are obvious - in contrast to one-step monitors, the distances are noticeably shorter and more reproducible. In addition, the sides of the body can be measured with good sensitivity. With the one-step method this is not possible even with the important nuclides of ^{60}Co and ^{137}Cs due to the large distances. Substantially better results are also produced for the head. Forearm detectors are significantly easier to integrate in a two-step monitor. An optimum sensitivity distribution is obtained with a triangular geometry with mean vertical division (Split-Delta from Rados). The sensitivity profile of this geometry is also tolerant against different sizes of person.

Also, modern geometries represent a compromise in detection characteristics, operating convenience and, not unimportant, costs. Improvements can still be achieved in the area of the shins, on the upper side of the feet and in the region of the upper arms, but with substantial extra expenditure. The measurement geometries now achieved have partial suitability for the detection of alpha contamination. Admittedly, a non-defined sensitivity profile is produced due to the extreme dependence of alpha radiation on distance, but, for example due to the split-delta geometry, large parts of the body and clothing come close enough to the detectors to enable good alpha detection.

Detectors

The market is currently dominated by large-area proportional counters for continuous operation. There are a number of reasons for this: They have high alpha and beta sensitivities with a low background, they can be produced economically in almost any dimensions and they can be easily repaired on site. Their main disadvantage is that they need a continuous supply of counting gas. Alternative sealed proportional counters only achieved limited success, because they exhibit practically no alpha sensitivity, have a noticeably lower sensitivity to low-energy radiation and, due to restricted dimensions, the devices constructed with enclosed detectors produce more dead zones. Added to this, much effort is required to replace the window foils so that they have to be more protected, giving a further reduction in sensitivity.

In principle, large-area plastic scintillation detectors are suitable, but there are still many fundamental problems to be solved. In particular, the detector material must be designed very thin (1 to 2 mm) so that it exhibits a low background with high beta sensitivity. Reading the light out from these types of plastics economical is still a problem, but if this can be achieved for a reasonable expenditure, then this type of detector would be a very interesting alternative to the proportional detector.

[1] DIN 25482 is applied in Germany

Interference Effects and their Treatment

The measurement is disturbed by a number of external influences - varying background count rate, xenon and radon clouds, xenon and radon attached to the clothes or hair or contamination on the detectors. In contrast, in modern devices electromagnetic interference is no longer a problem.

~~The most important disturbing influence is the varying background count rate. It is caused by natural~~ radiation (cosmic rays, building materials, etc.) and by artificial radiation sources (active piping, contaminated surfaces, etc.). Added to the normally slow changes in the background are those, for example, due to the large queues in front of the monitor. Often the field is also directional. There are a number of methods of background subtraction. Many of the methods are too slow or lead to extended downtime periods. A method specially developed for application in personnel contamination monitors operates with an exponential filter and two sliding median values. The two median values are formed from different numbers of pulses so that they have different response times. During the background measurement the signal from the exponential filter is checked for whether it is located within specified limits about the median values. Based on a range of criteria, the system decides which of the median values is regarded as the present background. With this method the monitor can adapt quickly to short-term changes in the background without downtimes and without sacrificing the required accuracy.

Xenon and radon clouds mainly behave as other background variations and are taken into account by the subtraction method. This is not the case with radon or xenon activity clinging to clothing. It only appears when the person enters the monitor. The large-area characteristic of this activity may give a clue, but is not sufficient to be used as a criterion in the classification as background, because contamination may also cover a large area. It is just these types of contamination that must not under any circumstances remain undetected.
The alpha channels also exhibit a background effect. This is situated in the region of 0.1 to 0.5 pulses/s, so that usual background subtraction methods cannot be used. Therefore, for the alpha background subtraction, methods are used which are specially developed for low pulse rates.

Data Processing and Networking

Whereas with the first generations of personnel contamination monitors the measurement data was lost after termination of the measurement, it is now possible to link the monitors distributed in the plant with a central computer where the measurement data can be collected. Practice shows that important conclusions can be drawn from this data, enabling for example, the origin of the contamination in the system or the presence of hot particles to be deduced. From this, appropriate measures for improving the radiation protection can be derived. The possibility of accessing information from the devices centrally also represents a significant alleviation in the workload for the servicing personnel so that it also increases the availability.

Modern Body Contamination Monitor RTM860TS with Split-Delta Geometry and powerful PC-Electronics

Future Prospects

Although personnel contamination monitors have now achieved a high technical standard, continual development will still take place in the future. Modern computer technology offers opportunities of improving the service friendliness and also the possibilities of networking and data evaluation have not yet been exhausted. An example here is the coupling with dosimetry. The latest developments show that progress can be achieved in the field of background subtraction. It is still to be seen whether the large-area proportional counters in use today can be replaced by other technologies. In any case however, refinements in the measurement geometry and the signal evaluation will produce further improvements in the measurement characteristics.

"HOT PARTICLE" INTERCOMPARISON DOSIMETRY*

ABSTRACT

Dosimetry measurements of four "hot particles" were made at different density thickness values using five different methods. The hot particles had maximum dimensions of 650 μm and maximum beta energies of 0.97, 046, 0.36, and 0.32 MeV. Absorbers were used to obtain the dose at different depths for each dosimeter. Measurements were made using exoelectron dosimeters, an extrapolation chamber, NE Extremity Tape Dosimeters™**, Eberline RO-2 and RO-2A™ survey meters, and two sets of GafChromic™ dye film with each set read out at a different institution. From these results the dose was calculated averaged over 1 cm^2 of tissue at 18, 70, 125, and 400 μm depth.

Comparisons of tissue-dose averaged over 1 cm^2 for 18, 70, and 125 μm depth based on interpolated measured values, were within 30% for the GafChromic™ dye film, extrapolation chamber, NE Extremity Tape™ dosimeters, and Eberline RO-2 and 2A™ survey meters except for the hot particle with 0.46 MeV maximum beta energy. The results for this source showed differences of up to 60%. The extrapolation chamber and NE Extremity Tape™ dosimeters under-responded for measurements at 400 μm by about a factor of 2 compared with the GafChromic™ dye films for two hot particles with maximum beta energy of 0.32 and 0.36 MeV which each emitted two 100% 1 MeV photons per disintegration. Tissue doses determined using exoelectron dosimeters were a factor of 2 to 5 less than those determined using other dosimeters, possibly due to failures of the equipment.

INTRODUCTION

Previous investigators used various methods to determine dose from hot particles including extrapolation chamber measurements (1-4), exoelectron dosimeter measurements (3,5), and radiochromic dye film measurements (2,4,6-9). The difficulty with such measurements arises from the extremely non-uniform dose distributions on contact with the particles (2,7). The results from radiochromic dye film dosimetry have shown differences of up to 40% for different imaging systems reading the same irradiated film (8).

METHODS AND MATERIALS

To evaluate the precision of appropriate systems for measuring dose from hot particles, an intercomparison study was carried out at Brookhaven National Laboratory (BNL) by researchers from four institutions. Five different methods from four institutions (Table 1) were used to measure doses from four hot particles with different beta- and gamma-emission characteristics (Table 2). Films exposed by the BNL group were read at the National Institute of Standards and Technology (NIST), and films exposed by the UBIRM group were evaluated at UBIRM. An empirically determined rule of thumb was used to convert the Eberline RO-2 and RO-2A™ measurements to dose averaged over 1 cm^2 at 70 μm depth (4).

The Tm-170, Sc-46, and Yb-175 sources were cut from foils into three-dimensional slab sources. The Co-60 particle was spherical (Table 3).

Sources were mounted on styrofoam blocks to minimize backscattered beta particles, and for containment, they were covered with a thin radiation-resistant cover of Kapton™ with a thickness of 13 μm and a density of 1.4 g/cc. Sources were placed on each dosimeter for a period that did not exceed the saturation level of the dosimeter.

*This work was supported by the U.S. Nuclear Regulatory Commission.

**Certain commercial products are mentioned by name for informational purposes. This does not imply endorsement by the researchers nor that they are the best or only products available for the purposes described.

Exposure times ranged from 5 s to several days. Absorbers were inserted between the source and the dosimeter to obtain doses near tissue thicknesses of 18, 70, 125, and 400 μm. Doses were corrected for decay to a reference time and computational methods were used to obtain dose at the density thicknesses of interest averaged over 1 cm^2.

Table 3. Dimensions and Densities of Particles

Particle	Density (g/cc)	Thickness (μm)	Length (μm)	Width (μm)
Tm-170	9.4	260	440	400
Sc-46	2.9	130	460±74[a]	330±42[a]
Yb-175	7.0	130	480	340
Co-60	8.4	210±11[a,b]		

a Average (±1 σ) from the batch of particles neutron activated at the same time.
b The Co-60 source was spherical.

RESULTS

The results showed agreement within 30% between the GafChromic™ dosimeters, extrapolation chamber, NE Extremity Tape™ dosimeters, and Eberline RO-2/2A™ ion chamber for 70 and 125-μm tissue depths (Table 4). The best agreement was for the Tm-170 particle, while the worst was for the Yb-175 particle; the reason for the latter is

not understood. The good agreement between the Eberline RO-2/RO-2A™ and the other dosimeters was surprising. Unfortunately, the detector saturated while measuring the Sc-46 particle. The significant under-response of the exoelectron dosimeters compared with other techniques also is not understood.

Co-60	400	5.7E-04	6.2E-04	5.0E-05	3.8E-04	2.2E-04	

CONCLUSIONS

Doses from four hot particles with maximum beta energies between 1 and 0.32 MeV were measured using five different dosimeters. With the exception of the exoelectron dosimeter, the different methods gave good (±30%) agreement for dose averaged over 1 cm² at 70 and 125 μm tissue depths.

"HOT PARTICLES" IN THE LUNGS OF PEOPLE FROM THE CHERNOBYL ACCIDENT WHO DIED OF ACUTE RADIATION SICKNESS

Peter A.Vlasov, and Yulia E.Kvacheva

State Research Center "Institute of Biophysics", Moscow, Russia

INTRODUCTION

Although the "Hot Particles" (*"HP"*) problem is known since the middle of the 1950s there is no common opinion concerning its threat to human health up to date. There exist extreme points of view - from absolute denial of the possibility, as well as any significance of "HP" intake into the lung to obvious exaggeration of "HP" danger (e.g. pulmonary tissue injury, carcinogenic effect) (1-3).

MATERIAL AND RESULTS

Lungs of 27 persons who were irradiated with a high dose-rate of uniform whole body gamma- and beta-irradiation (its range varied from 3.7 to 13.7 Gy) and died of acute radiation sickness within two first months after Chernobyl accident were investigated. Intakes of radionuclides, including "hot particles", by inhalation did not add a significant fraction to the total dose because of short-term exposure, as well as did not influence clinical picture and outcome in these 27 cases.

At the same time this unique material allows to consider "HP" problem at least in two aspects. The first - phenomenological aspect - deals with human lung particles intake, localization, number, size, radionuclide composition, behavior and so on. The second - medical aspect - arises from the necessity to assess the potential "HP" hazard for witnesses who survived after the accident.

Depending on individual location within the next few minutes and hours after the accident all of 27 victims were subdivided into two groups: The first one consisted of 18 persons (the nuclear reactor and turbines operators mainly) who were working indoors the 4th power unit at about 50, 100 and 200 meters' distance from the explosion epicenter. The second group included 9 persons (the firemen, guard and 1 railroader) who were staying outdoors at a distance up to 100, 200 and more meters. The minimal distance from the epicenter was equal to 35 m (the 1th group), the maximal - 1000 m (the 2nd group).

Pulmonary tissue samples, obtained from the central, peripheral and lung root areas of each lobe, were Formalin-fixed, dehydrated, paraffin-embedded and then serially cut at $3 \div 4$ μm. Sorted out by means of autoradiography (RM-1 X-ray film, Russia) the sections with radioactivity were exposed to histoautoradiography test (A-2 emulsion, Russia) and stained with hematoxylin and eosin.

Two types of emitting particles were detected: mixed alpha- and beta-emitting particles, as well as pure beta-emitting particles. The former "hot particle" type dominated. Any special examination of the "HP" radionuclide composition was not performed because it is well known from the literature (4). Being repeated every 2 years (1986, 1988, 1990 and 1992) our histoautoradiography investigation of the same material has confirmed those data. For instance, in 1990 and 1992 histoautographs the incidence of pure beta-emitting particles was found to be markedly decreased, however some of them (^{90}Sr or ^{106}Ru) were still observed.

The most particles were revealed in the lower lobes (central and lung root areas). All "HP" were localized into alveolar macrophages, which filled up some alveolar sacs and bronchioles, lying on alveolar walls and entering their thickness. Such histological picture is evidence of macrophages mediated "HP" mobility (redistribution) all over the lung leading to dose realization not only in strongly limited pulmonary structures, as it is considered, but through a bigger lung volume. On the other hand this fact illustrates the process of radioactivity elimination (sputum macrophages mediated "HP" pulmonary clearance).

We failed to detect "HP" size directly in histoautographs with the use of negative imprint "weakening" technique because of both "hot" and non-"hot" particles overloading of the macrophage-carrier. Another approach (the particle geometrical diameter measuring in 10 macrophages from 10 casual pulmonary tissue fields) has shown the named index to keep within 0.2-1.0 μm.

The maximal "HP" incidence was found in cases which formed the first group. The number of inhaled particles seems to depend on individual patient's location within the period following the accident (i.e. on aerosol clouds spreading) rather than the distance from the explosion epicenter and duration of staying at NPP. Indeed, 2 cases with the similar distance from the explosion epicenter ($35 \div 40$ m) and duration of staying indoors the 4th power unit (about $20 \div 40$ minutes) but different premises location were found to differ in their "HP" amount. The former had more than 20 "hot particles" per histological section (2 cm^2, $3 \div 4$ μm), the latter - 1 "HP" in a hundred of similar sections. Very few, if any, "hot particles" were present in the lungs of the second group. Like the first one there was no association between the "HP" incidence and the distance from the accident epicenter. Attention needs to be paid to respirator using (3 cases) which produced sufficient lung protection.

It must be noted that inferences drawn from present study are correct only for persons staying at NPP within the next hours after the accident. Some time later aerosol distribution becoming uniform resulted in risk "HP" inhalation for many witnesses.

Even in cases with the maximal "HP" loading of the lung, their number per macrophage appear not to exceed some units. Therefore macrophage activity value seems to correlate with one particle activity. For alpha-emitting particles it was found to keep within $5 \cdot 10{-}6 \div 8 \cdot 10^{-5}$ Bq (DTD CR-30 TASTRACK estimate; data presented be A.Marenny). Taking into account fuels' alpha- and beta-emitting particles ratio it could be considered that "HP" total mean activity was equal to $0.3 \div 5.0$ Bq (data presented by V.Kutkov).

"HP" short-term exposure in these 27 cases does exclude any biological effect development.

EQUIPMENT AND STANDARDS FOR SURFACE CONTAMINATION MEASUREMENTS

Maria Sahagia, Anamaria Razdolescu, C.Ivan
Institute for Physics and Nuclear Engineering, POB MG6, Romania

INTRODUCTION

The measurement of the surface contamination level with alpha and beta emitters is made generally by using contaminometers, equipped with large area detectors; they must satisfy some technical requirements, imposed by the International Standards [1], the most important being their response as function of the contamination level of the surface, R, [s^{-1} /(Bq cm^{-2})]. On this purpose such contaminometers must be developed and a wide variety of large area alpha and beta sources must be used for their calibration. These sources must also fulfill some requirements [2] regarding their activity, particle emission, uncertainty, uniformity. The present paper presents the equipment and methods used for the preparation and standardization of alpha and beta sources, as well as the main characteristics of a portable, alpha-beta contaminometer, developed in our Laboratory.

1. PREPARATION AND STATEMENT OF THE STANDARD SOURCES ACTIVITY

The most widely used large area standard sources are prepared by the adsorption of the radioactive material in a thin aluminium oxide layer obtained by the anodization of the surface of an aluminium plate [3]. The particle emission is measured directly by using large area windowless proportional counters [4], but their activity can not be stated, as the preparation procedure is not quantitative. In the case of thin alpha sources, the activity may be calculated from the particle emission with 2Πsr geometry from the relationship

$$A = 2E_{\alpha} \qquad (1)$$

where A is the activity [Bq], E_{α} is the 2Πsr particle emission [s^{-1}]. In the case of beta sources, due to self absorption and backscattering, relation (1) is no more valid. This is the reason for which, a long period, the well-known producing laboratories certified only the particle emission, but not the activity; only recently, an indirect method for determination of the activity from the emission value was developed by Janssen et al [5].

We adopted the following methods for the preparation of the sources . The alpha sources were prepared electrolitically from ^{241}Am, using stainless steel discs as supports; a maximum active diameter ϕ =22mm was obtained. The emission in a 2Πsr geometry is measured, and the activity is calculated according to the relation (1). The beta sources were prepared by the quantitative dispensing of standard solutions of ^{35}S, ^{147}Pm, ^{204}Tl, ^{90} (Sr+Y), on thin paper foil[6], 3mg.cm^{-2} thick. Equal mass drops, about 10 mg each were dispensed in each square centimeter marked on the foil; after drying, the paper was sealed between plastic foils 3mg.cm^{-2} thick and fixed on aluminium plates with a thickness of 3 mm; an uniformity better than 7.5% on the whole surface was found. The sources are recognized by the Romanian Bureau of Legal Metrology (RBLM), obtaining the certificate nr.5353/1991. The solutions were standardized absolutely by using the 4ΠPC proportional counter-γ coincidence equipment, 4ΠPC or efficiency tracer method [7], recognized as secondary standard of Romania [8,9]. The activity of the sources, A[Bq], was raced calculated as:

$$A = a.m \qquad (2)$$

where a is the activity concentration of the solution [Bq. g^{-1}], m is the mass of standard solution[g]. A maximum expanded uncertainty of ±(2-4)% for a 99% confidence level was obtained. The 4ΠPC characteristics were fully described in the paper [10].

2. MEASUREMENT OF THE PARTICLE EMISSION IN 2Πsr GEOMETRY

2.1. Windowless 2Πsr proportional counter.

Alpha and beta sources with a diameter inferior to 30 mm are measured directly in the superior half of the 4Π proportional counter, working in the regime of alpha or beta detection. The saturation backscattering corrections for ^{90}(Sr+Y) is 7% and is ensured by using the 3mm Al support; for other radionuclides, this correction is less than 1% and may be neglected.

For the large area sources emission measurement, we applied two parallel methods. One of them is based on the use of the 2Πsr windowless proportional counter and consists in the followings. During the preparation of the large area source, 3-4 sources with a maximum diameter ϕ=26 mm were prepared quantitatively from the same solution by using the same materials (paper and plastic foil). Their emission values, $E_{\beta i}$ [s^{-1} /2Πsr] were measured in the 2Πsr windowless proportional counter, and their individual efficiencies $\varepsilon_{\beta i}$ [s^{-1} / Bq] were calculated as:

$$\varepsilon_{\beta i} = E_{\beta i} / A \qquad (3)$$

The mean efficiency, ε_β and its standard deviation $S\varepsilon_\beta$ were calculated from $\varepsilon_{\beta i}$ values. The backscattering correction factors, f, were applied and the large area source emission was then calculated by using the relationship $E_\beta = f.\overline{\varepsilon}_\beta A$ (4) Table 1 represents some experimental values which allowed to verify the validity of the method. It was recognized by the RBLM as a technical Procedure [11] ($f\overline{\varepsilon}_\beta$) is the mean efficiency of a radionuclide.

Table 1

Radionuclide	Solution concentration a ,[Bq/g^{-1}]	$\overline{\varepsilon}_\beta$, [s^{-1}/Bq]	$S\overline{\varepsilon}_\beta$,%	f	$(\overline{f\varepsilon_\beta})$
(Sr+Y)-90	36560	0.4447	±1.5	1.07	0.4851± 1.1
	7165	0.4651	±0.9		
	1580	0.4460	±1.6		
	954	0.4579	±1.4		
Tl-204	88600	0.4143	±0.4	1.00	0.3985±4.7
	4964	0.3610	±3.5		
	1890	0.4203	±1.2		
Pm-147	21050	0.1305	±4.0	1.00	0.1243±4.1
	1972	0.1257	±4.1		
	1006	0.1168	±4.5		

The second method is presented at point 2.2

2.2. Large area 2Πsr proportional counter

A multiwire proportional counter, working with pure methane flow at the atmospheric pressure, 250x250 mm area, with an aluminized Mylar window, thickness 0.85 mg/cm was used for the direct measurement of the particle emission of the large area sources. It is placed in a 5cm lead shielding and is provided with a 4mm plate fixed at 5mm distance from the window, where the sources to be measured are placed. The background counting rates are 0.1s for alpha operation and 10^{-1} for beta. When a 2400 V high voltage. Two main characteristics of the counter were followed : the response of the detector and the edge effects. The response is defined both as the ratio between the counting rate, and emission E_β, R_1=N/E [s^{-1}/s^{-1}/2Πsr] or the ratio between the counting rate and activity R_2=N /A [s^{-1}/Bq]. In the case of alpha sources, seven ^{241}Am sources, prepared in our laboratory, with the activity in the interval (19-17000)Bq and four ^{239}Pu of the same type delivered by the LMRI-France with the activities interval (1.8-3600)Bq were used. The obtained values of R_1 and R_2 are presented in the table 2.

Table 2

Radionuclide	$\bar{R}_1 \pm \bar{S}_{R1}$	$\bar{R}_2 \pm \bar{S}_{R2}$
Am-241	0.748±1%	0.374±1%
Pu-239	0.712±3%	0.356±3%

In the case of beta sources, several sources of ^{137}Cs, ^{90}(Sr+Y), ^{204}Tl, ^{147}Pm with different dimensions, from point to (150 x 100) mm and separately with (220 x 180)mm, (250 x250)mm for ^{90}(Sr+Y) were used. The obtained results are presented in the table 3.

Table 3

Radionuclide	Source dimension	$\bar{R}_1 \pm \bar{S}_{R1}$	$\bar{R}_2 + \bar{S}_{R_2}$
Cs-137	point	0.94+3%	0.446+1.0%
(Sr+Y)-90	<(150 x 100) mm	0.94+3%	0.457+5.0%
	(250 x 250) mm	0.80+3%	0.403+6.0%
Tl-204	< (150 x 100) mm	0.95+3%	0.358+6.0%
	(220 x 180) mm	0.86+3%	0.335+6.0%
Pm-147	< (26 x 26)mm	0.83+3%	0.111+5.0%
	(150 x 100) mm	0.74+3%	0.092+7.0%
	(220 x 180) mm	0.64+3%	0.086+7.0%

One may notice the reproducibility of the results and the absence of edge effect for dimensions of the sources less than 150 x 150 mm. The same study, of the edge effect was made with a point ^{90}(Sr+Y) source measured at different distances from the center of the counter. The results are in good agreement with those presented in the table 3.

The system was certified by the RBLM certificate numbers 1826/1992, 1837/1993.

3. THE PORTABLE CONTAMINOMETER

A portable contaminometer, provided with two multiwire proportional counters (for alpha and beta detection) having an active area of 50 cm^2 and a window thickness of 0.85 mg.cm^{-2} working in regime of propane flow was developed. It was calibrated with large area alpha and beta sources presented at the points 1 and 2 and meets all the requirements of the IEC 325/81 document. The contamination level ranges are : for alpha contaminants ($8.4 \cdot 10^{-2}$ - $8.4 \cdot 10^{2}$)Bq/cm^2 and for beta contaminants ($0.2\text{-}0.67 \cdot 10^{3}$)Bq/cm^2 . It may be used continuously for a 20 hours period and is provided with an alarm system, announcing contamination levels superior to a preestablished threshold.

CONCLUSIONS

1. The equipment, standards sources and measurement methods developed in our laboratory offered us the possibility to solve completely the problem of the measurement of the contamination of the surfaces with alpha and beta emitters.

2. The traceability at both national and international level of the equipment, standards and methods used was once again demonstrated.

ABSTRACT (See instructions overleaf)

The need for effective monitoring of surface contamination is quantified in terms of activity per unit area; this quantity is used to specify the derived limits, that are incorporated in the national regulations of radiation protection. These regulations recommend the calibration of all health physics instruments every 12 months. In the case of surface contamination monitors, a special set-up and a method were developed at the Calibration Laboratory of São Paulo, using standard alpha and beta radioactive sources. At São Paulo the monitors are being calibrated using ^{241}Am, ^{14}C, ^{36}Cl and ^{90}Sr + ^{90}Y sources, and the instrument efficiency is determined for each case for alpha and beta radiation. Moreover, all instruments are being normally tested also with ^{241}Am sources of different activities (response linearity) and with ^{137}Cs, ^{244}Cm, ^{233}U, ^{238}Pu and ^{239}Pu sources (energy dependence). Instruments of different manufacturers and types were used for this study.

Institute for Nuclear Research, Kiev, Ukraine

1. INTRODUCTION

The development of rapid and sensitive devices for the monitoring systems of α-radinuclides in the environment is of a paramount importance, especially after Chernobyl accident. Alpha-spectrometry methods based on Si-semiconductor detectors proved to be among the most reliable ones up to now. Different kind of detectors have been developed and fabricated by authors for that purpose by means of the surface-barrier as well as of the planar technology. The description is presented for the Multichannel-Alpha-Radiometer-Spectrometer ("MARS-16") designed on the basis of the developed detectors for rapid measurements of the concentration of alpha-radionuclides in the environment (soil, fluids, air) and food. Strip-detector option of the "MARS-16" could be used for the high accuracy position determination of the alpha-radioactive contamination.

2. EXPERIMENTAL RESULTS

To provide alpha-spectrometry systems with high quality semiconductor detectors different technologies for the fabrication of the planar detectors were studied. The main physics-technology limitations for the production of silicon planar detectors with different topological configurations were determined.

The detectors were fabricated on the base of n-type silicon plates with diameter of 3 inch, <100> orientation and ~ 1 kOhm·cm resistivity. The plates were oxidized in water vapour with an addition of the 3-chlorine-ethylene at the temperature of 850-1000°C. Vapour-borned Si-oxide as well as a many layer dielectric with a Si-nitride were used for dielectric layers.

p^+-n junction was made by ion implantation of boron at energy E = 40 keV, ohmic contact on the rear side was made by implantation of phosphorus at energy 60 keV. The rear side and p^+-n junction of the detectors were metalized by 0.3 μm thick Al.

Planar detectors on the base of high resistivity silicon with area of 1 cm^2, 16 cm^2 and passive-mosaic detectors with total area of 24 cm^2 were developed. The application of passive-mosaic structures allows to produce the detectors with large active area for integral alpha-activity measurements. The energy resolution of fabricated detectors with area of 16 cm^2 and sensitive layer thickness of 250 μm for 5.5 MeV α-particles was 70-90 keV at the bias voltage of 50 V and leakage current of 60-100 nA. For the detectors with area of 1 cm^2 the energy resolution was 25-30 keV at bias voltage 20-60 V and leakage current 20-40 nA. Such detectors were used for express analysis of radionuclides in samples from various regions

contaminated during Chernobyl accident.

In particular, large area Si-detectors (up to 16 cm^2) have been used in the Multichannel-Alpha- Radiometer-Spectrometer ("MARS-16") designed mainly for rapid measurements of the concentration of alpha-radionuclides. 16 Si-detectors are housed in a vacuum chamber equipped by special preamplifiers with low noise for detectors with large capacitance. The vacuum chamber is inserted into a crate CAMAC together with amplifiers, strobe mixer, analog unit and crate controller linked to PC IBM-486. The developed software allows for analysis of spectra to extract values of alpha-concentrations by means of thin and thick samples methods (1). Fig.1 represents the example of the alpha-spectrum measured by one of "MARS-16" channels for the thin probe prepared by means of radiochemical separation of Pu-isotopes using ^{236}Pu as a tracing element.

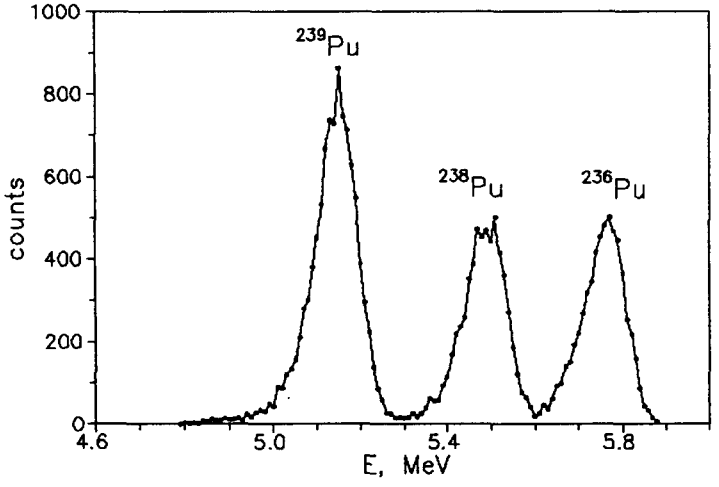

Fig.1. Alpha-spectrum measured for the thin probe prepared by means of radiochemical separation of Pu-isotopes.

The remarkable feature of "MARS-16" is an ability to provide selective alpha-radioactivity monitoring avoiding time consuming and expensive procedure of radiochemical preparation of samples. Fig.2 represents the example of an alpha-spectrum measured by "MARS-16" directly from the contaminated soil sample (histogram). Dashed lines show the contribution of various alpha-emitting isotopes, while the solid line represents their sum, as it follows from the Monte-Carlo simulation. We could easily reach the sensitivity to $^{238,239}Pu$ concentrations (at 20% statistical error) up to 20 Bk/kg without radiochemical sampling procedure and measuring time ~ 20 hours. Results obtained by means of thin and thick sample methods generally are in a good agreement , although in some cases the thick sample method gives higher concentration values.

Earlier unknown features for alpha-radiometry are introduced by strip-detectors widely used in high energy physics. Extremely good energy resolution (up to few keV for minimum ionizing particles) combined with high position determination accuracy even at very high counting rates

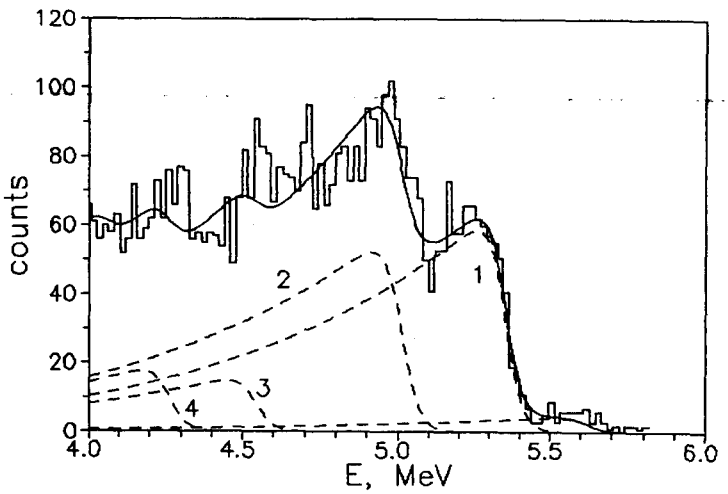

Fig.2. Alpha-spectrum measured for thick sample of soil. Dashed lines correspond to the contributions of different isotopes with distinguished energy of α-radiation: 1 - ^{238}Pu; 2 - ^{239}Pu; 3 - ^{234}U; 4 - ^{238}U. Solid line is their sum.

(up to hundred kHz for the total area of strip-detector) characterizes a strip-detector as an exceptional device for alpha-radiometry.

The design of the 128-channel Si strip-detector with submicron position sensitivity for alpha-radiometry purposes has been developed. Some information on the characteristics of fabricated and studied strip-detectors could be found in the Proceedings of this Conference. High accuracy of the 2-dimensional position determination is realizable by means of double-sided strip-detectors. The position accuracy for both "X" and "Y" coordinates could be essentially improved by a fabrication of the strip-detector with special strips configuration and exploring the method of submicron position sensitivity (2).

CALCULATION OF FLUENCE-TO-DOSE EQUIVALENT CONVERSION COEFFICIENTS FOR NEUTRONS TO BE USED FOR CALIBRATION OF PERSONAL DOSIMETERS

M. Yoshizawa[1] and Y. Yamaguchi[1]

[1] Japan Atomic Energy Research Institute, Tokai, Japan

ABSTRACT

Conversion coefficients from neutron fluence to the ICRU slab dose equivalent for personal dosimeter calibration were calculated using the MCNP-4 code and the cross section library based on JENDL-3.1. Influences given by the changes of neutron quality factor and phantom size were also investigated.

INTRODUCTION

The international Commission on Radiation Units and Measurements(ICRU) has recommended in its report No.47(1) that the dose equivalent at the depth of d in a 30×30×15cm ICRU tissue slab phantom, ICRU slab dose equivalent, $H_{si}(d,\alpha)$ (α: incident angle), should be used as the quantity for calibration of personal dosimeters. Though the scope of that report focuses on photons and electrons, the consistent calibration procedure requires the same quantity for neutrons as well. Conversion coefficients from neutron fluence, Φ, to $H_{si}(d,\alpha)$ for a broad parallel beam of neutrons incident in angle α are needed to apply the quantity $H_{si}(d,\alpha)$ to calibration of personal dosimeters. There are only a few published reports(2-4) on $H_{si}(d,\alpha)/\Phi$. To improve the reliability of the conversion coefficients, the calculation should be made with different techniques and nuclear data. In addition, neutron quality factors, Q_n, that mean the average quality factors for the neutron-induced heavy charged particles, have been recalculated based on the new data on stopping powers and ranges for protons and alpha particles(4), thus the influence of this alteration on $H_{si}(d,\alpha)/\Phi$ needs to be investigated. To clarify the contribution of neutrons and secondary photons to the dose in the phantom, it is important to compare the values of the conversion coefficients calculated for the phantoms with different size. This paper presents the calculated values of $H_{si}(d,\alpha)/\Phi$ at depths of 0.07, 3, and 10mm in the range from thermal to 20MeV in energy and from 0°(normal incidence on the surface of the phantom) to 75° in incident angle, and the influences of the alteration of Q_n and of the difference of the phantom size on the conversion coefficients are also described.

METHOD

The Monte Carlo code MCNP-4 was used in the calculation. The surface crossing estimators were employed to calculate spectral fluences of neutron and neutron-induced photon at depths of 0.07, 3, and 10mm on the mid-axis within the ICRU tissue slab phantom, irradiated by a broad parallel beam of neutrons incident in angle α. This type of estimator would be more effective than volume-type ones to evaluate the fluences that vary significantly with depth in the phantom. The estimator was a disk with a radius of 2cm, which was chosen by test calculations. The number of particle histories was selected dependently on energy and incident angle so that one relative standard deviation could be maintained within 1%.

The continuous energy cross section libraries employed in this work are FSXLIB-J3(5), generated from JENDL-3.1 evaluated in Japan(6), for neutrons, and MCPLIB, based on data from ENDF, for photons. Since $S(\alpha,\beta)$ data for treatment of chemical binding effect in thermal neutron scattering are not available for ICRU tissue, the data for hydrogen bound in light water were adopted in the calculation.

The absorbed dose was calculated by the kerma approximation. The kerma factors were taken from the data of Caswell *et al*(7) for neutrons and of Hubbell(8) for photons. The neutron quality factors used in the calculation of dose equivalent are the data of Schuhmacher and Siebert(9). In order to avoid the round error due to the structure of energy bins, we did not use energy bins, but each particle was weighted by the kerma factor and Q_n corresponding to the particle energy on the estimator.

RESULTS AND DISCUSSION

Figure 1 shows the conversion coefficients for normal incidence, $H_{sl}(d,0°)/\Phi$, as a function of incident neutron energy. $H_{sl}(d,0°)/\Phi$ increases significantly with energy in the range between 10keV and 1MeV due to a rapid augmentation of kerma factor in this energy region. No significant energy dependence of $H_{sl}(d,0°)/\Phi$ is observed in the low energy region (below ~10keV). This is because the contribution of slowing down neutrons to the dose is predominant in this energy region. $H_{sl}(d,0°)/\Phi$ increases with depth in the low energy region, and the values at 10mm depth are roughly two times higher than those at 0.07mm depth. The contribution of secondary photons to $H_{sl}(d,0°)/\Phi$ is also plotted in Figure 1. The secondary photons give 20-30% of dose equivalent in the low energy region, whereas they give quite a small contribution in the high energy region.

A variation of the conversion coefficient at 10mm depth with incident angle, α, is illustrated in Figure 2 as the angular dependence factor, defined as the ratio of $H_{sl}(10,\alpha)/\Phi$ to $H_{sl}(10, 0°)/\Phi$. As is apparent from this figure, $H_{sl}(10,\alpha)/\Phi$ depends significantly on the incident angle, and the angular dependence factors in the low energy region vary slightly due to the same reason in the above.

The calculated values of $H_{sl}(10,\alpha)/\Phi$ were compared with the data of the previous works(2,3). As a whole, the present results agree with the data of other authors within 15%, even though the cross section library and the estimator were different from theirs. In detail, the present values are about 5% less than those of the previous works in the high energy region, and the discrepancies increase up to about 15% with decreasing energy. Major differences in the method between the previous works and ours are cross section library, estimator, and the treatment of kerma factors below 0.025eV. They used the cross section libraries based on ENDF/B-IV, volume-type estimators, and the 1/v-dependent kerma factors below 0.025eV, whereas we used the library based on JENDL 3.1, surface crossing estimators, and the constant factors below 0.025eV though the data source is the same. The influence of each of these differences is now being studied.

The conversion coefficients $H_{sl}(d,\alpha)/\Phi$ using the revised Q_n (4) was calculated for normal incidence. Q_n was reestimated to be smaller than the previous one. Consequently, this reduces the conversion coefficients as seen in Figure 3. A large descent appears at several tens of keV.

Influence given by the change of the phantom size was investigated. A comparison of the values of $H_{sl}(d,0°)/\Phi$ calculated for a 40×40×15cm phantom with those for the 30×30×15cm one shows that the enlargement of the phantom leads to 3-10% growth of the conversion coefficients in the range below 10keV. A further comparison of each component of neutrons and secondary photons demonstrates that secondary photons induced in the phantom, rather than neutrons, have an important contribution to dose for neutrons below about 10keV.

CONCLUSIONS

$H_{sl}(d,\alpha)/\Phi$ for personal dosimeter calibration was calculated using the MCNP-4 code and the cross section library based on JENDL-3.1. The present results of the $H_{sl}(10,\alpha)/\Phi$ agree with data of other authors within 15%, even though the cross section library and the estimator were different from theirs. It is found that the recalculated Q_n reduces $H_{sl}(d,\alpha)/\Phi$ in all energies considered. A study on the influence given by the change of the phantom size makes it clear that secondary photons induced in the phantom, rather than neutrons, have an important contribution to dose for neutrons below about 10keV.

ABSTRACT

Ion-exchange membrane sources were applied to preparation of beta-ray calibration sources simulating filter paper for dust monitors. Concerning the influence of backscattering on counting efficiencies of detectors, the similarity between the filter paper and the prepared sources is discussed. The sources were proved to be more suitable for the realistic calibration of dust monitors.

INTRODUCTION

A calibration source for dust monitors consists of an active layer and a backing material(for example, aluminum or stainless-steel). Usually, the backing is thick enough to prevent the penetration of beta-rays backscattered by structural materials behind the filter paper. The sources can be standardized in surface emission rate[1)] but not in radioactivity. However, the actual filter is relatively thin and penetrable for the beta-rays. When the radioactive aerosols collected on the filter are measured, the backscattering radiation influences the counting efficiency of detectors. Taking account of the backscattering effect, the calibration source requires (a)the similarity in material to the filter paper and (b)the standardization in radioactivity. Taking these matters into consideration, the filter-simulated sources with ion-exchange membrane(hereafter, FSS) were prepared. This paper presents the preparation method of the calibration sources, and the discussions on such characteristics of the sources as self-absorption, release of radioactivity and the effect of backscattering.

EXPERIMENTS

The ion-exchange membrane sources were prepared by soaking ion-exchange membranes into the solution in which radionuclides and their carriers were mixed, washing and drying them.[2)] Three types of membrane sources(about 0.7, 3 and 6 mg/cm^2 in the thickness) were prepared for each radionuclide of ^{60}Co, ^{137}Cs and ^{90}Sr+^{90}Y. The activities of ^{60}Co and ^{137}Cs membrane sources were determined by the manner of relative measurement using a well-type HPGe detector. For the ^{90}Sr+^{90}Y membrane source, its activity was determined with ^{85}Sr as a tracer. The sources consist of protective film(polyester), the ion-exchange membrane source(polyethylene), adhesive(acrylic family) and backing material(polyester). The total thickness of FSS was approximated to that of filter paper (12.7 mg/cm^2). Experiments were made without the protective film and with two types of detectors, a plastic scintillation detector and a GM tube. The counting loss of beta-rays by the protective film(0.28 mg/cm^2) was about 2 % for ^{60}Co and less than 1 % for ^{137}Cs and ^{90}Sr+^{90}Y.

Since the active layer of FSS is about 0.7 to 6 mg/cm^2 thick, beta-rays are self-absorbed in the active layer. For evaluation of the self-absorption, an experiment was made. A thin ion-exchange membrane source(about 0.7 mg/cm^2) and several polyester membranes were layered. The total thickness of the layer was approximated to 12.7 mg/cm^2. The membrane source was inserted into any position of the polyester layer, the total thickness being kept constant. The beta-rays were measured for each position of the membrane source. Then, an absorption curve for each radionuclide was obtained as a function of source position. The correction factor of self-absorption was estimated by integrating the absorption curve in respect of the source position.

The radioactive aerosols are assumed to be collected on the surface of actual filter paper. In

order to compare the FSS with the actual filter paper, the calibration sources of which radioactivity was adhered on the surface of filter paper(hereafter, RAS) were prepared.

RESULTS AND DISCUSSION

Table 1 gives the counting efficiencies of plastic scintillation detector and GM tube measured with the RAS and the FSS. As seen in Table 1, the detectors can be calibrated with the FSS as well as the RAS. However, as for $^{90}Sr+^{90}Y$, the counting efficiencies for the FSS are systematically somewhat smaller than those for the RAS. The correction factors of self-absorption for each radionuclide with the plastic scintillation detector are shown in Fig. 1. The correction of $^{90}Sr+^{90}Y$ FSS is 2 % at most(in the case that the active layer is about 6 mg/cm^2 thick). Hence, the reason for the smaller efficiency is considered to be possible overestimation of the activities of $^{90}Sr+^{90}Y$ FSS.

Measurements with a dust monitor include the backscattered beta-rays by structural materials behind the filter paper. By using the FSS, the influence of backscattering was evaluated for three types of filter paper support. One of them is a stainless-steel mesh plate usually attached to the dust monitors. The others are stainless-steel and aluminum plates of 2 mm in thickness. The counting efficiencies were measured with these different supports and without supports. Although there are some structural materials behind the supports, the influence of backscattering is considered to be small because of sufficient distance between the support and the material. For $^{90}Sr+^{90}Y$, the efficiencies increase to 20 % or more using the stainless-steel plate, and to about 8 % using the typical mesh plate, in comparison to the efficiencies without supports. These results indicate that the influence of backscattering behind the filter paper is not negligible for more realistic calibration of dust monitors.

The counting efficiencies of plastic scintillation detector for the sources with a thick backing are shown in Fig. 2. The thick backing can prevent the penetration of beta-rays backscattered behind itself. The activities of the sources are assumed to be twice the surface emission rate measured by a windowless 2π-proportional counter. In the figure, the efficiencies for the FSS are also shown. The mean beta-ray energies of ^{60}Co and ^{137}Cs referred to the NCRP Report[3], and that of $^{90}Sr+^{90}Y$ was derived from the spectrum by a plastic scintillation spectrometer. The FSS makes the backscattered beta-rays penetrate through itself, and is standardized in radioactivity. The counting efficiency for the FSS includes the influence of backscattering, and the efficiency for actual filter paper as well. The differences in thickness and reference quantity of calibration sources reflect on the calibration of dust monitors.

When an unsealed source is handled in routine calibration works, the release of radioactivity from the source may lead to accidental contamination. Therefore, the RAS is not suitable to the routine calibration works. The ion-exchange membrane source is free from the contamination because the release of radioactivity is extremely small. With the protective film, the FSS becomes much safer against the contamination.

CONCLUSION

The FSS can be used for the calibration of dust monitor in consideration of the influence of backscattering. Although the active layer of FSS is several mg/cm^2 thick, its self-absorption can be easily estimated due to its simple structure. Especially, this source is more suitable for the realistic calibration if the main radionuclides are fixed in nuclear facilities. Moreover, the FSS can be safely handled in the routine calibration because of negligible release of radioactivity. This study confirmed that this type of source was useful for the calibration of dust monitors.

Mitigation of radiation dose through deposition to indoor surfaces

Roed, J[+].; Goddard, A. J. H.[*]; Lange[+], C. and M. A. Byrne[*]

[+]Risø National Laboratory, MIL-114, PO Box 49, 4000 Roskilde, Denmark

Introduction

When an accident occurs that involves releases to the atmosphere of toxic materials the first action of the civil defence authorities is to urge people to go indoors and close the windows and doors. A review of measurements of Indoor/Outdoor concentration of airborne pollutants (e.g. Alzona et al. (1979)) reveals that most substances of outdoor origin have a lower concentration in indoor air, but a more detailed knowledge of the magnitude and mechanism of this reduction is disireable.

Since inhalation dose is directly proportional to air concentration (for a given particle size) the dose reduction factor, DRF, can be defined theoretically as the ratio between the indoor pollutant concentration, C_i, and the outdoor pollutant concentration, C_o, integrated from the start of the cloud passage, t_o, to infinity. Considering the house to be a single box with an air exchange with an infinite outdoor volume a simple differential equation can be derived by equating the change in indoor concentration per unit time with the difference between the production (ingression from the outside) and loss of particles (indoor deposition). This equation can be solved analytically. The solution this equation shows that the time integrated DRF equals the equilibrium ratio for constant outdoor pollutant concentration:

$$DRF = \frac{\int_{t_0}^{\infty} C_i(t)dt}{\int_{t_0}^{\infty} C_o(t)dt} = f\frac{\lambda_r}{\lambda_r + \lambda_d}$$

where f is the fraction of particles in outdoor air penetrating the building envelope, λ_r is the air exchange rate and λ_d is the deposition constant. This is a general result for all shapes of passing clouds, as emphasized by Roed et al. (1991), when it is assumed that λ_r and λ_d are constant. The air exchange rate, λ_r, may change if the weather conditions change, but in all circumstances the value used in modeling will be an average value, which again will give an average value for the dose reduction factor. The deposition constant, λ_d, will vary with the particle size, but for each size class and type of pollutant the expression will be valid. Some authors , e.g. Engelmann (1992), have given a more optimistic expression for the DRF by including a term describing ventilation of the house right after the passage of an rectangular cloud and thus reducing or removing the contribution to dose from the 'tail' after passage, but this factor has been found to be to unrealistic to be included in the model.

Experimental

The indoor deposition is the least well known parameter determining the indoor inhalation dose. Very little information exists on the depostion of particles larger than 0.5 μm in houses. In order to improve our understanding of the mechanisms governing the indoor-outdoor air activity ratio Imperial College and Risø National Laboratory have developed a particle tracer technique, where silica particles are labelled with dysprosium and used as tracers for indoor depostion experiments. The idea is to disperse the particles in a real house and measure the decrease in tracer concentration by taking consecutive air filter samples. During the experiment, the air-exchange rate is measured and the deposition constant, λ_d was then to be found by subtracting the air exchange rate, λ_r, from the decay constant, λ_t. The air-exchange rate was measured by releasing SF_6 gas into the test room and monitoring the decrease in concentration by gas chromatography. The absolute decrease with time of both the tracer gas and the particle concentration is proportional to the concentration and the decay will thus follow an exponential curve if the experimental conditions are constant during the test. Both these decay constants are found by linear regression. For all the four houses studied the deposition velocity, v_d, has been calculated using the geometric surface, S, to volume, V, ratio. That is, no contribution from the surface of furniture, etc. has been included in the surface area of the furnished rooms. Such measurements would be difficult to make in an objective and reproducible way.

Results and discussion

Results and a detailed description of the individual experiments in the four houses have been given by Roed et al. (1991), Byrne (1995) and Lange (1995). Despite the differences between the test conditions in the various houses, the results are in good agreement, with increasing deposition velocity for increasing particle size and degree of furnishing. Table 1 shows the average results for furnished and unfurnished rooms. As tests only

were made with furniture in the room during the Jersie experiment there is actually only 'unfurnished' results from three houses. In all experiments, the deposition velocity was highest under the furnished conditions. In Table 1 the deposition can also be seen to increase with particle size as predicted by deposition theory for supra-micron particles, but the actual deposition velocities exceeds those predicted by the theories that only includes gravitational settling by a factor of 2 to 5. When the results were compared with the measurements of indoor deposition presented in Roed & Cannell (1987): Table 2 good agreement was observed. For Be-7 which is associated with particles in the size range of 0.5 to 1.0 μm, Lange (1994), an average deposition velocity of ~~0.71 x 10^{-4} ms^{-1}s was found. The indium particles had a AMAD of 0.5 to 0.7 μm, which is close to that of Be-~~ 7, and the deposition velocity has been found to be 0.61×10^{-4} ms^{-1} for unfurnished rooms and 0.82×10^{-4} ms^{-1} for a furnished room on average. Roed and Cannell found a v_d of 3.1 to 3.9×10^{-4} ms^{-1} for Ce-144. This corresponds to the v_d of 4 or 5.5 μm particles in Table 1 and this would be reasonable size for cerium as it belongs to refractory group of release products as described in Rulik et al. (1987).

Size [μm]	GSD [ ]	Avg. v_d Unfurnished [$10^{-4}ms^{-1}$]	Avg. v_d Furnished [$10^{-4}ms^{-1}$]
0.5	1.60	0.61±0.08(2)	0.82±0.08(6)
2	1.48	1.13±0.16(5)	1.36±0.50(5)
3	1.20	1.33±0.37(2)	2.25(1)
4	1.07	2.42±0.17(5)	3.11±0.6(5)
5.5	1.18	3.03±0.04(2)	3.24(1)

Table 1 Measurements of indoor Deposition Velocities in four houses. The first two columns show size and geometric standard deviation, GSD, of the test aerosol. The last two columns gives the average deposition to all surfaces measured in three different test houses. The numbers in the parentheses give the number of tests for each condition.

A data set was selected where the correlation coefficients were better than 0.95 for the tracer aerosol decay curves. Twelve results from unfurnished houses and fifteen results from furnished houses were chosen. Experiments where small mixing fans were operated during the test have been included in these data sets. A power regression and a linear regression have been made for the data, expressing the deposition velocity as a function of the particle size. Average deposition velocity was chosen rather than the deposition constant in order to take the different surface to volume ratios of the test rooms into account. The correlation coefficient is given in the parentheses:

$$v_d = 1.23(d_p)^{0.65} \; (r = 0.96)$$

where v_d is the average deposition velocity to all surfaces and d_p is the particle diameter. In both the unfurnished and the furnished rooms the power regression had the best correlation coefficient, i.e. 0.96 compared to 0.90 and 0.95. They found that the deposition velocity increased linearly with the particle size in the particle size range investigated. Since the formulae presented in equations (2.3) to (2.5) are purely empirical, it must be emphasised that they are not valid outside the particle size range investigated, i.e. 0.5 to 5.5 μm.

Present models of the effect of sheltering during releases of radioactive materials to the atmosphere consist of a single factor giving a common dose reduction factor, DRF, for all nuclides. A value of 0.5 is currently used in probabilistic accident consequence assessment codes, Brown (1989) (except noble gases for which DRF = 1.0, i.e. no reduction in inhalation due to indoor residence). In order to provide a more realistic model that takes into account properties of the released material the empirical formula for indoor deposition is used together with equation (2.2) to calculate dose reduction factors, DRFs. equation (2.6) shows the derived formula:

$$DRF = \frac{\lambda_r(U_{wind}, \Delta T)}{S/V * 1.23(d_p)^{0.65} + \lambda_r(U_{wind}, \Delta T)}$$

where the deposition constant, λ_d, is found by multiplying the average deposition velocity with an average S/V ratio for the buildings in question. In the review by Engelmann (1992) surface to volume ratios were summarised for a number of different buildings: 1.74 m^{-1} for apartment buildings/houses, 1.3 m^{-1} for office buildings and 0.66 m^{-1} for industrial buildings. These values do not include contributions from furniture and equipment in the room. The average S/V of the test rooms was 1.69 m^{-1} and a value of 1.7 m^{-1} has been used in the model calculations shown in Figure 1.

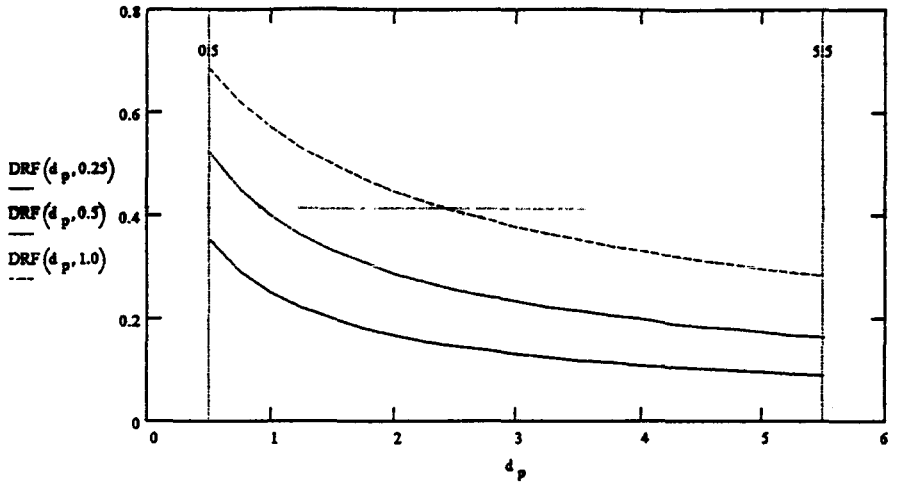

Figure 1 DRF's as function of particle size and air-exchange rate. The number after 'd_p' in the left margin of the figure is the air-exchange rate for that line style. A surface to volume ratio of 1.7 m^{-1} have been used corresponding to a medium sized living room. The vertical lines indicate the valid particle size range, i.e. 0.5 to 5.5 mm.

The air-exchange rate can be expressed as a function of the weather conditions, outdoor temperature and wind speed. The temperature difference over the building envelope can be expressed as the difference between the outdoor temperature and the indoor temperature, typically about 21 °C. The air-exchange rate was determined as a function of these parameters for a typical Danish houses by Kvisgaard et al. (1988). Engelmann (1992) quoted several references and used an equation similar to equation (2.3) for calculation of air-exchange rates for houses in the USA from data on wind speeds and temperature difference. In the Figure the DRF is plotted as a function of particle size for three different values of the air-exchange rate. An assumed surface to volume ratio of 1.7 m^{-1} was used in these calculations. It can be seen that the DRF decreases significantly with particle size. The three values for the air-exchange rate used (0.25, 0.5 and 1.0 h^{-1}) represents a low, medium and high value and the DRF varies between 0.1 and 0.7 or factor of seven depending on the particle size for these air-exchange rates. These relatively large variations in DRF clearly justifies a more detailed model for the DRF.

CAIRS-ALGADE PERSONAL ALPHA DOSIMETER

B. Bjorndal[1], G. Cubbon[1], R. Moridi[1] and C. Bertrand[2]

[1]Canadian Institute for Radiation Safety (CAIRS)
Toronto and Saskatoon, Canada
[2]ALGADE, Bessines-sur-Gartempe, France

INTRODUCTION

The CAIRS-ALGADE Personal Alpha Dosimeter (PAD) is a portable, lightweight personal monitoring system designed to measure individual exposures to radon and thoron progeny and Long-Lived Radioactive Dust (LLRD).

The CAIRS-ALGADE Personal Alpha Dosimeter consists of a CAIRS track etch detectors (dosimeter head) mounted in an ALGADE individual air sampling system designed to be worn on the belt of the individual to be monitored.

The PAD is worn by the individual for a period of one month. At the end of the month, the CAIRS dosimeter head is removed from the PAD and returned to the CAIRS National Laboratories in Saskatoon, Saskatchewan to be processed. Exposure results are supplied to the respective clients on a monthly basis. We will briefly discuss the CAIRS-ALGADE Personal Alpha Dosimeter, its operation and its capabilities for measuring radon and thoron progeny and LLRD.

ALGADE INDIVIDUAL SAMPLER AND CHARGER

The ALGADE individual sampler is an air pumping system designed to draw air through the CAIRS track etch detector (dosimeter head). A battery operated, centrifuge pump is enclosed in a durable polycarbonate box designed to be worn on the belt of the individual who is to be monitored.

The individual sampler is powered by a small rechargeable battery which, when fully charged, will operate properly for periods in excess of 10 hours. The sampler requires charging times of approximately 14 hours. The ALGADE individual sampler is designed to generate a nominal air flow rate at 4 l/h.

The following is a list of the technical specifications of the ALGADE Individual Sampler.

- A moulded polycarbonate box which houses the system;
- A centrifuge pump driven by a dc motor;
- An electronic module embodying:
  - a nickel-cadmium rechargeable battery, 1.2 V; 1.2 Ah;
  - a constant current charger;
  - a switch controlling the motor operation;
  - a light emitting diode illuminated when the battery is charging;
  - a magnet controlling the start-up of the charger;
- Operating time: in excess of 10 hours;
- Battery charging time: 14 hours;

  Dimensions: 94 x 79 x 63 cm;
- Weight: 230 g (excluding measuring head);
- Relative humidity: 0 to 100%
- Operating temperature: -10°C to 45 °C.

The ALGADE individual samplers are recharged using an ALGADE charging unit. The individual charging unit consists of a polycarbonate box forming a cell into which the individual sampler is placed. The charger includes an electronic card which generates a high frequency alternating current which feeds a coil. This coil supplies by induction the energy necessary to recharge the battery in the individual sampler. It also includes a magnetically operated switch which gates the power

supply to the electronic card when the sampler is placed in the cell and controls an hour-meter which makes it possible to measure the operating time of the sampler.

CAIRS DOSIMETER HEAD

The CAIRS Dosimeter Head is designed and manufactured in Canada. The dosimeter head is an adaptation of an integrated measuring head originally developed by the Atomic Energy Commission of France (CEA). The dosimeter head is designed to detect the presence of radon and thoron progeny and Long-Lived Radioactive Dust (LLRD).

The CAIRS measuring head is in essence, an alpha particle spectrometer capable of detecting separately, without electronics, the 5.99 MeV and the 7.69 MeV alpha particles from radon progeny (Po-218 (RaA) and Po-214 (RaC')) and the 8.78 MeV alpha particle from thoron progeny (Po-212 (ThC')). The alpha particles are detected by the damage they create on a cellulose nitrate film.

Spectroscopic separation of the alpha particles is achieved by using a three-channel collima-tor. Each channel contains an energy-absorbing piece of mylar whose thickness is chosen specifically for the alpha particle it is designed to identify. The design is such that the three alpha particles of interest hit the cellulose nitrate film when their dE/dx (energy loss) is at a maximum (the "Bragg peak" in the dE/dx versus E curve). They produce easily-identifiable holes in the film after etching.

The following is a list of the technical characteristics of the CAIRS dosimeter head:

- High density polyethylene end cap, barrel, collimator and barrel holder;
- Filter used: 25 mm diameter, 1.2 μm pore size;
- Film used: Kodak cellulose nitrate LR-115 Type II film;
- Absorbers used: Mylar absorbers;
- Diameter: 37 mm;
- Height: 43 mm;
- Weight: 21 g.

PAD OPERATION

In the operation of the CAIRS-ALGADE Personal Alpha Dosimeter, the ALGADE sampler draws air through the CAIRS dosimeter head at a nominal air flow rate of 4 l/h. Any attached radon and thoron progeny and LLRD in the air will become trapped on the filter inside the measuring head.

As the radon and thoron progeny and LLRD decay, alpha radiation is emitted. Some of the alpha radiation given off from the filter will travel up the three-channel collimator and pass through the absorbers attached to the collimator. Any alpha particles making it through the absorbers will strike the detector film located on top of the collimator. The detector film (LR-115 Type II) used in the dosimeter head is sensitive to alpha radiation, provided that the alpha particles have an energy of approximately 2.7 MeV.

To obtain the desired energy discrimination between the different alpha particles, each collimator is fitted with a mylar absorber of a specific thickness. The different thicknesses have been chosen so that the alpha particles of interest emerge from the mylar absorber with an approximate energy of 2.7 MeV. Other alpha particles will either be stopped by the absorber or pass through with an energy greater than the optimal 2.7 MeV required to leave clear uniform tracks on the film. All of the energy discriminated alpha particles emitted by the radon and thoron progeny are registered as tiny lines of damaged molecules on the film.

The tracks on the film are then enlarged by etching the films for 90 minutes in 2.5 normal sodium hydroxide (NaOH) solution at a temperature of 60 °C. This produces tiny holes or tracks in the opaque film which are approximately 5 μm in diameter. The enlarged tracks can then be counted using a microscope by placing a light source below the detector film. The LLRD deposited on the dosimeter head filter is counted together with a paired blank separately using a scintillation detector and an automatic sample changer system.

LONG-LIVED RADIOACTIVE DUST DETECTION

The CAIRS-ALGADE Personal Alpha Dosimeter also measures the presence of Long-Lived Radioactive Dust (LLRD). Any traces of LLRD present on the filter inside the CAIRS dosimeter head will remain there for extended periods and can be detected using conventional alpha radiation detectors.

Following a minimum waiting period to allow all radon and thoron December 8, 1995 progeny to decay, the gross alpha activity on the dosimeter head filter is measured using a Zinc Sulphide (ZnS) scintillation detector connected to a Ludlum Scalar/Ratemeter and a Nuclear Chicago sample changer. Each measurement of gross alpha activity on the dosimeter head filters is accompanied by a paired blank measurement to determine the corresponding number of background counts measured by the ZnS detector.

CAIRS PERSONAL ALPHA DOSIMETRY PROGRAM

The CAIRS-ALGADE Personal Alpha Dosimeter is worn daily by the individuals to be monitored. At the end of each working day, the PAD is placed into a charging unit overnight to recharge the ALGADE sampler battery. Radiation safety staff at the client work site are responsible for taking some of the necessary measurements required to determine the average air flow rates through the PADs.

At the end of each month, the CAIRS exposed dosimeter heads are removed from the ALGADE individual samplers and replaced with new dosimeter heads. The exposed dosimeter heads, together with PAD assignment and air flow rate information, are then returned to the CAIRS National Laboratories for processing. Monthly dosimetry reports are generated by CAIRS and distributed to the client.

CAIRS DOSIMETER HEAD TESTS

The CAIRS Dosimeter Heads are regularly tested in the CAIRS Calibration Chamber to ensure proper performance and accuracy. The tests involved the exposure of several dosimeter heads to radon progeny in the CAIRS Calibration Chamber. The dosimeter head results were compared to the CAIRS Reference Method (alphaNuclear alphaSMART 771 System) and manual Kusnetz Method samples.

The average percent difference between the CAIRS dosimeter head results in the CAIRS Reference Method results was 9%. The average percent difference between the CAIRS dosimeter head results and the Kusmetz Method results was 6%.

CAIRS also regularly participates in radon proficiency programs sponsored by the U.S. Environmental Protection Agency and the U.S. Department of Energy Environmental Measurements Laboratory.

BIOLOGICAL DOSIMETRY APPLIED TO TREATMENT WITH ^{131}RADIO-IODINE IN THYROID CANCERS

C. Parmentier - M. Schlumberger - R. M'kacher - N. Beron Gaillard - A. Gaussen - J.D. Légal.

Laboratoire de Radioprotection - Institut Gustave Roussy - F 94805 VILLEJUIF CEDEX

This study had 2 objectives :
Firstly to compare the number of unstable chromosomal anomalies (dicentrics, rings and fragments) obtained by the method of conventional cytogenetics with the number of translocations revealed by in situ hybridization (FISH) and secondly to estimate the mean whole body dose after treatment with 3.7 GBq (100 mCi) of ^{131}I.

MATERIALS AND METHODS

Dose effect curves in vitro were generated by the method of counting unstable anomalies and by the FISH method, using peripheral lymphocytes of healthy donors. Both curves were fitted by the linear-quadratic model. Conventional Cytogenetics was carried out on slides containing metaphase spreads stained by Giemsa. Only complete metaphases (46 centromeres) were scored for dicentrics, rings and fragments under a light microscope (1).

Hybridization in situ was carried out using a modified procedure of Pinkel et al (2). The technique was applied to chromosome 4 by means of a specific probe. Chromosome 4 was chosen because of its large size which facilitates the scoring of translocations. The FISH slides were read under a fluorescent microscope using blue light emission and filters for green and red fluorescence.
The pair of chromosome 4 had been labelled by the green fluorescence of Fluorescein isothiocyanate (FITC) and the other chromosomes of the genome counterstained with propidium iodide.
Scoring of dicentrics and translocations was done on a patient blood sample 24 hours before and then 4 days after the administration of ^{131}I.

The number of dicentrics was directly compared to the standard curve.
Since chromosome 4 represents 6,23 % of the total genome, the number of translocations obtained by FISH was extended to cover the whole genome by the following formula (3).

$$F_h = 2\, f_s\, (1 - f_s)\, F_b$$

were F_h is the translocation fraction found by hybridization, f_s the conterstained fraction of the genome and F_b the transloction fraction observed by G-banding which is set equal to 1.

PATIENTS

Patients had been treated with 3.7 GBq (100 mCi) of ^{131}I. The mean total body dose was 0.54 Gy (95 % CI : 0.45 - 0.61 Gy) by chromosome 4 painting. A close relationship was found between total body retention of ^{131}I at day 4 after ^{131}I treatment and the estimated dose by conventional cytogenetics and chromosome 4 painting. In contrast, no relationship was found between the uptake of ^{131}I in thyroid remnants and distant metastases and the dose estimated by biological dosimetry.

RESULTS

The ratio of translocations to dicentrics induced by ionising radiation is supposed to be 1, because a dicentric chromosome as well as a chromosomal translocation is the result of 2 successive events. However, we found that induced translocations were 3-8.4 times more frequent than dicentrics for each dose of irradiation ; this agrees with earlier findings (3).
When comparing the number of chromosomal aberrations found by FISH or conventional cytogenetics with the dose effect curve obtained by in vitro, exposure of normal peripheral lymphocytes, the total body dose was

estimated to be significantly higher than the estimation based on MIRD (4). Some aberrations (dicentrics and translocations) were found before ^{131}I treatment and no known previous exposure to irradiation may explain this.

DISCUSSION

The estimated mean total body dose is 2 to 4 times higher than that based on MIRD calculations (0.13 Gy) (4). In fact, MIRD calculations were derived from individuals with normal thyroid function and normal metabolic activity. Thyroid cancer patients are hypothyroid at the time of ^{131}I administration. The hypothyroid status decreases the renal clearance of radioiodine and thus increases the whole body dose which can explain the discrepancy between the MIRD estimation and the values found by biological dosimetry.

RADIATION INDUCED CHROMOSOME ABERRATIONS AND INTERPHASE DNA GEOMETRY

N. Nasazzi, D. Otero* and M. Di Giorgio

Ente Nacional Regulador Nuclear
* Comisión Nacional de Energía Atómica
ARGENTINA

SUMMARY

Ionizing radiation induces DNA double strand breaks (DSBs) and their interaction and illegitimate recombination produces chromosome aberrations. Stable chromosome aberrations comprise inter-chromosomal events (translocations) and intra-chromosomal events (inversions).

Assuming DSBs induction and interaction is completely random and neglecting proximity effects, the expected ratio of translocations to inversions is F=86, based on chromosome arm lengths.

We analyzed the number of translocations and inversions using G-banding, in 16 lymphocyte cultures from blood samples acutely irradiated with γ rays (dose range: 0.5Gy - 3Gy). Our results give F=13.5, significantly smaller than F=86. Literature data show similar small F values but strongly spread.

The excess of inversions could be explained by a "proximity effect", it means that more proximate DSBs have an extra probability of interaction. Therefore, it is possible to postulate a special chromosome arrangement during irradiation and the subsequent interval.

We propose a model where individual chromosomes show spherical confinement with some degree of overlapping and DSBs induction proportional to cross section. We assume a DSBs interaction probability function with cut-off length = 1μm. According to our results the confinement volume is $\approx$ 6.4% of the nuclear volume. Nevertheless, we propose that large spread in F data could be due to temporal variation in overlapping and spatial chromosome confinement.

INTRODUCTION

Ionizing radiation damages DNA and produces chromosome aberrations, generally recognized in metaphase using conventional staining, G banding or fluorescence in situ hibridization (Fish).(1-3)

The primary mechanism for the production of exchange-type chromosomal aberrations after irradiation of resting lymphocytes is the pairwise interaction of two double-strand breaks (DSBs) an their illegitimate recombination.(4)

The simplest aberrations to score in metaphase spreads are dicentrics, which are interchromosomal events, and centric rings, which are intrachromosomal events. These are unstable aberrations and they do not survive after cell division. The stable counterparts are reciprocal translocations and pericentric inversions, respectively, and they are used particularly in retrospective dosimetry due to the fact that they remain long after overexposure to ionizing radiation. The correspondence between unstable and stable aberration production has been generally confirmed.(5)

The observed ratio of interchromosomal interactions (dicentrics or reciprocal translocations) to intrachromosomal events (centric rings or pericentric inversions) indicates that it is smaller than predicted assuming complete randomness, it is there are more centric rings or pericentric inversions than expected.

The observed excess of intrachromosomal events may be due to a proximity effect (6): two DSBs induced in a short distance have an extra probability of pairwise interaction and recombination. Furthermore, there is evidence of chromosome localization during interphase (7).

Assuming that the excess of intrachromosomal events is due to the above mentioned facts, we propose a lymphocyte DNA spatial arrangement during interphase, where individual chromosomes are confined to spherical domains which interact among them under several constrains and we estimated, according to our experimental data, the size of the chromosome domain.

MATERIAL AND METHODS

The number of radiation induced translocations and pericentric inversions were obtained from 16 lymphocyte cultures of both sex donors, which are part of our calibration curve data set for low LET radiation using stable chromosome aberrations. Blood samples were acutely irradiated with γ rays from a Co^{60} source (Picker C4M60) with doses ranging from 0.5Gy to 3Gy (mean dose-rate: 0.5Gy/min). Heparinized whole blood from each donor was irradiated and cultured using micromethod for 48 h in 10 ml of RPMI 1640 medium containing 20% fetal calf serum and PHA (0.15 mg/ml). Colchicine was added to the cultures after 47 h of incubation at 37°C and air dried metaphase spreads were prepared.

Translocations and inversions were identified by G banding, according to Seabright technique, modified.(8) All metaphases were photographed and analyzed using enlarged prints. We observed 325 reciprocal translocations and 24 pericentric inversions in 1040 banded metaphases. The ratio of interchromosomal to intrachromosomal events is F = 13.5

MODEL

Let F represent the ratio of translocations to pericentric inversions. Assuming that DSBs are produced at random on a chromosome arm, proportional to its length in base pairs following a Poisson distribution and assuming, in addition, that pairwise DSBs interactions and recombinations are completely random and neglecting proximity effects, it is possible to estimate a theoretical value of F. (9-11)

$$F = \frac{\sum_{i=1}^{46}(L_i + S_i)(T - S_i - L_i)}{2\sum_{i=1}^{46} L_i S_i} = 86$$

where: L_i = length in megabases of *i*th chromosome long arm.

S_i = length in megabases of *i*th chromosome short arm.

T_i = length in megabases of average diploid set weighted for both sexes.

representing the numerator the average number of reciprocal translocations and the denominator the average number of pericentric inversions.

The convention for translocation counting assumes complete reciprocity. It is important to point out that when it is said that the theoretical F value neglects proximity effects, it means that the individual chromosomes are considered freely distributed in the nuclear volume filling fractions of this volume just according to their lengths.

The obtained value F = 86 is significantly higher than our experimental result F = 13.5 an those obtained by other authors considering unstable and stable chromosome aberrations and using radiation of different linear energy transference (12).

A plausible explanation for the observed small F values is that DSBs produced on the two arms of the same chromosome are in fact and on average more proximal. It implies additional chromosome confinement in domains during interphase, when DSBs are induced and recombined. The proposed spherical domain volumes are smaller than the nuclear volume. We accept several experimental an theoretical considerations (13) which suggest that the probability g(r) that two induced DSBs separated by a distance *r* will interact and produce an exchange event is the cutoff form:

g = constant if $r \leq h$ and g = 0 if $r > h$

Here h is a maximum interaction distance and its value is ≈ 1μm (14). It is interesting to consider that even if two DSBs are produced at a distance more than h apart and are possible to move to get in contact, they may be restituted before interacting and, anyway, it is possible to consider $g \approx 0$ for $r \geq h$.

Then, assuming chromosome spherical domains, two DSBs produced in both arms of the same chromosome have an extra chance of interaction than DSBs produced in different chromosomes because they will more probably lie within 1μm each other.

Now, we propose to analyze DSBs interactions assuming a spherical domain maximum packing model with 12 nearest neighbors in contact, corrected by nuclear surface effect. Moreover, we postulate that the DSBs production is proportional to the geometric cross section , defined as (chromosome length)$^{2/3}$

Based on the above described assumptions the theoretical relationship between reciprocal translocations and pericentric inversions results:

$$F = \frac{\sum_{i=1}^{46} (L_i + S_i)^{2/3} \alpha^{2/3} \beta \delta}{2 \sum_{i=1}^{46} (L_i + S_i)^{4/3} \frac{L_i S_i}{(L_i + S_i)^2}}$$

where: α = chromosome average length in megabases (140.3)

β = average number of nearest neighbor corrected by surface effect (12 * 0.58)

δ = correction factor due to maximum interaction distance (1μm)

Assuming a cell nucleus diameter d = 8μm and a maximum interaction distance = 1μm we calculated that spherical chromosome domains in contact have approximately an average diameter = 2μm. Under these conditions results F = 10.7.

If we consider higher domain diameter, they get some degree of overlapping and consequently the probability of translocations and F values increase. The total overlapping condition corresponds to a domain diameter equal to the nuclear diameter = 8μm and results F = 86.

According to our experimental results, F = 13.5 indicates that domains overlap giving a domain volume = 6.4% of the nuclear volume, with a diameter $\approx$ 3.2μm.

Literature data show strongly spread F values, even considering experiments using the same radiation quality. The present model allows to represent such dispersion just varying the domain diameter but keeping fixed the maximum interaction distance (δ). We proposed that in vivo chromosome domain dimension could vary temporarily during interphase, offering different scenarios to ionizing radiation.

ABSTRACT

Investigations were made to correlate biological and physical parameters in order to develope a biologically calibrated dosemeter system. Irradations of cell cultures and TLDs were performed. For this purpose a heatable irradition chamber was developed wherein the irradiation of TLDs together with cell cultures is possible. The heating (37°C) is necessary for the cell cultures during long time irradiations.
For measurements of the TL-response in correlation with LET-dependent biological effects the peak height ratio method developed for determination of the average LET in mixed fields was used. The genotoxic endpoints investigated are micronuclei, sister chromatid exchange, dicentric chromosomes and single strand breaks. These parameters will be correlated with the physical parameter of the peak height ratio. Irradiations were performed in Co-60- and thermal neutron radiation fields.

INTRODUCTION

One of the most important problems in radiation protection concerns determination of the biological effectiveness of ionising radiation. The present radiation protection model is based on the correlation of the physical parameter LET and the Q-factor which correlates with the biological effectiveness. From the physical point of view the absorbed dose as well as the LET and therefore the equivalent dose can be obtained with high accuarcy (1). On the other hand a lot of biological parameters as individual sensitivity of cells of different propands or stress cannot be excluded if the damage caused by ionising radiation is evaluated. To yield more detailed information of radiation action in tissue interest in measurements of genotoxic effects in cells has increased in the last decade. Several methods have been introduced for biological dosimetry (2, 3). For radiation protection purpose a biological calibrated dosemeter system would be of particular interest because of improved information of radiation action. The developement of such a dosemeter system is based on thermoluminescent dosimetry. Combined irradiation of cell cultures and TLDs performed in different radiation fields allows the correlation of different biological and physical parameters. Using this calibration, measurements with TLDs also in mixed radiation fields will allow predictions of genotoxic damage in tissue.

IRRADIATION CHAMBER

In order to perform these combined irradiations of cell cultures and TLDs several requirements have to be met. Since cell cultures need a constant temperature of 37°C for optimal growth a heatable waterfilled irradiation chamber was developed (fig. 1). It consists of a zylindrical waterfilled box containing a heating wire, a thermocouple and a slide-in-unit for the cell-cultures. The thermocouple is positioned in the middle of the box, the heating wire as far as possible from the cells to reduce inhomogenity of the radiation field through scattering. The TLDs are attached at the backside of the cell culture bottle. An external controller allows a temperature regulation with an accuracy of ± 1°C.

DETERMINATION OF PHYSICAL PARAMETERS

Measurements of the absorbed dose and the LET are performed using LiF:Mg,Ti TLDs. Analysing the peak 5 maximum the absorbed dose can be obtained with an accuracy of about 5%. For further analysis of the TLD glowcurves the High Temperature Ratio (HTR)-Method is used (1). The HTR correlates with the distribution of the energy deposition. For evaluation of the LET the HTR of the glowcurve is compared with the HTR of a Co-60 irradiation normalized on peak 5. Using a LET-calibration of the high temperature ratio the average LET of unknown mixed radiation fields and the quality factor can be determined. Figure 2 shows the LET-dependence of the HTR used for the LET-calibration.
Irradiations with a Co-60 source and with thermal neutrons were performed. Since the thermal neutron component is superposed by a gamma component the pair method (4) is used to seperate the gamma and the neutron fraction of the mixed field. For this purpose TLD-600 and TLD-700 are irradiated.

BIOLOGICAL PARAMTERS USED FOR INVESTIGATIONS

Different genotoxic endpoints show individual sensitivities against irradiation with ionising radiation. Besides micronuclei (MN) and dicentric chromosoms (DIC) which are rather sensitive for ionising irradiation, sister chormatid exchange (SCE) and single strand breaks (SSB) have been investigated. Tests have confirmed that

SCE are not sensitive for Co-60 irradiation (5). Analysing the SSB also no significant increase was determined after irradiation with Co-60. Therefore only micronuclei and dicentric chromosomes were used for gentoxic investigations. The measurements were performed with diploid human fibroblasts and the chinese hamster cell line V79.

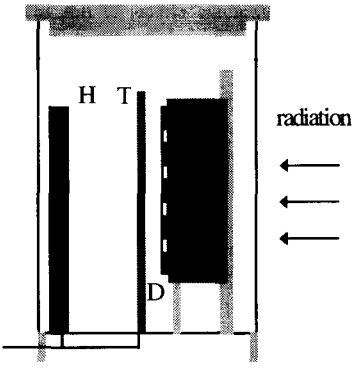

Figure 1: Scheme of the irradiation chamber for cells and TLDs; H ... heating wire, T ... thermocouple, D ... dosemeters, C... cell culture

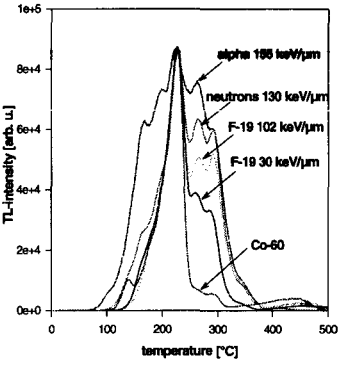

figure 2: TL-glowcurves showing the LET dependent high temperature region, glowcurves are normalized on peak 5 maximum.

RESULTS

Co-60 irradiations were performed with an irradiation source of the University Clinic of Radiation Therapy (11. 04. 86: 9821 Ci). A dose characteristic was measured in order to obtain the lower detection limit and the dose dependence of the genotoxic effects micronuclei and dicentric chromosomes. Table 1 gives the determined micronuclei induction and dicentric chromosomes and the high temperature ratios after Co-60 irradiations of fibroblasts. An increase of both gentoxic endpoints was obtained. Figure 3 shows the dose dependence of micronuclei for both irradiation series. It can be seen that the lower detection limit for micronuclei is about 0.5 Gy. Furthermore an increased MN-rate at 100 mGy compared with 200 and 400 mGy was determined for one irradiation series. The more detailed investigation of these results, especially of the dicentric chromosoms of series 2, is still in progress. The dose characteristic of fibroblasts will be compared with results obtained with V79.

Although the LET of Co-60 is 1 after ICRP 60 (6) it can be seen that the HTR increases with higher Co-60 doses. Figure 4 shows the dependence of the HTR on the absorbed dose. This is due to the supralinearity of the dose characteristic of LiF. Each peak of the glowcurve shows a different supralinear increase (7). Comparing peak 5 and the high temperature peaks 6 and 7 the ratio varies therfore not only in dependence on the LET but also with absorbed dose. Furthermore comparing figure 3 and 4 it can be seen that the dependence of the gentoxic parameter and the HTR on the dose is rather similar. This situation cannot be explained by the model of LET but efforts are made to describe this situation on the basis of microdosimetry.

absorbed dose [mGy]	MN/500	DIC	HTR	absorbed dose [mGy]	MN/500	HTR
0	2.5	1	-	0	7.1	-
94 ± 4	4.7	1	1.26 ± 0.06	87 ± 5	7.9	1.30 ± 0.03
196 ± 2	2.2	0	1.40 ± 0.06	172 ± 11	9.4	1.52 ± 0.09
381 ± 8	2.7	2	1.42 ± 0.13	349 ± 14	11.6	1.53 ± 0.16
611 ± 3	6.4	2	1.78 ± 0.24	550 ± 5	31.7	1.86 ± 0.21
819 ± 51	7.8	1	1.75 ± 0.07	696 ± 29	15.7	1.79 ± 0.08
970 ± 20	6.4	3.7	1.77 ± 0.17	935 ± 34	25.0	1.80 ± 0.13
2008 ± 187	8.7	7.9	2.36 ± 0.16	1874 ± 209	28.7	2.43 ± 0.07

table 1: Results of the dose response of micronuclei and dicentric chromosomes and the HTR after Co-60 irradiation. Evaluation of DIC for series 2 was not finished. Values given for absorbed dose as well as the HTR were determined with TLD-700. For each dose measurement three dosemeters were used.

Irradiations with thermal neutrons were performed at the TRIGA Mark II reactor of the Atomic Institute of the Austrian Universities. The thermal neutron flux is $1.4 \cdot 10^6$ n/cm²s, the gamma doserate is about 60 mGy/h. An increase of the micronuclei induction rate for an irradiation with about 50 mSv neutron dose and 500 mGy gamma was obtained with large uncertainty. Detailed investigations on the genotoxic effects of this mixed radiation field are under progress.

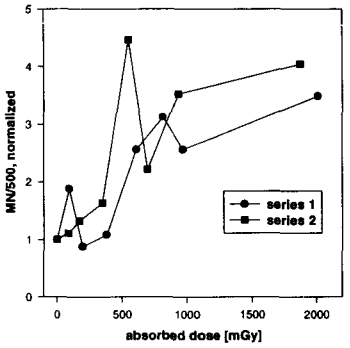

figure 3: Dependence of the MN induction with absorbed dose after Co-60 irradiation. The values are normalized on the controlling group (0 Gy). Lines are only to guide the eye.

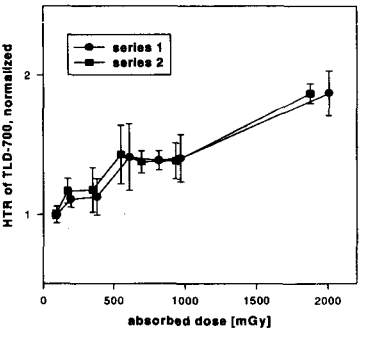

figure 4: Dependence of the HTR measured with TLD-700 after Co-60 irradiation. Results are normalized on the absorbed dose of 100 mGy. Lines are only to guide the eye.

CONCLUSION

For a biological calibration of a TLD-system combined irradiations of TLDs and cell cultures have to be performed using radiation sources with different biological effectiveness. For this purpose an irradiation chamber was developed which meets the proposed requirements. The dependence of the biological and physical parameters on the absorbed dose of a Co-60 irradiation was measured. An increase of the gentoxic parameters micronuclei and dicentric chromosoms as well as an increased HTR was obtained. Comparing the increase of the biological and physical parameters it can be seen that the increase with dose is rather similar. These effects cannot be explained using radiation protection models as LET. Therefore microdosimetric investigations are made to explain these results.

Since the gentoxic investigations show a great uncertainty the results have to be considered. Furthermore the increased MN-rate at 100 mGy for one of the irradiations will be studied in more detail. The irradiation of fibroblasts and V79 with a mixed thermal neutron - gamma radiation field showed an increase of the micronuclei induction rate with a large uncertainty which has also to be considered. Furthermore irradiations with protons of different energy are planned.

ACKNOWLEDGEMENT

We thank Doz. Binder and Dr. Schmidt of the University Clinic of Radiation Therapy, AKH, for their support concerning the Co-60 irradiations.

PERSISTENCE OF UNSTABLE CHROMOSOME ABERRATIONS IN MEDICAL STAFF OCCUPATIONALLY EXPOSED TO IONISING RADIATION

Vilena Kašuba, Šentija Karmela, Rozgaj Ružica

Laboratory for Mutagenesis, Institute for medical Research and Occupational Health, Ivan Meštrović sq. 16, 10020 ZAGREB, Croatia

INTRODUCTION

Chromosome aberrations in cultured human lymphocytes may serve as biological indicators of occupational radiation exposure. From earlier investigation during the history of radiation protection it is well known that the frequency of dicentrics, rings and acentric fragments remained stable for some time after irradiation (2). *In vivo* analyses of chromosome aberrations in peripheral blood lymphocytes of persons occupationally exposed to ionising radiation have shown various aberration frequencies. With this study we want to highlight the persistence of chromosome aberrations (CA) expressed as chromosome breakage in human peripheral blood lymphocytes in medical staff occupationally exposed to ionising radiation.

MATERIAL AND METHODS

The group of 46 subjects, all medical staff occupationally exposed to ionising radiation was divided into five groups. Analyses for chromosomal aberrations were repeated after 3-4 months (8 subjects), 6-7 months (12 subjects), 8-9 months (6 subjects), 11-12 months (10 subjects) and after 24 months or less (10 subjects). Lymphocytes from whole blood culture were examined for the presence of chromosome aberrations. Whole blood cultures were obtained according to routine protocol using F-10 culture medium (Gibco) containing 20 % foetal calf serum, phytohaemagglutinin and antibiotics. The cultures were incubated at 37^0 C for 48 hours. Colchicine was added during the final three hours of cultivation. Cells were harvested by centrifugation after three hours reincubation, then swelled in 0.075 M Kcl and fixed in 3:1, methanol-acetic acid fixative. Slides were stained by Giemsa method for chromosome aberrations.

RESULTS AND DISCUSSION

The examinees were divided in five groups (Tables 1-5). In the first group, in 25% of examinees obtained after 3-4 months remained unchanged, in 37.5% a decrease, and in 7.5% a increase of unstable aberrations were observed. In the second group, in 25% of examinees an increase and a decrease were observed and in 50% of examinees the finding remained unchanged. In 66.7% of subjects who were analysed 8-9 months after exposure a decrease of unstable chromosome aberrations was observed. In a fourth group, in 50% of examinees a decrease was observed, whereas in 40% the finding remained unchanged. In 60% of subjects investigated after 24 months or less (the fifth group) the finding remained unchanged. Regardless of the results, all examined subjects, except five (*), continued to work. As indicated by personnel monitor film badge, two subjects received the exposure dose that exceeded currently recommanded dose limits (**). The results point out the importance of chromosome aberration analyses for the detection of radiation induced damage, as well as the significance of implementation of protective measures. The individual differences in radiosensitivity as well as the frequency of cytogenetic aberrations depend on physiological conditions of each subject and on variability in DNA repair and misrepair processes (3). As time dependent changes in dicentrics may be subject to individual variations, it may be difficult to extrapolate from one case to another (1).The present results do not allow definite conclusions on the effects of ionising radiation during the occupational exposure, but are enough intriguing to motivate further investigations.

In some alpine regions of Austria the surface deposition of the fallout following the nuclear accident in Chernobyal reached levels up to 100 kBq/m² of ^{137}Cs. Parts of these regions can be characterized as upland ecosystems with high transfer-factors resulting in significant contamination of the local food production. Most affected are persons who are working in seasonal agricultural production at elevated sea levels during the summer time. This group still receive high Cs-burdens due to consumption contaminated nutrition and to the elevated gamma background.

The various doses from external gamma radiation and internal radiation (Cs, K, and radon decay products) in the sesonal working places in the mountain regions as well as in the valley residences of selected members of the group affected, have been assessed for each person seperately. These data allow to draw a dose-relationship for the individually in vivo induced chromosome aberrations. Due to preliminary investigations dose elevations of about 60% compared to natural background result in increased aberration rates of blood chromosomes. These findings are in accordance with studies carried out in the city of Salzburg one year after the Chernobyl accident.

PRESENT STATE OF BIOLOGICAL DOSIMETRY IN CUBA.

Omar Garcia, A. Lamadrid, J. Manzano, L. Morera, T. Mandina

Center for Hygiene and Radiation Protection. Havana. Cuba.

ABSTRACT

The most significant research in biological dosimetry by chromosome aberration analysis carried out in Cuba includes: the establishment of dose response relationship for chromosome aberration and micronuclei, the examination of 56 persons involved in minor radiological incidents, the study of 69 children from areas affected by the Chernobyl accident, and 10 persons irradiated in Goiania, as well as the co-ordination and performance of an intercomparison exercise in cytogenetic dosimetry with the participation of laboratories from Argentina, Brazil, Chile and Peru.

Biochemical indicators suggested for the evaluation of persons accidentally exposed to high radiation dose are available.

The possible use of nucleic acid concentration in blood leucocytes, as an early predictor of survival possibility of irradiated persons is now under study in whole body irradiated patients for bone marrow transplantation.

INTRODUCTION

Research in biological dosimetry started in Cuba in 1985 with the foundation of the Center for Hygiene and Radiation Protection. The main objective for biological dosimetry at that time was to introduce in the country the methods for cytogenetic dosimetry. Later, some researches with biochemical indicators of radiation injury were started. This paper presents the most significant results achieved in the past ten years.

CYTOGENETIC DOSIMETRY

Dose response relationship for chromosome aberration and micronuclei were obtained by "in vitro" irradiation of human blood with ^{60}Co in 0.5 - 4 Gy dose range at a dose rate of 1.26 Gy/min for chromosomal aberration and 0.43 Gy/min for micronuclei.

For obtaining metaphases, cultures of 48 hours of 1 ml of total blood in 9 ml RPMI 1640 culture medium supplemented with 10% of fetal calf serum with the presence of phytohemaglutinin were used. For obtaining binucleated lynfocytes equal rates of culture medium and blood, both volumes four times smaller, culture time of 69 hours and cytochalasin B in 6 μg/ml concentration were used.

The dose response curves have been fitted to the linear quadratic model by the Papworth method (1).

The relationship between the frequency of aberrations/ 100 cells (Y) and dose (Gy) is:

for dicentric $Y = 0.0+(2.84\pm0.97)D+(4.68\pm0.38)D^2$

for micronuclei $Y = 1.19\pm0.28+(1.48\pm0.55)D+(3.33\pm0.22)D^2$

Up to the moment, 56 persons involved in minor radiological incidents have been analyzed. Hospital workers are more frequently involved in such incidents. In five cases dicentric frequencies were above normal.

A computer program which includes U-test and dose estimation in total and partial irradiations was developed and is used in Cuba and other Latin American countries for cytogenetic dosimetry.

CYTOGENETIC STUDY OF CHILDREN FROM AREAS AFFECTED BY THE CHERNOBYL ACCIDENT

Children from areas affected by the Chernobyl accident have been receiving medical care in Cuba since 1990. As part of the radiological assessment, chromosome aberrations and micronuclei frequency were established in 28 (19 males) children evacuated from Pripyat, 21 (8 males) living in Kiev and 20 (10 males) from Ovruch. The number of scored metaphases and binucleated lymphocytes was: 11425 and 13500 in Pripyat, 5406 and 13959 in Kiev, and 2779 and 9891 in Ovruch.

Dicentric and micronuclei frequencies per 100 cells were: 0.02±0.01 and 0.56±0.06 in Pripyat, 0.04±0.03 and 0.60±0.06 in Kiev, and 0.03±0.03 and 0.87±0.09 in Ovruch. All individual frequencies were normal.

CYTOGENETIC STUDY IN PERSONS IRRADIATED IN GOIANIA

Translocations (G-banded cells), dicentrics and micronuclei frequencies were established in 1992 in 10 persons (4 males), 8 with 4.40 - 0.15 Gy dose and 2 "intra-utero" exposed during the Goiania accident.

Dicentric frequencies above normal were found in 2 persons (4.4 and 1.1 Gy). For the first person, the dicentric frequency has decreased 100 times, for the second one, 10 times since the accident occurred. All

micronuclei frequencies were normal. Translocations and dicentric frequencies were similar in a 4.4 Gy-exposed individual.

INTERCOMPARISON IN CYTOGENETIC DOSIMETRY

As a part of a regional IAEA collaborative project, laboratories from Argentina, Brazil, Chile, Cuba and Peru participated in an intercomparison in cytogenetic dosimetry. Human lymphocytes were irradiated with ^{60}Co (0, 0.75, 1.5 and 3.0 Gy). Code slides for chromosomal aberration and micronucleus analysis were prepared by the organizing laboratory and sent to the other participants. Dicentric and micronuclei frequency were used for dose estimates.

Eleven of the 15 estimates of dose based on dicentrics and 9 of the 12 based on micronuclei fell within ± 30% of the true dose. When considering the uncertainties of the dose estimates, the true doses fell within the 95% confidence limits of the estimates on 8 of the 15 occasions for dicentrics and 4 of the 12 for micronuclei. In summary, the scoring for all 5 laboratories was similar and it was concluded that they can contribute to the scoring of blood samples for dose estimations in a large scale radiation accident (2).

BIOCHEMICAL INDICATORS

Radiation produces a drop in concentration of nucleic acid in peripheral blood leukocytes (3).

The nucleic acid dynamics in 14 whole body irradiated patients for bone marrow transplantation and 16 breast irradiated women was studied. A peak on the nucleic acid concentration curve obtained was observed 16 - 18 days after whole body irradiation in successful cases. Fig 1 show the nucleic acid dynamics and leukocytes count in one patient irradiated up to dose of 10 Gy (4 Gy + 6 Gy in days -2 and -1 before bone marrow transplantation at day 0). The prospects of using this indicator in the follow-up of the bone marrow recovery is under study.

CELLS WITH MULTIPLE MICRONUCLEI IN CAT SCRATCH DISEASE

Omar F. García, A. Lamadrid and J. Manzano

Center for Hygiene and Radiation Protection. Havana. Cuba.

ABSTRACT

In several cytogenetic studies carried out in inhabitants of zones affected by Chernobyl accident cells with multiple aberrations have been detected. The presence of hot particles with beta and alpha activity in polluted zones has contributed to considering them as possible inductor agent. Even though the etiology of these cells has not been clearly established, viral infections are considered its most probable cause.

As a part of evaluation of the radiological impact of the Chernobyl accident, chromosome aberrations and micronuclei in lymphocytes with blockade of the cytokinesis frequencies were established in 14 children of affected areas, with the preliminary diagnosis of oncohematological affection.

The most outstanding cytogenetic finding was the presence of 4 cells that contained 7-11 micronuclei in a case, where 504 lymphocytes were analyzed and whose final diagnosis was cat scratch disease. The viral origin of this illness has been reported. This micronuclei distribution was not found in 6074 cells analyzed in the rest of the members of the group.

INTRODUCTION

The impact on the health of the Chernobyl accident has been evaluated by means of numerous studies. Among them, cytogenetic studies stand out as they use indicators of the highest sensitivity to the action of ionizing radiations. One of the most interesting findings of cytogenetic studies has been the presence of cells with multiple aberrations ("rogue cells") in some of the people studied. The presence of hot particles with beta and alpha activity in contaminated zones has contributed to considering them as a possible inductor agent.

The origin of these cells has not been clearly established, but their presence has been reported in numerous population groups that have not been exposed to chemical agents or ionizing radiations (1).

As a part of the evaluation that is developed in Cuba to children from areas affected by the Chernobyl accident, cytogenetic studies in several groups were carried out. The presence of cells with multiple micronuclei was detected during the study of a group of patient with presumed hematologic diseases, who arrived in the Island in 1990.

MATERIALS AND METHODS

The frequencies of stable chromosome aberrations and micronuclei in 14 patients with preliminary diagnosis of leukemia were established. They arrived in Cuba in 1990 from Ukrainian regions affected by the Chernobyl accident. The characteristics of these patients are shown in Table I.

*ALL-Acute Lymphoblastic Leukemia.
ANLL-Acute Non-Lymphoblastic Leukemia.

For the blood cultures and for obtainig metaphases and binucleated lymphocytes methods standardized in our laboratory were used (2), which in sum are: for obtaining metaphases, cultures of 48 hours of 1mL of total blood in 10 mL of RPMI 1640 culture medium supplemented with 10% of fetal calf serum and with the presence of phytohemaglutinin; and for obtaining binucleated lymphocytes, equal rates of culture medium and blood, but volumes 4 times smaller, culture time of 69 hours and the use of cytochalasin B in concentration of 6 µg/mL. Cases in which were possible to analyze at least 200 metaphases, and 300 binucleated lymphocytes were considered.

RESULTS AND DISCUSSION

Table II and III shown the presence of observed chromosome aberrations and micronuclei respectively.

* 4 cells with 7-11 micronuclei

The most outstanding cytogenetic finding was the presence of 4 cells that contained 7-11 micronuclei in case No.7. No cogent explanations were found to this phenomenon or to the high frequency of acentrics, until the diagnosis of cat scratch disease for this case was known finally.

The viral origin of this illness has been suggested based in epidemiological test (3), which lead us to believe that the most probable cause of this finding is the viral infection.

The relationship between cells with multiple aberrations "rogue cells" and virus has been suggested by several authors (4-6), and the relationship between chromosomal aberrations and micronuclei is known (7). These are the reasons why,in our case, we did not discard the possibility that cells with multiple aberrations have give origin to cells with multiple micronuclei. No typical "rogue cells" were found in analyzed metaphases.

High frequencies of acentrics in cases 1, 2 and 6; and of micronuclei in cases 1, 5 and 6 were also detected. The possibility of previous treatments with cytostatic to be the cause of these increments could not be discarded since practically all the cases had been treated before arriving in our country and it was impossible to determine the kind and duration of treatment.

CHROMOSOME ABERRATION OF ACCIDENTALLY EXPOSED PERSONS IN FRANCE : REVIEW OF CASES 1992-95.

Philippe Voisin, V. Durand, A. Le Roy, N. Paillole, I. Sorokine, V. Chambrette

Institut de Protection et de Sûreté Nucléaire, Département de Protection de la santé de l'Homme et de Dosimétrie, Section Autonome de Radiobiologie Appliquée à la Médecine, IPSN - B.P. n°6, F-92265 Fontenay-aux-Roses, Cedex, France.

INTRODUCTION

Since more than 20 years, biological expertise concerning dose estimation of suspected overexposure of personnel to ionising radiation has been undertaken by a small number of laboratories in each continent (1). Dose estimation by change of some biological parameters appears a useful compliment to clinical and physical dosimetries together with the knowledge of the health status of the potentially exposured people. It becomes particularly important when physical dosimetry is not present and clinical dosimetry is not consistent (2). Biological estimates of accident overexposure is usually obtained by the scoring of radio-induced unstable structural chromosome aberrations (dicentrics, centric rings and fragments) in peripheral blood lymphocytes (3). A correlation between the dicentrics yield and the physical dose can be obtained by reference with an *in vitro* dose-response relationship, which is related to radiation quality and dose rate (3, 4). Although some new biological indicators such as micronuclei or translocation yields may constitute interesting alternatives, dicentric scoring is considered as the most specific and sensitive biological dosimeter.

During the 1992 - 1995 years period, 33 persons were investigated by the Laboratory of Multiparametric Biological Dosimetry of the Institute of Protection and Nuclear Safety (I.P.S.N.) for a potentially overexposure accident. Although limited, this number of cases was considered large enough for a first statistical overview. This report summarises the related observations and conclusions.

METHODS USED

A blood sample is collected during medical examination of the patient by antecubital venepuncture in tubes containing lithium heparin as anticoagulant (Becton Dickinson).

After arrival in the laboratory, the lymphocytes are cultured using a protocol similar to that described in the IAEA technical report (4). Briefly, several replicates of each blood sample were added to a culture medium (Life Technologies) supplemented by phytohaemaglutinin (PHA, Life Technologies), a mitogenic factor of lymphocytes, heat-inactivated fetal calf serum and antibiotics. Bromodeoxyuridine (BrdU, Sigma), a thymidine analogue, is also included in the blood culture, in order to score unstable chromosome aberrations in the first metaphases.

After 46 hours of culture at 37 °C, a mitotic inhibitor (Demecolcine, Life Technologies) is added and culture delayed for 2 hours. Cells are harvested and metaphase spreads prepared according to standard techniques. The slides were stained with Fluorescence Plus Giemsa (FPG) so that cells in their first and second divisions can be distinguished.

Unstable chromosome aberrations (dicentrics, centric rings and fragments) are scored microscopically only in the first complete metaphases (with 46 centromeres). The estimation of potentially received dose is made by reference to dose response curve produced by exposing blood *in vitro* to ^{60}Co gamma rays at 0.5 Gy.min^{-1} :

$$Y = 0.042 \times D + 0.054 \times D^2$$

(Y = yield of dicentrics and D = dose in Gy)

RESULTS and DISCUSSION

Several reasons are behind an expertise of biological dosimetry by cytogenetics, in case of suspicion of exposure to ionizing radiation. The most common one is that potentially exposured people, professional or public, do not carry a physical dosimeter when an overexposure is suspected (24 out of 33 cases). Even when there is possibility of *a posteriori* dosimetric reconstruction, uncertainties linked to the former justifies the examination of a biological parameter linked to the subject himself. A second reason is that, although a physical dosimeter is

effectively carried in the frame of their professional activities, the registered dose was abnormally high or took into account only localised irradiation (9 out of 33 cases). Five cases have concerned people submitted to chronic or fractionated irradiations, so that the biological estimate appeared as a useful adjunct in the knowledge of the current status of the patient.

Suspicion of overexposure can be divided in two major categories (Table 1): people whose professional occupation consists of working with radio-activity, radio-active sources or close to them (so called « professional » in table 1), and persons whose activities (professional or private) do not usually include usage of ionizing radiation. These former ones are called in this report with the general term « public ». It can therefore be surprisingly observed in the period 1992-95 a global imbalance between these two categories, an imbalance that however is not found for all years. In addition, whatever the category of persons is, the suspicion of irradiation always concerns the external exposition, never the internal contamination.

Table 1. Distribution of the number of personnel suspected of overexposure during the period 1992-95, according to the « professional » or « public » status of exposured persons.

	Number of cases		
Years	« professional »	« public »	Total
1992	5	10	15
1993	3	2	5
1994	2	1	3
1995	7	3	10
Total	17	16	33

According to their main professional activities, three classes of workers can be distinguished under the vocable « professional » (table 2). The distribution of suspected overexposure accidents shows a relative homogeneity of the accidental origin for these three classes : gammagraphy sources for testing purposes that constitutes the majority of typical industrial irradiations generally involves problems linked to dysfunction of the devices. In the health institutions, whether for radiographic use or patient treatment, it most often concerns the inattention of operators to protection and safety details. The greatest variability of the origin of accidents is linked to nuclear industry. This was probably due to the introduction in this category of three foreign persons who came to France for medical examination. On the one hand, it concerns a maintenance worker of the Chernobyl nuclear power plant during several years following the fallout and a physicist having periodically studied the reactor core inside the sarcophagus for 4 years. On the other hand, it includes a foreign physicist with badly irradiated hands by an accelerator of electrons. No dicentrics were scored in the first case what was coherent with clinical status of the patient. In the second case however, the biological dose (0.42 Gy) was clearly under-estimated in contrast with the diagnosis of total sterility. For the last one, the physical dosimetry reconstruction has suggested a dose within the range 10-40 Gy to both hands. This is quite different from 6 dicentrics scored in 500 lymphocyte metaphases which gives an integrated dose of 0.3 Gy. This example underlines well the limitations of cytogenetic dosimetry in case of very localized irradiation.

Table 2. Distribution of professional workers in three categories, and presence or absence of physical dosimeter (generally chest dosimeter) during the suspected overexposure accidents.

Physical dosimeter	with	without	Total
industrial radiography	4	2	6
health institutions	1	4	5
nuclear organisations	4	1	5
Total	9	7	16

The Table 2 also shows the proportion of potentially classified workers who carried a physical dosimeter (finger, chest) during their professional activities and/or their overexposure period. As far as the limited number of

overexposed cases observed allows, it can be stressed, therefore, a radioprotection problem, especially for the health workers category.

Within the « public » category, many overexposure suspects imply persons who was working beside a source of ionizing radiation and who believed have been exposed accidentally; for example, unknowingly entering in the irradiation room when the source is functional. The result of all this is generally short, acute exposure. However, a case of particularly important chronic irradiation concerns a family (the father and two children) having recovered and stored a small source of 4 Ci (148 GBq) of ^{137}Cs. The father who recovered the source, has kept it only for a short time in his office before giving it to his son. The son has kept it for sixteen months in his bedroom, which was beside his sister's room. The doses estimated by biological dosimetry correctly reflected the duration of the exposition as well as the personal dose distribution (in equivalent whole body, 0.5, 0.9 and 0.64 Gy respectively). In contrast, it does not allow to reconstitute correctly the dose absorbed by the son notably because a strong lymphopenia.

More generally, the estimated dose has been « zero dose » or doses below 0.5Gy in the great majority of cases of these three years as summarised in Table 3. A « zero dose » means that no dicentrics have been found in the observed metaphases, often 500. However, there exists a possible minimum number of dicentrics to be observed in normal individuals, which is approximately 1 for 2000 metaphases. This suggests that the estimated dose is in fact included in the background considering that the accuracy of the method is proportional to the number of metaphases observed. On the curve of reference of the laboratory (^{60}Co, 0.5 $Gy.min^{-1}$), this corresponds to a 95% confidence interval of 0.2 Gy.

Table 3. The dose ranges estimated by biological dosimetry related to the repartition of the overexposured cases according to the different categories of implied people.

Dose range (Gy)	« zero dose »	0 - 0.19	0.2 - 0.49	0.5 - 0.9	Total Number
industrial radiography	2	1	3	0	6
health institutions	5	0	0	0	5
nuclear organisations	3	0	2	0	5
public	8	0	3	5	17
Total	18	1	8	5	33

It is necessary to note that the main limitation of the biological dosimetry is to give a dose integrated to the body, which poses problems in case of localized irradiations. It is indisputable that the majority of overexposures to ionizing radiations concern localized irradiations. In the three cases where hands have been mainly exposed to doses above 10 Gy, the dose given by dicentric scoring did not exceed 0.3 Gy. Furthermore, the selection of the reference curve has incontestably an importance on the estimation of the dose, independently of the presence or not of dicentrics, since it would have to take into account the quality of the radiation and the dose rate when they are known. In our experience for the years 1992-95, it appears that implied radiation sources are essentially from ^{192}Ir,^{60}Co, X -rays with a low dose rate. This justifies therefore the use of a reference curve established from gamma radiation of ^{60}Co with 0.5 $Gy.min^{-1}$. The comparison with the physical dosimetry in the cases where the former is known with a good accuracy shows elsewhere a good agreement with the cytogenetic estimate. Nevertheless, other reference curves for other qualities of radiation and dose rate are prerequisite.

THE DICENTRIC ELIMINATION IN LYMPHOCYTES OF PATIENTS EXPOSED IN THE TIME OF CHERNOBYL ACCIDENT

Vladimir Ju. Nugis

Institute of Biophysics, Moscow, Russian Federation

INTRODUCTION

The chromosome studies of atomic bomb survivors in Hiroshima and Nagasaki in some decades after the irradiation demonstrate a primary elimination of cells carrying unstable-type chromosome aberrations (dicentrics, rings, fragments). Its are met in less than 10% of all aberrant cells. A frequency of stable-type chromosome aberrations is remained almost unchanged in time in blood lymphocyte cultures of exposed persons (1). Therefore the stable-type chromosome aberrations are considered the most effective indicator of radiation dose in this time. However in first some years after exposure a level of dicentrics (a principal kind of chromosome aberrations for biological dosimetry in a near time after an irradiation) may be sufficiently high although over the first 4 years the decrease of the dicentric frequency at a rate of about 43% per year was observed (2). The number is a result of a cytogenetical investigation of a group of patients treated with X-rays for ankylosing spondylitis. Until recently the similar works with a use of therapeutic partial prolonged fractionated irradiation were a principal source of a data for study of the elimination chromosome aberration regularities. The initial (immediatly after an irradiation) and several repeated cytogenetic analysises after acute external total uniform or non-uniform exposures were carried out more or less in detail mainly for a small number of persons irradiated accidently (3-8). Unfortunately large numbers of persons irradiated different doses appeared after two radiation catastrophes of 1986-1987 years (Chernobyl and Goiania accidents). In this paper the results of reported counts of radiation-induced dicentrics for Chernobyl patients are presented. Its are important for an investigation of possibilites of biological retrospectival dose estimations.

MATERIALS AND METHODS

The initial chromosome aberration analyses of lymphocyte cultures from peripheral blood and bone marrow were made for a large number of exposed people during the nearest 1.5 days - 7 weeks after Chernobyl accident. The cytogenetical dose estimations were produced for 192 patients in the range from 0 Gy (dicentris were not found in lymphocyte cultures from 48 patients) to 13.7 Gy. Relatively uniform affection of a body (hemopoietic tissue) with the exception of a skin could be anticipated on the basis of a conformation of dicentric distributions to a Poisson distribution in lymphocyte cultures from the most of these patients who had been exposed at doses that were critical for the develepment of the bone marrow syndrome. Repeated cytogenetical examinations were made for the study of elimination chromosome aberration regularities. The peripheral blood lymphocyte cultures were incubated during 50 or 67 hours. The chromosome aberration counts were made in the first in vitro metaphase cells determined by fluorescense plus Giemsa staining.

108 lymphocyte cultures from 61 patients were investigated in the general time range from 3 to 30 months after accident. The number of repeatedly analysed lymphocyte cultures (in different times) for individual patients fluctuated from 1 to 4. The analysed cell numbers in several cultures varied from 15-41 cells (4 cultures) and 50-98 (9 cultures) to 100-200 cells (95 cultures).

RESULTS AND DISCUSSION

All patients were divided in development from initially estimated doses at 3 groups: exposed in doses 0.4-1.9 Gy (21 patiants, 34 repeated cultures), 2.1-3.7 Gy (26 patients, 48 repeated cultures) and 3.9-8.7 Gy (14 patients, 26 repeated cultures). After the termination of cytogenetical counts the percents of cells with dicentrics, average frequences of dicentrics and dicentric frequences in cells with dicentrics were selected for a sequent examination. The relationships (exponentional model) between percents from initial levels for repeated observed values of these cytogenetical indicies and the time after irradiation (in mounths) were received. The corresponding coefficients of the equations are presented in Table.

In general, our data evidently demonstrate the faster rates of decrease of average frequences of dicentrics and percents of cells with dicentrics in time after greater ininial doses than smaller initial doses. Also, dicentric frequencies in cells with dicentrics decreased in time slower than average frequencies of dicentrics. This fact and the reproduction of non-aberrant cells have to result in an apearance of the overdispertion of dicentric distributions by cells with respect to Poisson distribution. Apparently, the cells carrying the greater quantity of dicentrics relatively more rarely divide in vivo than cells with smaller quantity of dicentrics, although in general all cells divide some time or other. The dicentric frequency in cells carrying dicentrics made 1.00-1.25 in group of 0.9-1.4 Gy (that was greater 1.20 in 1 culture), 1,08-1,59 in group of 2.1-3.7 Gy (that was smaller 1.20 in 7 cultures and greater or equal 1.50 in 2 cultures) and 1.43-3.52 in group of 3.9-8.7 Gy (that was smaller 1.50 in 2 cultures).

The large individual variability was observed for rates and characteristics of decline of dicentric frequencies independently from initially valueted doses. Its could decline by degrees or by leaps. The long time periods of persistent yields of dicentrics could find out. Those were up to 19 mounths in the group 0.4-1.9 Gy, up to 11-12 mounths in the group of 2.1-3.7 Gy and up to 10 mounths in the group of 3.9-8.7 Gy. Sometimes the undulating changes of dicentric frequencies were observed 1 year after the accident (in general at the decreased levels in comparison with the initial yields).

Thus, essential difficulties and indefinities will appear in the time of the cytogenetical biological retrospectival dose estimations by dicentrics at the blood sampling delay of a few years.

CONCLUSIONS

1. The average rate of dicentric elimination was more after higher doses.
2. Dicentric frequencies in cells with dicentrics decreased in a development from time slower than average dicentric frequencies.
3. The essential individual variation was observed.

Table

The relationships between several cytogenetical indices (Y, % from initial values) and the time (t, months) after the irradiation at Chernobyl accident

THE FREQUENCY OF DICENTRIC CHROMOSOMES IN RELATION TO ^{131}I CONTAMINATION

D. Kubelka, A. Fučić and V. Garaj-Vrhovac
Institute for Medical Research and Occupational Health, Zagreb, Croatia

INTRODUCTION

In vitro investigations conducted by now have indicated a correlation between the applied doses of ionising radiation and frequency of dicentric chromosomes (1). In vivo investigations do not always confirm that relationship, especially not in case of subjects occupationally exposed to ionising radiation. The aim of this paper was to elucidate that possible disagreement between registered doses and the number of chromosomal aberrations may be ostensible. Risk estimation should therefore involve precisely defined groups of examinees and not individual subjects.

SUBJECTS

Out of the total number of 107 subjects included in the study, 41 subject were taken as a control group and 66 workers employed at a department of nuclear medicine represented exposed group. The subjects had not been exposed to radiation for therapeutic or diagnostic purposes over the preceding year and had not taken any chemo-therapeutic drugs.

The activity of the department of nuclear medicine involves the use of radioactive material for therapeutical treatment and diagnostics. The variety and wide range of specific jobs at the department of nuclear medicine requires the staff including different professions. All these employees; such as cleaners, nurses, technicians, physicians, biologists, physicists and chemists, have in common equal possibility to be irradiated in their everyday work. Irradiation may occur during the handling of radioactive material, in the process of application of radioactive material to patients, from the patient subjected to application of radioactive material and by contamination. It should be emphasized that work at the department of nuclear medicine involves a risk for the employees to be continuously exposed to ionising radiation over the whole working hours. Since the risk from external irradiation, from contaminatin and intake of radionuclides in the body depends mainly on the nature of specific tasks of the employees, the exposed group was divided into four subgroups by corresponding jobs and tasks performed daily at the department of nuclear medicine.

METHODS

Analysis of chromosomal aberrations were carried out on standard 24-hour lymphocyte cultures. Two hundred metaphases were analysed per each sample, and only first in vitro metaphases were analysed. Chromatid and chromosomal damages detected per each analysed metaphase were classified into chromatid breaks, chromosomal breaks and bicentric chromosomes (2).

Samples of urine to be gamma-spectrometrically analysed were collected in glass dishes over 24 hours. Daily aliquot in the volume of 110 ml per subject was taken for analysis. Gamma-spectrometrical analysis of 24-hour urine samples was carried out using Ge (Li) detector, resolution 1.78% (Co), efficiency 16.8% with 4K channel analyser, Canberra series 10. The detector was protected with a lead layer, thickness 10 cm, 1 mm of cadmium and 2 mm of copper. The samples were measured in a cillindric dish, volume 110 ml. Specific activities of ^{131}I were calculated on basis of known efficiency of the counter, percentage of gamma rays, quantity of the sample and intensity of photo peak.

RESULTS AND DUSCUSSION

The frequency of total chromosomal aberrations found in the control group was 0.75%, and in the group of employees of the department of nuclear medicine 1.84%. The frequency of individual chromosomal and cromatid aberrations per cell was given in Table 1.

Group	Cromatid break	Chromosomal break	Acentric	Dicentric
Control	1.34 ± 1.33	0.78 ± 1.0	0.63 ± 0.86	0
Exposed	1.97±1.22	1.56 ± 1.52	1.67 ± 1.62	0.48± 0.85

Table 1. Total frequency of cromatid and chromosomal aberrations per cell

By means of gammspectrometrical analysis ^{131}I contamination was stated in 11 subjects of the exposed group. Activity of I in urine ranged in some workers from 0 to 78.66 Bq/kg. In the control subjects ^{131}I contamination was not detected.

Comparing aberration frequency in the control and exposed group the difference between the groups was found at the level of significance $P < 0.05$, except for chromosomal breaks. The results obtained correspond with the data reported by Pohl-Ruling (3,4) pertaining to frequency of chromosomal aberrations in the lymphocytes of subjects exposed to external gamma radiation and internal radiation of radon and its decay products.

Comparing the frequency of dicentric chromosomes with ^{131}I burden in certain examinees no regularity was found between the two investigated parameters.

According to the obtained data and equal possibility of external exposure to radiation and contamination workplaces and tasks at the department of nuclear medicine, the staff was divided into four subgroups regardless of their profession.

The average values for the frequency of dicentrics per cell and examinees and data on average contamination by individual subgroups were given in Figure 1.

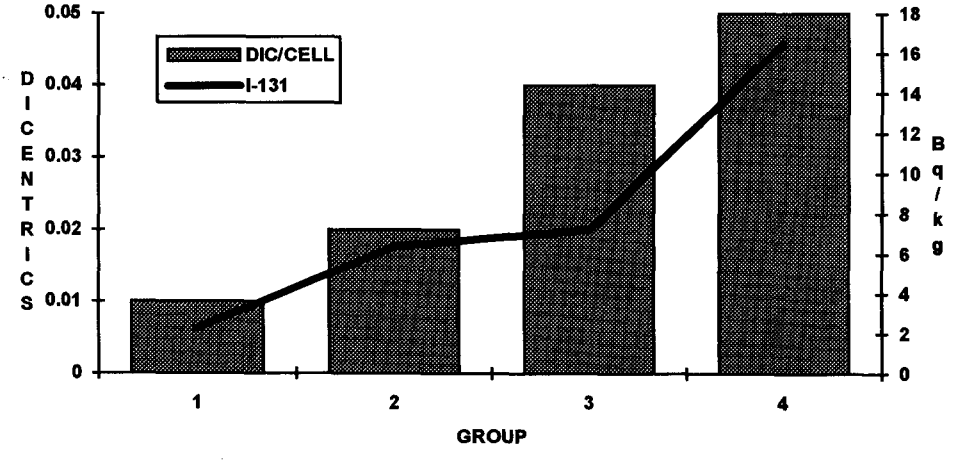

Figure 1. Average frequency of dicentrics, average contamination with ^{131}I for subgroups of examinees in the department of nuclear medicine

It can be seen that increase in the average ^{131}I contamination is followed by the average frequency of dicentric chromosomes in all four subgroups. The fact that dicentric chromosomes are found also in the subjects in whom ^{131}I contamination was not observed can be explained by the biological half-lives of ^{131}I and the time of its decay. As biological half-life of ^{131}I is 12 days and of the decay 8.04 days, there is low probability that it would be detected in urine during periodical sampling, taking into account that contamination is not

continuous. This fact is opposed by the fact that persistence of chromosomal aberrations takes several months to several years.

Taking this into account it seems appropriate to believe that for this reason the authors in previous investigations have not found any correlation between the registered doses and incidence of dicentric chromosomes.

The obtained data indicated the existence of regularity of the dose-response relationship in case of dicentric chromosomes even in cases of irradiation with small fractionate doses over the prolonged period of exposure.

Analysing the data obtained in this kind of investigations it should be mentioned that conclusions should not rely on physical measurements only. The subjects should be observed in subgroups due to their tasks which ensures great probability that doses received would be equal.

ABSTRACT (See instructions overleaf)

Chromosomal aberration in human T-Lymphocyte of peripheral blood are sensitive indicators of radiation exposures even at low levels of dose. At present, chromosome analysis is the method of choice for a biological estimation of an equivalent whole-body dose of actual or suspected over-exposures to ionising radiation.

Cytogenetic dosimetry is a valuable tool in supplementing physical dosimetry in practical radiation protection since, individual ; body doses down to 100 mSv. gamma-rays can be reliably detected. There are some limitations for a quantification of individual acute exposures below 50 mGy; for partial-body, chronic exposures and in particular for incidents with incorparation of radionuclides with selective depositions.

Four biodosimetric methods are used for the evaluation of the radiation dose, viz: glycophorin-A (GPA)-somatic mutations; chromosome translocations; micronulei; and dicentrics. Two of these biodosimeters; (GPA) and translocations are stable with time post-exposure and are therefore expected to integrate radiation damage under chronic exposure conditions. The other two (micronuclei and dicentrics); are unstable, and can only detect recent exposures.

Two different approaches were used to detect chromosome translocations in peripheral blood lymphocytes -viz: fluorescence in situ hybridization (FISH) and G-banding.

CYTOGENETIC DOSIMETRY OF RADIATION DAMAGES IN DOMESTIC ANIMALS

Ranko Kljajić[1], Z. Žunić[2], O. Zurovac Kuzman[1], S. Košarčić[1], and G. Joksić[2]

[1]Scientific Institute for Veterinary Medicine, Novi Sad, Yugoslavia

ABSTRACT

In case of mass radiation of people and animals the estimation of radiation dose is the basic prerequisite for undertaking protection measures and the triage of radiated individuals. In the early phase of the accident, estimation of radiation dose in animals only on the base of the physical dosimetry is often deficient and unreliable.

In this paper a possibility of using biodosimetric methods for estimation of absorbed radiation doses in domestic animals in case of an accident is discussed. For this purpose radiation of full animal blood with 6 different radiation doses was carried out. After the blood radiation, preparation and cultivation of lymphocytes as well as a certain number of specific chromosomal aberrations for each radiation dose were performed. The obtained results indicate that the number of specific chromosomal aberrations increases with the increase of radiation dose.

INTRODUCTION

It is necessary to know radiation doses in the first phase of an accident to be able to carry out protection measures effectively in case of radiation emergency (1). Estimation and measuring of exposure doses can successfully be performed by using physical methods of ionizing radiation dosimetry. However, from the aspect of the biological effect on live organisms, it is necessary to know the absorbed radiation dose in the tissue of each individual (2-4). Physical dosimetry methods can not be applied for measuring of the absorbed dose of ionizing radiation in case of an accident. This particularly refers to the estimation and establishing of the absorbed radiation dose in domestic animals and people, on the basis of which it is possible to estimate the level of radiation damage and to undertake further protection measures. Because of this, the aim of this investigation was to determine the level of radiation damage in pigs on the basis of cytogenetic methods of ionizing radiation dosimetry.

MATERIAL AND METHODS

The blood of healthy pigs, in which the number of spontaneous chromosomal aberrations was previously determined, was irradiated with 6 different doses of high-energy-X-rays (0.1; 0.2; 0.5; 1.0; 2.0 and 3.0 Gy). After irradiation, lymphocyte preparation and cultivation according to the modified method of Morhed were performed and the number of specific chromosomal aberrations dicentric and ringlike chromosomes) determined. The analysis of the number of chromosomal aberrations was carried out on at least 1000 good visible metaphase figures for each radiation dose.

RESULTS AND DISCUSSION

In the blood of healthy unexposed pigs aberrations of chromatid type as gas and chromatid breakage were mostly represented. The total number of spontaneous chromosomal aberrations in healthy pigs was 0.1%. After exposure of blood to high-energy-X-rays, already during the first 24 hours after irradiation a significant increase of the number of specific chromosomal aberrations took place (table 1).

Table 1. Frequency of chromosomal aberrations in lymphocytes of pigs after in vitro irradiation of blood with X-rays.

Dose in Gy	No. of anal. cells	Structural aberrations of chromosomes: Chromatid Gap	Chromatid Break.	Chromosomal Break.	Chromosomal Ac.fragm.	D+R	Change of ploidity	% of aberrations
0.0	1105	-	1	-	-	1	4	0.54
0.1	1000	4	1	-	3	3	4	1.50
0.2	1000	9	3	-	3	5	3	2.30
0.5	1000	2	-	-	7	6	3	2.80
1.0	1000	4	-	3	16	18	7	4.80
2.0	1000	15	-	1	91	76	8	19.10
3.0	1000	-	-	-	241	255	16	51.20

D - dicentric, R - ring

It can be noticed from the obtained results that with the increase of radiation dose increases also the number of specific chromosomal aberrations. For the lower radiation doses (up to 0.5 Gy), the number of aberrations was represented with a linear parameter, and for higher dose levels with a square parameter. On the basis of obtained results, it is possible to work out the calibration dose-response curve, which is the mathematical, statistical and graphic presentation of an experimentally determined relation between the number of specific chromosomal aberrations and the absorbed radiation doses, what will be the subject of our further investigations.

CONCLUSION

Cytogenetic dosimetry of ionizing radiation is one of the methods for early detecting of radiation damages in domestic animals. By applying this method, already during the first 24 hours after irradiation of pigs (much before the appearance of clinical symptoms of the disease) it is possible to estimate the level of radiation damage on the basis of specific chromosomal aberrations and to undertake protection measures and/or measures of economical exploitation of irradiated animals. For more reliable estimation of the absorbed radiation dose it is necessary to work out also calibration dose-response curves, which are a mathematical, statistical and graphic presentation of experimentally determined relationship between the number of chromosomal aberrations and the absorbed radiation doses. On the basis of these curves it is possible to estimate the absorbed radiation doses in people and animals in accidental and emergency situations.

SERUM PROTEINS IN ATOMIC INDUSTRY WORKERS

Vitaliy I. Telnov

Branch No. 1 of Russian Federation State Scientific Centre Biophysics Institute
456780, Ozersk (Chelyabinsk-65), Russia

INTRODUCTION

At present time the clinical and experimental materials have been accumulated, which evidence about the influence of irradiation on different sides of the protein metabolism (1). The most of these studies have been conducted at the early time period after acute and chronic irradiation exposures. Because data on more late consequences of irradiation influence on the protein metabolism in humans are not numerous and have some differences, it is necessary to have future studies of this problem. The results, obtained for the last years in epidemiological studies of humans, indicate on the relationship the protein metabolism changes with ageing, increased morbidity and mortality and confirm the importance to continue the studies in this area (2).

MATERIALS and METHODS

989 workers of the "Mayak" atomic industry plant (683 male, 306 female) at ages of 37 - 78, exposed to chronic external and/or internal irradiations 17-40 years ago, were examined. The summary doses of external γ-irradiation were in the range of 0.01 - 7.6 Gy. The incorporation of plutonium-239 in organism in the range of 0.148 - 25.27 kBq was determined for 723 persons examined, including 28.2% cases, in which incorporation exceeded 1.48 kBq. In serum the following parameters were determined: total protein level by the biuret reaction method, protein fractions by electrophoresis on acetate-cellulose membranes and further by densitometric estimation, the level of immunoglobulins (IgA, IgG, IgM) by radial immunodiffusion of Mancini. The absolute and relative values of protein fractions were calculated. The serum proteins entropy was used as integral index of relative content of electrophoretic fractions. Relationships between the studying parameters and 11 factors: 2 radiation and 9 non-radiation (age, sex, body mass index (BMI) in kg/m^2, smoking, alcohol abuse, chronic non-specific lung diseases (CNLD), chronic gastritis (CG), chronic cholecystitis (CC), and rheumatic arthritis (RA)) were estimated. The protein synthesis function (PSF) of liver was studied in separate investigation. Prealbumin (PA) by method of radial immunodiffusion Kit, albumin by reaction with BCP, and activity of cholinesterase (CHE) by method with achetylcholinechloride in blood serum of 190 workers were determined. Relationships of the serum proteins with radiation and non-radiation factors by stepwise regression analysis were studied (3).

RESULTS and DISCUSSION

The Table 1 presents the results of comparing the protein parameters in 3 groups of atomic industry workers with different summary doses of external γ-irradiation. The first group (the comparison group) consists of the persons who have the annual accumulated doses of external γ-irradiation not exceeded 0.05 Gy. The second and the third groups comprise the persons with more significant dose of irradiation. This Table also shows that there are changes of some serum proteins in examined persons with increasing of summary doses, e.i., the increases of total protein level, absolute value of alpha-1-globulin, absolute and relative values of alpha-2-globulin and beta-globulin, entropy values of serum protein, IgG level and the decrease of relative value of

albumin. On the whole, the changes were more significant in the group with more high doses of exposure. Levels of IgA and IgM in the groups compared did not significantly differ (see Table 1). The changes of protein parameters in people with different levels of plutonium-239 incorporation were not found. The obtained results indicate that there are relationships between the protein parameter changes in atomic industry workers and external γ-irradiation exposure. The multifactory analysis has been made for obtaining more precise dependence of the studuing parameters on the external irradiation, and for confirming the absence of relations of those with internal exposure, and for determining of contribution the irradiation and non-radiation factors in serum protein changes.

It was found by the stepwise regression that 8 of 11 factors, which were taken for analysis, have the significant relationships ($p < 0.05$) with the protein parameters. The Table 2 contains the partial determination coefficients, the values and the signs which characterize the influence of each factor, allowing to compare the factors. This table also includes the multiple determination coefficients.

The linear equations of multiple regression were obtained as the results of this analysis. These equations reflect the relible dependence of the protein parameters on the summary dose of external γ-irradiation and non-radiation factors:

Total protein, g/L =69.88+0.55*X3+0.14*X5 ($F=13.67$; $p < 0.001$)

Alpha-1 globulin, g/L =2.46+0.05*X3 ($F=4.49$; $p < 0.05$)

Alpha-2 globulin, g/L =5.73+0.21*X3+0.51*X4 ($F=20.94$; $p < 0.001$)

Beta globulin, g/L =7.44+0.16*X3+0.07*X5 ($F=14.62$; $p < 0.001$)

Proteins entropy, a.u.=1.1713+0.0016*X1+0.0217*X2+0.0091*X3 ($F=9.97$;$p<0.001$)

where: X1 - age, year; X2 - sex (1 - male, 2 - female); X3 - summary dose of γ-irradiation, Gy; X4 - smoking (1 - no, 2 - yes); X5 - BMI; F - Fisher criterion.

* - d=0.5-0.7: $p < 0.05$; d=0.8-1.2: $p < 0.01$; $d > 1.2$: $p < 0.001$

The values of regression coefficients for summary dose of γ-irradiation evidence that increasing the dose exposure by 1.0 Gy causes the increase of total protein level by 0.55 g/l, including alpha-1-globulin by 0.05 g/l, alpha-2-globulin by 0.21 g/l, and beta-globulin by 0.16 g/l. Proteins entropy at the same dose of exposure increases by 0.0091 a.u. Theses results were well coincided with the data received in atomic-bomb survivors in Japan (4). The level of PA in the workers with plutonium-239 incorporation more than 1.48 kBq was less (259+6.0 mg/l, $p < 0.05$) than in the control group (276+3.9 mg/l). Frequency of hypo-PA-emia in these workers was not increased, but hyper-PA-emia was absent. The level of albumin and activity of CHE in those was not changed. Level of PA and other indicators of PSF of liver in the workers with different summury doses of external γ-irradiation was not changed.

Thus, chronical external and internal irradiation influence on different sides of protein metabolism of the atomic industry plant workers exposed 17-40 years ago.

RADIATION INDUCED CHROMOSOME ABERRATIONS IN CULTURED LYMPHOCYTES FROM 4 PATIENTS WITH SKIN RADIATION INJURIES

T.V. Kondrashova, T.I. Ivanova, S.N. Katsalap

Medical Radiology Research Centre, Obninsk, Russia

INTRODUCTION

Therapeutic irradiation results sometimes (in about 20 per cent cases) in formation of long-term skin radiation injury. Its treatment is difficult and more often ineffective. As the majority of patients exposed under similar conditions has no long-term skin reactions, it seems plausible that such reactions are conditioned by an enhanced individual skin radiosensitivity. Determination of such individuals before the onset of radiation therapy should become an important prophylactic measure. Taking in mind this objective and assuming that the individual proneness to the formation of long-term skin ulcers is (at least partly) of genetic origin, we intend to elucidate whether the chromosome radiation response of patients with late skin injuries differs from that of healthy persons. Peripheral lymphocytes are chosen as the test system because radiosensitivity of blood is one of essential constituents of integral organism radiosensitivity.

Aliquots of venous blood were taken from 4 healthy volunteers (below referred to as donors 1-4) and 4 patients of the MRRC clinic with skin radiation injuries (patients 5-8) appeared after courses of therapeutic irradiation. Preparation of lymphocyte cultures followed standard technique (1), with slight modifications. Lymphocytes were exposed to ^{60}Co γ-rays at about 20 rad/min; irradiation schedules and doses are given below. Cells were harvested at 51 h after PHA-stimulation. On the obtained metaphase preparations, all the aberrations which needed no kariotype identification for their detection were scored. The following cytogenetic end-points were assessed: (1) aberration levels in unirradiated cultures, (2) radiosensitivity at the G_0 stage, (3) radiosensitivity at the G_2 stage, (4) capability to the induction of an adaptive response.

Abbreviations: PHA, phytohaemagglutinin; D., donor; D_m, mean value for healthy donors; AM, aberrant metaphases; CA, total chromosome aberrations; CsA, chromosome type aberrations; CsF, chromosome type fragments; CsE, chromosome type exchanges; Dic, dicentrics; CtA, chromatid type aberrations; CtF, chromatid type fragments; CtE, chromatid type exchanges; AR, adaptive response.

ABERRATION LEVELS IN UNIRRADIATED CULTURES

The data on aberration frequency in unirradiated cultures are shown in Table 1. As χ^2-test showed the homogeneity of the frequencies for healthy donors, the table gives the pooled values. Aberration yields in patients show a tendency to exceed those in healthy donors, but only in patients 7 and 8 the difference is significant for most aberration types, being the most expressed for chromosome exchanges. It is natural to suppose that the increased aberration yield in patients is associated mainly with therapeutic irradiation they had received earlier. Time elapsed after the irradiation was more than 20 months for patients 5, 6 and less than 16 months for patients 7, 8; thus, our results agree with existing data on decrease of frequency of *in vivo* induced unstable aberrations in lymphocytes with time after exposure (2). However, some features of the obtained data are in a contradiction with what should be expected as a result of *in vivo* local irradiation. These are the significantly increased frequency of chromatid fragments in patient 8, and Poisson-type cellular distribution of aberrations in patient 7. It is possible that these features are associated with individual peculiarities of spontaneous aberrations patterns in these two patients.

Table 1. Aberration frequencies (per 100 cells) in unirradiated lymphocyte cultures. In brackets, standard errors. *, significant difference ($P<0.05$) from D_m.

RADIOSENSITIVITY AT THE G_0 STAGE

In this set of experiments, the blood samples were exposed to 2 Gy gamma-rays; lymphocyte cultures were prepared and stimulated immediately after the exposure. The frequencies of induced aberrations are given in Table 2. χ^2-test having showed the homogeneity of values for healthy donors, except those of chromosome type exchanges, these values were averaged. Yields of total aberrations and of chromosome type aberrations exceed controls significantly in three of four patients; in addition, patients 5 and 7 reveal an increased frequency of chromosome type fragments, and patient 8 - that of chromatid type aberrations (fragments). Analysis of cellular distribution of various aberration types showed that for healthy donors all the distributions were poissonic, while for patients some were poissonic, others were not. However, two kinds of the distributions, namely that of total chromosome type aberrations and that of chromosome type fragments, differed from Poisson distribution significantly ($P<0.01$) for each patient.

The above results allow to suggest the frequency of chromosome type aberrations induced at the G_0 stage as an end-point which is essentially different in individuals with enhanced skin radiosensitivity as compared to healthy persons. The difference resides in the facts that in patients (1) this frequency exceeds the control value and (2) its distribution is non-poissonic.

Table2. Aberration frequencies (per 100 cells) in lymphocyte cultures irradiated by 2 Gy at the G_0 stage. In brackets, standard errors. *, significant difference ($P<0.05$) from D_m.

D.	AM	CA	CsA	CsF	CtA	CtF	CtE

5	45 (5)	68 (8)	63 (8)	28* (5)	5 (2)	2 (1)	3 (2)
6	49 (5)	73* (9)	71* (8)	21 (5)	2 (1)	2 (1)	0
7	46 (5)	79* (9)	71* (8)	29* (5)	8 (3)	4 (2)	4 (2)
8	57 (8)	126* (19)	94* (16)	26 (9)	31* (9)	26* (9)	6 (4)

RADIOSENSITIVITY AT THE G_2 STAGE

The below data were obtained only for donors 2-7. The lymphocyte cultures were exposed to 0.5 Gy 3 h before harvest. The comparison of aberration frequencies showed that there was no difference from mean donor values for patients 5 and 6, while for patient 7 essentially all the frequencies exceeded the controls significantly ($P<0.05$). The analysis of cellular distribution was made for frequencies of total aberrations, chromatid aberrations and chromatid fragments. For healthy donors, all the three end-points gave a non-poissonic pattern; the same was found for patients 6 and 7; in patient 5, on the contrary, all the distributions were poissonic. These results are insufficient to reveal an end-point permitting to distinguish between chromosome radiation responses of the patients and healthy persons. However, the data obtained for patient 7 suggest that the further investigation might be more fruitful.

ADAPTIVE RESPONSE

To study the ability of lymphocytes to produce the AR, the blood samples were exposed to the adaptive dose 0.05 Gy, then the cultures were set, stimulated and after 48 h incubation exposed to the challenge dose 0.5 Gy. This schedule of irradiation had been tested in our laboratory and proved to give a good reproducibility of the results of AR studies (3). The obtained data are shown in Table 3. If an aberration frequency induced by both the doses appeared significantly less than that induced by the challenge dose only, it was regarded as a positive AR. It can be seen from the table that the AR was observed for most of the investigated end-points in healthy donor 3 and in patient 7. In donor 2, on the contrary, a sensitizing effect of the adaptive dose was detected. For donors 4, 5 and 6 there were no differences between experimental alternatives.

Table 3. Data on the AR induction. Comparison of aberration frequencies induced by challenge dose only (0C) and by adaptive and challenge doses (AC). In brackets, standard errors. #, AC exceeds 0C significantly; *, 0C exceeds AC significantly ($P<0.05$).

3	0C	48(6)	88(11)	3(2)	0	3(2)	3(2)	85(11)	75(11)	10(4)
	AC	28(5)*	40(7)*	0	0	0	0	40(7)*	36(8)*	4(2)
4	0C	48(7)	79(12)	2(2)	2(2)	0	0	78(12)	59(10)	19(6)
	AC	52(5)	81(10)	5(2)	2(2)	2(2)	2(2)	76(10)	69(9)	7(3)
5	0C	47(7)	76(9)	2(1)	2(1)	0	0	74(8)	67(8)	7(3)
	AC	48(7)	100(10)	7(3)	5(2)	2(1)#	1(1)	93(10)	89(9)	11(3)
6	0C	42(6)	99(10)	4(2)	1(1)	3(2)	3(2)	95(10)	86(9)	9(3)
	AC	50(4)	92(7)	3(1)	2(1)	2(1)	1(1)	89(7)	87(7)	3(1)
7	0C	72(4)	197(14)	19(4)	12(3)	7(3)	5(2)	178(13)	154(12)	24(5)
	AC	52(8)*	98(15)*	4(3)*	2(2)*	2(2)	0*	92(15)*	83(14)*	9(5)*

The analysis of cellular distribution of aberrations showed that the AR observed in donors 3 and 7 was associated mainly with a decreased number of aberrant cells. Also, it seems noteworthy that for these two donors, and only for them, non-poissonic distributions obtained for aberrations induced by the challenge dose "give way" to poissonic distributions in the case of exposure to both adaptive and challenge doses. Conceivably this observation might be useful for understanding of the AR mechanisms. As to the question whether the examined patients can be distinguished from healthy persons by their ability to the AR induction, of course it cannot yet be answered basing on the above preliminary results, and needs further work.

CONCLUSION

A preliminary evidence has been gained that, in donors with enhanced skin radiosensitivity, lymphocyte radiosensitivity is also increased. This increase reveals itself in some features of "spontaneous" aberration level, and in elevated yield and shifted distribution of chromosome aberrations induced *in vitro* at the G_0 (and probably also G_2) stage.

INFLUENCE OF AGE, SEX AND LIFE STYLE FACTORS ON THE SPONTANEOUS AND RADIATION INDUCED MICRONUCLEI FREQUENCIES

Di Giorgio, Marina; Nasazzi, Nora; Heredia M. Laura.
Ente Nacional Regulador Nuclear
ARGENTINA

SUMMARY

Several endpoints have been used for monitoring human populations for environmental or occupational exposure to genotoxic agents, particularly ionizing radiation. The cytokinesis-block micronucleus (MN) assay in peripheral lymphocytes is a reliable method for assessing radiation induced chromosomal damage (DNA breaks and mitotic spindle disturbances) and thus, a suitable dosimeter for estimating in vivo whole body exposures.
To further define the use of this assay in Biological Dosimetry, a study to determine the influence of age, sex and life style factors (smoking habit) on the spontaneous and radiation induced MN frequencies was performed.
The estimation of MN frequencies was analyzed in lymphocytes cultures from 50 healthy donors aged between 4 and 62 years. On the basis of their smoking habit they were divided into 2 groups. A fraction of the sample was irradiated in vitro with γ rays in the range of 0.35 Gy to 4 Gy.
A statistically significant influence on the spontaneous MN frequency was observed ($R^2 = 0.59$) when the variables age and smoking habit were analyzed and also a statistically significant influence on the radiation induced MN frequency was obtained ($R^2 = 0.96$) when dose, age and smoking habit were studied. Sex did not influence MN variability significantly but there was a greater dispersion in the results for females when compared to males, possibly due to the loss of X chromosomes. The comparison of the data from smoking to non smoking donors supports the convenience to take into account the smoking habit for estimating in vivo whole body exposures to γ rays for doses below 2 Gy.

INTRODUCTION

Since Countryman and Heddle (1) first reported the induction of MN in human peripheral lymphocytes, the MN test has been broadly used to detect clastogenic effects (chromosome breaking) and aneugenic effects (effects on mitotic spindle resulting in abnormal segregation of chromosomes after nuclear division) due to chemical and physical (ionizing radiation) agents and thus, a suitable dosimeter for the evaluation and monitoring of genotoxic exposures in vivo and in vitro (2).
Scoring of MN in cytokinesis blocked binucleate peripheral blood lymphocytes is a relatively easy and fast procedure used as an alternative biological dosimeter to the conventional technique of analyzing unstable chromosomal aberrations (dicentrics + rings) for assessing radiation induced chromosomal damage, being particularly useful in the case of large scale radiation accidents.
MN are derived from acentric fragments or whole chromosomes that lag behind at anaphase and failed to become incorporated into either of the two daughter nuclei during cell division. Studies employing inmunofluorescence staining of kinetochores in MN with antikinetochore antibodies (3) have provided evidence that radiation induced MN are predominantly derived from acentric fragments.
After a genotoxic insult, only those cells that divided can express MN. Fenech and Morley (4) have developed a cytokinesis blocked method using cytochalasin B, which enables scoring of MN only in binucleated cells that have completed the first nuclear division (second interphase). Cytochalasin B inhibits cytoplasm division after nuclear division, resulting in binucleated cells.
For the purpose of Biological Dosimetry, the recognition of radiation induced changes in the cytogenetic status requires an adequate knowledge of the spontaneous MN frequency.
The mean spontaneous frequency for a pool of healthy donors previously obtained in our laboratory was 0,013±0,008 (5). This high spontaneous MN frequency shows a large interindividual variability. Some authors suggest that the variability is due to factors such as age, sex and life style conditions (smoking habit).
The objective of our work has been to evaluate the behaviour of MN dosimeter in the low dose range, analyzing the influence of the so called "confounding factors": age, sex and smoking habit on the spontaneous and radiation induced MN frequencies in order to characterize the extent of the application of this dosimeter, considering the confounding factors in the accidental overexposure dose assessment.

MATERIALS AND METHODS

The MN frequency was estimated on 81 peripheral blood lymphocytes cultures from 50 healthy donors ranging between 4 and 62 years, divided into two groups according to their smoking habit; age and sex. A fraction of the blood sample was irradiated in vitro with gamma rays from a Co-60 source (PICKER C4M60) ranging from 0.35Gy to 4Gy, with a mean dose rate of 0.70Gy/min.

Culture method: 0.2 -0.4ml of whole blood was incubated with 8ml of RPMI 1640 medium adding 20% (v/v) foetal calf serum for 72h. at 37°C. Cellular division was stimulated with phytohemagglutinin P (PHA P, 1μg/ml, Difco). After 44h. cytochalasin-B was added to a final concentration of 4.5μg/ml, in order to block cytokinesis. After 72h. of incubation, cells were centrifuged and treated with hipotonic solution (Iskandar method) in order to preserve the cytoplasm. The cells were fixed with methanol/acetic acid (3:1) and stained with 5% Giemsa (pH 6.8).

MN frequency was established evaluating 500 to 2500 binucleated cells per sample and per dose point. The criteria of Fenech (6), were applied for the identification of binucleated cytokinesis blocked cells and MN.

Statistical methods: In order to assess the age, sex and smoking habit influence on the spontaneous and radiation induced MN frequencies, two different evaluation methodologies were applied to the data:

I) Multiple linear regression model on transformed data:

MN frequencies were transformed by the natural logarithm to reduce non linear relationships among the frequencies and to reduce non normality in the data, both assumptions of this analysis.

The linear regression model can be expressed as: $y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \beta_4 X_4$

II) Poisson regression model. This is an alternative model (7) that seems to apply well to rare events such as MN induction, which follows a Poisson distribution. The Poisson regression model can be expressed as:

$y = e^{\beta 0 + \beta 1 X1 + \beta 2 X2 + \beta 3 X3 + \beta 4 X4}$

being for model I and II:

y = MN Frequency

β_0 = Spontaneous Frequency

β_1 , β_2 , β_3 and β_4 = Estimated Parameters

X_1 = Dose (0Gy - 4Gy)

X_2 = Age (4 - 62 years)

X_3 = Sex (0: Male - 1: Female)

X_4 = Smoking Habit (0: Non Smoker - 1: Smoker)

In order to assess the age influence on the spontaneous MN frequencies, a linear regression was applied.

Calibration curves for smoking and non smoking donors were fitted by applying an iteratively reweighted least square method, where the weight is the variance. The analysis of MN distribution in binucleated cells was carried out using the Papworth "u" test and the variance/mean relationship (σ^2/y). The heterogeneity factor and the variance/mean relationship were applied to correct the coefficient errors of the calibration curves and the Poisson variance associated with the experimental data respectively.

RESULTS AND CONCLUSIONS

Using a linear regression model, the age influence on the spontaneous MN frequency was analyzed, taking the data as a pool and differentiating smokers from non smokers (Fig.I). The results obtained, clearly suggest a significant positive correlation ($p < 0.0001$) of the spontaneous MN frequency with age. Data analysis considering two arbitrarily chosen groups: donors from 25 to 41 years and donors from 42 to 62 years, suggests that the differences observed due to the age on MN frequencies, between both groups, are smaller than the differences observed due to the smoking habit condition and that the smoking habit condition increases three times the frequency of MN with respect to non smoking condition, excluding donors under 25 years in this analysis.

The above mentioned facts justified the study of the dose response relationships for smoking and non smoking donors. The fitting of both curves resulted in a linear quadratic model, according to the following equations:

$y = c + \alpha D + \beta D^2$, where

y = MN frequency for the evaluated dose

D = dose in Gy

Coefficient errors were conveniently corrected taking into account overdispersion.

a) non smokers:

$c = 1{,}14 \cdot 10^{-2} \pm 0{,}14\ 10^{-2}$

$\alpha = (2{,}29 \cdot 10^{-2} \pm 0{,}73 \cdot 10^{-2})$ 1/Gy

$\beta = (3{,}08 \cdot 10^{-2} \pm 0{,}28 \cdot 10^{-2})$ 1/Gy^2

$\chi^2 = 53{,}3$ DF = 24

b) smokers:

$c = 2{,}32 \cdot 10^{-2} \pm 0{,}19 \cdot 10^{-2}$

$\alpha = (3{,}33 \cdot 10^{-2} \pm 0{,}79 \cdot 10^{-2})$ 1/Gy

$\beta = (2{,}28 \cdot 10^{-2} \pm 0{,}45 \cdot 10^{-2})$ 1/Gy^2

$\chi^2 = 57{,}22$ DF = 27

The analysis of the parameters obtained shows that the calibration curves intersect at the 2Gy dose point and then joint. From a preliminary comparison of the data from smoking and non smoking donors, it seems appropriate to increase the sample for donors ranging from 0Gy to 2Gy in order to evaluate the significance of the difference observed between both curves.

The analysis of MN distribution in cytokinesis blocked cells, both for spontaneous and radiation induced MN was carried out, using the Papworth "u" test and the variance/mean ratio in order to compare with the Poisson

distribution. The observed trend is: while the spontaneous MN frequencies do not differ significantly from the expected Poisson distribution, the radiation induced frequencies are overdistributed. Both, multiple linear regression and Poisson regression models were applied to the data base in order to asses the age, sex and smoking habit influence on the spontaneous and radiation induced MN frequencies. It was observed a significant positive correlation (R^2 =0.59) of the spontaneous MN frequencies (dependent variable) with the age and smoking habit (independent variables). Furthermore, a positive correlation (R^2 = 0.96) of radiation induced MN frequencies with the dose, age and smoking habit was observed too. Multiple linear regression performed better than Poisson regression in the case of spontaneous MN frequencies analysis while Poisson regression resulted more appropriate in the case of radiation induced MN frequencies.
Sex did not influence MN frequencies significantly, but it was observed a wider dispersion of the results for females compared to the one observed on males possibly due to the loss of X chromosomes in elderly females.
These results suggest that the confounding factors: age and smoking habit have a statistically significant influence on the spontaneous and radiation induced MN frequencies, being the smoking habit the strongest confounding factor. Additionally, the difference observed between smoking and non smoking calibration curves supports the convenience of taking into account the smoking habit for estimating in vivo whole body exposures to γ rays for doses below 2Gy.

MAJOR SCIENTIFIC TOPIC NUMBER 4.3 (see page 7)

ABSTRACT (See instructions overleaf)

The paper deals with absorbed doses determined on the basis of chromosomal aberrations in lymphocytes of 139 examinees, being residents of Zhlobyn area at the time of Chernobyl accident. They remained continuously there for another at least three months. Chromosomal aberrations in 25 230 cells been scored and by comparison with control subjects, the dicentric plus ring and excess acentric fragment frequencies are higher for these persons who worked in Zhlobyn zone.

Obtained results were compared with results of surface and human contamination monitoring program. Results of urine bioassay and whole body counter measurements are presented as well.

The results obtained proved necessity of defining criteria for further bio-medical surveillance.

ESTIMATION OF CYTOGENETIC RISK IN THE PROCESS OF NON-DESTRUCTIVE TESTING OF WELDS

A. Fučić [1], V Garaj-Vrhovac[1], D. Kubelka[1] and M. Novaković[2]

[1]Institute for medical research and occupational health,Zagreb,Croatia
[2]Ecotec ,Zagreb, Croatia

INTRODUCTION

In the process of non-destructive testing of welds the workers are very often exposed to both X-ray or gamma radiation and ultrasound , in dependence with the requirements of the test method applied.Despite training courses and awareness of workers that protection is necessary in the USA has been developed a special audit program for assuring radiation safety during radiographic examination operations (1). Such program can be actually implanted in every company which is licensed for weld testing activities. The advantage of this program is also that the number of radiographic inspections is controlled in order to prevent possibility of accidental exposures as the results of fatigue (2).

The estimation of dose based on chromosomal aberration analysis is a relible and generally accepted method, and it indicates genome damages earlier than any other method used in medicine. However, according to available literature data it could be seen that in the cases of overexposure of radiographers detected by film dosimeter only skin changes are quite often diagnosed even without heamatologocal analysis (3). Since no biodosimetrical study so far provides data on genome damages of radiographers caused by combined exposure to gamma irradiation and ultasound the aim of this study was to compare the effects of the exposure to ionizing radiation alone and combined with application of ultrasound during the process of weld testing.

SUBJECTS AND METHODS

Twenty three industrial radiographers working on testing of welds for an average of 10 years were chosen for cytogenetic examination.During radiography examinees used the ^{192} Ir source of ionizing radiation which had activity of 1,85 TBq.In the case of application of ultrasound the frequency ranged from 0,1MHz to 35 MHz.A control group included 20 male subjects from the general population, aged 35-45 years old. Among radiographers and control group those with recent X-ray exposure for diagnostic purposes and drug treatment were excluded from the study. Examined subjects did not exceed permited annual dose of 50 mSv measured by film dosimeter.

The chromosome aberration assay was carried out on the cultures of phytohemagglutinin-stimulated blood lymphocytes. Fixation of cultures and preparation of slides were carried out according to conventional methods (4).Two hundered well-spread and complete metaphases were analyzed for every person and results are presented as percentages.

RESULTS AND DISCUSSION

A group of 23 subjects occupationally exposed to ionizing radiation and ultrasound during the process of non-destructive control of welds was analysed using the cytogenetic method of chromosome aberration assay. The number of structural chromosome aberrations such as dicentric, ring, triradial and tetraradial chromosomes was significantly increased in exposed subjects compared to the control group. Table 1 shows that the frequency of unstable chromosome aberrations such as dicentric, triradial and tetraradial chromosomes are more frequent in cases of combined exposure to ionizing radiation and ultrasound than ionizing radiation alone.This finding corresponding with the data pertaining to occupational exposure to ultrasound emphasizes the importance of acceptaning and considering the ultrasound as a source of radiation with possible health consequences (5).

It can be concluded that in cases of combined occupational exposure estimation of dose received by radiographers using film dosimetry should be accompanied by cytogenetic monitoring because personal dosimeter for ultrasound has not been constructed yet.In order to minimize health risk biomonitoring can detect possible synergistic action of both ultrasound and ionizing radiation which is not measurable by any physical method.

INTRODUCTION

Nearly 3.5% of the reactor core have been released from the destroyed Unit-IV of the Chernobyl NPP into environment, including isotopes of uranium and transuranium elements. Plutonium radionuclides are among them. This part of radioactivity in the form of fuel particles of various dispersity has deposited mainly within the 30-km zone. However, as the investigations have shown, alpha-emitting nuclides of the Chernobyl origin have been found in Poland, Sweden, Bulgaria ands other countries [1]. In the composition of fuel particles plutonium displays low migration mobility. Partially they are in the soluble form and by the metabolism chains find the way into the organizm. The determination of plutonium in the organizms of the residents of the Gomel Region has shown, that its content exceeds the level attributed to the radioactive depositions as a result of the nuclear weapons test in the atmosphere. The internal doses, produced by plutonium account for fraction of per cent of the total irradiation of humans by natural radioactive sources. Inclusion of the possible contribution of transuranium elements into the formation of the distant after-effects should be taken into account, because in the process of the biogenic transformation the release of plutonium from the fuel particles into the mobile forms is possible. It increases the conversion coefficients in the chain soil-organizm and respectively the contribution into the radiation dose [2].

The existing methods for in-vivo determination of plutonium in organizm on the basis of the analysis of urine or blood don't enable the evaluation of this isotope in organizm within the acceptable accuracy, as the obtained values reflect to a considerable extent the transit function of plutonium, the value of which varies considerably depending on its additional ingress into organizm by inhalation or with food.

In recent years hair are used as the test-tissues in solving the sanitary problems. It has been shown, that hair can be both the tracer test-tissues in evaluation of the ecological situation and quantitative indicator of its content in organs and tissues of some microelements and radionuclides [3].

MATERIALS AND METHODS

The collection of hair in hair-dresser's shops of the populated areas of the Gomel Region and Minsk has been carried out. The part of the hair samples has been taken in children from the hospital of the Institute of Radiation Medicine for a check-up. The collected material has been studied at the individual and population levels. The chemical preparation of hair for the analysis has been conducted in agreement with the recommendations of IAEA [4].

The determination of plutonium after radiochemical extraction has been carried out on a alpha-spectrometer Aladin, using plutonium-236,242 isotopes as an internal standard. The method of the solid-state track detector by fission fragments has been also used. The irradiation has been conducted with the neutron flux $2 \cdot 10^{15}$ n/cm^2 on IRT-M reactor.

RESULTS

The first studies on the evaluation of the total content of the fissile radionuclides in hair of residents of populated areas in the Gomel Region (Khojniki, Bragin, Narovlya, Chechersk) have been carried out in 1986 and have shown, that the density of the tracks of the fission fragments is by 2 - 3 orders of magnitude greater, than in hair of the residents of Minsk. However, the impossibility to differentiate the tracks of natural uranium-235 and plutonium-239 has required the improvement of the method of the radiochemical extraction of plutonium-239 from hair [5].

After radiochemical extraction, the analysis with the use of the track method and alpha-spectrometry has shown, that the specific activity of plutonium-239 in hair of the residents of the territories suffering after the accident at the ChNPP is by two and more orders of magnitude greater than the content of these radionuclides in organs and tissues of the residents of the Earth, dependent on the global fall-outs as a result of the nuclear weapon tests, including the plutonium in hair of the workers of plutonium in the plutonium industry equal to 0. mBq/kg [6,7].

Thus, for instance, its content in hair of some individuals has reached 20.0 Bq/kg (the resident of Bragin, M.Z.M., born in 1963). High values of plutonium-239 content in hair of children have been found out (Table 1). The high level of the accumulation of plutonium in the hair of children is explained by the age peculiarities of metabolism of children organizm, which is supported by the experimental studies. In examination of the

distribution of plutonium-239 in animals the primary effect of age on the level of the ingress of plutonium into the fur has been shown: this process proceeds more intensively in young animals [8].

As investigations show, in recent years the reduction of concentration of plutonium in hair has took place. However. it should be noted, that individual high concentrations of plutonium-239 in residents of Bragin is seen systematically ($17.7 \cdot 10^3$ mBq/kg) alongside with the reduction of the average values, including the high concentration of plutonium in hair with relatively low densities of contamination of soils with plutonium (the Vetka town). It needs additional studies.

In order to determine the possibility of using hair as test-tissues for the in-vivo evaluation of the content of plutonium in human organs and tissue, in 1994 the content of this radionuclide in hair, liver, lung and ribs of the residents of the Gomel Region killed in the fatal accidents has been analysed (Table 2).

It follows from the given data, that the average values of the concentration of plutonium in organs and tissues of the residents of the Gomel Region on the average are by an order of magnitude higher in comparison with the residents of the European countries and caused by the global fall-outs. The range of variations between the maximum and minimum values of concentration are the most important. If the ratio between the maximum and minimum values in liver, lung and ribs of the residents of the European countries have been within the limits of 2 - 2.5 times, for the residents of the Gomel region these variations have been higher: for liver, for instance, they have reached 22 and for lung 110. It results from the uneven deposition of plutonium in the areas after the accident at the ChNPP in comparison with its deposition after nuclear weapons tests.

In analysis of the correlation between the content of plutonium in hair and inner organs, the statistically reliable dependence has been determined only between the content of plutonium in hair Ab) and ribs (Ap), which is approximated by the expression $Ap = 0.6 \cdot Ab + 4$. The correlation coefficient is 0.8 with the significance level 0.1 (Fig.).

Proceeding from the established dependence, the concentration of plutonium in skeleton of adult humans with the content in hair $19.4 \cdot 10^3$ mBq /kg) in 1987, has reached $13.6 \cdot 10^3$ mBq/kg. It is 30% of the permissible level of the content of plutonium in the skeleton of professional personnel (P_{CA}). The evaluation of the dependence between these values in children needs revision.

CONCLUSION

On the basis of the obtained results it is evident, that hair can be both the test-tissue in evaluation of the dynamics of the ingress of plutonium into organizm and the quatitative indicator of its content in skeleton. The later allows to organize the in-vivo observation over the process of migration of the radionuclides in the bioshere and its contribution into the internal dose of irradiation upon its ingress into organizm.

MAJOR SCIENTIFIC TOPIC NUMBER 3.5 (see page 7)

The last decade was noted with significant development of retrospective dosimetry methods. This qualitative and quantitative growth was prompted by attention to problems of dose reconstruction in context of Chernobyl accident. It is expected that an acute need in tools for assessment of individual doses would be met with variety of biological, instrumental, and analytical approaches. Unfortunately, enthusiasm connected with use of methods of retrospective dosimetry is not quite justified. There are still lot of challenges on the way from acceptance of principal applicability of methods to widespread practical reconstruction of individual doses.

Both instrumental and biological methods are endowed with similar difficulties. One of shortcomings is caused by an existence of sensitivity threshold. Another challenge is connected with need of development of adequate methods for conversion of dose determined *in vitro* to dose received by individual. Finally, recent investigation have revealed a great importance of artifacts for correct determination of doses.

Although methods of analytical dose reconstruction do not have a threshold, an accuracy of results depends a lot on different factors. Another typical difficulty in analytical dose reconstruction is connected with lack of primary information. These two problems are inevitably connected and should be treated together.

Another important challenge in field of retrospective dosimetry is problem of combination and assessment of results gained by different methods. Both cross-validation of various techniques and common use of dose assessments achieved by different means will assist in production of reliable values of individual doses applicable for practical use in risk assessment.

RETROSPECTIVE RADIATION DOSIMETRY USING OPTICALLY STIMULATED LUMINESCENCE ON NATURAL AND SYNTHETIC MATERIALS.

L.Bøtter-jensen, B.G. Markey and N. Agersnap Larsen
Risø National Laboratory
DK 4000 Roskilde, Denmark

INTRODUCTION.

Optically stimulated luminescence (OSL) techniques especially aimed at using natural materials for retrospective reconstruction of accidental radiation doses in populated areas were developed and studied at Risø as part of an EU research project. Quartz and feldspars separated from building materials, such as bricks and tiles, in addition to porcelain items had their OSL signals measured using different light sources for stimulation to assess radiation doses received by the material. Radiation doses were also evaluated from OSL measured directly on unseparated samples i.e. directly from the surface of brick and tile materials.

APPARATUS AND TECHNIQUES.

The apparatus used for the experimental work were mainly OSL units developed as attachments to the existing automated Risø TL reader and include monochromators for obtaining wavelength resolved luminescence measurements. An automatic OSL scanning instrument was also developed with the aim of being able to perform continuous OSL scanning measurements of brick cross-sections, allowing radiation depth dose profiles to be measured directly.

The basic OSL unit developed contains light sources for both green light and infrared stimulation, enabling measurements of OSL signals from both quartz and feldspar samples. (Bøtter-Jensen and Duller , 1992).

A compact module was developed that allows for the monochromatic illumination of samples in the wavelength range 380 to 1020 nm, enabling the measurement of energy resolved OSL (Bøtter-Jensen et al. 1994 a, Bøtter-Jensen et al. 1994 b). A schematic diagram of the combined OSL attachment is shown in Fig. 1A.

A continuous OSL core scanner system was developed that allows the optical sensors to be moved across either sediment or brick cores. The core is scanned using an excitation slit beam of 1.0 mm x 1 mm which determines the resolution of the system. OSL dose normalization is made either by using short wave UV light or exposing the brick cores to a Cs-137 gamma field and afterwards scanning the OSL sensitivity across the brick profile. A schematic diagram of the OSL scanner system is shown in Fig. 1B.

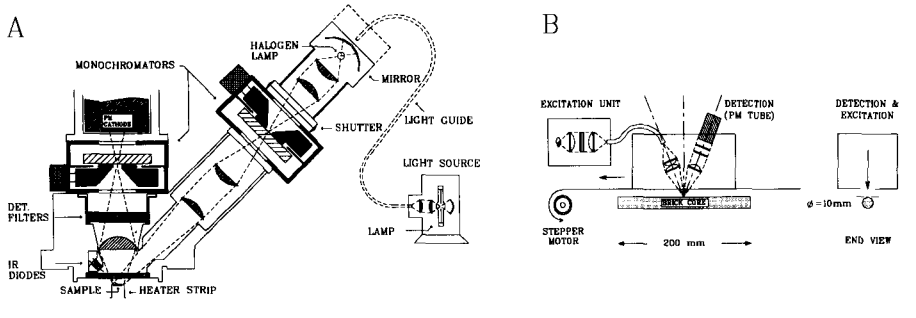

Fig.1.
(A) Schematic diagram of the OSL attachment showing the excitation lamp system with monochromators mounted on both the excitation side and the detection side.
(B) Schematic diagram of the automatic OSL brick core scanning system: the excitation beam is 1 mm wide.

OSL DOSIMETRY CHARACTERISTICS OF QUARTZ.

An attempt to determine the lower detection limit for OSL stimulated with green light on fired quartz was made by obtaining the dose response curves for a variety of quartz samples extracted from different specimens such as bricks, burnt stones and clay. An example of OSL versus dose for a sensitive quartz extracted from burnt clay obtained using the multiple aliquot method is shown in Fig. 2A. As seen, the lowest detectable dose for this material is well below 1 mGy. (Bluszcz and Bøtter-Jensen, 1995).

Quartz grains were extracted from a 40 years old brick and the absorbed dose was determined by GLSL using the additive dose technique. As seen from the dose response curve in Fig. 2B the dose was estimated to be about 200 mGy which is in very good agreement with the expected value based on an annual dose rate of about 5 mGy/y from the environmental radiation and the natural radioactivity in a typical brick. For this particular brick the lower detection limit for an additional accidental dose would be of the order of 20 mGy (10% above the background).

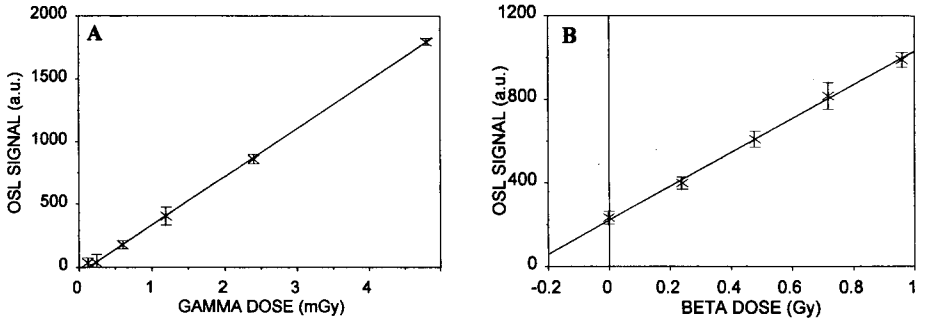

Fig.2.
(A) OSL versus ^{60}Co gamma dose (multiple sample technique) for quartz extracted from a burnt stone.
(B) OSL growth curve (multiple sample technique) for quartz extracted from a 40 years old brick.

OSL DOSIMETRY CHARACTERISTICS OF UNSEPARATED BRICK MATERIALS.

Depth-dose profiles in bricks were determined by measuring the OSL signals directly from the unseparated material across the brick using the automated OSL scanning system (Bøtter-Jensen et al., 1995). Examples of the normalized OSL as function of depth into brick material are shown for a ^{137}Cs irradiated bricks in Fig. 5A and 5 B. The fitted exponential curve also shown, correspond well with the expected attenuation in the brick material.

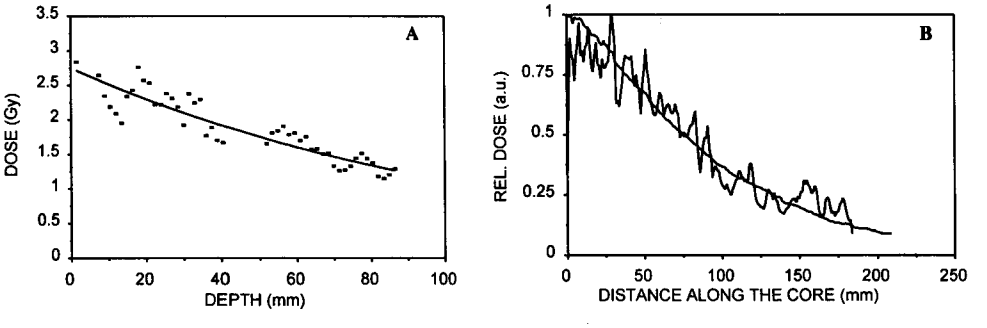

Fig.5.
(A) Dose versus depth into a brick irradiated with ^{137}Cs gamma radiation from one side. Measurements were made using green light OSL on 8 mm x 1 mm slices cut from a core through the brick.
(B) Relative depth dose profile into the same brick from ^{137}Cs gamma radiation exposed from one side and subsequently measured with the automatic OSL core scanner. The attenuation curve calculated by the Monte Carlo code MCNP is shown for comparison.

OSL DOSIMETRY CHARACTERISTICS OF PORCELAIN.

In view of the relevance of using OSL on porcelain in the field of retrospective dosimetry, we studied materials from a collection of mass produced ceramics that we consider would be representative of materials commonly found in many households. (Bøtter-Jensen et al. 1996).

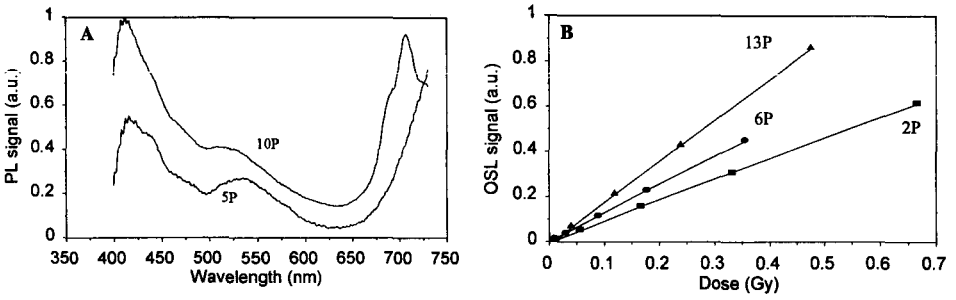

Fig.6.
(A) PL spectra (PL versus wavelength) for two bulk porcelain samples. The emission from Al_2O_3 is clearly demonstrated by the typical peaks at 410 and 700 nm.
(B) OSL versus ^{60}Co gamma dose for three different porcelain samples.

The time stable photoluminescence (PL) emission spectra were recorded with UV stimulation produced by a halogen lamp, filtered with U-340 filters (peak transmission at 340 nm). Fig. 6A shows PL spectra obtained from 2 different porcelain samples. The PL spectra compared with that obtained from Al_2O_3:C TL material, which has been shown to be an extremely sensitive OSL dosemeter material (Poolton et al.,1995).

Measured dose response curves, i.e. OSL versus ^{60}Co gamma dose, are shown for three porcelain samples in Fig 6B. For most porcelain samples the OSL signal increases linearly from 10 mGy up to 20 Gy and shows a further sublinear increase up to at least 200 Gy.

AN OVERVIEW OF RETROSPECTIVE OCCUPATIONAL DOSIMETRY AT BNFL

A V KITE[1] and R W ANDERSON[2]

[1] BNFL, Risley, Warrington, Cheshire, WA3 6AS, UK

[2] BNFL, Sellafield, Seascale, Cumbria, CA20 1PG, UK

INTRODUCTION

During recent years a key area for occupational dosimetry in BNFL has been the retrospective review of recorded doses, particularly those generated in the 1950s and 1960s when the nuclear industry and many of the associated methods of work were in their infancy. The event which triggered this interest in retrospective dosimetry was the litigation (Reay and Hope versus British Nuclear Fuels plc) which alleged that pre-conception paternal occupational radiation exposure had been a material contributory cause of leukaemia and lymphoma in children. While in the event the cases failed, the detailed investigations carried out in support of the litigation have provided a wealth of knowledge to enable retrospective judgements to be made regarding both the efficiency of the monitoring systems in use in the early years of the nuclear industry and ultimately the validity of the recorded doses. While initially applied to the litigation cases, this knowledge base has subsequently been developed and used for other current applications including the industry-based Compensation Scheme for Radiation Linked Diseases and epidemiological studies into the effects of occupational exposure on the workforce. The paper provides an overview of the main findings in relation to retrospective occupational internal and external dosimetry and the key applications of litigation, Compensation Scheme and epidemiology.

DOSIMETRY REVIEW

A major review of occupational dosimetry systems used at Sellafield since the start of site operations in 1950 has been carried out in BNFL over recent years prompted by the litigation referred to above. The main conclusions from this review have been incorporated into scientific papers either published (1), (2) or in preparation (3), (4) and are summarised below. The implications of the dosimetry review on the applications of litigation, Compensation Scheme and epidemiology are shown in the attached table.

External Radiation Dose

Photon Dose

Film badges of various designs over time have been used for routine personal monitoring and the measured doses recorded in individual's dose records since the start of operations. The primary reason for monitoring was that of control of radiation exposure by comparison with contemporary standards. The review of recorded doses took into account the performance of the various film badge designs used and the characteristics of the radiation fields in which they were worn, along with the dose recording conventions used. The performance of the film badges used is considered to be satisfactory,with the main uncertainties in recorded dose associated with: (a) the limitations of the early film badge designs in use prior to 1963 which, combined with the varied photon energy spectra on the site, would result in positive or negative bias depending on the working area; (b) the general contribution of 'storage dose' from raised background levels on the site while the films are stored between shifts; (c) the proximity of general levels of occupational dose to the detection threshold of the badges, particularly in the 1980s and 1990s; and (d) the procedures used in the event of lost or damaged badges which have varied from not entering dose estimates in the early years to using dose estimates based on the pro rata to the annual dose limit in later years. Overall, the cumulative recorded doses are judged to be within a factor of two of the true dose and are more likely to be an overestimate than an underestimate of dose.

Neutron Dose

The main sources of neutrons on the site were the reactors and the plants processing plutonium extracted from irradiated fuel. The areas of neutron exposure were generally limited and localised by shielding, particularly on the reactors, and while portable neutron detectors were used for operational control, personal neutron dosimetry has been a very difficult technical area (5) because of the complex and varied nature of the neutron fields on the site. It is now recognised that the dose records of some workers on the BNFL sites, particularly at Sellafield, do not fully reflect the likely neutron doses received, with the potential for unrecorded neutron dose arising from:

(a) the lack of availability of a suitable personal neutron dosemeter in the period 1950-59 when plants like the Windscale Piles and the associated plutonium processing plants were in operation and would have been expected to make a significant contribution to the overall external radiation dose of a small part of the workforce,

(b) the poor performance and relatively limited issue of early neutron dosemeters in use from 1959-78, resulting in doubts regarding the validity of the neutron doses recorded for workers on the reactors (the Magnox stations at Calder Hall and the prototype AGR) and the plutonium processing plants operating during this period.

Internal Radiation Dose

Doses from intakes of radioactive materials have generally been much smaller than external doses. However, for some workers internal doses have been significant, mainly from intakes of plutonium and uranium. Unlike external doses, early records for individuals do not generally contain assessed doses, but rather the "raw" results of monitoring, for example activity content of biological samples . Control of exposure was exercised by comparison of the results of monitoring with investigation levels and action levels set directly for these parameters. Conversion to dose was rarely necessary. Retrospective dose assessments are therefore carried out for litigation, compensation, or epidemiological purposes using modern methods and models in conjunction with the recorded results of monitoring and sampling. The principal difficulties experienced that are particular to the early historical data are the poor quality of the measurements, and the lack of detailed and reliable work histories for individuals. The poor quality of the measurements arises both from the comparative lack of refinement of the analysis methods in the 1950s and 1960s, and of the collection methods(6). These in turn led to high limits of detection, and frequent contamination of samples by non metabolised material. The lack of good work histories for individuals leads to difficulty in interpretation of samples since conversion of excretion history to dose relies on assumptions concerning mode and timing of intake. The uncertainties in assessed internal doses are therefore generally much greater than those for external doses.

SUMMARY

Reconstruction of occupational radiation doses in BNFL has been shown to be feasible but has required a significant level of technical resources to cater for the complexity and range of the plants involved and is generally limited in scale of use because of the key requirement for detailed work history information in the dose reconstruction process. The main dose reconstruction work required in BNFL has involved neutron doses for litigation and Compensation Scheme purposes, reflecting the historical difficulties associated with personal neutron dosimetry. Early indications are that the level of reconstructed neutron dose is, in general, small compared to the recorded photon dose.

TABLE - IMPLICATIONS OF DOSIMETRY REVIEW ON KEY APPLICATIONS

Area of Dosimetry	Litigation	Compensation Scheme	Epidemiology
External radiation:			
Photon dose:	Retrospective adjustments were made to the early film badge results (pre-1963) for the Gardner case-control subjects resulting in generally small changes compared to the recorded doses. The need for individual work histories limits the extent to which this is practicable.	Recorded doses are accepted as generally conservative and as a result a reasonable estimate for Compensation Scheme purposes.	Dose reconstruction is not practicable for cohort studies and is unlikely to be warranted. Further consideration of the uncertainties in recorded photon dose to epidemiological studies is warranted.
Neutron dose:	Reconstruction of neutron dose was carried out for Gardner case-control subjects with the assessed doses generally small compared to the recorded photon dose. Reconstruction represented a major technical programme requiring detailed knowledge of historical plants including the assessment of work place neutron doses through the interpretation of historical neutron measurements and the identification of worker occupancy patterns.	Reconstruction of neutron doses is being carried out for individual claims for Sellafield workers . The reconstruction process uses a set of neutron dose protocols prepared for each plant and incorporating the main features identified in the litigation section. Twelve protocols have been prepared and are now being applied; they require specific work history information for the individual and are time consuming to apply. The assessments are generally conservative and early indications are that the level of neutron dose is small compared to the recorded photon dose.	Further consideration of the implications of unrecorded neutron dose is needed but in general the level of unrecorded dose is relatively small and is likely to be of limited consequence to cohort studies involving BNFL dose records. Reconstruction of neutron dose for the Sellafield cohort is not practicable and unlikely to be warranted. Reconstruction of neutron dose for the limited numbers involved in case-control studies is feasible with development of the Compensation Scheme neutron dose protocols to remove the main areas of conservatism.
Internal radiation:			
Internal dose:	Reconstruction of the doses for the Gardner subjects was made using conservative assumptions but the doses were small compared with external dose.	Internal doses are estimated from available monitoring data using conservative assumptions to favour the claimant under a jointly agreed protocol.	Owing to the complexity and cost of internal dose assessment, and the limit to which assessments can be automated, doses are not readily amenable to cohort studies. Overall, some progress has been made recently to use internal dose data by providing confidence levels to the assessments made.

ABSTRACT (See instructions overleaf)

Most of our knowledge about the long-term effects of radiation on people comes from studies of the Japanese atomic bomb survivors. At distances over 1 km from the Hiroshima detonation, transport calculations predict a far lower fluence of thermal neutrons than that determined from activation measurements. To help resolve this discrepancy, we have performed neutron measurements at various distances from the bare critical assembly at the U. S. Army Pulse Radiation Facility for comparison with long-range transport calculations.

Neutron fluences and energy spectra were obtained using a multisphere neutron spectrometer with 12 detectors, each of which contains a BF_3-filled pulse ionization chamber. Measurements were made at distances of 715, 1084, and 1588 m from the critical assembly when the ground was very wet and at distances of 300, 1588, and 1986 m when the ground was relatively dry. Gamma-ray energy spectrum and dose-rate measurements were also made.

The shape of the neutron spectrum did not change much with distance. The ratio of thermals to fast neutrons was larger when the ground was wet. The falloff of the thermal neutron fluence with distance matches that for the thermal neutrons at Hiroshima determined from activation measurements. This suggests that some higher-energy fission-like neutrons may have escaped from the weapon. If the Hiroshima survivors were exposed to significant numbers of fast neutrons, and not just to gamma rays, estimates of the health risks from exposure to all types of radiation would be affected.

ABSTRACT (See instructions overleaf)

Thyroids of many Ukrainian people were highly exposured due to the Chernobyl accident. Because of this the problem of dose reconstruction is very important for different groups of population and especially for evacuated people.

49,360 inhabitants of Pripjat were evacuated shortly after the Chernobyl accident (most of them within 35-37 hours after the accident). During the evacuation they often passed through highly contaminated territories. According to the results of wide scale public survey (more than 10,000 questionnaire data about behaviour after the accident), only about 50% of evacuees left contaminated areas within 5 days and 30% of them stayed there for more than 30 days. Thyroid doses were estimated for the group of evacuees who were measured on the ^{131}I content in thyroid. Their individual intake functions were derived from the information about route of evacuation. The collective doses and radiation risks for thyroid cancer were assessed for different age groups on the base of these astimations.

The method for the individual thyroid dose assessment was also developed for the group of evacuees from Pripjat who were not measured. For this purpose the empirical equation was used to describe the correlation between calculated doses and behaviour parameters (place of residence in Pripjat, consumption of stable iodine and the age at the time of the accident).

STOCHASTIC MODELS FOR INDIVIDUAL EXTERNAL DOSE RECONSTRUCTION OF POPULATION EVACUATED AFTER THE CHERNOBYL ACCIDENT

INTRODUCTION

As a result of the Chernobyl accident, the residents of Pripjat and other settlements of the 30-km zone were affected by substantial amounts of radiation with the potential of delivering them significant radiation exposures before their evacuation. A reconstruction of individual doses of evacuees, including the determination of the uncertainty of the results, is of interest for epidemiological investigations. Dose rate measurements conducted in the time span between accident and evacuation and individual behavior data obtained by a questionnaire survey involving more than 30,000 evacuees allow for a reconstruction of individual external doses of a large fraction of the evacuated population. A first assessment has been reported in (1). The results revealed a large variation range for doses of different individuals, showing the importance of performing individual dose reconstructions.

This paper reports on developments and results of a second stage of individual external dose reconstruction. In particular, stochastic models based on Monte Carlo methods (2) were developed in order to determine uncertainty distributions of calculated doses from an assessment of the uncertainty of the data.

INDIVIDUAL DOSE RECONSTRUCTION FOR EVACUEES FROM PRIPJAT

In the city of Pripjat, dose rate measurements started two hours after the accident and lasted until after the completion of the evacuation two days later. They were conducted by two independent teams in intervals of 3.5 hours on the average. Figure 1 shows the position of the measurement points and dose rates measured 30 hours after the accident. Information on individual pre-evacuation histories of about 16,000 evacuees from Pripjat was obtained by a questionnaire survey (1). As indicated in Figure 1, the city was divided into eight sectors according to the measured open air doses and the evacuees were asked to reconstruct their location (indoor or outdoor, and in which sector) hour by hour until their evacuation.

The stochastic models developed for calculation of individual external doses are designed with a modular structure, separating the calculation of parameters which do not depend on individual behavior from the final computation of the individual dose. The uncertainty of the parameters are represented by frequency distributions of the parameter values. They are obtained from an assessment of data uncertainty by Monte Carlo sampling methods coded in the program PRISM (3). Taking the parameter values, the external dose for each individual is repeatedly (for example, 500 times) calculated, obtaining a frequency distribution representing its uncertainty. The individual external effective dose distribution E is calculated according to

$$E = C \cdot \sum_{h=1}^{h_{evac}} D(h,s) \cdot \Delta t \cdot L(h) \qquad \text{with } \Delta t = 1 \text{ hour.}$$

The summation extends over each hour h to the time h_{evac} the individual was evacuated; C is the conversion factor from absorbed dose in air to effective dose. The D(h,s) are uncertainty

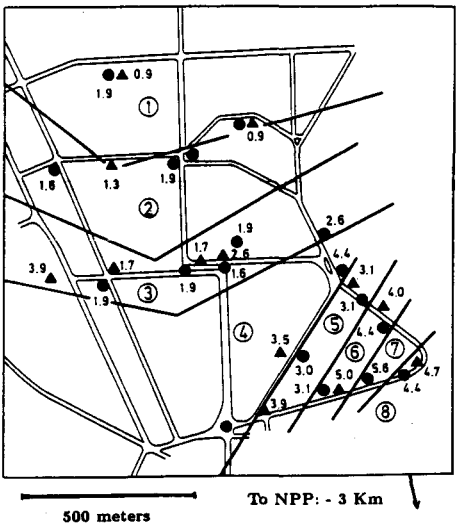

Figure 1. Plan of the city of Pripjat showing the points where dose rate measurements were performed by two independent teams (triangles respectively circles). Also indicated are dose rates in mGy/h measured 30 hours after the accident and the subdivision of the city into sectors for the questionnaire survey.

distributions of dose rate relative to reference area for the hour h and the sector s in which the individual was staying at this hour; the L(h) are location (shielding) factors appropriate for the indoor or outdoor location at which the individual had been at the hour h.

The distributions D(h,s) of dose rate relative to reference ara describe the uncertainty of the average dose rate of the sector and the variability of the dose rate within the sector. They are determined from the dose rate measurement data combined with information on the environment of each measurement point and an assessment of the uncertainties due to measurement errors and modifications by the environment. Incorporating time interpolations and Kriging methods (4) for interpolations in space in the PRISM code, the set of dose rate distributions D(h,s) is obtained. Figure 2 shows the distribution resulting 30 hours after the accident for one of the sectors of Pripjat.

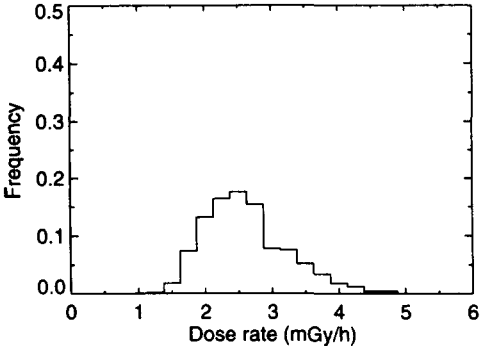

Figure 2. Frequency distribution of dose rate relative to reference area in sector 3 of Pripjat (compare Figure 1), 30 hours after the accident. The distribution reflects the uncertainty of the average dose rate of the sector and the variability of dose rate within the sector.

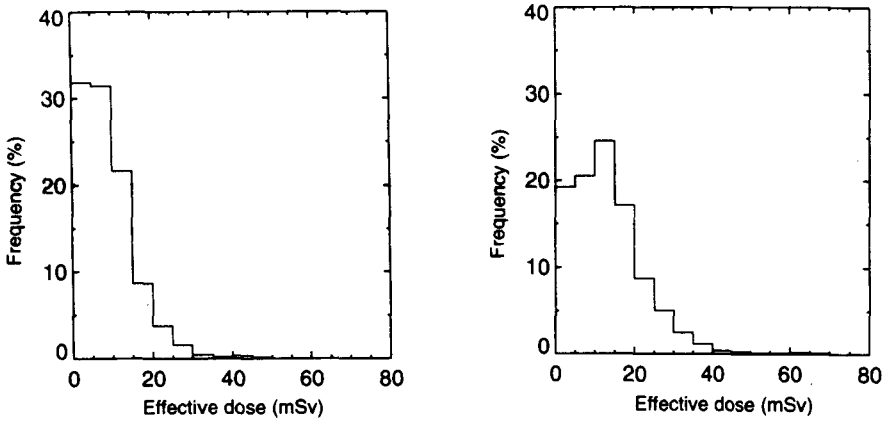

Figure 3. Relative frequency distribution of individual external effective doses of children (age group 3-7 years, left side) and adults (age group 25-55 years, right side) evacuated from Pripjat.

Location factors, defined as the ratio of dose rate at a particular indoor or outdoor location to the dose rate at a reference area (5), were calculated by Monte Carlo photon transport simulations for a specific five storey housing block typical for Pripjat. The results of separate calculations for different source configurations and energies provide a data base for estimating location factors and their uncertainty ranges. From a first analysis, for Pripjat a location factor of 0.05 with a range of 0.01 to 0.2 was estimated for indoors and of 0.8 for outdoor locations.

Based on the distributions of dose rates relative to reference area and the estimated location factors, distributions of individual external effective doses of 12,653 evacuees from Pripjat are being calculated. In a first step, deterministic calculations were performed with this data, obtaining a mean external effective dose for this population of 11 mSv, which is only slightly lower than the value of 11.5 mSv reported in (1). Frequency distributions of individual external doses for children and adults are compared in Figure 3. Children had been staying a larger fraction of time indoors, so that their external doses are generally lower.

CONCLUSIONS

The development of stochastic models which allow to determine uncertainty distributions of external effective dose individually has been discussed for population evacuated from Pripjat. Similar models are being developed for evacuees from the other settlements of the 30-km zone. The results will allow to obtain a clearer vision of values and uncertainty ranges of individual doses received by population from the near zone of the Chernobyl nuclear power plant before its evacuation.

MAJOR SCIENTIFIC TOPIC NUMBER 3.5 ..... (see page 7)

ABSTRACT (See instructions overleaf)

In the Russian Federation the areas most affected by the Chernobyl accident are the western districts of the Bryansk Region. At the time of the accident 112 thousands residents happened to live in the 'strict control zone' (SCZ with caesium-137 contamination in excess of 0.55 MBq/sq.m). Over 250 thousands of whole body measurements on caesium radionuclides contents were carried out in the SCZ and at some settlements in adjacent territory, including 150 thousands made in the first two years after the accident. 10 thousands individual measurements of exposure to external radiation were made with TLD in samples of people from settlements inhabited by 90% of the total population of the SCZ. Due to results obtained from a limited set of reliable measurements of iodine-131 in the thyroid gland made in May 1986, a method of thyroid dose reconstruction was developed. The method was employed to assess the distribution of individual thyroid doses at residents of the SCZ. With the aim of effective use of available information to reconstruct individual doses, a data bank is under development in the Institute of Radiation Hygiene. This data bank includes primary records on radiometric examinations of people and on questionnaire surveys, environmental and social information relevant to exposure conditions. Some results of individual dose reconstruction for population in the SCZ as well as examples of distributions of personal doses (individual doses ascribed to identified persons) are presented in the paper. Discussion is given on methodology of personal dose reconstruction.

RETROSPECTIVE EVALUATION OF EXTERNAL COMPONENT OF INDIVIDUAL DOSES FOR TECHA RIVERSIDE RESIDENTS

INTRODUCTION

The discharges of liquid wastes into the Techa river (1949-1956) by Mayak, first Soviet industrial nuclear facility should be listed among the most significant waste accidents. The Techa river belongs to Iset-Tobol-Irtysh-Ob river system. During only period 1949-1951, 76×10^6 m^3 of liquid radioactive wastes were discharged, with total activity of 100 PBq (1). Internal exposure of the Techa riverside inhabitants was caused mainly by the incorporation of Sr-90. The values of the dose due to Sr-90 can be estimated on the basis of the measurements of body burdens using the whole body counter. There is no possibility to determine experimentally the individual contribution of external exposure by the Techa river. The average value of this contribution for each community was estimated on the basis of the measurements of gamma dose rate along the banks of the river, on the shore within a few hundred meters of the water in specific areas of villages, and inside certain houses. Validation of these estimations and their comparison with individual data are also of considerable importance.

Recently, a method was found for individual dose assessment using tooth enamel and *Electron Paramagnetic Resonance* (EPR) spectroscopy for dosimetry. The method is based on the measurement of the concentration of radiation induced radicals CO_2^- in hydroxyapatite which is the mineral component of tooth tissues and bones. This paper presents the first preliminary results of the use of EPR method for retrospective evaluation of external component of individual doses for Techa riverside residents.

SAMPLES AND METHODS

Totally 28,000 people resided on the Techa banks during the period of massive releases. About 4,500 of them were living in the upper Techa, up to 65 km downstream of the site of radioactive release. These people received mainly external dose of irradiation from the Techa river as it was confirmed by measurements with whole-body counter (2). The residents of the middle and lower Techa (78 - 237 km) received the doses of internal irradiation mainly due to Sr-90. Twenty-nine teeth from 27 Techa riverside inhabitants were measured using EPR method. Five of them were from upper Techa. Collected teeth were extracted in accordance with medical indications. All Techa riverside inhabitants studied were also investigated using whole-body counter for Sr-90 developed at Urals Research Center for Radiation Medicine (URCRM) (3).

An important component of the method of EPR dose reconstruction is the procedure of sample preparation. The details of this procedure and experimental parameters of EPR measurements were already given in a few previous publications (4,5).

The dose reconstruction was done by the additive dose method with unweighted linear least-square-fit employing the Levenberg-Marquart algorithm. Six-five measurements, one original and four after additional irradiation in steps of 300 mGy each were used for the linear fit.

Since 1974 the large scale investigations of Techa riverside residents with body counting system SICH-9.1 (the Russian acronym) were started. The content of Sr-90 in the skeleton is determined with this equipment. The detailed description of SICH-9.1 and procedure of measurements was given in (3).

RESULTS AND DISCUSSION

The results of EPR reconstruction (doses absorbed in tooth enamel) for the Techa riverside inhabitants versus the distance between the place of permanent residence during 1949-1956 and the site of release are shown in Fig. 1. The dote line in this figure is the fit of experimental data by Gaussian, whereas the solid line is site-specific average dose from gamma emitters at the same distance from the point of release. These average external doses were taken from (2).

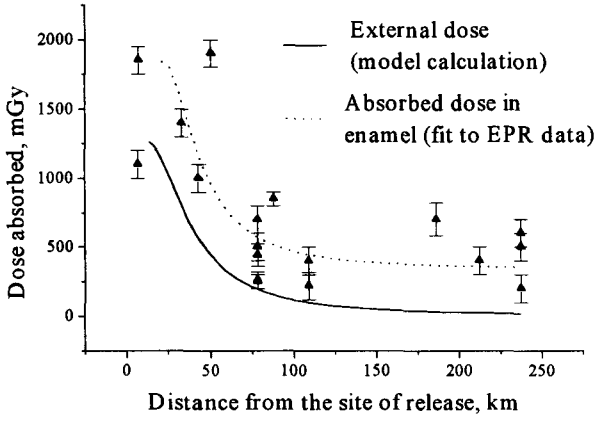

Figure 1. Correlation of absorbed dose in tooth enamel measured by EPR and distance between the place of residence and the site of release.

As it is seen from Fig. 1, the shape of experimental and calculated dose-distance curves is similar, however, results of EPR reconstruction are always higher calculated doses from gamma emitters on 300-500 mGy. The latter can be explained by the necessity to take into account the contributions to dose absorbed from the sources other than the Techa river. Another important peculiarity of Fig. 1: there is no dependence of dose on distances more than 78 km from site of release. The village of Muslyumovo is located at the distance of 78 km and according to our previous evaluations the internal component of exposure begins to play a main role downstream of this point.

In the present rough analyses of doses received by the residents of the Techa communities we have selected three groups of sources contributed to the total dose: 1) external exposure from the Techa river and it's banks; 2) internal exposure due to incorporation of radionuclides ingested with river water and local food-stuffs; and 3) other sources of exposure (natural background, medical procedures, radon, global and local fallouts etc.). The population of the upper Techa received the most essential dose contribution from external exposure, because the exposure dose rates near the river during the period of massive releases were extremely high (2). For the residents of the middle and lower Techa internal exposure mainly due to Sr-90 was predominant. The annual background dose could be taken from our results of EPR reconstruction for the 86 residents of the town of Kamensk-Uralskii (5). The linear

approximation of dose-age dependence gives 4.0 mGy as annual dose rate for the Urals region. The value obtained allows also to explain the excess of results of EPR reconstruction for the South Ural nuclear workers in comparison with data of individual monitoring cited in (4). The excess dose for workers (about 200 mGy) is close to the average EPR dose for Ozyorsk residents (4) and may be interpreted as background level.

As noted above, the internal exposure of the Urals population occurred due to the incorporation of mainly Sr-90. The tooth enamel is irradiated by Sr-90 incorporated in tooth dentine and enamel itself, since path length of beta particles from Sr-90 - Y-90 in bone tissue is about 1 mm. Hence the dose absorbed by tooth enamel depends on strontium metabolism in dentine and enamel. Tooth enamel is the most mineralized part of the skeleton and the metabolism in the enamel for adults is extremely slow. Therefore whole-body counter data have to reflect Sr-90 content in dentine which determine the dose reconstructed by EPR.

The suggestion that EPR doses for the residents of the middle and lower Techa indicate mostly internal exposure is confirmed by correlation between the results of EPR reconstruction and data of Sr-90 body burden. The linear regression (Y=a+bX) of this correlation gives a=260 mGy and b=20 mGy/kBq. The value of 260 mGy is very close to the dose registered for the Kamensk-Uralskii residents of the same age (5), which shows the reasonableness of the choice of the last group of people for the assessment of background level. The coefficient of linear regression between the value of Sr-90 body burden and dose absorbed by tooth enamel (20 mGy/kBq) allows to estimate the Sr-90 contribution for the residents of the upper Techa. The results of calculations of Sr-90 and background (annual dose rate 4 mGy) contributions are summarised in Table 1. The difference between sum of Sr-90 and background contributions and result of EPR reconstruction is due to external dose of the Techa river. As seen from Table 1 the contribution of background and internal doses to the total value varies from 15% to 75%, so it is significant part of the total dose in tooth enamel for the upper Techa. This table also shows the comparison between individual external doses and average external doses for the settlements where these persons lived.

Table 1.

Per. n°	Age, year	Sr-90 body burden, kBq	Total dose absorbed (EPR), mGy	Background component, mGy	Internal component, mGy	External component, mGy	Average external dose, mGy
1	51	5.0	1100	200	100	800	1300

ABSTRACT (See instructions overleaf)

Usually in the EPR-dosimetry technique ones proceed from the assumption of the linear relation between intensity of radiation-induced EPR signal and the value of the absorbed dose. Such the assumption is true only in some cases since in the general case both the value of the absorbed dose and the intensity of the EPR signal are a sum of few components. The dose accumulated by a tooth D_{accum} is a sum of such components: the accidental component; component due to environmental radiation and the contribution of roentgen procedures. The measured intensity of the EPR signal from radiation-induced centers consists of the following items: I_{accum}, depending on the accumulated dose; caused by the exposure to ultraviolet light and caused by mechanic deformations. Only the relation between I_{accum} and D_{accum} has the linear form with a proportionality coefficient depending on geometry and energy of the incident radiation.

Apart from errors in the determination of items described above, some additional error may occurs at the secondary exposure of enamel while the additive dose method is used. This inexactitude is effected through next factors. Firstly, the radiation sensitivity of the fine-grained enamel sample may differ from the sensitivity of the whole tooth, and secondary, the geometries of irradiation of tooth *in vivo* and tooth enamel particles under laboratory conditions are also different.

The present paper addresses a thorough investigation of the above-mentioned aspects of the EPR-dosimetry technique with tooth enamel.

ALKALINE-EARTH METAL DITHIONATES-BASED SPIN-RESONANCE β -RADIATION DOSIMETERS

I.Ugolev,[1] S.Bogushevich,[1]

[1]Institute of Physical Organic Chemistry, Belarus Acad.Sci., Minsk, Republic Belarus

Our previous studies have revealed that stable paramagnetic centres (PMC) classified as ion-radicals SO_3^- and characterized by the EPR isotropic signal (ΔH~5 G, g=2,0036) are formed on γ-irradiating the alkaline-earth metal dithionates of a general formula $MeS_2O_6 \cdot xH_2O$, where M is the alkaline-earth metal (1). Further studies gave us the reason to suggest barium dithionate ($BaS_2O_6 \cdot 2H_2O$) as a γ-dosimeter in the range of 10^{-1} to 10^4 Gy (2).

The study of ionizing radiation effect on the alkaline-earth metal dithionates has revealed also that this class of substances is not only γ-sensitive but β-sensitive as well. The literature on the subject cite only a few chemical compounds and materials used for the purposes of electron radiation dosimetry (3-6), e.g. L-alanine with the operating measurement range of 10^2 to $2 \cdot 10^5$ Gy (6). This paper describes a problem of dithionates application for the purposes of spin-resonance electron radiation dosimetry.

Barium and strontium dithionates were chosen as samples. The purity was tested by means of X-ray phase analysis, EPR technique and IR-spectroscopy. The preground salt powders were subjected to external and incorporated β-irradiation. External β-irradiation was carried out in the air at 20°C by the electron flow (10^{11} to 10^{14} cm^{-2}, E=4 MeV) and $^{90}Sr+^{90}Y$ sources of 10^4 and 10^5 Bq activity. Internal β-irradiation was performed by ^{90}Sr radionuclides of 10^3 and 10^4 Bq activity introduced into the substances structure during their recrystallization with $^{90}Sr(NO_3)_2$.

Ion-radicals SO_3^- were exclusively stabilized in the result of external β-irradiation of alkaline-earth metal dithionates by monoenergetic flows (E=4 MeV) and $^{90}Sr+^{90}Y$ radionuclides as well as in the case of γ-irradiation. The primary stage of homolytic decay of the excited $S_2O_6^{2-}$-anion S-S bond was believed to be the reason of radiation-induced SO_3^- formation. And this very, the so-

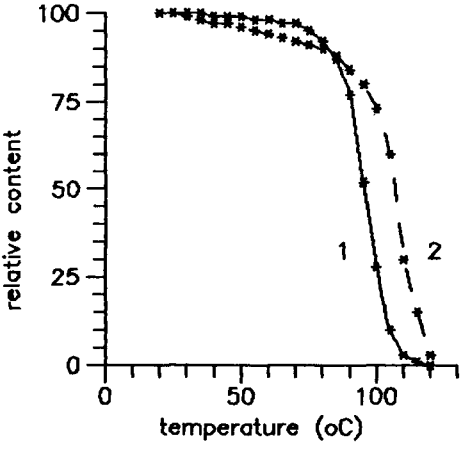

Figure 1. Crystallization water (1) and ion-radicals SO_3^- (2) content (%) vs temperature for $BaS_2O_6 \cdot 2H_2O$

called predissociative decay which essence is the preceding excitation energy migration and concentration on a particular bond, was suggested (7) for some (O-O, C-C, C-H) bonds, S-S bonds including.

Our studies have revealed that the process of stabilization of radiation-induced SO_3^- in the structure of dithionates was affected by the crystallization water. These PMCs were found to be very stable at 20°C. Nevertheless, even insignificant sample heating caused gradual recombination. Figure 1 (curve 2) shows the plot of SO_3^- relative concentration in $BaS_2O_6 \cdot 2H_2O$ structure versus temperature. This Figure shows insignificant annealing of radicals at about 90°C and their intensive recombination in the crystallization water removal region (curve 1). Noteworthy is that both processes terminate practically at a time. Besides, impossibility of dithionate original structure recovery by annealing SO_3^- was noticable. These observations had led to the conclusion that the processes of radicals recombination and crystallization water removal are interrelated. Such interrelation was also found out for radical particles stabilized in another non-organic systems, e.g. mixed crystals of $CaCO_3$ and $CaHPO_4 \cdot 2H_2O$ (8).

The comparison of external γ- and β-radiation effects reveals that the values of EPR signal intensity when exposing barium dithionate to equal doses of both kinds of radiation SO_3^- PMCs agree within the measurement accuracy (20%, 1σ) (Fig. 2). The intensity of EPR signal of

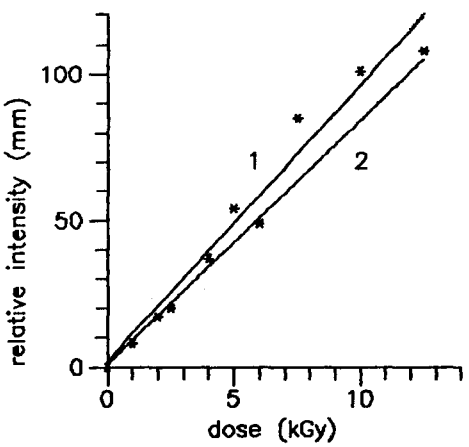

Figure 2. EPR signal relative intensity vs barium dithionate external gamma- (1) and beta-radiation (2)

SO_3^- was always a linear function both of β-radiation dose and exposure time for various activities of $^{90}Sr+^{90}Y$ sources used. Naturally, the angle of a straight line with the abscissa was changing. For example, the change of the source activity by one order (from 10^4 to 10^5 Bq) caused the increase of radiation-induced SO_3^- accumulation rate by about 7 or 8 time (Fig. 3).

The experimental data available made it possible now to preliminary estimate the external β-radiation absorbed dose by comparing the EPR signal intensities for γ- and β-radiation cases. Hence, the alkaline-earth metal dithionates may become promising spin-resonance dosimeters of β-radiation.

At present, large difficulties are experienced in β-radiation dose measurements for the case of incorporated radionuclides. We have attempted to compare the doses due to external electron and

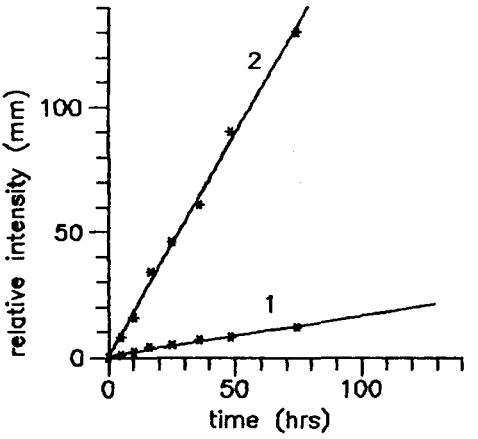

Figure 3. EPR signal relative intensity vs time. External β-irradiation of $BaS_2O_6 \cdot 2H_2O$ by $^{90}Sr+^{90}Y$ radionuclides of 10^4 Bq (1) and 10^5 Bq (2)

incorporated radiations. The intensity of a corresponding EPR signal was a working hypothesis when comparing the doses. When investigating crystal $BaS_2O_6 \cdot 2H_2O$ doped by $^{90}Sr+^{90}Y$ in the air at 20°C, the EPR signal was detected; this was a signal of radicals SO_3^- and its intensity was increasing linearly in time. Consequently, as it was the case of external β-radiation, it became possible to estimate the value of the absorbed dose of internal radiation by the very same method of compariny the number of radiation-induced PMCs respective to the applied dose of external γ- and internal β-radiation.

Thus the submitted material points out the below described advantages of alkaline-earth metal dithionates used as spin-resonance β-radiation dosimeters. Such advantages are high sensitivity to external and incorporated β-radiation, the narrow isotropic EPR signal for radiation-induced SO_3^-, large interval of linear accumulation, the PMC stability and discovered unsusceptibility to solar light. The instability at high temperature may be considered as a disadvantage of dosimeters described. Nevertheless, as it has been already pointed out, the ion-radicals SO_3^- are very stable at room temperature. The study of EPR signal intensity upon time has revealed that the intensity value is practically stable at temperatures below 40°C for at least 2 years (with ±10% accuracy (2σ)). This feature may provide for the lasting storage of information by sealed dithionate dosimeters.

SYNTHETIC HYDROXYAPATITES AS A POSSIBLE EPR DOSIMETER

Alexander A. Romanyukha[1], D. Regulla[2] and E.A. Ignatiev[1]

[1] EPR-Spectroscopy Center, Institute of Metal Physics, Russian Academy of Sciences, 620219 Ekaterinburg, Russia

INTRODUCTION

Considerable interest to investigations of irradiation effects in synthetic hydroxyapatite, $Ca_{10}(PO_4)_2(OH)_6$, by electron paramagnetic resonance (EPR) (see, for example, (1-4)) is provided mainly by two reasons. Firstly, natural hydroxyapatite as a mineral component of tooth enamel, dentine and bones could be used for retrospective dosimetry. Therefore the knowledge of origin of different components of its EPR spectrum is important for development of the correct procedure of dose reconstruction. Secondly, increasing application of EPR dosimetry with alanin asks for the search of possible alternatives. From this point of view, such parameters of tooth enamel as threshold dose (100-200 mGy), time (10^7 years) and thermal (80° C) stability, sensitivity to irradiation by alpha-, beta-, gamma-, x-rays, UV and heavy ions allow to consider hydroxyapatite as a possible EPR dosimeter. EPR dose reconstruction and EPR dosimetry are based on the measurement of the concentration of radiation induced radicals in hydroxyapatite. Above radicals in hydroxyapatite originate from the carbonate impurity. Therefore the concentration of carbonate plays an important role in EPR dosimetry with teeth and bones and determines radiation sensitivity of hydroxyapatites. In the present contribution we are reporting some preliminary results of EPR study of irradiated hydroxiapatites synthesised at various pH and with different carbonate content. The parameters of this compound as EPR dosimeter are discussed. On the base of results obtained a hypothesis about origin of background signal in EPR tooth enamel spectrum and variation of its radiation sensitivity are proposed.

MATERIALS AND METHODS

Synthetic apatites with different carbonate content were prepared by hydrolyzing monetite, $CaHPO_4$, in $NaCO_3$ solutions at 95° C, as it was described in (1). The carbonate concentration in apatite was regulated by variation of $NaCO_3$ content in solution. Three different concentrations of $NaCO_3$ were used in this investigation - 0.01, 0.1 and 0.25 mol/l. The conditions of chemical synthesis were also modified by variation of pH. Three different pH every is higher than 9 were tested. Totally nine different samples were investigated in this study. All samples have been investigated with X-ray diffraction, which showed sharp and well resolved peaks characteristic of well-crystallized apatite.

Three different types of irradiation sources were used for irradiation in this investigation, namely: medical ^{60}Co source (Eldorado), X-ray tube (60 kV, 40 mA) and UV lamp (NK 6/12 Heraeus). This UV lamp is low-pressure mercury lamp with power of 6 W and major spectral line 254 nm.

EPR measurements were made at room temperature with an X-band Bruker ESP 300 spectrometer with 100 kHz modulation and with microwave power 12 mW.

RESULTS AND DISCUSSION

There are two types of components in EPR spectrum of both biological and synthetic carbonate hydroxyapatite. The first type signals correspond to spectrum of non-irradiated hydroxyapatite. Second type signals are induced by irradiation.

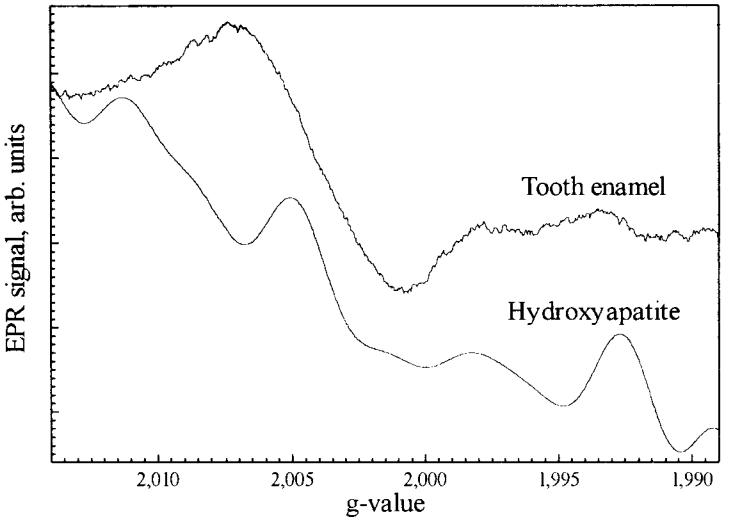

Fig. 1. EPR spectra of tooth enamel and synthetic hydroxyapatite obtained with 0.01 M of $NaCO_3$.

Among first type EPR signals in tooth enamel so-call background component (ΔH=0.9-1.0 mT, g=2.005) can be selected. The origin of this signal is not exactly established. Existence of this signal essentially limits a threshold of retrospective dosimetry with tooth enamel. Our comparative analysis of EPR spectra of the synthesized samples and irradiated tooth enamel has shown that amplitude and structure of background signal depends on carbonate concentration and pH during synthesis. Fig. 1 demonstrates EPR spectra of non-irradiated synthetic hydroxyapatite (0.1 M of Na_2CO_3) and tooth enamel. In spite of some difference in details the structure and parameters of background signals in these samples are very close. Our investigations of synthetic apatites with different concentrations of carbonate allow to suggest connection of these background signals with existence of other impurity carbonate phases in compound obtained. Most typically is $CaCO_3$. Such conclusion was also confirmed by X-ray diffraction. Possibility of synthesis of impurity carbonate phases are connected with pH in solution. Therefore, in considerable degree the individual variation of the radiation sensitivity and amplitudes of background signal in tooth enamel are caused by individual value of pH in the saliva. The latter allows to suggest, firstly, not so wide variation of radiation sensitivity inside a group of the people with similar diet and, secondly, strong dependence of this parameter on distortion of pH at some problems with metabolism.

As known (1,2), four different signals (caused by four different radicals) were found after irradiation: i) isotropic signal with g_x=2.0115, ΔB=0.33 mT (CO_3^- at phosphate lattice site); ii) anisotropic signal with g_x=2.00170 g_y=2.00084, g_z=2.0060, ΔB=0.34 mT (surface CO_3^-); iii) isotropic signal with g=2.0006, ΔB=0.30 mT (CO_2^- at phosphate lattice site); iv) anisotropic signal with g_x=2.0030 g_y=2.0015, g_z=1.9970, ΔB=0.18 mT (surface CO_2^-) of so far minor

significance. Our investigations were shown, X-ray and UV irradiations mainly produce the isotropic signals (i) and (iii), and Co-60 irradiation produces the anisotropic signal (iv). The observation of different EPR spectra in synthetic apatites after irradiation by Co-60, X-rays and UV allows, in principal, to distinguish between the these radiation types. In case of Co-60 irradiation a lower detection threshold of about 1 Gy was found so far; it could, probably be improved by changing the conditions of chemical synthesis and increasing the carbonate content. For X-rays and UV radiation the sensitivity is considerably higher. The existence of a non-stable line in the spectrum of synthetic hydroxyapatite after X-ray and UV irradiation can be used to estimate the time elapsed between irradiation and measurement.

ABSTRACT (See instructions overleaf)

Search for biological active substances for preventive treatment and therapy of radiation influences is still actual. The results of development of preparation for protection of normal tissues on condition of irradiation cancroid's therapy and human organism in the regions of radiation accidents and radionuclides polluted areas are presented. For this purpose effectiveness of synthetized antiradiation compounds- derivates of phenilacetophenon, dithiocarbomates and ethylene diamine, antitoxix preparation with adaptogenic properties and antibacterial preparation was studied. These compounds are synthesized on the base of the structure analogues of nature compounds. The famous radioprotector- cystamin- effective on sharp irradiation conditions was used for comparing. BALB-line mouses were subjected to chronic gamma-irradiation with doze power 20 Gr during 60 days. Preparation were infused intra peritoneum or per orum every day during the first 30 days. Among them we found the effective preparations which protect BALB-line mouses from acute irradiation and had prophylaxis and therapy action on condition of chronic external gamma-irradiation. This preparation increase average life duration on condition of acute irradiation; on condition of chronic irradiation they are slow down the development of leycopenia, reduced lipid peroxide oxidation(LPO),r-protein level and distant citogenetic effects, bringing it close to norm. Animals external appearence,activity and mass normalization seven mouths later after the experiment.

NON-IONIZING AND IONIZING DOSIMETRY IN A SPACE RADIATION ENVIRONMENT WITH GaAs and SiC LEDs

ABSTRACT

This paper describes a dosimetry experiment that will be carried onboard the Russian MIR space station. The experiment will compare the ionizing and Non-Ionizing Energy Loss (NIEL) in semiconductors of the radiation encountered in space. The ionizing dose will be detected using ThermoLuminescent Dosimeter (TLD) whereas SiC and GaAs LEDs will be used to measure the non-ionizing component. The tray will be mounted on the outside of the station for a minimum period of 4 months. The goal of the experiment is to determine the feasibility of using SiC and GaAs LEDs as NIEL dosimeters in space.

INTRODUCTION

Devices fabricated with GaAs and other compound semiconductors are expected to play an increasingly important role in space electronics. Satellites in space are exposed to the radiation belts, solar flares, and cosmic radiation. In contrast to silicon devices, the radiation damage to GaAs devices is caused by displacement of atoms from their crystal lattice sites by incident energetic particles. Burke et al. (1), Summers et al. (2), and Barry et al. (3) have shown that atomic displacement damage is proportional to the NIEL of the radiation in the semiconductor. In order to assess the sensitivity of compound semiconductor devices to space radiation, it is of great interest to develop a practical NIEL dosimeter. A second objective of the mission is to investigate a possible method of discriminating between radiation damage due to electrons and heavy particles.

EXPERIMENT DESCRIPTION

The monitor package will be installed on an aluminum tray measuring 300 mm × 75 mm. Three different experiments will be fitted on the tray. The NIEL experiment will occupy 68 mm × 75 mm and consists of i) 20 GaAs LEDs; ii) 10 SiC LEDs; iii) 13 locations for TLD 700s of varying thickness; iv) 4 pieces of 10^{15} n-doped; and v) 4 pieces of 10^{16} n-doped GaAs wafer. Figure 1 shows a schematic diagram showing the relative position of the various TLD 700s (B_1-B_4, D_1-D_3, F_1-F_3 and I_1-I_3), the SiC LEDs (A_1-A_5 and J_1-J_5), the GaAs LEDs (C_1-C_5, E_1-E_5, G_1-G_5, and H_1-H_5) while positions X_1, X_3, X_5, and X_7 and X_2, X_4, X_6, and X_8 are the 10^{15} and 10^{16} n-doped GaAs wafers, respectively.

In order to probe different energy regions of the radiation field (i.e. different points on the dose depth curve), the package is divided in 4 compartments: #1 in which all the devices, TLDs, SiC and GaAs LEDs and GaAs wafers are directly exposed to the radiation field; #2 in which all devices are covered by protected 13μm thick Kapton sheet; #3 is covered by a 51 μm steel sheet under a protected 51 μm thick Kapton sheet; and #4 in which all devices are covered by a 3 mm thick Tantalum absorber, itself covered by two different thicknesses (13 and 51 μm) of virgin Kapton sheet.

PRE-FLIGHT QUALIFICATION TESTS

The lens and caps of the GaAs and SiC LEDs (which were manufactured by Telefunken and CREE Research, respectively) were removed in order to directly exposed the chips to the radiation

environment and avoid any shielding due to these components. However, in order to stabilize the electrical characteristics and to protect them from Atomic Oxygen (AO), they were nitrided. Sample LEDs and TLDs were exposed to AO for 120 minutes (corresponding to approximately 3 months in low earth orbit) using a Large area Microwave Plasma (LMP) facility with an O_2-SF_6 mixture excited in the radio-frequency mode. The package will be exposed to temperature extremes in space; therefore, the sample LEDs and TLDs were subjected to repeated temperature cycling between liquid nitrogen and 115°C. The tests indicated that the samples suffered no apparent deterioration.

NIEL MONITORS

The use of LEDs as NIEL monitors was developed by Barry et al. (4) and their response over a wide energy range has been established (3). The NIEL is proportional to the change in the inverse of the minority carrier lifetime (5), which is deduced from the frequency response of the LED prior to and after exposure. However, due to the relatively short time the experiment will be in space, only a small dose is expected.

In order to maximize the precision for the small NIEL dose anticipated, a set of 25 GaAs LEDs (from 200) and 15 SiC LEDs (from 100) were selected for optimum repeatability and minimum standard deviation of their measured lifetime. The temperature sensitivity has been carefully measured and a correction factor is applied to the data by the software. A group of these LEDs are being stored as "standard" for checking any drift in the lifetime measuring equipment.

For low energy particles, a significant correction to the measured NIEL, due to the energy loss in the surface layer of the LED, is required. Thus the thicknesses of the epitaxial layers were determined from the threshold in the variation of the change in the minority carrier lifetime with proton energy (5).

The epitaxial top layer of the GaAs LEDs was measured to be 30 ± 2 microns. Using TRIM-92 code, the energy loss of a proton as it travels through the epitaxial layer, steel, Kapton, and Tantalum is estimated. With this information, the sensitivity of each compartment is determined: > 1.9 ± 0.1 MeV for Compartment #1; > 2.2 ± 0.1 MeV for Compartment #2; > 4.9 ± 0.2 MeV for Compartment #3; > 53 MeV for Compartment #4. Thus LEDs in Compartment #4 will be used as "background" monitors and compared to the series of LEDs kept in the laboratory.

GaAs WAFERS

The damage (the Gallium vacancy V_{ga} and Silicon at the Arsenic site Si_{As}) due to room temperature irradiation with 0.6 to 200 MeV protons anneals out to a large part at 550°C, while that due to 7 MeV electrons anneals to a much less extent (6). The purpose of the n-doped GaAs wafers is to investigate the use of this phenomenon to differentiate between electron and proton components in the space radiation.

CONCLUSION

Dosimeters for measuring the total and the NIEL of radiation in space has been shipped to the Ukrainian Space Agency and will be installed on the MIR space station for a minimum period of 4 months probably in early 1996. The post-flight analysis of the data will be carried out as soon as the tray is returned to the ground. A dose depth curve for the NIEL will be obtained from the analysis.

ACKNOWLEDGEMENT

The authors would like to thank Prof. R.C. Tennyson, Director of the University of Toronto Institute of Aerospace Studies for many useful discussions and for facilitating the flight of this flight. The work is supported by Space Systems Directorate, Canadian Space Agency, Contract # 9F028-5-5162/01-XSD.

INTRODUCTION

The extensive studies aimed at finding out the dose-effect relationship in the area with increased in-door radon content and thus with supposed increased lung cancer incidence risk are carried out in the Czech Republic. The important part of such studies is to estimate the long term dose from radon and its short-lived progeny to lungs for each followed person. Usually, measurements of the activity of ^{222}Rn and its progeny in the in-door air of houses and the extrapolation to the past levels are the base for dose estimation There is also the possibility to assess the intake of short lived radon progeny deposited in the lungs by the in-vivo measurement of long lived radon progeny ^{210}Pb originating by their decay and then transported to other parts of the body and deposited mainly in bones. Annual average intake of ^{210}Pb is estimated to be 44 Bq which results in effective dose equivalent of 0.12 mSv (1). There is an effort to determine the amount of ^{210}Pb both in-vivo and in environmental samples by the detection of its 46.5 keV gamma rays. With regard to the efficiency of measurement the determination of ^{210}Pb deposited in bone surfaces of the skull seems to be the best solution for in-vivo measurement (2). The in-vivo determination is very difficult due to low yield of its gamma rays and also due to their low energy. In addition the activities which can be expected in the human body even with long term inhalation of high activities of radon and its short lived daughters are very low. At present time, the most serious problem is the sensitivity of instruments used. Even if this problem would be solved, the interpretation of activity of ^{210}Pb measured directly in-vivo in skull will be quite complicated because of direct intake of ^{210}Pb through inhalation and ingestion. The monitoring of amount of ^{210}Pb entering the body via direct ingestion and inhalation in areas with increased radon levels and comparison with areas considered as control, i.e. with average levels, is necessary for proper discrimination of individual components of ^{210}Pb retention. Therefore, in addition to the basic problem - calibration of special detectors for the measurement of ^{210}Pb in-vivo - an effort was undertaken to determine ^{210}Pb content in out-door air and particle size distribution of aerosols with attached ^{210}Pb, the content of ^{210}Pb in fallout and in drinking, mineral and table water. During the study the most suitable detector system was sought.

METHOD

The measurements of ^{210}Pb require special equipment with very low background. The equipment consists of special detectors (n type HPGe detectors, HPGe well detectors, HPGe planar detectors, LEGe detectors, special scintillation detectors - phoswichs). Very good shielding is substantial. In the NRPI there are 6 HPGe detectors available for the measurement of ^{210}Pb. Three of them are reverse electrodes detectors with thin Be window (n-type detectors). One well-type detector was used in the study. For the special case of measurement of low energy gamma emitters two LEGe (low energy Ge) detectors with beryllium and carbon-epoxy windows are used. The LEGe detector is a large area detector with a thin boron-implanted outer contact for high sensitivity at low energies. Because of device geometry, the capacitance is low, and this results in excellent resolution at low to moderate energies. The parameters of the detectors are summarized in Table 1. For comparison of capabilities of different detection systems also one p-type coaxial HPGe detector was included in the study. In addition to semiconductor detectors the possibility to use scintillation detectors was studied. Two scintillation NaI(Tl) detectors were used, one 5in x 4in with thin Al window (SC1) and one thin NaI(Tl) detector of 7 mm thickness with Be window (SC2).

RESULTS AND DISCUSSION

Sensitivity of different detection systems was studied. Because of low gamma energy of ^{210}Pb (46.5 keV) and low intensity of this energy line (4.05%), detector with high detection efficiency in this energy region and with low background is suitable. It was found, that all detectors with beryllium windows have approximately the same ^{210}Pb peak in their background, regardless of their detection efficiency (size), so that the source of ^{210}Pb is very near to the detector. As the lowest background in ^{210}Pb peak area was found with well detector (which endcap is from very thin aluminium with no beryllium), it was most probable that the source of ^{210}Pb is in beryllium window. The results of background measurements in the region of interest are summarized for semiconductor detectors in Table 2. There was the attempt to decrease the background by using additional shielding materials in close geometry e.g. copper, tungsten, steel, however with no significant effect. The

effort to decrease minimum detectable activity for ^{210}Pb resulted in complete reconstruction of endcap parts of LEGe detector No. 13, in which the beryllium window was replaced by the window from carbon-epoxy. The background count in the 46 keV peak area decreased approximately 10 times. This conclusion is very important for purchasing HPGe detectors when user has a.o. the aim to detect low activity of ^{210}Pb. The LEGe detector No. 20 was already purchased in special low-background arrangement.

Table 1 Parameters of semiconductor HPGe detectors used for ^{210}Pb measurement

Detector No.	Manufacturer	Type	Rel. efficiency 1333 keV [%]	FWHM 1333keV[keV]	FWHM 46.5keV [keV]	diameter [mm]	length [mm]

[2] efficiency for source inside well

Minimum detectable activity for different types of semiconductor and for scintillation detectors was calculated for typical geometry used for measurement of environmental samples, i.e. planar source with diameter of 5.2 cm. The results for 100000 s measurement time and for 5 % risk of error type I and II are included in Table 2. The determination concentration of ^{210}Pb in out-door air was the first attempt to estimate the amount of ^{210}Pb in various components of environment (3). High volume aerosol samplers (with air throughput from 60 $m^3.h^{-1}$ to 200 $m^3.h^{-1}$) were used for the aerosol collection altogether in four different places. Aerosol filters (PC-S, produced in SLZ, Hnúšťa, Slovakia), on which aerosol was collected one week, were measured without any treatment by semiconductor gamma spectrometry. Filters were measured in close geometry, using measuring time at least 100000 s. The average concentration of ^{210}Pb in the aerosol in out-door air in Prague for the whole sampling period 9 years (1986-1994) was found 540 $\mu Bq/m^3$. This value is in accordance with values given by UNSCEAR Report for the same geographical latitude. Similar values were found on other places in Czech republic, too. The ratio of activity of short lived progeny of ^{222}Rn and to the activity of radon itself to the activity of ^{210}Pb is approximately one order of magnitude higher in in-door air that in out-door air. It means that in-door aerosol with ^{210}Pb has much shorter mean time of life than the one in out-door air. There is higher

is higher probability of attachment of the particles on the walls and surfaces in-door than out-door. The ventilation of the room could influence ^{210}Pb content in in-door air, too.
Particle size distribution of aerosols with attached ^{210}Pb on their surfaces was studied with the use of 6-stage cascade impactor (Sierra Andersen, Model 236) attached to a high-volume air sampler Sierra Misco with a flow control system (Model Sierra Misco 5000). Flow-rate 0.565 $m^3.min^{-1}$ was used. Slotted fibreglass filter, sucked with solution of silicone grease to reduce re-entrainment and bounces of aerosol particles was placed on each stage. After the 6th stage the back-up filter for catching the rest of the particles was placed. Samplings with cascade impactor were performed both out-door and in-door. Main part of ^{210}Pb is attached both in out-door and in-door air to the small aerosol with aerodynamic diameter under 0.4 μm. Particle size distribution does not differ significantly from aerosol particle size distribution of short lived radon progeny. No difference in aerosol particle size distribution for the out-door and in-door air was found.
The yearly intake of ^{210}Pb by inhalation from out-door air is about 4 Bq (in accordance with UNSCEAR value). In the houses with elevated radon concentration, yearly intake by inhalation is from 70 to 700 Bq.
Table and mineral waters could be important contributors to the ingestion intake especially if their source is in places with high amount of uranium series radionuclides in the bedrocks. Water samples were measured in native form, after evaporation of 1 to 10 litres of water and after radiochemical separation of ^{210}Pb . Altogether 54 samples of potable, mineral and table water including one sample of pilsner beer were measured. The volume activity of ^{210}Pb ranged from detection limit (approx. 0.003 Bq/l) to 1.4 Bq/l. Majority of samples had the volume activity of ^{210}Pb below 0.1 Bq/l. Activity of ^{210}Pb in potable water was from less than 0.005 Bq/l to 1.4 Bq/l, activity in 16 samples of mineral and table water was lower with maximum of 0.2 Bq/l. Assuming the yearly consumption of potable water to be about 770 l for an average adult, the maximum intake of ^{210}Pb in exceptional cases could be about 1kBq which results in the dose of 1.3 mSv. The average yearly consumption of mineral and table water is for an adult about 14 l so the dose from ingestion of ^{210}Pb in this water is negligible.
A semiconductor LEGe detectors No.13 before and after reconstruction and No. 20 were used for in-vivo determination of ^{210}Pb in skull of people. Assumed distribution of ^{210}Pb on the skull bone surfaces was simulated by planar source moved on outer and inner surfaces of the skull. . The minimum detectable activity of ^{210}Pb in skull was determined for 5400 s measuring time to be about 20 Bq , i.e. about 130 Bq in total skeleton.

CONCLUSION

The study proved that the high resolution semiconductor gamma spectrometry is promising method for determination of ^{210}Pb in various kinds of environmental samples. Its sensitivity can be further improved using concentration and separation radiochemical methods for sample pretreatment. However, the most important field of application of semiconductor gamma spectrometry in measurement of ^{210}Pb is in-vivo determination of its amount in human body. For the detection of ^{210}Pb in-vivo in human skull further effort to decrease background in the 46.5 keV region is needed. The sensitivity can also be increased using geometry for simultaneous measurement with several LEGe detectors. Interpretation of measured values of ^{210}Pb in-vivo needs also the correction for enhanced direct intake of ^{210}Pb by inhalation in radon houses, which is enabled by the sampling and measurement of in-door air.

ACKNOWLEDGEMENT

This study was partly supported by research contract No. 7716/RB "The Particle Size Distribution of ^{210}Pb in the Air" as a part of IAEA Co-ordinated Programme: Radon in the Human Environment: Instrumentation, Modelling, Dosimetry and Survey.

THE THEORY OF INDIVIDUAL VARIABILITY OF OSTEOTROPIC RADIONUCLIDES METABOLISM.

N.LYUBASHEVSKY, V.STARICHENKO, A.GOLUBEV, E.SHISHKINA.
Institute of Plant & Animal Ecology, 620219, Ekaterinburg, RUSSIA.

The greatest radiation accidents - Kyshtym (in the Urals), on the Three Miles Island, in Chernobyl led to increased accumulation of artificial radionuclides in organisms of tens of thousands of people, and also in animals. Unfortunately, new similar and even more dangerous accidents are possible. Health condition examination and controlling of such great population contingent are unlikely possible. The only rational way is to reveal and to analyze groups of the increased risk. Individual dose overloading or prognosis of dose overloading from the internal radiation is one of criteria of these groups. Obviously, revealing of individuals with the increased defeat possibility has great medical , social, agricultural and economic importance.

Osteotropic radionuclides are of specific danger for human being long time after accident. This is connected first with such fact that most of them have a long half-life period and secondly, they can be selectively accumulated in the skeleton, being tightly bound with bones, Reaction to the inner irradiation by incorporated radionuclides depends on their kinetics that defines the dose load besides of individual radio sensitivity.

Despite the fact that thousands of works and dozens of mathematical models [5] are devoted to osteotropic radionuclides metabolism only isolated ones promise satisfactory reconstruction of individual absorbed doses in future and no one leads to their individual prediction.

The aim of this paper is to study mechanisms of individual peculiarities of osteotropic radionuclides skeletal metabolism, and to develop approach for dose value prediction. Some regulations explaining the importance of skeleton in radionuclides metabolism and showing the direction of search of its quantitative regularities are taken as a basis of these theory. The first, there are three evolution trends: universal significance of calcium in the cells in the row beginning from bacteria to highest organisms and increase of its regulator role in the multycellular on the level of organism; ability of calcium salts to increase mechanical strength of supporting tissues; growing connection of metabolic and supporting function. The second, bone is involved in metabolism of radionuclides as a structurally functional wholeness. The third, metabolic way of radionuclide from blood into bone consists of a number of stages. At each stage a life of radionuclide depends on its physical chemistry properties (alkaline earth, actinides and so on). The stages can be combined with respect to time and place. Radionuclides in blood are in ionized or colloid condition, they are partly fixed with proteins, blood cells, bioligands. At the same time they are mixed in circulation and are carried through capillary walls. Permeability is higher in the form of ions, high-dispersed colloids, complex compounds which are fixed neither with proteins nor with form elements of blood. "Deponing agent" of citrate type, breaking away radionuclid from proteins and cells and promoting permeability of capillary wall into extravascular space of a bone (20 $mm^3/gr.$) with its connective tissue and osteogene cells in which actinides are deposited appreciably, was found in bone capillaries. The next stage is bone surfaces having a number of local peculiarities. The processes of ion exchange, of adsorption and chemical combining, of diffusion are taking place here. Isotope is moving forward deep into bone along canaliculi-lacunar net. When in bone radionuclide is subjected to translocation, walling, resorption together with reorganized bone tissue. Their removal out of bone occur in the result of diffusion, desorption from the surface and cell resorption. Recirculation leads to new deponing. The fourth, radionuclides metabolism in skeleton is defined by 10 limiting morpho-physiological factors (LMPF). LMPF are physiological processes, physical chemistry reactions, biochemical substrata and hystological structures participating in the metabolism of radionuclides in skeleton tissues.

As a whole they are an integrated system which is necessary and sufficient for the complete description of radionuclides exchange in vertebrates skeletons. The influence of each of them is independent of the influence of others. They were distinguished from "innumerable" quantity of outward and inward factors influencing metabolism of radionuclides in skeleton. LMPF is: F_1 - blood circulating through skeleton; F_2 - ability to transcapillarity transfer; F_3 - deponing agent; F_4 -competitor role of intensity of radionuclide accumulation in soft tissues and its removal together with excreta; F_5 - desorbtional ability of the bone surface unit; F_6 - total area of skeleton; F7 - resorption; F_8 - growth leading to walling radionuclide being deposited on the surface and

accompanied by its local dislocation; F_9 - exchange inside of osteogenic cellular elements; F_{10} - surfacevolume correlation (effectivity of removing depends on a quantity of radionuclide deponed on the surface and in the volume of a bone). An individual variability can concern each of LMPF. Principle possibility of data using an individual kinetics of osteotropic radionuclides in dose loading retrospective evaluation and prediction has been studied by means of mathematical model (Fig. 1).

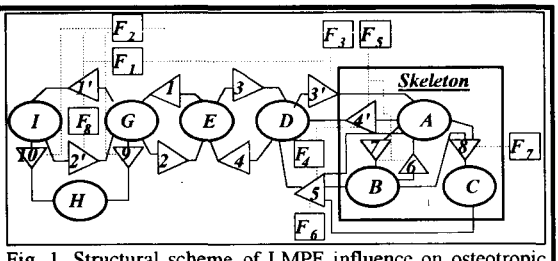

Fig. 1. Structural scheme of LMPF influence on osteotropic radionuclides metabolism.

Circles - chambers (A - bone surface; B - non-walled up; C - walled up volume; D - extravascular liquid of bone; E - blood; I - extravascular liquid of soft tissues; G - soft tissues; H - excreta. Triangles (arrows) - communications. Rectangles, F - LMPF.

Intercommunication of LMPF and their integral effect are represented in this model as an eight chamber model, in which the meaning of communication constants is defined by LMPF. A big number of chambers is justified by the fact that each of them reflects physiological reality. Thus chamber of extravascular space of bone and soft tissues introduced in the process of work turned out to be extremely significant. They allowed to describe processes of desorption taking place on the bone surface and in soft tissues more fully, that led to refusal from correction coefficients. The model is described by the system consisting of 8 linear differential equations having constant coefficients. In order to quantitatively characterize LMPF their parameters "a_1" were introduced. We illustrate specified approaches with some examples.

KO3 -is a velocity of transition out of extravascular space of a bone onto a bone surface which is defined by its sorptional ability and which is 88 times as high as permeability of capillary membrane KO3=58291.

K6,K7 - are the velocities of transition out of non-walled up volume onto the bone surface and from the bone surface into non-walled up volume, they are accordingly defined using the curves of washing off and accumulation of ^{90}Sr out of bone fragments.

Numerical values of parameters of LMPF of rats, mice, dogs, fish and men were defined. Qualitative agreement of radionuclides metabolism curves depending on their physical-chemical properties, species and physiological condition of organism (man, norm and Pedget illness) with real indexes was got with the help of this model.

An example of the results of study of individual variability of metabolism of osteotropic ^{91}Y and LMPF in the experiment and with the model is shown in the Fig. 2. The following parameters of LMPF were got: ability for permeability, part (0,16; 0,10; 0,22); skeleton surface area, cm^2 (569, 545, 731); desorptional ability, relative units(0,008; 0,017; 0,010); resorption, part/hour (0,015; 0,0009; 0,0009); surface-volume of a bone ratio, cm^{-1} (69;62;49). Average-species meanings of three other LMPFs are used in the model: blood-circulating, part (0,115), deponing agent, part (0,2), intensity of soft tissues metabolism and excretion, relative units (0,1). Satisfactory alignment of experimental points (vital registration) and calculated meanings of curves of removal is noticed.

In order to study the distribution of dose loading of internal β-radiationthe method of TLD-dosimetry was used (research are carried out in cooperation with dr.T.Betenekova, USTU-UPI). The distribution of ^{90}Sr in dog's and in rat's skeletons was measured TLD-dosimetric detectors of Al_2O_3 were used. TLD-indexes of absorbed dose for the unit of time (relative units) are shown in Fig. 3. You can see that ^{90}Sr is distributed along bone surfaces of a skull extremely irregularly (beginning from 6,4 relative-units in back part of a head till 22,6 relative units in the region of eye-sockets). Indications of TLD in the teeth (in enamel, dentine, cement) were also measured. They call for a separate discussion. Besides physiological aspects of metabolism of tooth, tissues the interest in tooth as to "an individual dosimeter" is very considerable. Interpretation of ESR-signal of enamel allows to evaluate adequately an absorbed dose of γ-radiation. However, this method is not adapted for β-radiation. β-source, including ^{90}Sr, in the result of peculiar structure, composition and physiology of different

reflected in the value of absorbed dose. Quantitative revealing of patterns of manifestation of these specific features for ^{90}Sr must become a bases for transition from absorbed dose in tooth tissues to the doses on the cells of skeleton surface, red bone marrow and inside the whole body.

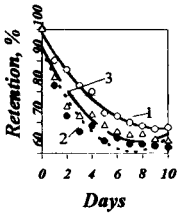

Fig. 2. Curves of retention of ^{91}Y with different individual parameters of LMPF in rats.

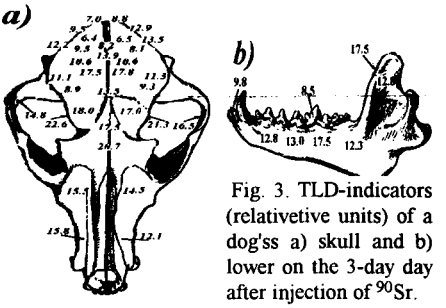

Fig. 3. TLD-indicators (relativetive units) of a dog'ss a) skull and b) lower on the 3-day day after injection of ^{90}Sr.

Specific features of radionuclide metabolism of teeth in our mathematical model are reflected in the following way: radionuclide comes from extravascular space of tooth pulp through the layer of odontoblasts to dentine surface and then to dentine canaliculi. In the framework of this model these stages are identical to extravascular space, bone surface, and bone volume. Radionuclide diffuses into enamel from dentine canaliculi which is described as a bone volume. Radionuclide also come into enamel from saliva (additional chamber and communicational constants: blood-saliva-enamel). Radionuclide moves along dentine canaliculi (analogy with bone volume) and from pericementary capillary net (in such a way as on the bone surfaces) into cement of tooth's root. An important peculiarity of tooth tissues is shown in removal of radionuclides deponed in teeth: normally they are subjected to remodeling very slightly (cement, dentine). Hence the most valuable in dosimetric relation quality of teeth: the most part of dentine and cement and practically all the enamel, being formed during the period of generation, are kept during the whole life, while any other area of bone is replaced repeatedly. Removal of radionuclides out of tooth tissue is made practically only by diffusion-desorption. Parameters of all LMPF of a tooth are quite accessed to quantitative definition and are identified now. Of course, not only kinetic data but steriometric relations between radiating tissues are taken into consideration when defining absorbed dose in tooth tissues with the help of ESR-method. So, dose loading is provided not so much by deponed isotope in it, as by the adjacent teeth and soft tissues, saliva and radionuclides of ration. Thus, the description of processes of radionuclides deponing in tooth tissues requires definite corrections in a structural scheme of a model and evaluations of parameters of appropriate chambers and communication constants.

Thus it is shown that individual peculiarities of kinetics of radionuclides in bones reflect quantitative differences of parameters of several limiting morphological and physiological factors (LMPF). This theory allows to hope that data of individual absorbed dose can be obtained from the results of living organism tests for LMPF parameters.

RADIATION DOSE STRUCTURE FOR RESIDENTS EXPOSED TO DUE TO MAYAK PLANT OPERATION AND NATURAL FACTORS IN THE URALS REGION; METHODS FOR OPTIMIZATION OF RADIATION PROTECTION

E.M. Kravtsova, N.V. Kolotygina,
L.V. Pudovkina, O.S. Kravtsova

Urals Regional Radiology Center,

RF State Committee for Epidemiologic Survey, Chelyabinsk

The studies interpreting the impacts of radiation accidents in the South Urals are mainly focused on the doses due to industrial sources of contamination of the territory. There is a lack of works dealing with assessment of total population exposure doses from all sources of ionizing radiation including natural, medical industrial and other types of uses of man-made radiation.

With the purpose of determining the structure of exposure doses for residents of 30 villages located in contaminated areas of Chelyabinsk, Sverdlovsk and Kurgan Regions the current doses from the following sources were analyzed:

- background (natural) external and internal radiation;
- medical radiation exposure of population due to roentgenologic diagnostic procedures;
- environmental exposure due to releases of Sr-90, Cs-137 and Pu isotopes in the environment.

The method described in [1] was applied to assess the gamma-background levels differentiated according to radiation sources.

Estimation of contents of radon, radon daughter products (RDP) and thoron daughter products (TDP) aerosols in the air inside dwellings and communal buildings was made on the basis of the routine schematic combining instant volumetric activity (VA) measurements of RDP and TDP aerosols with the use of aerosol radiometers [2], and measurements of radon VA in the air using integral radon track detectors (IRTD). This approach allowed a prompt yield of results, which is of special importance in screenings, on the one hand, and, on the other hand, it allowed a correct assessment of average annual values of the equivalent balanced volume activity (EEVA) of radon in the air inside dwellings in the surveyed area. The latter circumstance is very significant

for decision-making on the necessity of undertaking a comprehensive radiation investigation based on the data of screening studies.

The dose coefficients applied for calculating doses due to radon and thoron included those listed in the Report of UN SCEAR: the average annual equivalent balanced volume activity of radon equal to 1 Bq/cu m results in an effective doses (ED) equal to 0.061 mSv/yr inside dwellings, and 0.025 mSv/yr inside production buildings (at an 8-hour working day). Average annual EEVA for thoron equal to 1 Bq/cu m results in ED = 0.29 mSv/yr inside dwellings and ED = 0.11 mSv/yr inside production buildings. ED resulting from inhalation pathways of RDP was calculated on the basis of the radon volume activity measured using IRTD, and ED due to inhalation intakes of TDP was estimated on the basis of instant thoron EEVA values.

To estimate the external exposure due to environmental sources it was necessary to study the intakes of artificial radionuclides with foods. For the purpose of estimating the content of radionuclides in foodstuffs and vegetation the recommendations given in [3] were used. The estimation of Sr-90 was effected by selective extraction using monoisoactilic methylphosphonate (MIOMPK) of yttrium-90 balanced with Sr-90 from 0.3-0.4 of normal nitric-acid solutions of food ashes with a subsequent measurement of Y-90 activity on NRR-610 TESLA radiometer. The background counting rate of NRR-610 radiometer is 0.04 impulses/sec which ensures measuring activity of the order of 0.06 Bq/test, with an error restricted to a maximum of 30%.

Cs-137 estimation was conducted according to the same method [3]. The method is based on Cs-137 concentrations in the sediment of nickel ferrocyanide and its subsequent separation in the form of antimonous iodide or X-chlortelluric salts. Cs-137 measurements were performed using NRR-610 radiometer.

Assessment of external exposure was made using a differentiated approach with respect to natural and artificial radionuclides [1]. Current effective doses of man-made radiation exposure were estimated according to the method described in [4]. The values of average annual effective doses from medical exposure were calculated on the basis of the roentgenologic data collected on the surveyed territory, and averaged dose parameters of the most common roentgenologic procedures. The information obtained was processed using the software "Region-At1U.K" elaborated by V.V. Nikitin

(Saint-Petersburg Research Institute for Radiation Hygiene).

The analysis of the results obtained has shown that the contribution of natural radiation sources to the structure of current doses to population constitutes 94%, it particularly applies to products of radium and thorium. It follows from the data presented in the paper that this contribution is especially significant for rural residents. This fact can be explained by the peculiarities of the construction of rural dwellings. In contrast to armored concrete floors built in multi-storeyed town dwellings the wooden floors in rural houses do not prevent radon from penetrating from the rocks into the room air. Besides, a rather severe climate of the Urals region makes the residents try to keep warmth inside the houses which results in inadequate ventilation and exchange of air in dwellings. The latter feature is typical of private houses. On the average, exposure doses due to radon and thoron are 3-4 times higher for rural than for urban dwellers. A higher contribution of thoron should be noted (9-10% vs the commonly observed 1-2%). The doses due to radon and thoron correlate well with the rates of natural radioactive mineralization of the underlyinbg rock in the surveyed area; thus, particularly high doses of natural exposure were registered in the villages Allaki and Tatarsky Karabolka located within the bounds of South Konevsky zone of elevated radon potential.

Doses due to medical exposure proved to be near the average values for developed countries, and under the conditions of the Urals region contributed up to 18% of the total dose. The task of minimization of doses resulting from medical procedures for exposed population persists as very urgent in the Urals region. It particularly applies to Sverdlovsk region where the average effective dose from roentgenologic procedures amounts to over 1.0 mSv/man vs the respective all-Russia value of 0.9 mSv/man.

The contribution to the total dose made by current average individual effective doses resulting from environmental radiation sources is the lowest. In 18% of the villages studied this exposure source contributed up to 2.5% of the total dose. In the critical population group this contribution amounts to 25% of the total dose. The table presents information on the dose structure in villages which were studied in a most thorough way.

RISK ANALYSIS IN APPLICATION TO POST-ACCIDENT MANAGEMENT

Vladimir F. Demin

Russian Research Center "Kurchatov Institute", Moscow, Russia

INTRODUCTION

As it follows from the experience in the assessment and analysis of the consequences of nuclear accidents or nuclear weapon tests as well as in the implementation of the protection and restoration measures, there are some reasons, on the one hand, to go beyond the scope of the radiation protection and to consider the non-radiation sources of risk as well. On the other hand, remaining in the framework of the radiation protection, it is not enough to base oneself only on the dose approach and using the current concept of the effective dose D_E, even though only the stochastic effects of exposure are under consideration (detailed discussion on these aspects see in (1)).

Values of risk determined by D_E do not involve the time and cannot make allowance for local and age features of population cohorts (or personnel) for which the aftereffects are estimated. The necessity of estimating non-radiation risks goes from the following:

- Some countermeasures being implemented can have negative side consequences of a non-radiological nature for a population; for example, the relocation, as follows from the experience available, may adversely affect the human health because of changing the social and other living conditions;
- Some possible trouble with the health of the population caused by local or national-wide social living conditions requires, in the context of the most efficient investitions in health protection, to assess by a unified way—through the risk analysis—the state of health as a whole and the background radiation and non-radiation risk causes;
- As it follows from the present-day methodology of estimating the radiological risk, the background values of carcinogenic risk must be known for the application of this methodology (models of relative risk).

All these points show that for assessment of consequences of nuclear accidents or tests and decision making on their mitigation health risk assessment from various radiation and non-radiation risk sources should be developed and used.

METHODOLOGY AND DATA BANK FOR RISK ASSESSMENT

To meet these needs a methodology and a bank of data for risk assessment and management are developed.

In the frame of the CIS state research programmes (Chernobyl and Altai case studies) and the international (EU–CIS) project JSP2 the research subproject "developing the methodology (MAR) and data bank (BARD) on risk analysis" started in 1994. The first version of MAR is published in (1). Main functions of BARD are:

- assessment of the radiological and non-radiological consequences of nuclear tests and accidents,
- assessment of the health of a population in terms of risk indices.
- analysis of effectiveness of radiation and social protection measures.

One version of BARD is developed as a module for the decision support computer system for a post-accident management.

BARD includes

1. Service and calculation codes realizing the methodology mentioned;
2. Health-demographic data (HDD: the age-cause-specific death rates and the age distribution density) which are neccessary for radiation and non-radiation risks assessment.

HDD have been prepared for population of many regions of Russia for different years, for some regions of CIS and some countries around the world.

Input data for BARD are: 1) values of absorbed or equivalent doses (short-term exposure) and dose rates (chronic exposure) of different human body organs due to radiation exposure from a source considered. These doses or (and) dose rates should be given in their dependence on age, time at exposure, countermeasures adopted etc.; 2) HDD from the internal BARD data base; 3) primary radiation or non-radiation risks models.

BARD to a certain extent analogous to the computer codes ASQRAD and SPIDER being developed by CEPN (France) and NRPB (UK). BARD differs from them by the large intrinsic HDD data base, the possibility of calculating non-radiological risks, areas of application etc.

BARD is constantly supported and developed in the two versions: local and distributed. The last one can be accessible through Internet (`http://144.206.130.230/`) at RRC "Kurchatov Institute" (Moscow, Russia).

RESULTS AND CONCLUSION

With these RAM and BARD estimations of health effects of the nuclear weapon tests on the Semipalatinsk test site and the Chernobyl accident respectively for population of the Altai region and Russia regions adjoined to the Chernobyl zone were made. The goal of the study is to obtain data on consequences of the tests and the Chernobyl accident for planning social protection measures. Two examples of these estimations for the rural population of the Bryansk region (for the most contaminated territory, the variant of exposure doses without countermeasures) are given (see Fig. 1 and 2).

Using risk assessment results can change notions about consequences of the nuclear tests or accidents and effectiveness of countermeasures.

A role of the approach based on the risk analysis in decision making on protection and restoration measures is discussed. One should note that in Russia the additional development of regulation documents for radioactively contaminated territories with using the risk assessment results has already began.

* RESSAC: Radioecological research on Ecosystems Submitted to Accidental Situations in Controlled conditions

INTRODUCTION AND OBJECTIVES

In case of significant atmospheric contamination following a severe accident on a nuclear plant, it is crucial to be able to predict if, and how, the polluted environment may be detrimental to life, and in particular, human being. This prediction objective is currently supported by the development of controlled experimentations dedicated to elucidate : a) how, and to which extent, ecosystems and human-targetted food chains will be contaminated by radionuclides and, b) the appropriate actions to be undertaken, or not.

In this frame, IPSN developed a unique research facility were the study of radionuclides behaviour within ecosystems is undertaken. The facility, located into the Cadarache Nuclear Research Center, features in particular a 52 m long greenhouse specially designed for handling significant quantities of radioactive contaminants (Figure 1). The most immediate goal consists in clarifying, for a set of representative European environments, how radioactive contaminants will affect the food chains, due to : a) their specific interaction with water, soils and plants and, b) their fluxes of transfer through these compartments. A CEC supported European scientific collaboration has been assembled in the RESSAC Programme to address these questions.

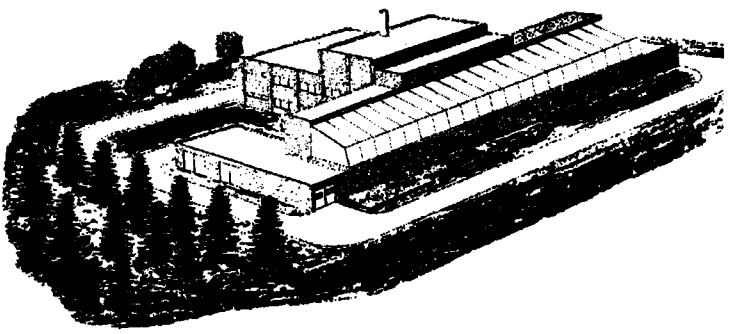

Figure 1: General view of the facility.

Figure 2 : Sample of soil (monolithe) extraction.

DESCRIPTION OF THE MAIN ASPECTS OF THE FACILITY

1) The large LYSIMETERS as realistic soil samples.

In order : a) to limit « border effects » which, at small scales, modify roots development, and b) to respect the vertical distribution of horizons and texture of the original soils, large undisturbed monolithes (2x2x1.4m, 20 tons mass each) have been extracted from selected sites in the surroundings of european

nuclear plants. Seven such « samples of soils » have been transported from, Belgium, Spain, Germany, the United Kingdom and France, for installation into the facility at Cadarache, (see Figure 2). Specific efforts have been devoted to reproduce, within each lysimeter, an hydric potential similar to that prevailing at the original sampling site. For this purpose, each lysimeter floor has been equipped with a special porous layer which contacts a water reservoir where the hydraulic pressure is controlled.

2) Simulation of the contaminated aerosols released from a PWR in accidental situation

A specific device has been developed (POLYR: Pollution of the LYsimeters Ressac) to carry out this simulation (Figure 3). POLYR consists in an inductive furnace which drives a fraction of 10^{-7} of a PWR core inventory to reach a temperature of 3 000°C, in a steam-saturated atmosphere at 80°C. The simulated corium in the furnace contains fifteen elements including fuel, clad, structure and control rods materials. ^{90}Sr and ^{137}Cs are also introduced as the two major radionuclide isotopes of radioecological relevance. A thirty minutes duration heating phase is required to reach the temperature plateau of 3000°C. Growth and maturation of the simulated aerosols require a fifteen minutes phase at this temperature. The resulting contaminated aerosols are next transferred above the lysimeters to be polluted. The pollution takes place by the natural fall down of the aerosols, a process which requires a duration of 24 h. Each lysimeter has been contaminated such as to reach an overall deposit of about 50 $MBq.m^{-2}$ for each of the two radio-elements. It must be noticed that this source-term can be modified on purpose to contaminate a variety of experimental objects in a variety of conditions.

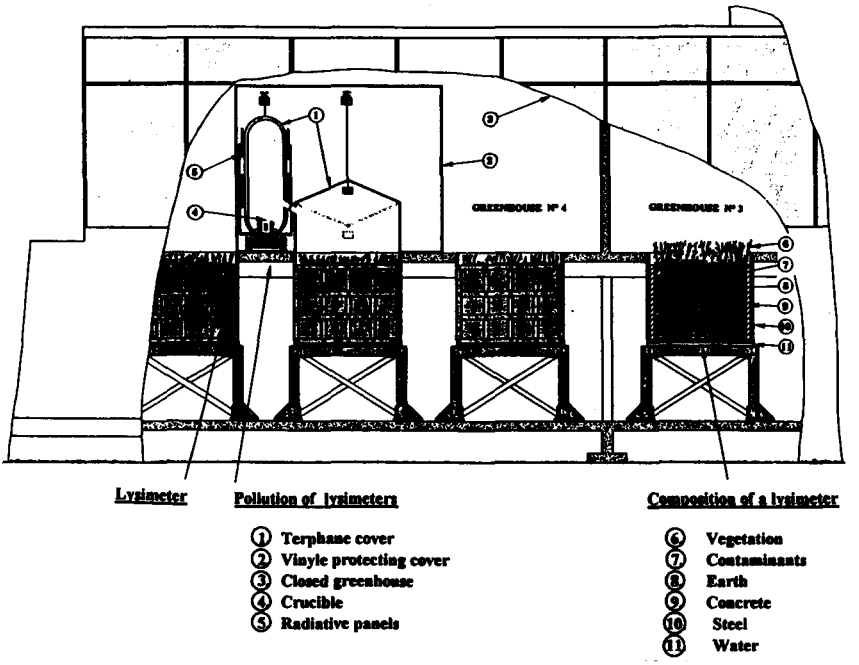

Figure 3 : The « POLYR » contamination device and installation of the lysimeters into the facility.

3) Climatic control within greenhouses for simulation of representative environments.

The facility includes four independent greenhouses (50m^2 on floor and 4m high) in a depressurised nuclear containment, associated with a radio-chemical laboratory. Physical and chemical preparation of the samples, as well as the gamma and beta countings, are carried out in this laboratory. In its lower part, the facility can host twelve large lysimeters, the surface of which is lining up the floor of the greenhouses in the upper part of the building (Figure 3). The lower part of the facility, where the lysimeters are installed along with their respective hydric potential control systems, is temperature-regulated, independently from the above-lying climatic conditions in the greenhouses. The controlled parameters on the ecosystems are : atmosphere temperature (0 to 35 °C) and relative humidity (10 to 90 %), rains, ligth irradiation (same spectrum than sun), underground temperature (5 to 20 °C) and soil hydric potential (0 to - 900mbar below atmospheric pressure).

CONCLUSION : FIRST EXPERIMENTAL RESULTS

The facility was totally operational at the beginning of 1994 and has first been used to study the interaction of radionuclide-containing aerosols with plant canopies (Figure 4), (1,2). As foreseen, the contamination has reached 30 to 80 Mbq.m^{-2} for ^{90}Sr as well as for ^{137}Cs. The wheat development stage influenced markedly the interception rates of ^{137}Cs and ^{90}Sr : small plants intercepted a reduced fraction of the aerosols deposit whereas large mature plants intercepted both radionuclides with a factor up to 90%. At each plant development stage, both radionuclides behaved similarly. Translocation of both radionuclides to the grains harvested from the wheat plants after they had reached maturity, showed that the grains were mostly contaminated by ^{137}Cs. The translocation to the grains was increasing when contamination of the plants occurred late in the plant development cycle, i. e. at a date close to maturity.

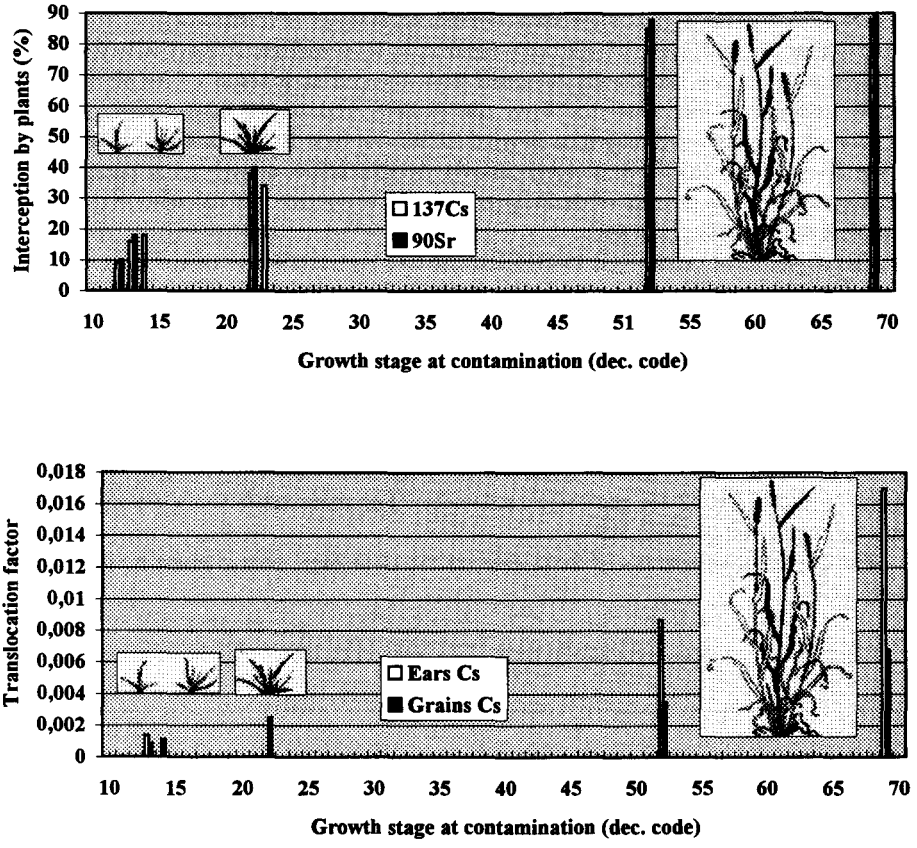

Figure 4 : Interception and subsequent translocation to grains of ^{137}Cs and ^{90}Sr versus wheat development

COEFFICIENT OF SOIL DECONTAMINATION FROM STRONTIUM-90 AT THE TERRITORY OF EAST URAL RADIOACTIVE TRACE (EURT)

[1]A.V.Bazhenov [2]M.A.Izymov [1]P.V.Volobuev

[1]Institute for Industrial Ecology UB RAS, Ekaterinburg, Russia
[2]Management on rehabilitation of EURT territories in Sverdlovsk region, Ekaterinburg, Russia

The knowledge of coefficient of soil decontamination is necessary for predictions the dynamics in development of radioactive situation, for retrospective estimation and reconstruction of the initial radioactive contamination levels of territories.

By effective coefficient of soil decontamination from radionuclides (CSD) we mean the multiple of a nuclide completely removed from the soil as a result of its physical decay, active removal of radionuclides from the ground into water ecosystems, as well as biogeochemical and wind migration beyond EURT borders. Its dimension can be expressed in the divisible relation (in how many times?), in percentage, as well as in periods of half-desintegration, if the process of desintegration is the exponent. The calculation is made on a complete nuclides supply in soil.

The objective of the study is to calculate the effective coefficient of soil decontamination from ^{90}Sr on the basis of the analysis of the experimental materials received at EURT territories in Sverdlovsk region.

Three sources of the information were taken.

1. Minimum and maximum data received by central plant laboratory of combinate No 817 (CPL), Leningrad scientific-research institute of radiation hygiene Ministry of Public Health of the USSR (LSRIRH) and Institute of Applied Geophysics AS of the USSR (IAG), as well as data of Experimental scientific-research station at PA "Mayak" (ESRS PA "Mayk") in 1957-1962 for the same settlements. For these settlements we have out own data for the period of 1992-1994.

The comparative analysis of these data for the same local sites is given by the following coefficients (tab. 1):

Table 1.

Coefficient of soil decontamination from ^{90}Sr received by the comparative analysis of various initial data

Statistical parameters	CPL, IAG LSRIRH (at minimum values)	ESRS at PA "Mayk"	CPL, IAG LSRIRH (at maximum values)	On the integrated data (CPL, IAG,LSRIRH ESRS at PA "Mayk")
Mean	4,53	3,74	6,91	4,96
Confidence level (95%)	3,13 - 5,92	2,86 - 4,63	5,09 - 8,74	4,09 - 5,82
Standard error	0,71	0,45	0,93	0,44
Minimum	1,28	1,03	2,56	1,03
Maximum	10,29	7,18	13,71	13,71
Count	14	16	13	43

On evidence of ESRS at PA "Mayak" - 3,7±0,7, on minimal values of CPL, LSRIRH and IAG - 4,5±0,5, on maximal values of CPL, LSRIRH and IAG - 6,9±0,9. Basing on the integrated data of all organizations the effective coefficient is equal to 5,0±0,4 (range from 1,0 up to 13,7; confidence level at P=0,95: from 4,1 up to 5,8, n=43). At defectation of the doubtful minimum variables giving coefficients less than 2,4 (i.e. coefficient on pure physical decay of ^{90}Sr, fig., curve 1), the CSD becomes equal to 5,5±0,5 (range from 2,4 up to 13,7, confidence level at P=0,95: from 4.6 to 6,4, n=37).

2.The second source of calculation - data from the analyses of practically annual selections of undisturbed soil samples from 1975 till 1992 on two far remote experimental plots of radiological laboratory of chemical station of the Sverdlovsk region. These coefficients were calculated for practical purpose, and in the table they are submitted in percentage of soil decontamination of ^{90}Sr per year. CSD depends on a long period of time after the accident (tab. 2). So, in the first year the coefficient decounts for 6,2 percents, within the first five years - for the average of 5,8% per year, in the first decade for 5,3 and throughout the whole 36 year-long period - on the for average of 2,7% per year, i. e. the migration of ^{90}Sr has the tendency of decrease in time, the process of decontamination is not submitted to the exponential law (Fig., curve 2). According to these obtained data the CSD for the period from 1957 till 1993 is more then 5.

3. The third source of the information - materials of Sverdlovsk regional Sanitary Epidemiological Service. The comparative analysis was conducted for *the same areas of radioactive contamination* (more than 250 km^2) on the 1958 map (more than 10 Ci/km^2) and on the 1968 map. At comparing the levels of pollution it was revealed, that only in a compared decade the density of radioactive contamination by ^{90}Sr has decreased 5 times. Taking into account, that this coefficient concerns only to the first decade and not to the whole 36 year-long period, as we have calculated from the above reasoning it clear that of soil decontamination was much more, than five times.

Table 2

Coefficient of soil decontamination from ^{90}Sr, percents per year.

Years	Coefficient	Years	Coefficient	Years	Coefficient
1958	6,21	1970	4,97	1982	3,73
1959	6,11	1971	4,87	1983	3,63
1960	6,00	1972	4,76	1984	3,53
1961	5,90	1973	4,66	1985	3,42
1962	5,80	1974	4,56	1986	3,32
1963	5,69	1975	4,45	1987	3,22
1964	5,59	1976	4,35	1988	3,11
1965	5,49	1977	4,25	1989	3,01
1966	5,38	1978	4,14	1990	2,92
1967	5,28	1979	4,04	1991	2,84
1968	5,14	1980	3,94	1992	2,76
1969	5,07	1981	3,83	1993	2,68

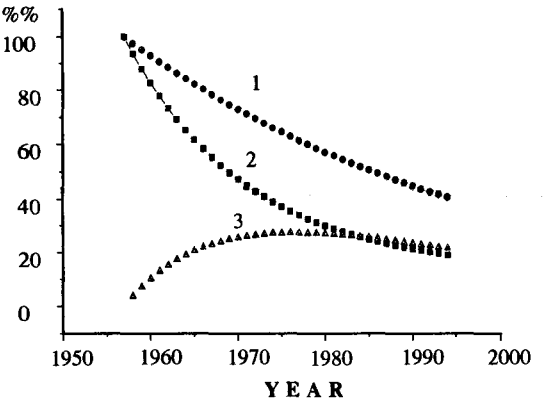

Fig. Dynamics of soil decontamination from ^{90}Sr.
Residual contamination, 100 per cent in 1957: 1 - On the physical decay, 2 - On the effective decay of soil decontamination. 3 - On the cumulative biogeochemical decontamination

Thus, the most probable coefficient of soil decontamination from ^{90}Sr in the Urals region for a 36 year-long period after the accident is equal to five.

In the following discussion of the received data we would like to call attention to the following:

On a data (Ionizing Radiation Levels and Effects, 1972) the soil loses in a year up to 2,5% ^{90}Sr at the expense of mechanical processes. Proceeding from these given during 37 years quantity of strontium has decreased in 2,8 times, we have this value equal 2,6. It should be noted, that the coefficient 2,8 takes into account not complete migration of nuclide from soil, as far as in it has a share of ^{90}Sr, entering of vegetable cover, with further partially coming back in soil.

Here we are dealing with the effective coefficient of soil decontamination from ^{90}Sr, which includes, as was stated above, its physical decay (this coefficient is equal to 2,4 per 36 years, fig., curve 1), active removal of radionuclides from the ground ecosystems into water ecosystems (lateral migration at the bottom of the lakes, bogs, rivers and ocean), as well as biogeochemical and wind migration beyond the EURT borders.

The correctness of application of the calculated coefficient of soil decontamination should especially draw attention to the analysis of highly-contaminated continuous of plots at EURT-territories (in "head part" of trace, for example) with virtually closed biogeochemical radionuclides cycle.

It should be especially noted that the biogeochemical decontamination in the first years after the accident was higher and in the subsequent years the availability of ^{90}Sr has sharply decreased. The dynamics of ^{90}Sr migration is so, that already since 1983-1985 the active biogeochemical soil decontamination in EURT zone is accounted for by the physical decay of ^{90}Sr (fig., curve 1, 3). It does not mean, that ^{90}Sr penetration to animals (including humans) can be relatively low, on the opposite, migration of ^{90}Sr can be higher than the legal normative statements, that should be taken properly into account in practical activities.

THE PROBLEM OF INHALATION DOSE ESTIMATION IN CHERNOBYL NPP 30 km-RADIUS ZONE

A.K.Sukhoruchkin, S.V.Kazakov

Dosimetric Control Board of Research and Industrial Association "Pripyat"

Compared to initial accident period, dose rate of external exposure had reduced by today tens and hundreds times as much; after accident release products had fallen out of atmosphere on underlying surface and ^{131}I had decayed, sharp inhalation exposure has been discontinued. Nevertheless the problem of radiation safety securing of personnel within 30km-radius zone of ChNPP remains sufficiently actual. Considerable contingent of persons, working (and living) constantly on radioactively contamenated territory is subjected to chronic or episodic exposure on the part of uncontrolled sources.

The difficulty of the individual inhalation dose determination is caused by (i) spatial and temporal nonuniformity of the air radioactive contamination, (ii) presence of the radioactive fuel aerosols, (iii) radionuclide mixture content in the human body.

AIR MEDIUM RADIATION STATE CONTROL SYSTEM

Air is controlled at 24 stationary posts and also with the aid of movable sampling apparatuses on automobile roads and in places of the most intensive works with the solid radioactive wastes. Every month 76 samples of air and 62 samples of fallout are analysed for determination of gamma-ray emissing nuclides content and also 25 samples of air and 10 samples of fallout - for determination of ^{90}Sr and isotopes of $^{238,239,240}Pu$.

CONTENT OF RADIONUCLIDES WITHIN LAND LAYER OF AIR

The main source of joining radionuclides with air within the zone of ChNPP is radioactively contaminated underlying surface. Considerable similarity as to nuclide ration (%) in soil and air witnesses this (the data on ChNPP 5 km-radius zone in 1995):

	^{90}Sr	^{134}Cs	^{137}Cs	^{238}Pu	$^{239,240}Pu$	^{241}Pu	^{241}Am
Soil	20.7	1.1	46.6	0.23	0.64	30	0.65
Air	17.0	1.6	69	0.09	0.25	11.8	0.25

At present according to data of measurements at the stationary control posts resuspension factor is estimated on the average over the range from $2 \cdot 10^{-10}$ to $5 \cdot 10^{-9}$ m^{-1}. During the period of 1986-1988 concentrations of radionuclides in air were quickly decreasing but over the last five years they have been remaining almost unvariable. Peaks of concentrations are not infrequently in step with dry windy weather and dips - with humid weather. Seasonal changes take place as well: concentrations grow in spring, after snow cover had vanished and soil had dried, and diminish in winter. Radioactive contamination of air increases in the event of forest fires. As a whole, during post-accident period concentration of radionuclides in air lowered a million times as much. Depending on the position of measurements the total average annual concentration of the radionuclide mixture ranges from 0.078 to 21.5 mBq/m^3. According to data of 1987-1990 an activity median aerodynamic diameter (AMAD) is over the range of 5-7 μm: ^{134}Cs - 5.0-7.2; ^{137}Cs - 5.3-7.2; ^{144}Ce - 5.5-6.5; $^{239,240}Pu$ - 5.0-5.5(1). In due course AMAD of aerosols almost does not change.

According to the data obtained from the stationary air samplers on the average the inhalation doses do not exceed 1% of the established annual limit of 20 mSv.

FUEL AEROSOLS INFLUENCE UPON INHOMOGENEITY OF PERSONS EXPOSURE

A great part of common activity of aerosols in the 30km-radius zone of ChNPP is concentrated on so-called fuel particles. These particles are met in air quite seldom therefore it should be expected that inhalation doses are distributed to contingent of persons unevenly even if these persons are under equal production and life conditions.

Specially realized researches show that 1000 m^3 of air contain on the average no more than 34 radioactive particles. About 33% of the particles contain alpha-radiating nuclides (1). Using these amounts and deposition factor for particles with AMAD of 5 μm we will obtain that mean number particles forming inhalation dose, makes up, for example, in Chernobyl 0.15 particles per year and in industrial zone of ChNPP - 1.1 particles per year.

Distribution of such rare events has been accepted to describe by the Poisson law. Then, for example, under conditions of the Chernobyl town two particles have been laying in lungs for a year, by probability 0.01 (or at 1% of persons), that is 13 times the mean number; in industrial zone of ChNPP four particles have been laying in lungs for a year, by probability 0.02, that is almost 3.6 times the mean number for this point.

SPACE AND TEMPORAL IRREGULARITY OF CONCENTRATIONS' FIELD

Source intensity of secondary contamination of the land-layer of the air depends on many parameters: contamination density, physical and chemical forms of radionuclides, weather conditions, state of surface.

Average annual concentrations of radionuclides in air within periphery of the 30km zone and in its central part differ more than by two orders.

The local concentrations in the ChNPP zone that happen by mechanical or fire influences the contaminated surfaces are tens and hundreds times the concentrations measuring with the stationary samplers. Especially high concentrations were monitored by simple operations (transportation, loading) with slightly solid radioactive wastes. (See Tabie).

The local concentration (C_L) of $^{239,240}Pu$ in air in comparison with the concentration (C_B) measured in the stationary sampler, mBq/m^3 and estimates of the commited dose equivalent (H_T) and committed effective dose (H_E) from the ingalation of local contamination air during 100 hours

Working place	Concentration		H_T, mSv			H_E, mSv
	C_B	C_L	Bone surface	Lungs	Red bone marrow	
The roadway	0.008	1.6	0.64	0.092	0.028	0.043
Loading the ground	0.052	13.0	5.09	0.73	0.23	0.34
The solid waste repository dumping	0.052	340	134	19.2	5.94	8.9

Changeableness of weather conditions and technological regimes in the ChNPP zone, considerable differences in physical processes of forming background and local concentrations put obstacles in the way of establishment of correlation relationships between these concentrations.

Inhalation doses calculated by taking into consideration the assumption that a person without means of individual protection is being in the field of the local concentration during 100 hours, that is, 5% of annual working time, are shown in Table also. Under these conditions the principle dose limits are not exceed but it is obvious that in individual cases inhalation doses may be quite considerable and as a whole pronounced inhomogeneity of personnel's inhalation exposure takes place.

INCORPORATED RADIONUCLIDES CONTROL

Within the ChNPP zone inhalation doses are caused mainly with transuranium nuclides but there are the certain limitations of possibilities of their registration, especially in the presence of ^{137}Cs.

In 1994 26% of workers within 30km zone had content of ^{137}Cs over 1500 Bq, 9% - over 3700 Bq, 2% - over 11000 Bq according to data of measurement on the whole-body counter.

Content of ^{137}Cs in organism of persons being within the ChNPP zone is hundreds times the significant content of ^{241}Am; the latter is estimated by a magnitude of several Bq. For example, in 80 days after inhalation entrance on the level of one ALI (200 Bq) about 9 Bq of ^{241}Am were laid in all bone tissues (2).

Practical measurements at the modern measuring complexes confirm availability of difficulties when determining transuranium nuclides against a background of gamma radiation of ^{137}Cs. In the work of the Nuclear Safety and Protection Institute (France) the content about 20 Bq of ^{241}Am and about 1500 Bq of ^{239}Pu in the presence only 300 Bq of $^{134,137}Cs$ was determined. ^{241}Am registration limit by the content 2300 Bq of $^{134,137}Cs$ is estimated by the magnitude of 6.5 Bq by the time of measurement 60 min (3). The content of ^{241}Am on a high level 4...8 Bq by the content of ^{137}Cs on a low level 400...600 Bq was determined at the Ukrainian Scientific Center of Radiation Medicine also.

NORMATIVE SUBSTANTIATION OF INHALATION DOSES LIMITATION

The calculations of ^{137}Cs content in lungs and a body by the content of nuclides mixture on the authorized level were made (4) and was demonstrated that in nuclides mixture sizeable more low (8...2000 times as little) ^{137}Cs content, compared to regulated magnitudes. Thus, even background content of ^{137}Cs under conditions of the ChNPP zone by itself does not guarantee strict keeping established dose limits.

Normative documents do not reflect all specific properties of Chernobyl release radionuclides. According to data of 1993 about 42% of ^{137}Cs containing in the air has been in fuel aerosols (particles). This so-called fuel caesium is hard soluble and belongs to the lung Y class. Created by this ^{137}Cs dose in lungs is 80 times as high as proper dose of ^{137}Cs of D class (5), and only the latter is standardized in the ICRP Publication 61.

INCORPORATION OF RADIOCESIUM BY THE POPULATION OF REGIONS IN BELARUS, RUSSIA AND THE UKRAINE AFFECTED BY THE REACTOR ACCIDENT IN CHERNOBYL

P.Hill , R.Hille
Forschungszentrum Jülich GmbH, ASS, D-52425 Jülich

SUMMARY
This paper reports on the results of a 3-year humanitarian aid project in the CIS funded by the German Federal Ministry of the Environment. The main objective of the project was to supply the population with independent information on radiation burdens and thus improve their psychological situation. More than 317000 measurements of post-Chernobyl body burdens of Cs-137 were performed in Belarus, Russia and the Ukraine from 1991 to 1993. In about 90 % of the cases annual doses derived from the body burdens did not exceed 0.3 mSv. Less than 2% of the measurements resulted in annual doses higher than 1 mSv. Open communication of the results helped to reduce fears in the population.

INTRODUCTION

On behalf of the Federal Ministry for the Environment, Nature Conservation and Nuclear Safety, Forschungszentrum Jülich GmbH (KFA) organized and supervised a measurement programme at a total cost of DM 13 million to determine the radiation exposure of the population in the environment of Chernobyl after the reactor accident. This measurement programme was the Federal Government's response to a relevant request for help by the former USSR. The declared aim of the measurement campaign was to contribute towards objectively informing the population about their actual radioactive exposure. As was known from experience, this helped to eliminate many unjustified fears.

In order to examine the incorporation exposure mainly due to radiocesium taken up with food, a total of 317,000 measurements were performed on persons in 241 settlements in the period 1991 - 1993. Other γ-emitting nuclides were not observed.

EQUIPMENT

Three semitrailers were deployed in towns and major localities. The vehicles were each equipped with two nuclide-resolving whole-body counters of the FASTSCAN type from Canberra for incorporation measurements. This counter is equally suited for adults and children. During a measurement time of one minute it is still possible to detect 250 Bq Cs-137. For babies and very small children a special whole-body counter developed by the KFA was available from 1992 with which even 150 Bq Cs-137 could be detected. A further radiometric measuring system from Herfurth served as a standby for days with peak demand. The data were recorded by means of PCs. The results were stored in a data base.

In villages and youth camps, four smaller measurement vehicles equipped with radiometric measurement systems (QBM-1, Nuclear Enterprises) were used in 1991.

They were replaced in 1992 by a box-type van in which an incorporation monitor HM13010 (Herfurth) was installed.

RESULTS

Effective communication of the measurement results was an important prerequisite for achieving the humanitarian goals of the measurement campaign. A form with a registration number and the most important personal data was prepared for every person measured. The original was handed to the test person and one copy each was given to the local health authorities and the Research Centre Jülich. On this form, the measured value was confirmed and the radiation hazard assessed. For this purpose, the measured persons were classified into three categories (see *Table 1*). The threshold between categories 1 and 2 corresponds to an internal radiation dose of 0.3 mSv per year. The threshold between categories 2 and 3 corresponds to a radiation dose of 1 mSv per year.

The results are compiled by states in *Table 2*. In the first year, the measurements were completely concentrated on Russia. Measured values in category 3 were only obtained in just under one per cent of 163,000 cases. In the second year, the measurement campaign was extended to Belarus and the Ukraine. The cases in category 3 increased to 1.5 %, which should be attributable to a reduced number of test persons in less exposed regions of Russia and to the inclusion of further Russian measurement sites in zones with high soil contamination. In the third year, the number of cases in category 3 further increased since measurements were performed at locations with higher exposure in Ukraine and the measurement campaign in Russia concentrated more on settlements where high measurement values had already been found in the preceding years. Averaged over all three states and all three measurement years, however, the fraction of measurements in category 3 remained below 2 %. We recommended that this group of persons should be treated as is common practice in the Federal Republic of Germany for occupationally exposed persons, which means that they should be thoroughly examined at least once a year and that the incorporation profile should be controlled at regular intervals.

Table 3 shows average ingestion doses for adults in 1993 at locations in the Gomel region (Belarus). The doses were calculated from the arithmetic mean of measured activities. The highest dose of 2.2 mSv/a was observed in Kirov, a village near a forest, which was been partially evacuated. At this location, the highest activities were indeed measured during the entire three-year measurement campaign. Exposures of up to 770 kBq Cs-137 were determined corresponding to an ingestion dose of 29 mSv/a. The current annual dose limit of 50 mSv for occupationally exposed persons in Germany was thus not exceeded in this extreme case either. Average annual doses around 0.3 mSv/a, as observed in Leltschitzy, Narovlja and Svetilovitschi, must still be regarded as elevated. In Narovlja and Svetilovitschi this is due to elevated soil contamination. In Leltschitzy, on the other hand, soil contamination is fairly low. At this location, soils with a high transfer factor for the transfer of radiocesium from soil into plants are to be assumed as the cause for elevated exposure.

TABLE 1: CLASSIFICATION INTO CATEGORIES AS A FUNCTION OF MEASURED CS ACTIVITY

	children	adults
category 1	< 4 000 Bq	< 7 000 Bq
category 2	< 15 000 Bq	< 25 000 Bq
category 3	≥ 15 000 Bq	≥ 25 000 Bq

TABLE 2 : RESULTS OBTAINED ON INCORPORATION MEASUREMENTS IN 1991 - 1993

	Total	cat. 1	cat. 2	cat.3
1991 Russia	163033	93.7%	5.3%	1.0%
1991 Total	163033	93.7%	5.3%	1.0%
1992 Russia	49858	85.8%	11.7%	2.5%

ENVIRONMENTAL MEASUREMENTS IN RUSSIA, BELARUS AND UKRAINE FROM 1991 - 1993

K. Heinemann and R. Hille
Forschungszentrum Jülich GmbH, D-52425 Jülich, FRG

INTRODUCTION

In the years 1991 to 1993 the Research Centre Jülich organised and conducted environmental measurements in the areas of Russia, Belarus and Ukraine which were contaminated by the reactor accident of Chernobyl. Within the scope of the "Measuring Program of the Federal Republic of Germany", investigations of soil contamination, area dose rate and measurements of food produced in these regions were performed. Some aspects of these investigations are to be discussed.

MATERIALS AND METHODS

More than 7000 environmental measurements have been conducted within the contaminated areas. Many teams from different institutions in Germany have participated in the three measuring campaigns each between three or four weeks a year.

The soil contamination was determined by taking soil samples and measurements with a gamma spectrometer in a mobile laboratory (measuring van) or by in-situ-gamma spectrometry. The depth profiles changed within short distances. This means that at each position the depth profile had to be determined separately which strongly extended the measuring time.

The gamma area dose rate was measured by small portable equipment.

But the main aim of our measurements was the determination of the contamination of food locally produced. For this purpose, food was brought to our van by the public after the announcement by the local authorities one day before. Immediately after the measurement a certificate in Russian language was handed over to the people which included the true measured value and a comment in regard to the Russian contamination limits which are similar to the international ones. Sometimes the measurements were difficult because the mass or the volume of the single samples were too low to be measured within the 10 minutes used normally or the geometry of the samples (e.g. meat) was different from the one used during calibration.

RESULTS

Each single measurement is listed in the reports (1 -3) of the different years or are available as data files. Therefore the single measurements shall not be reproduced in this paper but the ranges of the food measurements are given in Table 1.

In general it can be stated, that only a few samples in a few settlements are above the Russian contamination limits; e.g. self-produced milk in some settlements in the north western part of the Klincy district (Briansk region, Russia) showed high contamination levels.

DISCUSSION

1. MILK CONTAMINATION

Fig. 1 shows the mean values of Cs-137 milk contamination of different settlements in the Klincy district. It must be stressed again that these are the contamination values of the milk produced in the settlements and not the milk which could be bought in the local shops. The last one is much lower contaminated (about 20 Bq/l). From 1991 to 1992 the decrease of the milk contamination is obvious. But from 1992 to 1993 there was an increase in the milk contamination in some villages (Guta Korezkaja, Lopatni and Blisna). This can be explained by

- the lack or reduction of fertiliser given to the meadows or
- the measurements were not statistical representative

If the annual mean values of all single measurements carried out in all settlements in the Klincy district in 1992 and 1993 are compared, a small decrease in the milk contamination remains for 1993 in regard to 1992.

In Fig. 1, there are also given mean values for different settlements for the year 1994 which were made available by the Novozybkov Branch of the St. Petersburg Institute of Radiation Hygiene. The last measurements show that the general decrease with time of the milk contamination is going on in 1994 even if there are exceptions e.g. Beresowka, Guta Korezkaja.

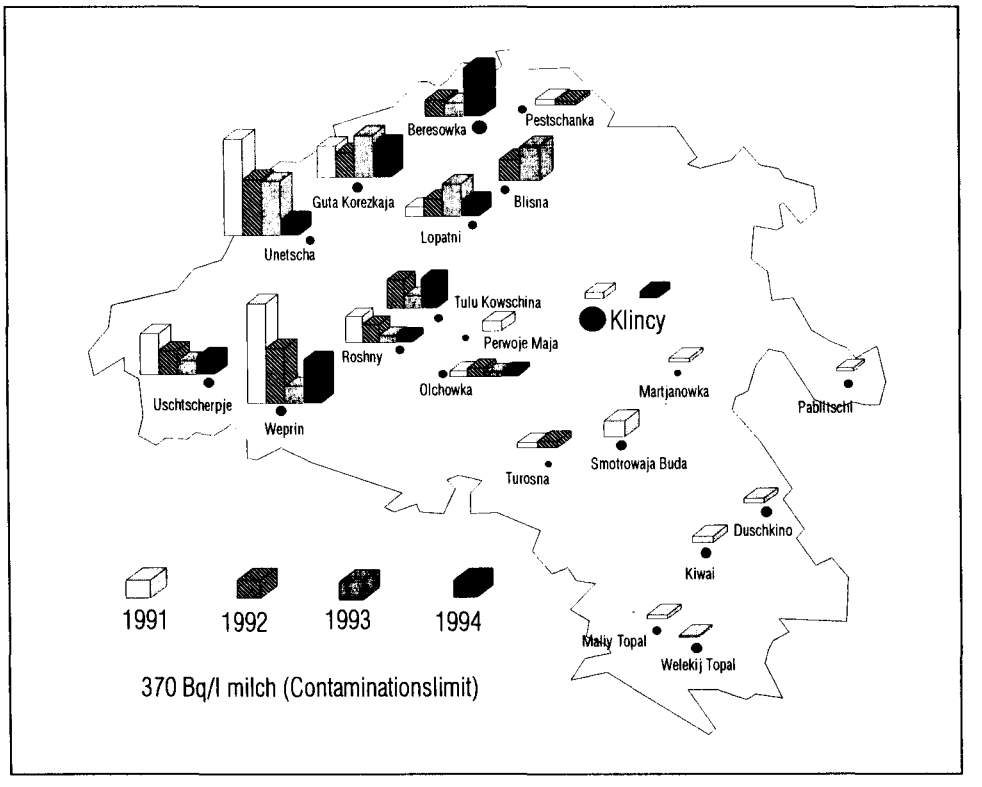

Fig. 1: The mean values of Caesium milk contamination in different settlements

2. AREA DOSE RATE

A correlation between Cs 137 soil contamination and the area dose rate measured 1 m above ground (same position) has been assumed. The area dose rate is due to contributions from mainly Cs 137 soil contamination as well as other nuclides like Cs 134, K40, the nuclides of the decay chains of the natural uranium and thorium families and the cosmic radiation. In Fig 2 the cross area dose rate is given as a function of Cs 137 soil contamination.

The good correlation regarded separately for meadows (undisturbed ground) and acres (disturbed ground) is most surprising (single measurements!) because each point in the figure is a composition of two independent determinations of the area dose rate and the soil contamination each of which has an uncertainty. These correlations enable us also to prove if there are incorrect single measurements.

The value of the area dose rate for the Cs 137 soil contamination "zero" is determined only by the contribution of the natural background and the background of the instrument. It results for the two correlations, (disturbed and undisturbed ground) in the same value of 0.20 μSv/h. For the Cs 137 soil contamination the net area dose rate above meadows is about twice the one over acres. For 1000 Bq Cs 137/m^2 we get an cross area dose rate of 0.69 μSv/h over acres and 1.28 μSv/h over meadows.

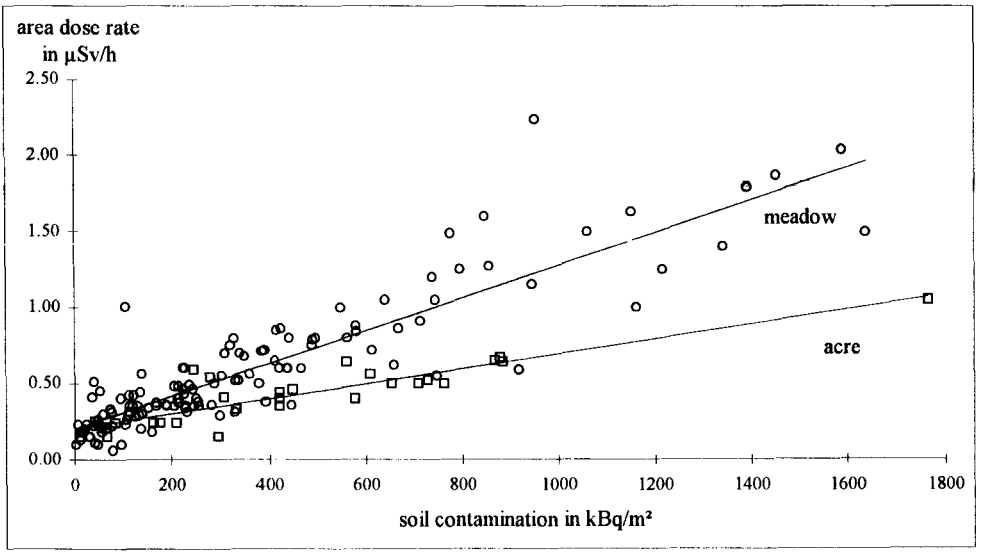

Fig. 2: Area dose rate as a function of soil contamination

3. FOOD CONTAMINATION

A comprehension of the single values determined in food measurements (1 - 3) is given in Tab.:1.From the table it becomes obvious that the food grown in gardens or acres is less contaminated than berries, mushrooms or meat of wild animals from the forest. Fish of prey is also highly contaminated

Tab.: 1 Measuring Ranges of Food Groups

area	fruits of the forest (Bq/kg)	fruits of the garden (Bq/kg)	cereals and their products (Bq/kg)	meat (Bq/kg)	fish (Bq/kg)
Klincy	<18 - 12320	<2,5 - 1270	79	4 - 4590	23 - 1170
Gordcjewka	89 - 18000	<4 - 514		<20 - 820	71 - 86000
Krasnaja Gora	119 - 16900	1,6 - 758	<3 - 8	27 - 500	28 - 2925
Belarus	<10 - 64000	<4,1 - <350	14 - 25	23 - 7311	61 - 607
Ukraine	<7,6 - 304	<1 - <10		<1

CONTRIBUTION OF THE SHORT-LIVED ISOTOPES INTO RADIATION SITUATION IN BELARUS AFTER CHERNOBYL NPP ACCIDENT.

Dubina Y.V.,Guskina L.N.

Institute of Radioecological Problems Academy of Siences Belarus, Minsk

The reconstructed data about the radiation contamination of the some regions of Belarus was studed. The individual character radiactive fallout in verious regions has been found out. The contributions of short-lived isotopes in the integral activity and generation of the exposure dose rate was estimated. For reconstruction and systematization the contamination was used statistical treated data of the integral radiation-ecological data bank of the Institute of Radioecological Problems of the Academy of Science of Belarus. The data bank contain the results of gamma-spectrometric mesurements of the early soil samples (May - June, 1986), wherein La-140,Ba-140, Ce-141,Cs-136,I-131,Te-132 and I-132 radionuclides have been identified.

DATA BANK FOR THE DATA AT EARLY MEASUREMENTS OF RADIOACTIVE CONTAMINATION IN BELARUS AFTER CHERNOBYL NPP ACCIDENT

INTRODUCTION

Radiation and ecological data bank of the Institute of Radioecological Problems/Academy of Sciences of Belarus (till 1992 the Institute of Nuclear Power Engineering/Academy of Sciences of Belarus (INPE ASB) was formed in June 1986 [1]. In 1986 the Institute of Nuclear Power Engineering was a leading institution in the Academy of Sciences of Belarus on studying radiation situation where the data of radiometric measurements of different organizations for analysis, forecasting the situation and mapping the contamination of the territory of Belarus were concentrated. For classification, verification, storage and timely processing of the information accumulated at the INPE ASB the data bank was created at computer ES-1061. As a software a program complex ASPID-5/ES was used which was developed at the Institute of Mathematics/Academy of Sciences of Belarus [2] . The initial data bank included only the results of gamma-spectrometric and radiochemical measurements of ring samples of soil which were selected and treated according to regulation documents developed and approved by INPE ASB and Goshydromet USSR on June 13, 1986. The very first results of gamma-spectrometric measurements of samples of the objects of the environment (soil, water, vegetables, etc.), obtained in May 1986 were not included into the data bank, because the distinguishes available of the techniques of their selection and measurement did not allow a unique data processing to be carried out. These data were only partially used for the analysis of radiation situation and mapping in 1986-1987.

Owing to active participation of many organizations in the works on selection and measurement of soil samples, as well as to timely processing of the data with the help of the formed data bank, in August 1986 the map of the contamination with ^{137}Cs of the whole territory of Belarus was drawn up at the Institute, and in November 1996 - the maps of contamination with ^{90}Sr and isotopes of Plutonium. For mapping more than 11600 gamma-spectrometric measurements of the objects of the environment from 1386 settlements and about 2100 radiochemical measurements were used [3].

Further the data bank was modified to some extent and added with a package of applied programs what made the preliminary processing and verification of the data be easy [4, 5].

ORGANIZATION AND STRUCTURE OF DATA BANK OF EARLY MEASUREMENTS OF RADIOACTIVE CONTAMINATION IN BELARUS

Last years an interest to reliable estimations of doses, obtained by the population during the first year after the Chernobyl NPP accident when they were the largest ones, was increased. It stimulated a further development of the data bank for more full presentation of early results of gamma-spectrometric measurements of samples of the environment as well as for more convenient processing of theirs. For that purpose in 1991 a new data base management control systems for computers PC AT/286/386 were developed at the Institute [6]. In this system every data base is represented by a set of files of relational type of DBF structure, but there are some distinguishes as to the description of fields formats in comparison with a traditional presentation of DBF files. An additional format was introduced for presentation of digital data with a float point "E". For the operation with such files an original interface was developed. The files created with the help of this interface are recognized by all similar systems (DBASE, FOXBASE, etc.), which process the files of DBF structure, but here the fields of "E" type are presented as symbolic ones.

Main functions of the system, providing with the access to the data, processing and modification of data bases, formation of complicated queries for data retrieval, generation of reports, etc., are realized in the form of menu tree.
Data bank presents a set of data bases of various assignment. The information about the measured samples of the objects of the environment (type of sample, technique and place of sample's selection, date of selection and

measurement of sample, exposure dose rate at the place of sample's selection, who selected and measured the sample, isotope activity in the sample and others) is stored in 18 files of DBF structure. Official information necessary for functioning of the system is stored in 17 files of DBF structure. Moreover, there are data bases of reference and normative information necessary for users.

APPLICATION PACKAGE FOR DATA PROCESSING AND CONTENT OF THE DATA BANK

For analysis, classification and verification of the data of early measurements a package has been created for data processing, which are presented in files format of DBF structure. The package includes the following main programs:

- programs for carrying out statistical analysis;
- programs for the calculation of exposure dose rate according to the isotopic composition of gamma-emitted radionuclides measured in the sample as well as recalculation of isotopes activity as of the specified date;
- verification programs for measurements of activities of genetically related radionuclides (for example, ^{140}Ba and ^{140}La, ^{95}Sr and ^{95}Nb);
- verification programs for measurements of activities of "similar" radionuclides (for example, ^{141}Ce and ^{144}Ce, ^{103}Ru and ^{106}Ru);
- verification programs for measurements of soil samples as to the ratio between dose rate of gamma-radiation above the surface of soil, measured when selecting the sample, and calculated according to the measured isotopic composition;
- verification programs of activities of non-volative radionuclides;
- programs of activities' reconstruction of genetically related isotopes with small periods of half-life-decay.

For investigation of space distribution of radioactive fall-outs on the territory of Belarus a geographic information system GEOS has been developed which is connected with the data bank [7]. The system GEOS has its own cartographic data base where there are the digital maps structured in a vector form, describing in equivalent form topographical maps of 1:200000 scale of the territories of Gomel and Mogilev regions. The system GEOS gives the possibility to carry out an additional analysis of the data when studying space dependence of activities' ratios in samples, their correlation connections as well as to draw various thematic maps for graphic supplements [8].

At present the data bank contains the results of radiochemical and gamma-spectrometric measurements of soil samples and grass samples selected from 1532 settlements of Gomel, Mogilev and Brest regions in 1986 and in 1987. The number of gamma-spectrometric measurements of samples constitutes:

12190 - ring samples of soil;
795 - "non- ring" samples of soil;
918 - samples of grass.

Short-lived isotopes were identified in a considerable part of these samples. Table gives the data about the number of samples of soil measured in 1986 and in 1987, where the activity of short-lived isotopes was measured.

Table

Number of soil samples in the data bank where short-lived radionuclides were identified

Radionuclide	Gomel region		Mogilev region		Brest region	
	1986	1987	1986	1987	1986	1987
^{132}I	66	-	-	-	2	-
^{132}Te	137	-	1	-	5	-
^{131}I	1075	-	605	-	52	-
^{136}Cs	651	-	276	-	24	-
^{140}Ba	158	-	1	-	2	-
^{140}La	717	-	257	-	2	-
^{95}Zr	4044	938	1454	186	495	59
^{95}Nb	4452	1194	2131	271	638	157
^{103}Ru	4647	321	2524	203	740	92
^{141}Ce	3742	198	932	186	375	89

At the nearest future the data bank is planned to be supplemented with available early measurements of samples of soil, grass and food-stuffs from the other regions of Belarus as well as the verification programs of the data to be modified with due account of changeable isotopic composition of fission fragments depending on burnup of fuel assemblies of RBMK-1000 reactor.

ESTIMATION AND FORECAST OF THE RADIATION SITUATION ON THE TERRITORY OF THE REPUBLIC OF BELARUS AFTER THE CHERNOBYL NNP CATASTROPHE

Zhukova O. M., Matveenko I.I., Germenchuk M.G., Shagalova Eh.D.

State Committee for Hydrometeorology of the Ministry for Emergencies and Protection of the Population after the Accident at the ChNPP
Minsk, Belarus

INTRODUCTION

During 10 years after the accident at the ChNPP the large amounts of the data on the content of radionuclides in the soil have been collected, using the network of the radiation monitoring stations.

In the after-accident period, the aerial photography of the territory of Belarus has been done, all populated areas have been investigated, including the agricultural and forest areas.

The information has been processed with use of the geoinformation RECASS system of construction of maps of distribution of caesium-137, strontium-90 and plutonium isotopes on the territory of the Republic.

The maps of the distribution of caesium-137, strontium-90 and plutonium isotopes on the territory of Belarus after the accident have been presented.

RADIOACTIVITY CONTAMINATION

The territories of 46,45 thousands of square kilometers have been contaminated with Cs-137 radionuclides with radiation density more, than 37 kBq/m2. 27 towns and more than 3000 populated areas with 2 millions of people, or nearly 1/5 of the population of Belarus, are located at the contaminated territories (Fig.1).

The Gomel, Mogilev and Brest Regions are the most contaminted as a result of the accident The radioactive contamination is of uneven, "spotted" character. There are cases, when within the same populated area on the relatively small areas, practically "clean" and highly contaminated plots are found close by. The Kolyban populated area of the Bragin Area, the Gomel Region can be taken as an example, where the lewels of the contamination with caesium-137 are in the range 170-2400 kBq/m2. Maximum levels of caesium-137 in the soil of the populated areas of the nearest zone have been fount out in Kruyki populated area of the Bragin Area, at the distance of 23 km from the ChNPP and consist of 28000 kBq/m2, and in the distance of 250 km in the Chudyany populated area of the Cherikov Area of the Mogilev Region are 28000 kBq/m2. The contamination of the territory of the Republic with strontium-90 is of local Character (Fig.2). The levels of the contamination of the soil with strontium-90 of 5,5 kBq/m2 have been fount out at the area of 21.1 thousands of square kilometers, which amounts to 10 per cent of the total territory of Belarus. The maximum levels of strontium-90 at the populated areas of the nearest zone have been found out in the Orevichi populated area of the Chojniki Area which is located at the distance of 28 km from the ChNPP and consists of 1800 kBq/m2.

The contamination of the soil with plutonium isotopes of 0,37 kBq/m2 has been found mainly in the Gomel Region and the Chudyany populaxed area of the Mogilev Region. The levels of the contamination of the soil with plutonium isotopes in the range 0.37 - 3.7 kBq/m2 have been found out in the Bragin, Norovlya, Chojniki, Rechitsy, Dobrush and Loev Areas of the Gomel Region. The levels of the contaminatin of the soil with plutonium isotopes of 3.7 kBq/m2 and more are Characteristic of the 30-th km zone around the ChNPP.

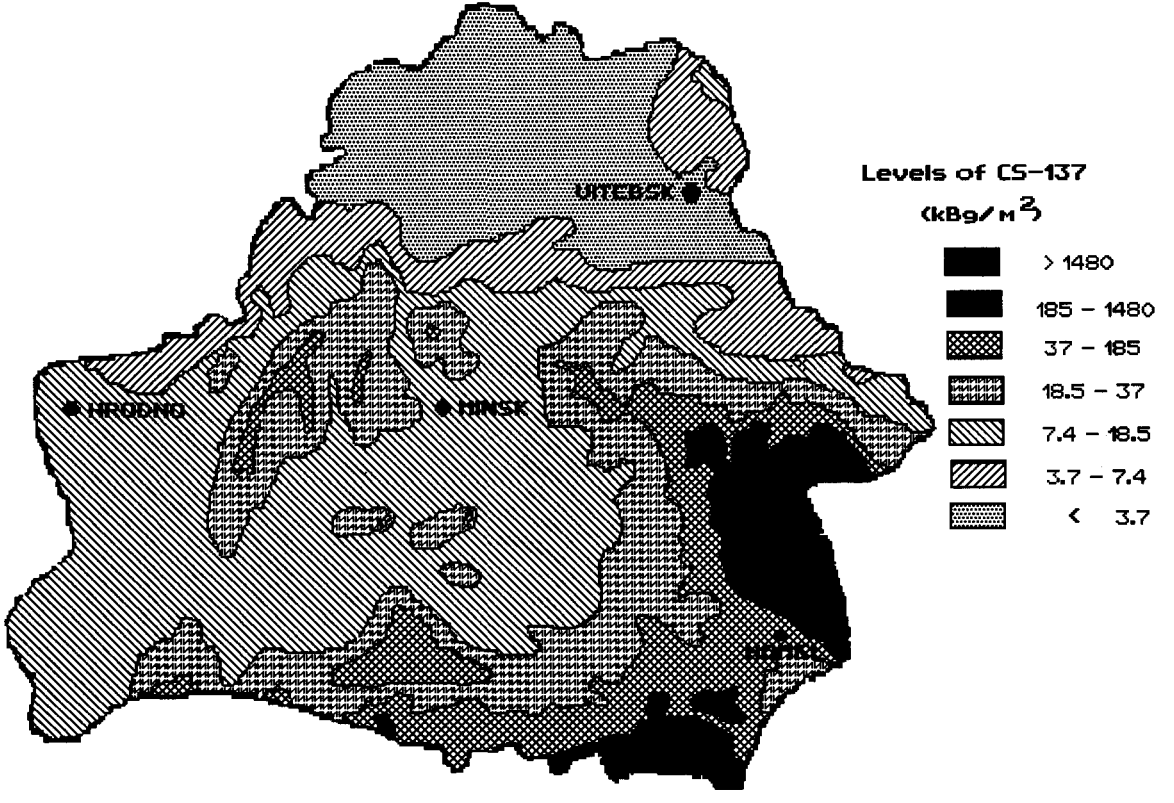

Figure 1. Radioactivity contamination of CS-137 in soil on the territory of Belarus (01.01.1995)

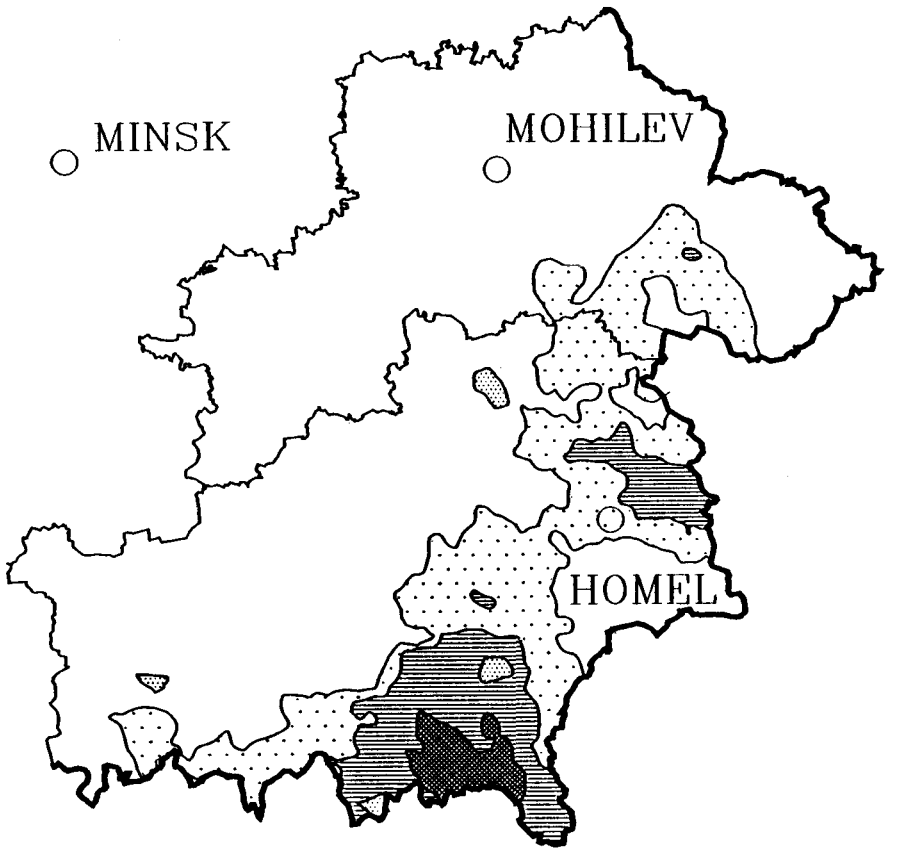

Figure 2. Radioactivity contamination of Sr-90 in soil on the territory Homel and Mohilev regions of Belarus (01.01.1995)

The forecast maps of the caesium-137 and strontium-90 inventory in the soil have been constructed with allowance for the natural decay of radionuclides for 2016 [1].

THE RETROSPECTIVE ESTIMATION OF RADIATION SITUATION ON THE TERRITORY OF REPUBLIC OF BELARUS IN THE FIRST PERIOD AFTER THE CHERNOBYL NPP CATASTROPHE

Marya Germenchuk, O.M.Zhukova, I.I.Matveenko, E.D.Shagalova

State Committee for Hydrometeorology, 110, F.Skaryna, BLS-220023, Minsk, BELARUS

INTRODUCTION

The most complicated situation at the territory of Belarus has been observed in the first period after the accident at the ChNPP owing to the great quantity of the deposited short-lived radionuclides and the radionuclides with half-lives up to 1 year.

In 26 April 1986, the radioactive isotopes, including radioactive noble gases and iodine isotopes have initially reached the height of 1.8 km and began transport with air flows in the Nort-West direction through the western and central areas of Belarus. The analysis of the subsequent meteorological situation has shown, that the meteorological conditions of the movement of the radiation-contaminated air masses in 26 April to 10 May, 1986 have determined the radioactive contamination of Belarus, in the first phase with short-lived radionuclides.

RADIOACTIVITY CONTAMINATION

The reconstruction of the distribution of iodine-131 according to the situation for 10.05.86, ruthenium-106 and cerium-144 for 30.05.86 has been carried out (Fig. 1,2). The Methodical Approaches on evaluation of the contamination of the territory of the Republic with these radionuclides have been suggested for construction of the maps-reconstructions.

In April-May, 1986, the nearest zone (10-30 km) has been mostly contaminated with iodine-131, that is, the Bragin, Chojniki, Narovlya Areas of the Gomel Region (the levels of the contamination of the soil with iodine-131 have reached 37000 kBq/sq.m and more the dose rates of 25-100 mR/h, including the Chechersk, Korma, Buda-Koshelevsk, Dobrush Areas, where the levels of contamination of the soil with iodine-131 have reached 5550-11100 kBq/sq.m, 11100-18500 kBq/sq.m.

The Elsk, Lelchithi, Zhitkovichi, Petrikovichi Areas of the Gomel Region, Pinsc, Luninets, Stolin Areal of the Brest Regions have been highly contaminated with iodine-131.

In 1986-1989, the significant contribution into the radiation situation at the territory of Belarus have made such radionuclides as cerium-144 and ruthenium-106. The Narovlya, Bragin, Chojniki Areas are the most contaminated with cerium-144 areas (the levels of contamination are 555-1480 kBq/sq.m). In the zone of the relocation of the population, the contaminations with this radionuclide have amounted to 1480-3700 kBq/sq.m. The Narovlya, Bragin, Chojniki Areas are the most contaminated with ruthenium-106 areas (the levels of contamination are 185-555 kBq/sq.m). In the zones of the levels of the contamination with these radionuclides have accounted for 555-1480 kBq/sq.m.

The restoration of the situation in the first period after the accident can be used for the evaluation of the doses, obtained in the period.

Dr J. LALLEMAND
EDF, Service de radioprotection, PARIS

L'accident de Tchernobyl a entraîné une très importante contamination en Ukraine, autour de la centrale accidentée, mais également en Belarus, république voisine de 12 millions d'habitants et en Russie (district de Bryansk).

Cette contamination a été secondaire aux rejets d'iodes et de césiums radioactifs. Son importance n'est pas seulement corrélée à la distance par rapport à Tchernobyl. Un bilan long et méticuleux publié par l'AIEA a permis d'en préciser, fin 1990, la géographie en "taches de léopard". La méconnaissance des niveaux de pollution radioactive dans les jours et semaines qui ont suivi l'accident n'a pas conduit à l'application de mesures prophylactiques et a entraîné une irradiation, à des niveaux variables, de la population biélorusse. Les enfants, dont la thyroïde est particulièrement radiosensible, ont reçu les doses les plus élevées.

De nombreuses initiatives nationales et internationales d'aide et d'assistance ont été prises dès 1986 dans un double but humanitaire et scientifique. Elles concernent essentiellement l'Ukraine et manquent cruellement de coordination.

C'est dans ce contexte et dans un souci de solidarité entre électriciens que les directions d'EDF ont décidé d'établir, en 1992, un plan d'aide et de collaboration avec les autorités

One of the consequences of the Chernobyl accident was the spread-out of an important contamination both Ukraine and Belarus (12 million inhabitants), as well as Russia (Bryansk district).

This contamination is correlated with the disposal of radioactive iodines and cesiums. The importance of this contamination is not only correlated with the distance to Chernobyl. A very long and thorough study, issued by AIEA specialists at the end of 1990, i.e. three and half years after the accident specified the precise geography of the contamination called "leopard spots". Since people discovered this contamination level as late as 1990, they did not apply the countermeasures and, as a consequence, the population, especially the bielorussian were severely irradiated. Children, whose thyroid is especially radiosensitive, received the highest doses.

Lots of national and international measures of help and assistance have been taken as early as 1986 both for scientific and humanitarian purposes. This help was essentially devoted to Ukraine and suffered from a deep lack of coordination.

In this context and to serve the common interests of electricity producers, the management of EDF decided in 1992 to set up a assistance and collaboration plan with the belarus authorities, having to face and deal with the medical consequences of the Chernobyl accident in their

biélorusses confrontées à la difficile gestion des conséquences sanitaires de l'accident de Tchernobyl sur leur territoire.

C'est ainsi qu'un contrat a été signé en février 1993 par EDF d'une part et par le gouvernement biélorusse d'autre part (Ministères de la Santé et de l'Energie, Comité Gouvernemental d'Etude des Conséquences de l'Accident de Tchernobyl et Académie des Sciences).

Ce contrat est actuellement établi pour une durée de 3 ans et porte sur une enveloppe globale de 10 millions de FF.

Ce contrat prévoit :

- participation française :

EDF a choisi d'inscrire cette collaboration dans le cadre d'une action concrète. Elle comporte 2 volets :

a) Fourniture de matériel dosimétrique et technique (*) :

- un spectromètre Gamma a été installé à l'Institut de l'Energie
- une soixantaine de dosimètres d'ambiance et 600 dosimètres individuels ont été fournis au Ministère de l'Energie.
- 80 balises de surveillance d'environnement ont été mises à la disposition des autorités biélorusses.

b) Mais l'essentiel de ce programme s'articule autour de la fourniture de matériel médical (*) et dans ce domaine, il s'agit surtout de répondre de façon rapide et utile aux attentes prioritaires des médecins confrontés à l'augmentation importante des cancers de la thyroïde chez l'enfant.

C'est ainsi qu'une gamma-caméra Sopha-Médical a été installée à l'Institut des Radiations à Minsk en 1994. Cet équipement est indispensable au diagnostic, au suivi et au traitement du cancer de la thyroïde, et jusqu'alors, il n'y avait pas d'installation de ce type en Bélarus. Cet appareil est à présent tout à fait opérationnel et pour en assurer une utilisation optimale, deux médecins ont été formés en France, au Centre Hospitalo-Universitaire de Créteil.

own country.

An official contract was set up in 1993 between EDF and the Belarus Government (Health ministry, Energy ministry, Governmental Committee on Chernobyl Consequences and Academy of Sciences).

The terme of this contract is 3 years and the costs for EDF are FF 10 million.

- French participation

EDF choose to provide concrete collaboration, by

a) supplying technical and dosimetric equipment :

- a gamma spectrometer has already been installated at the Energy Institute.
- 60 ambiance and 600 individual dosemeters have been supplied to the Energy Ministry.
- 80 environmental survey devices have also been supply to Belarus authorities.

b) But the main programme is devoted to medical equipment and, in this field, it appeared very urgent to respond to the inquiries of medical doctors involved in the treatment of thyroid cancers in chilren.

Within this framework a SOPHA MEDICAL gamma-camera arrived in Minsk (Radiation Institute) in 1994. This equipment is essential to diagnose, treat and control thyroid cancer. This EDF gift was the first device of this type installated in Belarus. It is now well operating ; two medical doctors from the Minsk Radiation Institute have been trained in a Parisian hospital (Médecine Nucléaire - Créteil) for 3 months.

Rappelons, en effet, qu'en Bélarus, le problème médical essentiel, suite à l'accident de Tchernobyl, concerne la pathologie thyroïdienne et, en particulier, l'augmentation importante de l'incidence des cancers de la thyroïde chez l'enfant (environ 500 cancers en excès depuis 1990). Ceci peut s'expliquer par l'importance des rejets d'iodes radioactifs (^{131}I, mais également isotopes à périodes plus courtes) lors de l'accident, la fixation élective de ces radioéléments sur la thyroïde et la radiosensibilité particulière de cet organe chez l'enfant.

- participation bélarus :

Elle s'inscrit, quant à elle, essentiellement autour d'une information en retour portant sur les divers aspects de cette catastrophe, en particulier et surtout sur le suivi sanitaire et médical des populations irradiées du fait de cet accident.

Il apparaît tout à fait fondamental de tirer le maximum d'enseignements de cette catastrophe, en particulier au plan médical. C'est là l'une des justifications de cette action.

(*) Il s'agit là des actions entreprises dans le cadre de la première année de collaboration.

As we all know, the most dramatic medical problem in Belarus, after the Chernobyl accident, concerns the thyroid pathology, especially thyroid cancers in children : 500 cancers have been recorded since 1990. The increase of this pathology can be correlated with the amount of radioactive iodine released in may 1986 and the high radiosensitivity of thyroid in children.

- Belarus participation

We are, of course, very interested in any available information on the medical consequences of this accident.
It is more than ever essential to learn as much as possible from this disaster especially in the field of medical consequences.

ABSTRACT (See instructions overleaf)

To find out regularities of formation of internal dose of the Russian population living on the territory contaminated with long-lived radionuclides, we investigated food rations of over 2700 inhabitants of the Bryansk region and measured actual content of Cs-134,137 in the body of them in different periods after the Chernobyl accident| in 1987, 1990, 1993, 1994-1995. The paper presents the data about urban and rural inhabitants of both sexes. The questionnairy included information about annual food ration of a person before the accident, its changes connected with the accident, the results of radiometry of the body and information about individual countermeasures. We have also studied the content of Cs-134,137 in agricultural and natural food products. Thus, the internal exposure dose was estimated by two methods| as calculated with contaminated ration and according to the actual content of radionuclides in the body. The role of natural products (mushrooms, forest berries, fish)in the formation of the dose undoubtedly increases in remote terms, since natural decontamination of the natural ecosystem from transportable forms of radioactive cesium occures considerably slower than that of the agricultural ecosystem. Countermeasures in agricultural product ion and delivery of non-contaminated products decreased intake of Cs-134,137 with food ration by a factor of 3-10. The paper presents quantitative statistical analysis of the role of different food products and of different countermeasures in formation of the internal doseof the population in different periods after the Chernobyl accident.

PRESENTING AUTHOR (IF DIFFERENT) E.E. Petrov

MAJOR SCIENTIFIC TOPIC NUMBER 4.3 (see page 7)

ABSTRACT (See instructions overleaf) The Association of Radiological Issues of Russia amalgamating Research Institutes in Obninsk carried out detailed radiological survey of more then 10000 private farmsteads in 125 rural settlements (about 170000 inhabitants) of Kaluga Region contaminated by the Chernobyl accident. The exposure dose power over the whole area of a farmstead, the amount of radionuclides (Cs^{134}, Cs^{137}, Sr^{90}) in soil and agricultural products and also in the surrounding's elements (pastures, forests, reservoirs) were measured.

The following results were obtained from the analysis of the data:

- statistical distributions with large dispersion of the exposure dose power, contamination of farmsteads soil and its agricultural products and also correlations between them;
- correlation of farmstead contamination with radicesium content in children bodies;
- radionuclides distribution across soil depth;
- radionuclides distribution in forest systems, including distribution in annual trunks;
- radionuclides content in air and in water.

The main conclusion is that inhabitants of one rural settlement live in different irradiation doses conditions. Information obtained allows to evaluate individual doses of external and internal irradiation for each inhabitant and to choose groups of risk to take special medical and financial support.

Presently the authorities prefer to use collective doses approach when strategic decisions are adopted. But in this case the interests of highest risk groups are taken into account incompletely.

WEATHERING OF RADIONUCLIDES DEPOSITED IN INHABITED AREAS

ABSTRACT

When determining the long-term consequences of an accidental deposition of radionuclides from a nuclear power plant in an inhabited area it is essential to be able to predict the migration with time of the deposited radiocaesium.

Through the years that have passed since the Chernobyl accident occurred in 1986, the weathering effects on deposited radiocaesium on different types of surface in urban, suburban and industrial areas have been followed through six measurement campaigns to the Gävle area of Sweden. The weathering effects after the Chernobyl accident were also investigated in towns in the Ukraine and in Russia.

The radiocaesium level on asphalt and concrete pavements was found to decrease rather rapidly. It was found that the weathering effects over the first decade could be described by a double exponential function. Similar analytical functions were derived for the other urban surfaces. However, the weathering half-lives of radiocaesium on walls and roofs of buildings were found to be much longer.

Even in urban centres, the largest contribution to the dose-rate immediately after deposition often comes from the open grassed areas and areas of soil. As the dose-rate from such surfaces usually decreases slowly, depending on the soil type, the relative importance of these surfaces will often increase with time.

After a decade, the dose-rate from horizontal pavements will decrease by a factor of 10 or more, but the dose-rate from an area of soil or a roof may only be halved. Correspondingly, the dose-rate from a wall decreases by only 10-20 %.

INTRODUCTION

Typical relationships have been identified between the contamination levels on different types of urban surface shortly after the Chernobyl accident (1). These relationships change considerably with time, due to various 'weathering' processes (depletion of the retained material by such effects as wind, precipitation and mechanical impact of human activity) in the urban environment. An essential requirement for the process towards an estimation of the long-term consequences of an accidental deposit of radionuclides is therefore an adequate knowledge of the effect of weathering. For this purpose, investigations have been conducted in urban environments which received either a wet or a dry deposit of ^{137}Cs after the Chernobyl accident.

URBAN WEATHERING MEASUREMENTS IN SWEDEN

Since the Chernobyl accident, the weathering effects on different types of surface in urban, suburban and industrial areas have been followed in the Gävle area in Sweden, which received a high level of contamination with a heavy rainshower shortly after the accident. In situ measurements with germanium detectors shielded/collimated with lead were made in the centre of Gävle, in a light industrial area about 1 km east of the town centre and in a suburban/rural area about 13 km to the north-east of the town centre.

The radiocaesium levels were measured on various kinds of surface, including walls, grassed areas, pavements, walkways and roads. Six measurement campaigns were conducted in the Gävle area in the period 1987-1994. Table 1 shows a representative selection of the measured data.

Table 1. ^{137}Cs levels measured in Gävle, Sweden in 1987, 1988, 1990, 1991, 1993 and 1994

Location	Surface	Material	Orientation	^{137}Cs levels measured in Gävle, Sweden					
				1987	1988	1990	1991	1993	1994
City hall	wall	plaster	south-east	-	0.78 ± 11%	-	-	-	0.53 ± 12%

Gevalia	cross-roads	asphalt		-	1.19 ± 9%	-	-	-	-

Although the first campaign was made in 1987, a comparison with other measurements made in the same area in May-October 1986 (2) made it possible to approximately relate the measured results to the initial radiocaesium deposition in the area.

The dose-rate reductions which were recorded in Gävle on grassed areas were found to be greatly dependent on the soil type, and the investigated soils displayed many different shapes of vertical profile of ^{137}Cs. Generally, the dose-rate from areas of soil was found to decrease by 40-60 % through the first 8½ years after deposition.

As can be seen from the table, very little, if any decrease in the levels of radiocaesium contamination on walls of buildings was identifiable 8½ years after the deposition. In one case, the level has actually increased at one point. This change is, however, not highly significant, but may have been caused by a wash-down of radioactive substances from the upper parts of the wall. Anyway, the measurement at this site the following year showed the expected decrease. Although it is difficult to distinguish between the weathering rates on the walls in Gävle previous efforts have shown that radiocaesium is retained most effectively by micaceous construction materials, especially those that have been fired at comparatively low temperatures, where the small openings in the mica structure are intact. A yellow brick wall of the fire station has a very low contamination level compared with the other walls because it was exposed to only dry deposition as the structure of the building prevents the wall from precipitation.

In contrast to the situation on walls, the levels of radiocaesium on asphalt surfaces have now decreased so much that less than 10 % of what was measured in 1988 is left. A comparison with the results of Karlberg and Sundblad (2) shows that this means that less than 2 percent of the initially deposited radiocaesium is now left on the road. These levels are now generally below the detection limit. This ties in with the results of laboratory investigations, which have shown that only a very little fraction of a caesium contamination is associated with the bitumen fraction of the asphalt. A large fraction of the caesium has been found to be associated with the more mobile street-dust, which usually contains micaceous substances weathered off various surfaces.

As for the concrete paved surfaces, the remaining 10 % of the initially deposited radiocaesium seems very firmly fixed. No significant decrease has been recorded over the latest 3 years. The weathering on horizontal hard surfaces was generally found to be faster in the more heavily trafficked spots.

Clay roof tiles which were contaminated due to the Chernobyl accident and exposed to the wind and weather in Gävle for four years were collected and brought to Risø, where the contamination level at this stage was assessed. The tiles were subsequently exposed to Danish weather after having been placed on a specially constructed scaffold. A decrease in the radiocaesium contamination level of between 28 and 35 % was recorded over the following 19 months period.

This is in reasonably good agreement with measurements on different types of roof contaminated by Chernobyl fallout at Riso, from which a semi-empirical model was derived (3). The weathering processes on both roofs, walls and horizontal pavings were found to have a slow and a fast component and could be adequately described over the first decade by two-component exponential functions. Some typical values of the parameters are given in Table 2.

Table 2. Typical weathering parameter values on different types of urban surface (slow and fast component)

Surface:	Fraction	Half-life	Fraction	Half-life
Roofs	0.7	$7.0 \cdot 10^3$ days	0.3	$3.5 \cdot 10^2$ days
Pavings	0.5	$7.0 \cdot 10^2$ days	0.5	$7.0 \cdot 10^1$ days
Walls	0.9	$2.0 \cdot 10^4$ days	0.1	$7.0 \cdot 10^1$ days

URBAN WEATHERING MEASUREMENTS IN THE FORMER USSR

Measurements of dry-deposited ^{137}Cs in the Pripyat area in the summer of 1993 with shielded germanium detectors showed that the contamination level on sandstone walls was in the range of 199-350 kBq/m^2 (the decrease since 1986 must have been very small), compared with 0.9-28 kBq/m^2 in other towns, where deposition occurred with rain. On the 'impervious' horizontal surfaces, such as roads and pavements, the caesium contamination level was found to be in the order of 30-350 kBq/m^2 in Pripyat, with the highest levels on concrete pavements and the lowest on asphalt.

From the contamination level and distribution of radiocaesium in local soil it was possible to estimate the caesium contamination level on pavings in the area shortly after the accident to about 1.5 MBq/m^2. This means that a much larger fraction remains on the paved surfaces in Pripyat than in Gävle. However, there has been very little traffic in Pripyat since the Chernobyl accident. If the weathering processes in the two towns had been the same, the remaining fractions in Pripyat would probably have been the smallest at this stage. Anyway, it was easier to remove caesium in Pripyat by forced decontamination trials than in other towns. The reason for this is believed to be that the contamination in Pripyat (near Chernobyl) took place with large (insoluble) core fragment particles.

CONCLUSIONS

The effects of weathering in towns and industrial areas have been investigated through field measurements in areas of Sweden and Russia, which were contaminated with ^{137}Cs after the Chernobyl accident. The radiocaesium levels on road pavings were found to have been halved after less than one year, and after about 3 years only about 10 % remains. The dose-rate contributions from roofs and soil areas were approximately halved in the first 8½ years after deposition, while measurements on walls showed little or no decrease in contamination level. Analytical expressions for the weathering processes on roofs, walls and pavings were derived and estimates of typical parameters were made. Measurements in Pripyat indicated that the impact of human activity on the decrease of the contamination levels can be great.

INVESTIGATIONS TO THE DISTRIBUTION OF CS-137 AND K-40 IN A COW

H. Rabitsch,[1] E. Pichl,[1] J. Pletz,[2] G. Kahr[1]

[1] Technische Universität Graz, Austria
[2] Fachabteilung für Veterinärwesen der Steiermärkischen Landesregierung, Graz, Austria

INTRODUCTION

It is of particular interest to study the distribution of radionuclides in domestic animals after a long-term ingestion of radionuclides. We performed a study to determine the specific activities of Cs-137 and of the naturally occuring K-40 in different tissues, organs and in the gastro-intestinal tract of a cow. As a consequence of the fallout following the Chernobyl accident in April 1986, the cow ingested chronically heavily contaminated forage during four years. It is the aim of these investigations to find out regions of high activity concentrations in the cow and to compare the activity concentrations of Cs-137 and K-40 in the samples of the whole cow. Of particular interest are the activities of radiocaesium in edible tissues (meat) and organs.

EXPERIMENTAL PROCEDURE

The cow was slaugthered in November 1992 and dissected in anatomical parts. Samples of the whole body of the cow were taken during or immediately after slaughtering. Most of the samples had to be deep-frozen and were thawed before measuring. We performed exclusively mechanical procedures to separate complex structures to get samples in correspondence to their anatomical sites and their physiological function (1,2). The activities of Cs-137 and K-40 were determined simultaneously by gamma counting with the help of semiconductor-detectors and the usual software. Marinelli-beakers or small cylindrical containers of perspex were used as containers for the samples. Some samples containing fat and vascular systems were molten to obtain the activities of pure fat. Other samples were cleaned with water to get the activities of the pure parts.

EXPERIMENTAL RESULTS

All activities are related to November 14, 1992, the day of slaugthering. Values for the specific activities, for the activities and their ratios are presented with a confidence level of 2σ.

Muscle tissues

Table 1. Highest specific activities in muscle tissues.

	Spec. activ. Cs-137 (Bq/kg)		Spec. activ. K-40 (Bq/kg)
M. masseter	389.5 ± 20.7	M. semitendinosus	129.2 ± 6.2
M. gracilis	381.8 ± 6.6	M. iliopsoas	122.9 ± 4.5
M. pterygoideus	371.5 ± 33.3	M. longissimus dorsi (b)	122.2 ± 4.5
M. temporalis	354.6 ± 31.8	M. gracilis	121.8 ± 3.0
M. obturator	352.9 ± 22.3	M. splenius	120.6 ± 10.5
M. semitendinosus	352.9 ± 14.1	M. latissimus dorsi	119.0 ± 6.6
M. glutaeus	352.5 ± 6.5	M. triceps brachii	116.1 ± 4.1
M. iliopsoas	352.5 ± 8.7	M. quadriceps femoris	115.7 ± 3.5

Table 1 shows the highest specific activities of Cs-137 and K-40 observed in the muscle samples. The samples were measured without any special preparation and contained pure muscle tissues, tendons and remainders of fat. The values of the specific activities of Cs-137 and K-40 range from 213.0 Bq/kg (M. levator labii maxillaris) to 389.5 Bq/kg (M. masseter) and from 62.8 Bq/kg (M. buccalis) to 129.2 Bq/kg (M. semitendinosus), respectively. In all muscles of the head we found low specific activities of K-40, whereas high specific activities of K-40 were observed in the important edible muscle tissues. These tissues contain only less tendons.
High values of the ratio of specific activities of Cs-137 and K-40:
M. masseter > M. pterygoideus > M. temporalis > M. zygomaticus > M. buccalis.
All these muscles are located in the head.
Low values for this ratio:
M. cutaneus maximus < M. extensor digitorum lateralis < M. splenius < M. extensor digitorum communis < M. extensor carpi radialis.

Pure muscle tissues
These samples consisted of pure muscle cells, connective tissues were separated. Highest values of Cs-137 were found for M. masseter and M. gracilis: 415.0 ± 37.1 Bq/kg and 408.6 ± 10.9 Bq/kg, respectively. The specific activities of K-40 showed a moderate variation.

Tendons
Table 2. Specific activities of Cs-137 and K-40 in cleaned (washed) tendons.

	Spec. activ.Cs-137 (Bq/kg)	Spec. activ.K-40 (Bq/kg)
M. gastrocnemius	72.7 ± 8.7	25.8 ± 4.0
M. longissimus dorsi (f)	88.8 ± 10.8	25.8 ± 6.9

It was observed that flat-spread tendons accumulate more Cs-137 than tendons of other compact shapes.

Fat
The samples contained fat and vascular systems. The specific activities of Cs-137 in fat, correspond roughly to the activities of Cs-137 in the pure muscle tissues. In the rank of the specific activities of K-40 structures with great contents of pottassium (Ligamentum nuchae, Glandulae suprarenales) are included. Some samples of fat were molten and then the activities of pure fat were measured. The activity levels of Cs-137 and K-40 of the pure fat were found to be at the detection limits of the spectrometers (0.5 Bq - 1.0 Bq).

Lymph nodes
The highest specific activities of Cs-137 and K-40 were found in the lymph nodes of the head: (326.2 ± 39.7) Bq/kg and (89.5 ± 29.8) Bq/kg, respectively. Rank of the specific activities of Cs-137 in lymph nodes:
Head > Muscle tissues > Rumen > Kidneys > Udder > Mesenterium commune.
The specific activities of K-40 in different lymph nodes are within the confidence limits and may be considered nearly constant.

GI-tract
Values of the specific activities of Cs-137 and K-40 in all digestive organs are summarized in a previous work (3).

Organs

Data in Table 3 are valid for the activities of the pure samples without connective tissues.

Table 3. Specific activities of Cs-137 and K-40 in selected organs.

	Spec. activ.Cs-137 (Bq/kg)	Spec. activ.K-40 (Bq/kg)
Heart	196.2 ± 11.8	77.4 ± 7.5
Lung	135.4 ± 4.3	63.0 ± 3.2
Liver	194.1 ± 5.4	102.9 ± 4.2
Gall bladder	43.8 ± 2.2	25.3 ± 2.0
Pancreas	274.6 ± 24.6	106.3 ± 13.0
Kidneys	301.6 ± 10.9	62.1 ± 3.7
Spleen	217.0 ± 13.8	111.5 ± 10.0
Skin	35.8 ± 0.4	20.0 ± 0.4

Total Activities of Cs-137 and K-40

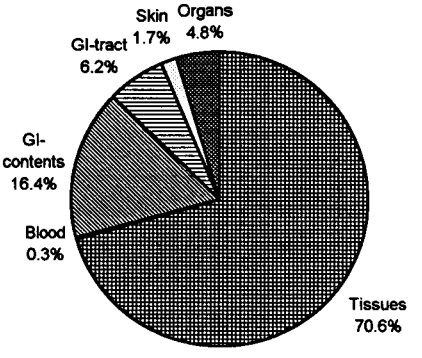

Fig. 1. Percentage of the activities of Cs-137 in different compartments.

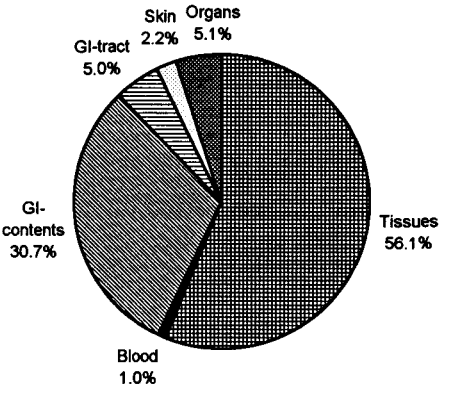

Fig. 2. Percentage of the activities of K-40 in different compartments.

The compartment "tissues" includes muscle tissues and connective tissues.. Total mass and total activities of Cs-137 and K-40 (without the compartment "GI-contents") were estimated to be 302 kg, 50.1 kBq and 21.7 kBq, respectively.

ACKNOWLEDGEMENT

The authors are grateful to Univ. Prof. Dr. Hj. Müller, Reaktorinstitut Graz, for his effective help and substantial financial support.

RADIOACTIVITY DURING THE FIRST 5 YEARS AFTER THE CHERNOBYL ACCIDENT AND COMMITTED EFFECTIVE DOSES

Constantin Milu, R. Gheorghe, A.Sorescu, L.Pahomi

Institute of Hygiene, Public Health, Health Services and Management
Bucharest 35, Romania

INTRODUCTION

The Chernobyl accident from 26th of April 1986 has had an impact on radioactivity in Romanian territory. Consequently, since second part of 1986, a long-term survey on effects regarding radioactivity of environmental and on health of the population was established in Romania.

METHOD

Data on radioactive contents of water and of food (milk and dairy products, meat, bread, vegetables and fruits) reported by the Radiation Hygiene Laboratories from Arges, Bacau, Brasov, Caras-Severin, Cluj, Constanta, Dolj, Galati, Iasi, Mures, Maramures, Prahova, Sibiu, Suceava, Timis and Bucharest were processed by the Institute of Hygiene, Public Health, Health Services and Management - Bucharest, using an INDEPENDENT computer. Knowing the annual consumption of the population from Romania and applying appropiate dose conversion factors (committed effective dose per unit intake), the individual and collective doses for the period 1987 - 1991 have been calculated.

RESULTS

Since 1987 to 1991, the Sr-90 and Cs-137 radioactive content continuously decreased, down to unsignificant levels.

In comparison with 1986, the Sr-90 content was maximum in some vegetables (in 1987, up to 0.98 Bq/kg) and it was minimum in drinking water (0.03 Bq/l).

The Cs-137 content was maximum in some dairy products. It decreased from about 62 Bq/l in 1987 to 5 Bq/kg during the following years (1).

The resulted individual and collective doses due by Sr-90 and Cs-137 content in drinking water and foodstuff are presented in figures 1 and respectively 2.

CONCLUSION

For an adult, the individual dose decreased from 0.331 mSv in 1987 to 0.018 mSv in 1991, mainly due to Cs-137 content. As Cs-137 content decreased, the contribution to the committed dose from Sr-90 increased.

For the whole interval (1987-1991), the resulted collective dose for the population of Romania due by ingeration of drinking water and foodstuff and by their content in Sr-90 and Cs-137 was 11,298 man·Sv, 62,7% being done by the radioactivity level from 1987.

PRESENTING AUTHOR (IF DIFFERENT)

MAJOR SCIENTIFIC TOPIC NUMBER 4.3 (see page 7)

ABSTRACT (See instructions overleaf)

Transfer of ^{137}Cs to man from the forest ecosystem is high in Sweden. The main pathways are soil-plant/mushrooms-game animals-man, soil-berries-man and soil-mushrooms-man. Ericoid plants show high uptake of ^{137}Cs and are very important fodder plants for some game animals such as moose and roe deer. Even higher levels of ^{137}Cs is found in fruitbodies of fungi and mushroom picking is very common in Sweden. Mushrooms are also very important as fodder for game animals particularly for roe deer. We have determined transfer parameters for the various transfers and by using them, the mean ground deposition of ^{137}Cs in Sweden or in specific regions of Sweden and data of production and consumption of various food products from the forest ecosystem the potential transfer of radiocaesium to man has been calculated.

The ^{137}Cs levels in moose and roe deer has not decreased from 1986 to 1994 indicating a very long effective ecological halflife of ^{137}Cs in the forest ecosystem. We use the physical halflife as an estimation of the effective ecological halflife. The potential transfer of radiocaesium to man by game animals - moose and roe deer - correspond to a time-integrated dose commitment of about 2,000 manSv i Sweden. The corresponding value for berries is 1,500 manSv. Only rough estimation of the corresponding value for mushroosm will be presented due to lack of knowledge about the consumption pattern.

The conclusion is that a major fraction of the potential doses to the Swedish population due to the Chenobyl fallout will be due to transfer of ^{137}Cs from the forest ecosystem.

ANALYZING Cs-137 AND Cs-134 CONCENTRATION IN MOSSES SAMPLES IN CAMPANIA REGION - ITALY AFTER THE CHERNOBYL ACCIDENT

C.Fontana, M.L.Aebischer

Italian Red Cross Central Laboratory Section of Environmental Radioactivity, Rome, Italy

INTRODUCTION

The Chernobyl accident caused an exceptional relapse of radioactive material. The consequent fall-out it in several European countries, including Italy (1).

Term and height of aeriform effluent radioactivity admitted into the atmosphere, the distance of place of origin and the variability of meteorologic qualifications existence (wind, rain, etc...), determined the level of contamination of radioactivity in the air with a consequent deposition of soil much variable depending on space and time.

Following the Chernobyl accident the situation of artificial deposition in Italy is considerably changed. In order to obtain arrange a new map of contamination of radioactivity in the soil. All over italian territory has been organized radioecological campaign to arrange a new zero point (2).

The Central Laboratory of Italian Red Cross (L.C. - CRI) is part of the National Network for the monitoring of the environmental radioactivity in Italy co-ordinated by National Environmental Agency (ANPA). The L.C. - CRI took part in the national campaign for the monitoring of the environmental radioactivity to evaluate the deposition of artificial radioactivity on Italian territory (3). Fig.1.

In Italy to obtain the radioecological map the gamma spectrometry technique is used. In fact this technique is more sensitive and is answering several kinds of information. The gamma radioactivity on the place is a more appropriate method, in reality isn't use due to the lenght of time.

In this work, in particular, living organism by *bioindicators* have been used as a mosses (bryophytes). The experience carried out at national and international level demonstrated that mosses can be used to map the radioactive fall-out (4). Studies were also performed on mosses which appeared to have some advantages with respect to lichens.

The mosses are organisms made up chlorophyll and therefore photosynthesis. Mosses generaly live in environmental sub-air, they have not roots and do not have a vascular system to allow the transport of material from substratum for diffusion and to absorb atmospheric water.

The present work was orientated to use specific types of mosses which act as a passive trap to collect radioactive particules and mosses are distributed in all mountain ecosystems whether in Italy or in other countries.

The monitoring of gamma radioactivity for Campania region has been delegated to the Section of Environmental Radioactivity of the L.C. - CRI. To this task the cooperation with the Ministry of Agricolture and Forestry and together with the help of the Department of the State Forestry Corp of Campania.

This work presents the data of the surveys carried in 1993-1994. The mosses were picked up in four different locations of Campania region and measured by means of ray spectrometry, according to a national standard procedure, to evaluate the content of Cs-137 and C-134. The content of K-40 was also measured.

MATERIALS AND METHODS

In this paper the measures concern n.44 samples of mosses; this mosses have been collected in four States Forest Corp posts in the provinces of Salerno, Caserta, Napoli. In particular, the localities are: Laviano, Piaggine, S.Gregorio Matese and Boscotrecase.

The species of the mosses picked up are *Hypnum cupressiforme* and *Homalotecium lutescens.*

The samples were gathered in late autumn (November - December) only on the rock and show horizontal growth, with formation of carpets thickness between 2 - 4 centimetres.

The samples have not received any chemical treatment and after drying up in the air have been utilized.

The samples underwent analysis of gamma ray spectrometry: the measures have been carried out using high purity Germanium detector (Hp), relative efficiency 25 %, in to a well of the lead 10 centimetres thick. Radionuclide concentrations were determined by automatic peak fitting using a spectroscopy applications software package (PCA II - GDR). Detector was calibrated using a calibration standard (359 RLM-ENEA) in the liquid form (Marinelli 500 cc) through participation in national intercomparison. For the samples, the counting error, expressed with an accuracy of ±1%. Consequently the samples placed in Marinelli Beakers in the volume of 500 cc. The count time was 72.000 sec (20 hours).

The concentration of mosses is reported on the 1st July 1993 and is expressed as Bq/m^2.

The counting time which is ratherlong allowed to obtain a standard deviation on peak of height intensity of Cs-134 of ± 10%.

Fig. 1
from : "Mapping of radioactive fallout using mossese as bioindicators"
International Conference Taormina (Italy) October 1993; pagg. 215-226 (3)

RESULTS

The table n.1 shows the average concentration of the Cs-137 and Cs-134 on relating to 44 samples of mosses examined in four places for cathering. The values of average concentration of mosses in the Campania region are: 374 Bq/m² of Cs-137 , 16 Bq/m² of Cs-134 and 151 Bq/m² of K-40. Tab.1

Tab. 1
Cs-137 - Cs-134 and K-40 activity in mosses

LOCALITIES	*Cs-137 (Bq/m²)*	*Cs-134 (Bq/m²)*	*M k-40 (Bq/m²)*
S.GREGORIO (TORNARE)	*505*	*22*	*175*
LAVIANO (CACARI)	*375*	*16*	*134*

TRENTINO	3500	250
UMBRIA	350	25
VALDAOSTA	1300	90
VENETO	3000	210

CONCLUSIONS

In this paper the results of the concentrations of the Cs-137 and Cs-134 in the mosses confirm an uniform distribution of the radioactivity post Chernobyl in the regional territory. The reluts are in accord to the previous date (1992-1993). Tab.2

The concentration of K-40, in all samples examined, has a costant value.

Currently we are investigating the possibile correlation between the concentration of the Cs-137 and Cs-134 in the soil and in the mosses of the same spots (5-6).

INTRODUCTION

On Friday, May 2, 1986 a cloud containing radioactive particles from the Chernobyl accident reached Belgium during the morning. At noon, an activity in the air of 58 Bq/m^3 was measured in Gent. Together with short living isotopes (^{131}I, ^{132}Te, etc.) a concentration of 5 Bq/m^3 of the long living ^{137}Cs was registered (half live 30 y). One day later, on Saturday, May 3, the air activity was already reduced to a few percent of this peak value.
The aim of this research is to evaluate the situation concerning the residual radiocesium concentration in different parts of Belgium nearly 10 years after the Chernobyl accident by means of *in-situ* γ-spectrometry.

EXPERIMENTAL PROCEDURE

The *in-situ* γ-spectrometry technique using efficient high resolution Ge-detectors allows a fast, accurate and sensitive determination of radionuclides in the soil. This method is described by Beck et al. (1) and more recently by Miller et al. (2, 3). The ICRU report nb. 53 (4) (December 1994) gives a complete review on the subject.
In this work, the measurements were performed with two different measuring chains, one of the University Gent (RUG) and the other of the SCK-CEN Mol. The RUG detector is a 20.2 % p-type (energy resolution 1.7 keV) with a normal 30 litre dewar. The SCK chain uses an n-type HPGe coaxial detector (resolution 1.83 keV and efficiency 10%) mounted on a small multi-attitude cryostat. Both spectrometers were calibrated completely independent and intercompared during two in-situ measurements at locations in Mol and Tihange. All results are in good agreement within the total experimental error of about 15%.
Laboratory analysis at the SCK-CEN of soil samples confirms the in-situ data. Details about the calibrations and the intercomparison are given in internal reports (5, 6).
After some preliminary measurements in Gent, Mol and the Ardennes, a systematic survey of the Belgian territory (30507 km^2) by in-situ gamma spectrometry has been carried out. About 50 measurements, equally distributed across the country were executed (the western part by the RUG-team and the eastern part by the SCK-CEN group). For all measurements, pastures that we know as undisturbed during the last 10 years were selected. In the calculations of the ^{137}Cs concentration we use a depth profile with relaxation parameter α = 20 m^{-1}; for the natural isotopes we assume a homogeneous distribution with α = 0 m^{-1}.
This relaxation parameter is rather critical for the calculations of the ^{137}Cs concentration; with α = 33.33 m^{-1} as used in earlier measurements (5,6) the values given in fig. 2 should be reduced by a factor 1.356. To improve our knowledge on the actual ^{137}Cs distribution in the soil, further investigations based on spectrometry of soil samples are in progress. Our actual choice of α = 20 m^{-1} (relaxation length 5 cm) complies with the data for aged fallout (table 3.5 in (4)). Fig. 1 gives a typical spectrum of a measurement with the RUG-detector in a high activity region; one can easily see the 662 keV ^{137}Cs line together with the 1461 keV ^{40}K line and the typical lines of the natural U and Th series. A measuring time between 30 and 60 minutes allows an accuracy better than 15% at the actual remaining ^{137}Cs concentrations from Chernobyl in Belgium (typical values from .5 to 5 kBq/m^2). Even a quick 10 minutes test measurement can give a good indication on the concentration.

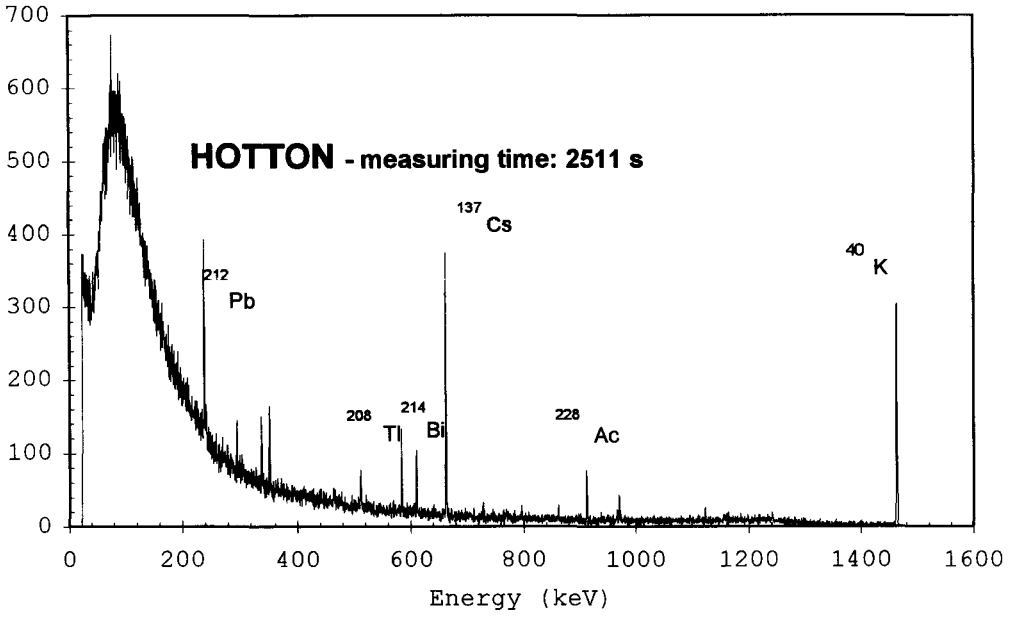

Figure 1: typical in situ gamma spectrum; ^{137}Cs concentration is 4600 Bq/m^2

RESULTS AND INTERPRETATION

The map (figure 2) summarises the results of our survey for ^{137}Cs; all values are calculated with $1/\alpha = 5$ cm. The results of 3 measuring points (indicated with *) are not available at the moment. The occurrence of regions with higher concentration (a peak value of 4610 Bq/m^2 was obtained near Hotton) coincides roughly with the zones of higher deposition as mentioned by Govaerts et al. (7). Some discrepancies between neighbouring points can be explained by the variations in the use of the grassland. Although our careful selection of the measuring sites, it can not be completely excluded that some pastures have been ploughed or modified in some way, disturbing the natural distribution of the Cs. A new control measurement at some locations will give a final value in some cases. At the moment, we are still studying the correlation of the actual concentration with the deposition, the rainfall and other meteorological conditions in the May 1986 period. More detailed information will be available on the poster during the conference.

ACKNOWLEDGEMENTS

The RUG-team is indebted to Prof. H. Dumont (Ecology Laboratory, RUG) for transportation facilities. The SCK-CEN authors wish to thank all their colleagues of the γ -spectrometry group who participated in the measurement campaign.

ABSTRACT (See instructions overleaf)

The Marshall Islands was the site of the United States atomic weapons testing program in the Pacific. Sixty-six atomic weapons were detonated in the island country during the years 1946 through 1958. For several decades, radiological monitoring by the U.S. Department of Energy (and its predecessor agencies) has been conducted on the two test site atolls and neighboring atolls. However, 70% of the land area of the 1200 islands was never systematically monitored prior to 1990. For a five year period (1990-1995), the Government of the Republic of the Marshall Islands has undertaken an independent program to assess the radiological condition throughout it's 29 atolls. Over 1300 in-situ high resolution gamma spectrometry measurements have been made on more than 400 islands at an average spatial density of one measurement per 0.15 km^2. Native foods including coconuts and other tropical fruits have been sampled as well as more than 200 soil profiles and more than 800 surface soil samples. The fruits and soil samples were analyzed for gamma emitters with an emphasis on ^{137}Cs, the surface soils were also analyzed for $^{239,240}Pu$. External exposure-rates from ^{137}Cs vary, depending on location, from 1 μSv/year to over 2 mSv/year. Estimates of possible internal doses from ^{137}Cs, depend on location and dietary habits, and can range from 10 μSv/year to 50 mSv/year. The objective of this presentation is to report the first comprehensive summary of the radiological conditions throughout the Marshall Islands.

ABSTRACT (See instructions overleaf)

The release of radioactive material during venting procedures of the containment of BWR and PWR after a postulated melting of the core results in an exposure of the public in the environment. This exposure can be significantly reduced by disaster control. The methods and the extend of the disaster control have to be determined with suitable forecast-models based on measured activity-concentrations in the atmosphere of the containment. The dose caused by the release of radioactive iodine is caused by conservative release-assumptions. The release of radioactive noble-gases and the resulting dose hereby can be reduced significantly by the installation of delay-systems. The instruments to optimize venting procedures for the environment from the viewpoint of radiation protection are shown and discussed.

AB: Application of deterministic calculational modeling indicates that the most significant radiological impacts from low-level radioactive waste (LLW) disposal could result from long half-life components such as: I-129, Tc-99, U-238, Pu-239, etc. However, alternative assessment methods have demonstrated that this may not necessarily be the case. For example, application of isotopic equilibrium analysis (IEA) indicates that presence of stable iodine (I-127) in the environment would necessarily cause isotopic dilution of I-129 released from a waste disposal site. Since the total iodine content in the human body is regulated by homeostatic processes, and since the I-129 /I-127 ratio in the human body must equillibrate to that in its environment, any significant dose consequence from I-129 would be precluded except under very unusual conditions. Other evidence indicates that in the cases of U-238 and Tc-99, radiological consequences may be minor relative to the chemical toxicity effects resulting from ingestion of these materials. Alternative evaluation techniques such as IEA and probabilistic analysis have been applied in assessing potential impacts from the Savannah River Plant LLW burial grounds. The results can be used to augment and elucidate predictions determined by calculational modeling.

EXPERIENCE AND RESULTS OF COOPERATION IN RADIATION PROTECTION BETWEEN SWEDEN AND EAST EUROPE COUNTRIES

Jan Olof Snihs
The Swedish Radiation Protection Institute
171 16, Stockholm, Sweden

INTRODUCTION

From 1991/92 until July 1995 the Swedish Government has allocated SEK 55.1 million (about 10 M $) for cooperation in radiation protection with countries in Central and Eastern Europe, particularly the Baltic states (Estonia, Latvia, Lithuania) and Russia but also to less extent so far Byelorussia, Poland, Ukraine and others. The Swedish Radiation Protection Institute (SSI) is in charge of this program, which is often referred to as Project Radiation Protection East. In addition, SEK 8 million have been reserved for SSI activities promoting safety during decommissioning of the former Soviet naval reactors training center at Paldiski, Estonia and the subsequent transfer of responsibility for the site from Russia to Estonia (the PIERG project).

Radiation protection covers a broad area of the society. Already at an early stage it was realized that supporting cooperation was necessary and of interest over the whole area. Therefore extensive discussions on priorities between parties concerned have been and are necessary. The choice of projects is based on a "Protocol", that is the eventual result of priority discussions signed by representatives of both countries (bilateral agreements).

Most of the projects within "Radiation Protection East" mean a longterm build-up of radiation protection in a broad sense. Some projects concern new problems, other projects concern problems that the country inherited from the earlier Soviet Union. Other projects may concern acute problems as e.g. lost strong radioactive sources, radioactive contaminations etc.

Even if most of the projects within Radiation Protection East are bilateral there is a substantial international input and cooperation. There are many projects that are run in cooperation with the IAEA, OECD/NEA, EU and together with other countries particularly the Nordic countries.

There is an increasing need of financial support as the many preparatory phases are passed and the follow up efforts are more expensive. The other party will also gradually be more susceptible for more advanced cooperation.

THE OBJECTIVES AND TERMS OF REFERENCE

The idea of activities within the Project Radiation Protection East is the following:

Efforts adjusted to the need of the country to improve the radiation protection and make it more effective and to solve acute radiation protection problems.

The cooperation means support to these countries but it is also of mutual interest. Uncontrolled releases of radioactive material and bad handling of radioactive sources in a cooperation country might in some circumstances mean a potential risk to health and environment also in Sweden. Therefore, a successful cooperation within this project might have a positive influence on radiation protection in Sweden as well. Furthermore, the cooperation is instructive for both parties and is very stimulating and productive for development of mutual understanding and future cooperation.

A condition that is to be fullfilled in the choice of a project is that it comes up to one or several of the following requirements:

- it is fundamentally important for the cooperation country
- it is expected to lead to decreasing unnecessary radiation doses in that country
- it is of interest for Sweden and the Baltic Sea region
- it means education and training of relevant persons of the cooperation country
- it has a common interest for the two countries in the areas of research or information.

Requirements are set on both parties - both Sweden and the cooperation country as e.g. preparatory domestic work, to inform, motivate, engage and fill concerned persons with enthusiasm. Share of the costs of the project is another way to show interest and create partnership.

SOME PREREQUISITES FOR COOPERATION

The cooperation is individually decided for each country after discussions and negotiations, the results of which are manifested in the Protocol. There are some components of the infrastructure of the cooperation country that are essential for continued cooperation in radiation protection and therefore have the highest priority in the first phases of the cooperation.

They are:

- radiation protection law and legislation that define the national actors, devide responsibilities between them and defines their duties and rights
- radiation protection authority(ies) with functioning organisation, competent personnel and modern equipment
- a national strategy for handling, storage and disposal of radioactive waste
- a national monitoring system with measurement stations as a part of an early warning system, coordinated with other countries
- a laboratory for measurements on environmental samples and a national program and strategy for environmental control in general for the purpose of radiation protection.

During the few years of cooperation within the Project Radiation Protection East some of the important components mentioned above have now been established largely as a result of the cooperation. Points of contact have been established, problems common for several countries have been identified and can be treated in a more rational and costeffective way.

Completed laws need directions, equipped laboratories need supplementary training of personnel and programs for sampling; when the strategies for radioactive waste are decided there is a need to realize the strategies, etc. There are many examples of continued and expanded cooperation e.g. concerning the radioactive waste management and disposal in Russia and the Baltic states, the decommissioning and dismantling of the earlier Paldiski submarine training center, the Sillamäe tailing ponds in Estonia and the emergency preparedness plans and training.

THE PROJECT MANAGEMENT

The projects are devided into the following main categories:

1 *Upgrading of national authorities, 18 projects*
Legislation, organization, information, computer support, etc.

2 *Emergency preparedness, early warning, 7 projects*
Organization, education, dose predictions, gamma monitoring, communication etc.

3 *Nuclear power and research reactors, 4 projects*
Safety at work, releases, organization and other plant related issues not dealt with elsewhere.
4 *Instrumentation, 12 projects*
Laboratories, mobile and stationary measurement equipment, education etc.
5 ~~*Decommissioning, waste, environmental control, 24 projects*~~
National waste strategies, plant specific programs (i.e. Paldiski, Sillamäe), radiological clean-up, measurement programs, education etc.
6. *General radiation protection, 40 projects*
Medicine, radiological protection of workers, dosimetry, radioactive lighthouses, radon, non-ionizing radiation etc including research support.
7. *Other project costs*
Projects not covered by any of the categories above.
8. *Project management and administrative support*
Includes resources needed to plan, organize and report on the various projects.

That means more than 100 projects since 1992. Some have been finished and some are still in the planning stage. Normally, radiation protection specialists of the staff of SSI are project leaders and also take active part in the projects. The management manpower of the Project Radiation Protection East is in total about 2 personyears per year.

Two examples of cooperation projects are given.

Emergency preparedness, early warning

Automatic gamma stations

Expansion of the Early Warning System in Estonia, Latvia and Lithuania with a central unit and four automatic gamma stations in each country. The expansion was made during December 1993 by Finnish ALNOR (RADOS). During 1994 the system was tested and found to function properly (although some stations had problems with the telecommunications). The test period is thus finalized and the one year warranty period started in 1994-12-01. Bilateral agreements were made during Jan-Feb 1994. The systems were formally handed over during 1995.

Decommissioning, waste, environmental control

National waste strategy (in Lithuania)

A study is made to present a background for decisions on a national waste strategy for handling all kinds of radioactive waste - from the Ignalina NPP, from hospitals, research establishments, industries etc. Parties involved are identified and their roles, mandates and liabilities are assessed together with the legal framework. Available methods for transport, conditioning and intermediate and final storage of the waste are assessed. Problems around the Ignalina waste are specially considered. The report is presented to the Lithuanian Minister of Energy. Additional follow-up projects with high priority are expected.

CONCLUSIONS

The cooperation between Sweden and the countries in the eastern part of Europe has developed well. Good contacts and exchange of information with other western countries as regards planned and ongoing cooperation with the countries in eastern Europe is essential to avoid duplication and gaps. The cooperation has already lead to some improvements of the conditions for good radiation protection in these countries but there is still much to do. The cooperation has also a mutual, stimulating effect upon those persons and organisations involved in it and it opens channels for further contacts and cooperation. It will therefore continue.

Cs^{137} AND Sr^{90} DIETARY INTAKE AND URINARY EXCRETION FOR CHILDREN, AFTER THE CHERNOBYL ACCIDENT

Maria Toader[1], Radu A. Vasilache[1], Mirela L. Toader[2], Monica I. Vasilache[3]

INTRODUCTION

Since the accident from Chernobyl, an important number of studies were focused on the effects of the accident but, nine years after the accident, we still don't know enough about its impact on public health and environment.

A major problem after the Chernobyl accident was to asses the effects of the irradiation for different age groups, especially for children. Our group measured Cs^{137} and Sr^{90} dietary intake and urinary excretion for children of different ages (between 4 and 12 years), at different time intervals after the accident. From the intake data, a trend of the annually committed effective doses was deduced. The paper presents the dose values for different age groups, as well as the balance of the intake and excretion, given here as the "observed ratio", defined as:

$OR = (\frac{Cs-137_{urine}}{K_{urine}}) / (\frac{Cs-137_{intake}}{K_{intake}})$ for Cs^{137}, and

$OR = (\frac{Sr-90_{urine}}{Ca_{urine}}) / (\frac{Sr-90_{intake}}{Ca_{intake}})$ for Sr^{90}. Both Ca and K are given in grams, while the Cs ans Sr contents are in Bq.

MATERIAL AND METHODS

The group which undergone the study consisted of children, separated in three age subgroups : 4-6 years old, 7-9 years old and 10-12 years old . These children were living in the kindergardens and schools hostels. The data for the dietary intake and urinary excretion for the children was compared with similar data for the adult women working as teachers and educators at the schools, and taking their meals together with the children. These women were aged between 24 and 49 years. The food samples were prelevated from the schools' cafeterias. The 24 hour urine samples were prelevated the next day after the prelevation of food samples.

All the measurements were performed by radiochemical methods of analysis [1,2]. After the radiochemical separation of caesium and strontium, the radiometric measurement was performed with a low-level anticoincidence beta counting system, with high efficiency.

RESULTS AND DISCUSSION

During 1986 - 1995, we have selected four time periods in which we have studied the dietary intake and urinary excretion of Cs^{137} at children, for all three age groups, in comparison with the adult women group. We will present here the differences between the first period, (caharacterised by a strong contamination), and the last period of study.

The first period was September 1986 - December 1987. From the point of vue of the ingestion and excretion processes, this was the most complex period. During this period, an intake peak occurred in October 1986 at all the age groups, including the women. After this date, Cs^{137} dietary intake is continuously decreasing, but the slope of the decrease is age-dependent. The OR for this period is presented in Fig. 1.

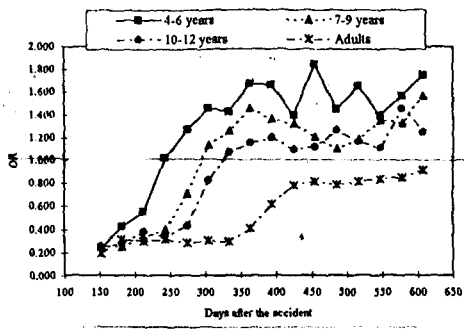

Fig. 1: OR for Cs^{137}, during September 1986 - December 1987

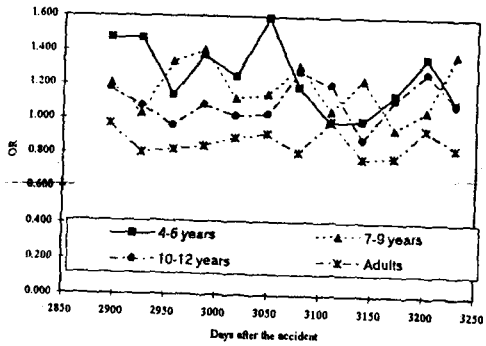

Fig. 2: OR for Cs^{137} during April 1994 - March 1995

At 4-6 years and 7-9 years children, the OR reaches a plateau in April 1987 while at 10-12 years old children the plateau occurs in May 1987. The values of the OR, in the plateau zone, are also different, the value for 4-6 years children being the highest, and the value for adults being the lowest. The OR for the last period (April 1994 - March 1995) took values situated in the plateau area , for all age groups, as can be seen in Fig. 2.

As it can be seen, within the same age group, the OR tends to decrease as the time goes by; for example, at the 4-6 years old children, the OR decreased from an average value of 1.643 in 1988 - 1989 to 1.256, nine years after the accident.

During 1986 - 1994, we have selected three time periods in which we have studied strontium-90 dietary intake and urinary excretion for the same three groups of children compared with adult women. The first interval of study was September 1986 - September 1988. The maximum strontium intake in children was 1.198 Bq/(gCa.day), reached in October 1986. The observed ratio, has different values for the two age groups studied in the first period, as can be seen in Fig. 3.

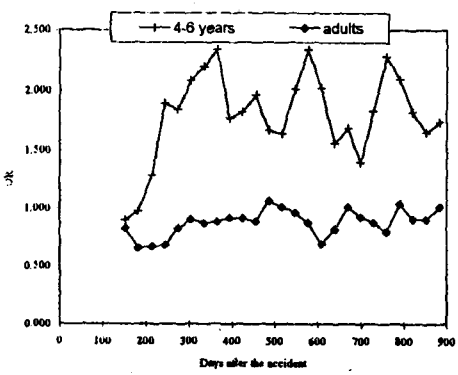

Fig. 3: The OR for Sr^{90}, during September 1986 - September 1988

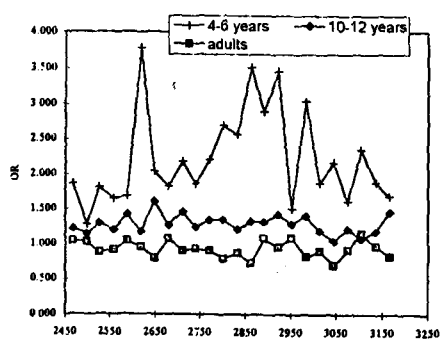

Fig. 4: The OR for Sr^{90}, during January 1993 - December 1994

The last period of study - since January 1993 until December 1994 - included measurements of Sr^{90} dietary intake and urinary excretion for two children groups - 4-6 years and 10-12 years - and the group of adult women. The OR evolution is shown in Fig. 4. This period is caracterised by low values of Sr^{90} dietary intake and urinary excretion. The average amount of ingested strontium for this period was 0.073 Bq/(gCa.day) for 4-6 years children and 0.102

Bq/(gCa.day) for 10-12 years children. As it can be seen from Fig. 4, Sr^{90} urinary excretion had higher values than the dietary intake, for both children groups (OR>1), while ce for adult women the two values are roughly equal (OR~1).

The intake values for Sr^{90} and Cs^{137} resulted in the effective doses committed annually. In order to calculated these doses, we used the dose factor recommended by ICRP 67 [3]. The effective doses committed due to Cs^{137} intake, in each time interval studied, are presented in Fig. 5. As it can be seen, the lower the age, the lower the dose and, for all age groups, the doses are decreasing as the time goes by. The doses committed due to Sr^{90} intake are presented in Fig.6.

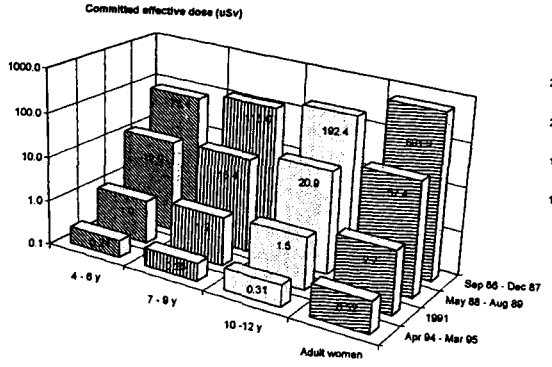

Fig. 5: Effective doses committed due to Cs^{137} intake

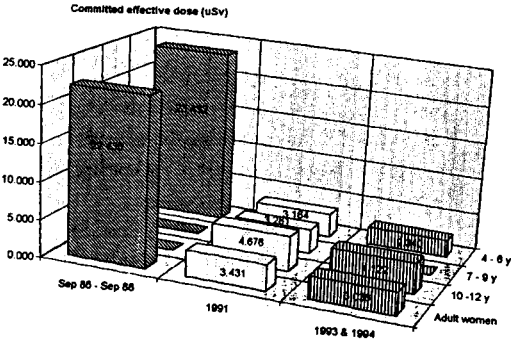

Fig. 6: Effective doses committed due to Sr^{90} intake

These doses were obtained by suming the doses to red marrow and bone surface (Toader and Vasilache, 1995 [4]). In this case, there is no more linear age dependence of the dose. Fig. 6 seems to indicate that the highest doses were committed by the 10-12 years old children, but the data are not suficient to consider this hypothesis as sure. However, the doses committed due to Sr^{90} are decreasing as the time elapses, as the doses due to Cs^{137} do.

CONCLUSIONS

The results of this study allowed us to estimate the effective doses committed due to Cs^{137} and Sr^{90} intake. The effective doses committed by the children , due to Cs^{137} intake, are lower than the doses committed by the adults. As in the case of the doses committed by the adults, the doses committed by children decrease as the time goes by. In the case of the doses committed due to Sr^{90} intake, the values for children are comparable to the values for adults.

ASPECTS OF THE RADIOACTIVE CONTAMINATION OF FOOD AND HUMANS IN ROMANIA, AFTER THE CHERNOBYL ACCIDENT

Ion Chiosilă, Constantin Milu

Romanian Society for Radiological Protection

INTRODUCTION

The radioactive contamination of the environmental factors in Romania, was shown four days after the accident, by a massive increase in the radioactivity of the air, deposits, soil, and vegetation. It was found that some areas were more contaminated, due to the currents of air that favoured the movement of the masses of contaminated air, and to the fall-out driving the radionuclides toward the ground. Areas with low levels of contamination were identified in the western part of the country, while the most contaminated areas were the mountain regions and the areas in the north-east of the country.

Twenty-one radionuclides were identified by gamma spectrometry, to which Sr-90 and Sr-89 were added, that were detected by radiochemical analysis.

The contents of Cs-137 in the atmospheric deposits did not exceed 80 kBq/m^2, which places the level of contamination in Romania below the levels reported in Ukraine and Belarus (over 200 kBq/m^2), or in Sweden (over 100 kBq/m^2)[1,2] .

MATERIALS AND METHODS

The samples of drinking water and foodstuffs were collected from the whole area of Romania, once a month during 1986-1987, and once a trimester between 1988 and 1992[3] .

Cs-137 and Sr-90 were chemically separated out of large volumes of water (100-300 l), then measured by spectrometry and beta radiation of the Y-90, respectively [4,5] .

The samples of foodstuffs, after being weighed and calcinated, were measured by gamma spectrometry, to determine their contents of Cs-137 and Cs-134. From the same calcinated samples Sr-90 was separated, then measured by means of its daughter Y-90.

The gamma spectrometric measurements were performed by means of Canberra analysers with 4096 channels, endowed with Ge(Li) detectors. The beta measurements were carried out with anticoincidence facilities, Nuclear Enterprises (U.K.)[4,5] .

The concentration factors (CF) in the trophic link soil-plants were also computed, as the ratio between the activity of a radionuclide in a mass of 1 kg of fresh plant, and the activity in 1 kg of soil.

The human contents of Cs-137 and Sr-90 was measured by antropogammametry. The human contents of Cs-137 and Sr-90 was also estimated by computation, as a function of the contents of the radionuclides in the ingested food [2,4-6] .

RESULTS AND DISCUSSIONS

The values of the contents of Cs-137 and Sr-90 in drinking water increased during May 1986, but did not exceed 1 Bq/l. During the following months, the activity of the two radionuclides decreased continuously, until, in 1990, it reached values of only 2-10 mBq/l that were also found prior to the nuclear accident.

Throughout May-July, the contents of Cs-137 in cultivated vegetation was of the order of hundreds of Bq/l, but decreased quite rapidly during the second half of the year 1986 and during the following years, until, in 1989, it reached values lower than 1 Bq/kg. When comparing the activity of this radionuclide in wheat grains to its activity in corn grains, the contents of Cs-137 in wheat was higher by at least one order of magnitude than that in corn (up to 500 Bq/kg).

In 1986, the contents of Cs-137 in animal products (milk and dairy products, meat and derivatives, etc.) showed high values, hundreds of Bq/kg of fresh mass. During 1987, the values decreased by at least one order of magnitude, and in 1990 they reached less than 1 Bq/kg. Isolated peaks of increased contents of Cs-137 were detected at the beginning of the year 1987, mainly in dairy products, due to the use of contaminated vegetation that was stocked during the summer of 1986.

The values of the contents of Sr-90 in vegetation and foodstuffs of animal origin were much lower (with one to two orders of magnitude) than those found for Cs-137.

The contents of Cs-137 in daily menu in the southern part of Romania was about 100 Bq/day during 1986 and the first half of 1987, reached values below 10 Bq/day during the second half of 1987 (the highest intake was due to the wheat flour ground from the crop of the previous year), was only 1 Bq/day since 1988, and decreased even further after 1990. The contents of Sr-90 was lower than 10 Bq/day during 1986, and decreased to about 1 Bq/day in 1988. The two radionuclides detected in the menu during 1987 were mainly due to the flour ground from the crop of the previous year. When it was replaced by the flour from the crop of the year 1987, the contents of Cs-137 in the menu decreased to about 2 Bq/day.

The concentration factors of these two radionuclides in plants, computed for the interval 1987-1992, showed values below one (between 0.01 and 0.11), which explains the rapid decrease of the contents of the radionuclides in plants, then in animals and products of animal origin.

The contents of Cs-137 in human body was maximum during the years 1986 and 1987, approximately 10,000 Bq, and continuously decreased since 1988 due to the low intake from food, reaching, in 1991, values below 100 Bq. Sr-90, computationally estimated as a function of the degree of contamination of the ingested food, was below 100 Bq even in 1986, but decreased much slower than Cs-137.

The relatively rapid metabolic process of Cs-137, and the low intake of this radionuclide from food even since the end of the year 1987, resulted in a quite rapid decrease of its contents in human body, to values below 100 Bq in 1991. As for Sr-90, the intake from food was also low starting with 1987, but the much slower metabolic process of this radionuclide resulted in a much smaller decrease of its radioactive contents, as compared to Cs-137.

In Romania, the level of human and food contamination with Cs-137 and Sr-90 was close to the levels reported in other European countries (Hungary, Poland, etc.), and much lower than those found in Ukraine and Belarus [1].

CONCLUSIONS

1. The radioactive contamination of food reached high values for Cs-137 (hundreds of Bq/l or kg), and lower values for Sr-90 (10 to 100 times lower than Cs-137), during the months May-July 1986.

2. The values of the contents of the radionuclides Cs-137 and Sr-90 in water and food decreased rapidly, even during the second half of 1986, and in 1991-1992 they reached the levels recorded for the periods prior to the accident.

3. The concentration factors for Cs-137 and Sr-90 in plants had low values, usually below one, even since 1986, which explains the rapid decrease of food contamination.

4. The evaluation of the human contamination indicated maximum values by the end of 1986, about 10,000 Bq Cs-137, and less than 100 Bq Sr-90.

ABSTRACT (See instructions overleaf)

Average thyroid dose in children under three years of the Bryansk region, the most suffered territory of Russia after the Chernobyl accident was about 2 Gy with maximal individual values up to 10 Gy in the most contaminated settlements. Prognosis of medical consequences for population of Bryansk region showed that thyroid cancer would be the most significant effect of people exposure due to the Chernobyl accident. Now about 50 thyroid cancer incidents were registered among children and teenagers of Bryansk region irradiated in 1986.

Thyroid dose estimations for population of the Bryansk region were based on the results of 17 000 measurements of I-131 content in thyroid of inhabitants (10 000 - children and teenagers under 18 year) in May-June 1986, data of questionnairies of the inhabitants about their life-style and food consumption, data of the regular environmental monitoring that has being fulfilled in the Institute of Radiation Hygiene from May 1986 till now.

Dosimetric models used for the reconstruction of group and individual thyroid doses are discussed in the report. Comparison of different parts of I-131 measurement database showed quite satisfactory agreement of dose estimations made independently by different groups of investigators with different equipment. About 20% of measured people got thyroid doses more than 0.3 Gy, 5% - more than 1 Gy. Among children under 8 years 44% and 15% of the investigated children had thyroid doses more than 0.3 and 1 Gy.

Using of this dosimetric data base for a epidemiological study of thyroid cancer morbidity in inhabitants of Bryansk region are discussed in the report. Preliminary estimations of radiation induced thyroid cancer risk coefficients are presented.

PRESENTING AUTHOR (IF DIFFERENT)

MAJOR SCIENTIFIC TOPIC NUMBER ..... (see page 7)

ABSTRACT (See instructions overleaf)

The paper discusses quantitative estimations of different radioecological factors which determine exposure doses to population residing on the territory contaminated with Sr-90. The internal doses of Sr-90 result from Sr-90 intakes with diet and depend to a great degree on the content of this radionuclide in the food which, in its turn, is governed by many radioecological factors: level of contamination of the territory, distribution of radionuclides, topography, land-use practices. Additional factors influencing Sr-90 intakes with food are chemical composition of the soil (depending on soil type), soil moistu - ring, radioactive surface water run-off, accumulation of dung and ashes from firewood at certain sites, etc. In terms of food it has been established that the main contributor is milk which is due to using hay from contaminated lands to feed the animals. The peculiarities of forage production, the contribution of pastures and haylands and other ecological factors to Sr-90 ingestion are analyzed.

RADIOECOLOGICAL STUDY OF FRESH WATER ECOSYSTEMS INFLUENCED BY THE OPERATION OF NUCLEAR CYCLE FACILITIES IN THE URALS

Alexander Trapeznikov
Institute for Plant and Animal Ecology
Yekaterinburg, Russia

Nuclear cycle facilities have been functioning in the Urals for over four decades which resulted in significant impacts on the environment.

The researchers of the Department of Continental Radioecology of the Institute for Plant and Animal Ecology (IPAE) has for long years conducted radioecological studies of the river Techa and water basins in the East-Urals Radiation Trace (EURT) area, and in the vicinity of the Beloyarsk APS.

The present paper only contains integral indices, such as inventory of the radionuclides contained in the ecosystems studied.

Radioecological conditions in the Urals region were to a significant extent a result of operation of the Mayak Industrial Association (MIA) and a major accident that occurred at the plant. It was in the South Urals that the USSR's first reactor (1948) and first radiochemical plant (1949) were started. Their task was to make the first Soviet atomic bomb.

Releases of radioactive wastes from the radiochemical plant into the river Techa were going on from 1949 through 1956. Seventy-six million cu m of effluents with total beta-activity of 2.8 million Ci were disposed into the river in the period indicated. About 95% of total activity entered the river from March 1950 through November 1951. During that period the average daily discharge of activity constituted 4.3 thousand Ci and the radionuclide composition of sewage waters: 0.8% of Sr-89, 11.6% of Sr-90, 26.8% of rare element radionuclides, 13.6% of Zr-90 + Nb-95, 25.9% of Ru-106. Radioactive releases into the river system were sharply decreased during the next 5 years and made up 9.5 thousand Ci/yr in 1952 and from 0.5 to 2 thousand Ci annually in the period of 1953-1965 (1).

Currently, 0.7×10^{14} Bq of Sr-90 and 1.3×10^{14} Bq of Cs-137 are contained in the river Techa according to measurement data, the bulk of the activity being deposited in the bottom sediments of the river. The Techa floodplains contain 1.3×10^{14} Bq of Sr-90 and 1.7×10^{14} Bq of Cs-137 (Table 1).

Inventory of Sr-90 and Cs-137 in the Techa River and its Floodplains

Components	Sr-90	Cs-137
The river	0.7×10^{14}	1.3×10^{14}
Floodplains	1.3×10^{14}	1.7×10^{14}
Total inventory (river+floodplain)	2.0×10^{14}	3.0×10^{14}

According to the calculations made by the researchers of Department of Continental Radioecology, IPAE, and the National Laboratory, RISO (Denmark), under the supervision of Dr. A. Aarkrog and on the basis of our own results and literature data, approximately 1×10^{15} Bq of radioactive releases (Sr-90 + Cs-137) were migrating from the river Techa into the river-system Iset-Tobol-Irtysh-Ob over 4 decades (2).

The explosion of a tank of volume 300 m^3 which contained 70-80 tons of high-level waste (mostly in the form of nitrate-acetate compounds) occurred on September 1957 on Mayak's production site

About 2 million Ci (out of 20 million Ci of radioactive substances from the tank) were released into the air to the height of up to 1 km which led to the formation of a plume. The deposition of radioactive substances from the plume led to the contamination of an area of 23 thou km^2 in Chelyabinsk, Sverdlovsk and Tyumen Regions. The contaminated area was designated by the term East-Urals Radiation Trace (EURT). The dispersed radioactive substance consisted mainly of short-lived radionuclides. However, it was the long-lived Sr-90 in the mixtures (2.7% of total activity) released that presented the main long-term hazard.

Radioecological monitoring of three lakes (Tygish, Bolshoi Sungul and Chervyanoye) was being carried out by our laboratory for several years in the EURT area, close to the boundary between Sverdlovsk and Chelyabinsk Regions. The results of this work was summarized in an inventory drawn for Sr-90 contents in lakes.

Maximum Sr-90 contents were found to be contained in the Tygish Lake: 374 GBq; while the contents for the Sungul and Chervyanoye were 240 and 167 GBq, respectively (Table). The data used in calculations were only those that were included in our monograph [3].

Table 2

Distribution of Sr-90 in the main components of some lakes on the EURT in Sverdlovsk Region (1992)

Lake	Sr-90 contents, GBq		
	In water	In bottom sediment	Total for the lake
Tygish	35.1	338.8	373.9
B. Sungul	21.8	218.3	240.1
Chervyanoye	15.2	151.7	166.9

Beloyarsky APS named after Kurchatov, the first electric station in the USSR was put on line in 1964. At present one of the blocks FN-600 is functioning on fast neutrons generating 600 Megawatts of power. Two other blocks, one for 100 and the other for 200 megawatts, were shut down.

The scientists of the Department for Continental Radioecology, IPAE, assessed the contents of the principal artificial radionuclides, Co-60, Sr-90, Cs-137, released by the APS into the Beloayrsk Water Reservoir [4].

The cooling pond of the APS contains 244 GBq of Co-60, 144 GBq of Sr-90 and 668 GBq of Cs-137. The concentration of these radionuclides in the bottom sediments constitutes 90%. From 2 to 8% of the total radionuclides indicated above are registered in water and less than 0.01% in plants (Table 3).

Table 3

Distribution of radionuclides among components of the Beloyarsky Water Reservoir

Components	Co-60		Sr-90		Cs-137	
	MBq	%	MBq	%	MBq	%
Water	6600	2.7	9900	8.0	12000	1.8
Sediments	238000	97.3	114000	92.0	656000	98.2
Aquatic plants	26	0.01	12	0.01	15	0.002

It should be mentioned in conclusion that the impacts of the radioactive contamination in the Urals resulting from the operation of a nuclear facility had a regional and local aspects. Thus, the discharges of radionuclides into the Techal led to the pollution of the entire Ob-Irtysh basin.

The accident of 1957 at Mayak IA resulted in the scatter of radioactive matter over the area of 23,000 km^2 . Although the radioecological conditions in the area around Beloyarsky APS are much safer, there is a local pollution of the Beloyarsk Reservoir. Taking into account the unique character of the environmental situation observed in a number of water reservoirs, it would be necessary to conduct further in-depth investigations.

CHERNOBYL IS NOT EVERYWHERE - A CRITICAL REVIEW OF EMERGENCY PREPAREDNESS 10 YEARS AFTER CHERNOBYL

Hans H. Brunner
GSEDI / Nationale Alarmzentrale, CH-8044 Zurich, Switzerland

The Chernobyl shock had positive consequences for emergency preparedness. But have the right conclusions been drawn and the lessons really learnt? Some countries which were not ready when Chernobyl happened, have based their new concepts too closely on the Chernobyl scenario and do not seem to realize that a next accident may be completely different. Many concepts and developments are too academic and not adapted to the severe operational requirements of real emergency conditions. The information of the public still shows most of the deficiencies which were the cause of the only real "catastrophic" consequences of Chernobyl outside the former Soviet Union. the information failure.
A critical review of the developments in the various aspects of emergency preparedness, based on international comparisons (a.o. from NEA International Emergency exercise INEX-1 and both NEA and FS Workshops [1-7]) shows both real improvements and mistakes or weak points and leads to the following ☺ *positive* and ☹ *negative observations*, ➔*conclusions and proposals for future action*(given in short-hand form due to limited space):

Characteristics and trends of emergency preparedness

characteristic	before Chernobyl	after Chernobyl	optimal concept
attitude	egocentric	(more) cooperative	flexible
range of events	own NPP only	cross-boundary	all radiological events
hazards considered	external exposure	mainly internal exposure	all exposure paths
decision support means	manual + brain	computers academic software	common sense + user-friendly operational software
information of public	"his master's voice" from ivory tower	problems unsolved media dominating	take back initiative use everyday language

Concepts
☺ Cross-boundary and far-field consequences are considered. Some concepts include not only large-scale releases but also design base accidents. ICRP 63 and IAEA-BSS / SS 109 [7] serve as guidelines. Even non-nuclear countries introduced emergency preparedness. Eastern European countries are willing to catch up and to learn, but are hindered by old structures and little transparency. Regional comparison and harmonization of concepts (Scandinavia, D-CH) [4,6]
☹ Many late-coming countries prepare only for Chernobyl-type accidents with emphasis on internal exposure via food path.
➔ Concepts should include all types of events with radiological consequences or hazards. Agreed concepts for optimal monitoring and for forecasts of consequences are needed. Distinguish between emergency phases and return to normal situation. Most late phase and long term problems should be handled by normal competent authorities and means, not by emergency organisations. Test concepts on several scenarios in table-top exercises. [1,3,4]
-> Optimization is best application of available information at the right time (Potter [4])
Criteria
☺ Scandinavian harmonization of intervention criteria. Dose-action-concepts with predetermined derived criteria and Intervention levels (IL) for range of realistic scenarios. [4]
☹ Criteria expressed in non-operational quantities. Discussion and decision on criteria delayed until emergency will happen.
➔Operational criteria depend on national circumstances -> general harmonization not possible, but protective goals should be comparable. Derive operational, scenario-specific Intervention Levels for qualities that can be directly measured during emergency.
Organization
☺ Legal basis for emergency organisation in radiation protection legislation (CH). Coordination of all available national and regional means. Same EO for all types of radiological events. One national contact point for all event types. [3-6]
☹ Reorganization in emergency = chaos. Different (and competing) lead authorities for different event types. Missing coordination if several provinces are affected. Several not corresponding contact points for one country.
➔ As normal as possible, as extraordinary as necessary, as simple as possible: involve normal authorities, hierachies and emergency services as far as possible. Exchange liaison officers between the main partners and with neighbouring countries.
Monitoring
☺ Most countries have installed or planned nation-wide automatic monitoring networks. Some countries begin to optimize their entire stationary and mobile monitoring organization. International monitoring data exchanges are in test phases. [3-6]

☹ Data graveyards of unverified and not representative data. Sampling and monitoring methods not standardized, quality control insufficient. Data exchange prevented or made difficult by not standardized data formats and transmission protocols, different specifications of national telecom hard- and software etc.

➔ Develop concepts for optimal monitoring. Standardize, quality-control and intercompare methods. Define minimum required types and amounts of monitoring data. Do not flood partners with unwanted data, but make data easily retrievable on request.

Data Management (assessment, processing, storage, presentation) [4]

☺ A few countries have developed operational, user-friendly and field tested systems suitable for various event scenarios. Close interactions between data management and information of public have been recognized. Exchange of experiences has started.

☹ Too many systems answer post-Chernobyl requirements but are not suited for other emergencies. Large academic system development programs without operational experience and consultation do not prevent countries to develop their own operational systems. Some systems are pure tv games. Simulators have training value but limited operational use. History writing analysis systems such as developed to analyse Chernobyl data are not suited for operational purposes except in late phase.

➔ Design goals: simplicity, modularity, reliability. Operational data management systems must be tailored to the needs of the particular organizations and users and tested under field conditions. Clearly define for which emergency phases and users a system is designed. Centralise data bases and data evaluation, make only verified and representative data available to users. Fight NIH (not invented here) syndromes and tendencies to re-invent the wheel, intensify open exchange of experiences, also of problems and mistakes. Keep (manual) backup methods operational, use rules of thumb for quick estimates and checks. The products of data management must be suitable for use in information of the public and must allow black/white fax transmission. Color codes of monitoring and contamination maps and headings (coordinates etc) should be standardized.

Decisionmaking [3,6]

☺ Recognition of necessity to make decisions based on uncomplete information, e.g. plant parameters. Preparation of sets of probable decisions for selected scenarios. Protective early countermeasures initiated before release starts. Catalogue of countermeasures as decision basis.

☹ Source-term fixation: source term and forecasts based on source terms are never available in time for early decisions. Political decisionmakers rarely participate in exercises. Normal limits are misused as intervention levels. Reasons for decisions are not clarified or explained. Political or ideological motives are disguised as "health protection".

➔ Decisionmaking cannot be replaced by expert systems. Sophisticated systems alone do not provide good emergency management if concepts and organization are not appropriate. Do not rely on early availability of source term or forecasts. Train for timely decisionmaking based on early incomplete and fuzzy information. Delegate decision for early countermeasures to a team available round the clock and connected to contact point. Provide legal basis for countermeasures and emergency actions. Differentiate between limits for normal use and investigation levels for emergency use. Distinguish between health protection and economic or political reasons. Decisionmaking on countermeasures is a two-step process: Step 1: yes/no decision on need for countermeasure based on dose expected without it. Step 2: if several choices, select the action with the highest dose averted. But: Dose averted is only one of several parameters in selecting the appropriate countermeasure, some others are feasibility, timeliness, negative side-effects, economic costs, psychological and political acceptance.

Countermeasures [1,3,4-6]

☺ Wide acceptance and similar application of major early countermeasures such as sheltering, evacuation, iodine prophylaxis. Emergency planning zones where early countermeasures are considered usually have a radius of about 10 km.

☹ Agricultural and food countermeasures often academic, not realistically feasible or accepted by customers and market. Old lessons from nuclear weapons fallout have been forgotten. It is difficult to overcome established customs and to implement up-to-date concepts.

➔Concentrate on efficient early phase countermeasures. Late phase rehabilitation is not emergency business. Learn from experiences of other types of emergencies (chemical accidents, earthquakes, floods, food poisoning, plagues, firefighting, large traffic accidents), as many problems and solutions are similar. Motivate people to take care of themselves and to understand reasons for countermeasures. In preparing and using countermeasures cooperate with specialists from the relvant fields, radiation protection is only part of the total problem. Even if only a few real cases with health problems are expected, a large part of the affected population will need some kind of psychologic and medical counselling and needs to be calmed down by at least a contamination check. Exit control of affected region should be combined with such services.

Communications [3,6]

☺ Modern technology allows quick transmission of data to several receivers in parallel.

☹ Communications easily overloaded; insufficient backup systems, insufficient testing under stress conditions.

➔ Use only thoroughly tested and instructed systems. Provide backup systems that are less overloaded. Use dedicated lines/systems between key installations. Make full use of modern technology, provided the users are familiar with it.

Information [4,6]

☺ Most countries have recognized that information of the public is decisive for success of emergency

management. and are attempting to coordinate information. Local safety committees (Sweden) are an excellent solution for continuous information of the public and for gaining confidence.
☹ Uncoordinated information by several authorities produces contradictions and loss of confidence. Language is too scientific. Media take initiative from the beginning and dictate rhythme and style of information. Information to tourists and guest-workers in other than the national language(s) is mostly insufficient. Information sources talk about topics outside their competence.
➔Advance information and instruction of population on planned countermeasures is indispensable. Integrate media in emergency organization. Do not fight the media but make sure that official announcements are not mutilated or modified. Do not hide anything, full transparence is the only choice. Use an unambiguous terminology and a clear everyday language. Try to regain the initiative from the media.
The Danish concept of a centralized information database containing both basic and event-related information accessible by all information services, should be internationalized [4]. Information must be coordinated and compatible, delegated down to the front and to the region of the event. Each staff or authority informs only about the topics within its competence and makes its information available to the other information services. Hotlines for answering questions from the public need backup by specialists and by staff with detailed knowledge of the affected region. Include local opinionmakers such as medical doctors, pharmacists, teachers etc. into information concept.

Training and Exercises [2,3,6]

☺ Most countries with an emergency organization have also started training and exercise programs. Especially valuable are the bilateral, regional and international exercises (e.g. CH-D, Nordic, NEA INEX-1 and 2) [2,3].
☹ Many exercises stick to the Chernobyl scenario or to some standard scenario with large release and neglect the large variety of other, more realistic scenarios. Some countries do too many exercises and have no time to evaluate them, draw conclusions and implement the necessary improvements. The real political decisionmakers are rarely actively participating in exercises and receive no training in emergency management. Media pressure and information of the public are rarely part of exercises. In large-scale command-post and field exercises the individual participant sees only a frog's view of the scenario and the organization and has difficulties to define his own place and role.
➔ Motivate key people and show the general picture and the interactions in table top exercises which have a high benefit/cost ratio. Use command-post exercises to test specific phases of a scenario, the communications, decision support and decisionmaking. Field exercises (monitoring) can be run separately from command-post exercises.
Systematic training not only of the teams forming the emergency organizations but also of the political decisionmakers and of their staffs and, if possible, of journalists, is indispensable. Check the cost/benefit ration of exercise programs. Carefully evaluate each exercise, draw conclusions and implement the necessary improvements which then are tested by the next exercise.

International Cooperation [3-6]

☺ Chernobyl intensified international cooperation. Most countries participate in IAEA notification and assistance agreements, Europeans in ECURIE. IAEA and NEA provide useful guidelines and promote exchange of experiences and treatment of important topics in workshops and working groups. The NEA International Nuclear Emergency Exercises are a success and attract more and more countries, also from Eastern Europe, Asia and the Americas. Bilateral and regional cooperation increases. The FS has a useful bilateral (CH-D) Working Group on Emergency Management.
☹ Cooperation on the level of the radiation protection and emergency management specialists is better than on the level of decisionmakers. Cross-boundary assistance may be delayed or blocked by stupid administrative obstacles (customs, prestige etc.). Many of the means listed in the IAEA assistance tables would not really be available in a large scale emergency because they would be needed by the country itself.
➔ Continue and intensify international cooperation in working groups, workshops, seminars and joint exercises. Provide training and practice opportunities for emergency managers and staff from countries which are in the process of forming an emergency organization.

Comprehensive Optimized Emergency Preparedness

should provide for: coordination of all available national means, both civilian, civil defense and military ones / key monitoring and data management systems used routinely for environmental monitoring / one contact point and one front-line emergency management center and team available around the clock , dealing with all types of events with radiological hazards or consequences, having competence to alarm and protect population and to manage emergency and information during first 1-2 days of an event / coordinated information concept. ABSTRACT (See instructions overleaf)

To effectively direct an emergency response, an emergency manager needs to be able to quickly obtain the magnitude of an event that involves the release or potential release of radioactive or hazardous materials. By using facility-specific hazardous material and meteorological data, dose calculation methods of the International Commission on Radiological Protection, and the seven emergency classification levels of the International Atomic Energy Agency, an emergency assessment resource manual or summary (EARM or EAS) can be developed as a tool for rapid response to local site emergencies. Such tools provide a summary of the facility's operations, hazardous material inventories, worst-case consequence analyses (maximum impact distances) for all probable events, and distances to potentially impacted populations. These manuals/summaries allow the emergency manager to make immediate, conservative, and accurate decisions during an emergency and also provide an excellent pre-planning tool for development of exercise scenarios.

This paper describes the process and input materials used to prepare these emergency management resources for widely divergent facilities and sites within the U.S. Department of Energy (DOE) complex. Their implementation at the local sites and at DOE Headquarters during exercises has rapidly aided the evaluation of questions such as: What are the upper bound consequences to be expected from an event? What are the consequences most likely to be? What else can or could happen?
